In an apparatus somewhat similar to that described above, one mole of aluminum chloride and one-half a mole of potassium fluoborate were heated by means of an oil-bath for four hours, with the temperature slowly increasing from 150 to 175°. The product was condensed in liquid nitrogen. The recovery of pure boron chloride was 0.26 mole, a yield of 56%, based on the potassium fluoborate used. Under comparable conditions yields of around 30% of boron bromide have been obtained.

Summary

Boron fluoride and potassium fluoborate have been found to react with aluminum chloride or bromide to produce good yields of boron chloride or bromide. The conditions of the reactions are given and the use of boron fluoride is particularly recommended as a means of preparing boron bromide. No fluorochlorides or fluorobromides of boron have been isolated in this investigation.

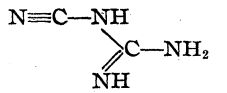
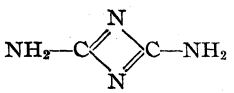
The Crystal Structure of Dicyandiamide

BY E. W. HUGHES

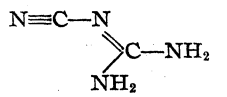
Several different structures have been proposed for the dimer of cyanamide but no absolutely conclusive evidence has ever been given for any one of them. In past years many people have preferred the cyanoguanidine[1] structure I.



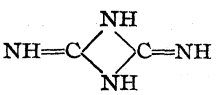
I



II



III



IV

But even fairly recently[2] arguments have been advanced in favor of the cyclic structure II. The closely related alternatives III and IV, which differ from I or II only in the disposition of hydrogens and double bonds, also have been proposed. I have made an X-ray examination of crystalline dicyandiamide for the purpose of resolving this long-standing controversy, with the results reported below.

Several previous crystallographic investigations have been recorded. In 1911 Heydrich[3] reported the crystals as monoclinic holohedral with $a : b : c = 1.1109 : 1 : 1.4213$, $\beta = 115° 20'$. He also found strong positive birefringence and that the acute bisectrix makes an angle of about 11° with c in the acute angle β'. The cleavage on {100} is excellent and that on {001} is good. In 1927 Baier[4] made an independent examination. Although he chose a different axial system, with $\beta = 90° 31'$, his axial ratios, $a : b : c = 1.0021 :$

1 : 0.4854, are compatible with Heydrich's (within somewhat large experimental error) when recalculated for the older axial system. He confirmed Heydrich's crystal class and birefringence assignments. At the same time a superficial X-ray examination was made by Dehlinger.[5] On the basis of insufficient data, and following the axial system of Baier, he reported a cell with $a = 13.8$ Å., $b = 4.4$ Å., $c = 6.2$ Å. and $\beta = 90°$. The space group was said to be C_{2h}^3 $(= I2/m)$ with four molecules per cell. No structure was proposed.

The Unit Cell and Space Group

The material used in this examination was kindly supplied by Professor A. W. Browne of Cornell University. Crystals were grown from water solutions by evaporation in a thermostat at about 35°. They were lath-like needles elongated along b. Complete sets of oscillation photographs were made about b and c (Heydrich's axes) using Cu radiation. An additional oscillation picture was made about a to confirm the length assigned to that axis. One 5° oscillation photograph with Mo radiation was made about b to observe the reflection 12,08, which is beyond the range of Cu radiation, but of important intensity.

A preliminary attempt to index the b axis pictures using Dehlinger's unit showed that the latter was incorrect and that the dimensions had to be doubled in both the a and c directions, yielding a cell with sixteen molecules and an inconvenient type of centering. By reverting to Heydrich's axes a much simpler unit was obtained for which was found $a = 15.00$ Å., $b = 4.44$ Å., $c = 13.12$ Å. (all ±0.5%, CuKα, $\lambda = 1.540$ Å.) and $\beta = 115° 20'$ (Heydrich). This cell contains eight molecules of $H_4N_4C_2$. The calculated and observed (Heydrich) densities are 1.405 g./cc. and 1.404 g./cc., respectively. The only consistent extinctions, hkl when $h + k$ is odd and $h0l$ when l is odd, indicate the space group $C2/c$, thus confirming Heydrich's assignment to the holohedral class.

Two pictures were made for each oscillation range, their exposure ratios being always 6:1. From these the $h0l$, $hk0$ and $hk \pm 1$ intensities were carefully estimated visually and corrected for the Lorentz-polarization factor. The structure factors derived from them by taking their square roots are recorded in Tables I, II and III. They have been adjusted to approximately absolute scale by comparison with the corresponding values calculated from the final structure and are arranged in order of decreasing spacing. The $hk0$ and $hk \pm 1$ intensities are not as reliable as the $h0l$ values because in recording them the needle axis was perpendicular to the oscillation axis. However, the lath-like needle was extremely thin (not over 0.1 mm.) in the direction perpendicular to the {100} faces and about 0.3 mm. perpendicular to the {001} faces so bad absorption need be feared only for a few reflections for which the emergent beams were almost exactly parallel with the needle axis. These have been indicated in Table II.

occupy one of the eightfold general positions of $C2/c$: (000 ; $\frac{1}{2},\frac{1}{2},0$) + x, y, z; $\bar{x}, \bar{y}, \bar{z}$; $\bar{x}, y, \frac{1}{2} - z$; $x, \bar{y}, \frac{1}{2} + z$. There are thus eighteen parameters to be determined, neglecting, as is customary, the hydrogens.

Because of the unusual shortness of the b axis, which is only slightly longer than the ordinary van der Waals separation of the atoms involved, it was decided to evaluate first the x and z coördinates which define distances perpendicular to this short axis. For this purpose, the $h0l$ intensities were used to prepare a Patterson projection onto (010). The series summed was $P(x, z) = \Sigma_h \Sigma_l F^2_{h0l} \cos 2\pi (hx + lz)$. The summation was effected by Beevers–Lipson strips[6] at intervals of $\frac{1}{60}\,a$ and $\frac{1}{30}\,c$, and the function is plotted as a contour map in Fig. 1. Since for $C2/c$, $h0l$ reflections always occur with both h and l even, only a fourth of the cell, containing only two molecules, need be considered.

This function tends toward maxima at values of x and z corresponding to the differences between the x and z coördinates of all the atoms of the cell taken in pairs. Because of the relatively large number of atoms involved, the extremely large number of such maxima possible superimpose and are not resolved individually. Each of the various peaks observed in Fig. 1 is the result of dozens of interatomic interactions falling near together and the interpretation of the result is consequently very difficult and uncertain. In the present instance, however, some simplification is introduced by the shortness of b. The smallest distance to be expected between two atoms in different molecules is about 3.0 Å., corresponding to a hydrogen bond >N—H. . . N<. Because every atom has others only 4.44 Å. above and below it in the y direction, the shortest possible component of this nearest approach parallel to the xz plane is easily calculated to be $\sqrt{3^2 - b^2/4}$ = about 2.0 Å. Consequently all interactions between atoms in different molecules are two or more ångströms from the corners of the plot. The area so blocked off is indicated in Fig. 1 by the heavy circles of two ångströms radius about the corners. The details inside these circles must be explained by the interactions arising inside single molecules and thus depend only on the shape and orientation of the molecules but not upon their positions.

The only striking point about this portion of the plot is that the large central peak at (0,0), which comes from the interaction of each atom with itself, is not symmetrical but is considerably elongated along a line making an angle of about 35° to c in acute angle β'. This indicates that a

(6) Lipson and Beevers, *Proc. Phys. Soc.*, **48**, 772 (1936).

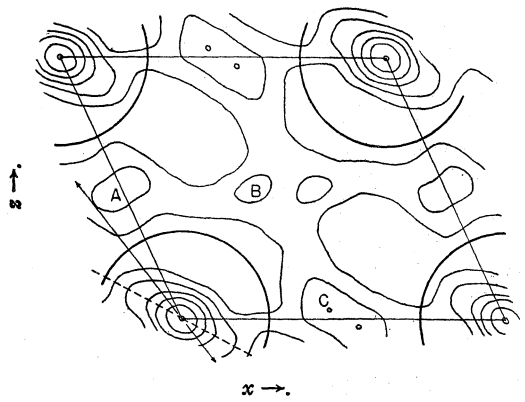

Fig. 1.—$P(x, z)$. The cell outlined is only a quarter of the true cell. P is in arbitrary units and negative contours have been omitted.

number of interatomic distances, probably chemical bonds, are oriented in this direction. The number can be estimated by approximately resolving the peak in the following way. The values of $P(x, z)$ along the ridge of the peak are plotted against distance from the origin and likewise the values of $P(x, z)$ in a direction perpendicular to the ridge, as in Fig. 2. If we assume that there are no important interactions exactly in the direction perpendicular to the direction of the ridge, this latter curve represents approximately the true shape of the central peak. The difference between the two curves (dashed curve) then represents the distorting maximum sought. It is seen to fall at about 1.2 Å. from the origin and is nearly half as high as the central peak, although these values are very uncertain because the base for the curves can only be estimated. Since the central peak corresponds to six atoms per molecule, the distortion must represent two or three atomic interactions and from their distance from the origin they must be the xz components of two or three nearly parallel chemical bonds. Now the direction of easiest polarization of the molecule, as given by the position of the acute bisectrix, is only 11° from c in acute angle β', as indicated in Fig. 1 by the arrow through the origin. We are thus led to a molecular model which has two or three bonds approximately parallel, but making an angle of about 24° with the direction of easiest polarization of the molecule on one side only of the latter. This eliminates quite clearly both cyclic formulas II and IV since their bonds are symmetrically distributed about the long axis of the molecule. Either I or III is acceptable, however. They differ very little as far as carbons and nitrogens are concerned and do in fact have three parallel or nearly parallel bonds making a suitable angle with the long way of the molecule. Such molecules are expected to be at least approximately coplanar. The orientation of the planes of the molecules was set approximately at plus and minus 45° to b, because Heydrich[3] had found the two smaller refractive indices of the crystal to be very nearly equal (α = 1.5212, β = 1.5493, γ = 1.8471, D lines). If the planes of the molecules were all even approximately parallel, one of these smaller indices would be considerably larger than the other

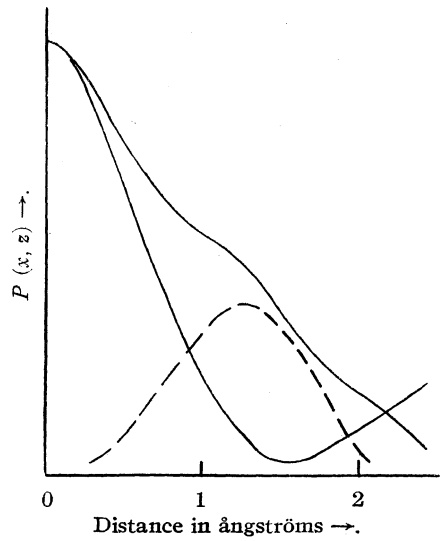

Fig. 2.—Cross section curves resolving the peak at the origin of Fig. 1.

The above arguments completely determine the approximate configuration and orientation of the molecule. The projections of the three parallel bonds are parallel to the long axis of the central peak, that of the long axis of the molecule is parallel to the acute bisectrix and the planes of the molecules make angles of about 45° alternately plus and minus with the b axis. All the interactions contributing to $P(x, z)$ which arise from within the same molecule were now marked on the plot as required by this model. Average bond distances and angles were used as no choice had yet been made between I and III. These interactions explained quite well the peak marked A but left the peaks B and C to be explained almost entirely by interactions arising between different molecules. An examination of the problem shows that these latter interactions form a pattern which depends only upon the shape and orientation of the mole-

cules. But the position of the pattern as a whole depends upon the position of the molecule. The pattern suggested by the above model was drawn to proper scale on tracing paper, placed in proper orientation on Fig. 1 and shifted about to obtain the best possible fit with the observed peaks, paying attention of course to the additional interactions produced from the pattern by the action of the symmetry elements of the projection. The possibilities are considerably restricted by the fact that all these interactions must fall outside the 2.0 Å. circles. The x and z coördinates of the atoms were determined from the position giving the best agreement. These parameters were then tested by computing the $h0l$ structure factors. The scattering factors of Pauling and Sherman[7] were used with a temperature factor of $e^{-B \sin^2\theta/\lambda^2}$, where $B = 2.00$. The factors for NH_2 were estimated by adding to those for N the differences between those for O and O″. These differed very little from nitrogen factors except at small scattering angles. In these early calculations model III was used to identify atoms but no significant error could be introduced in this way. The agreement between the observed F's and those calculated from the approximate parameters was unexpectedly good and it was possible to proceed at once to refine the parameters by Fourier syntheses.

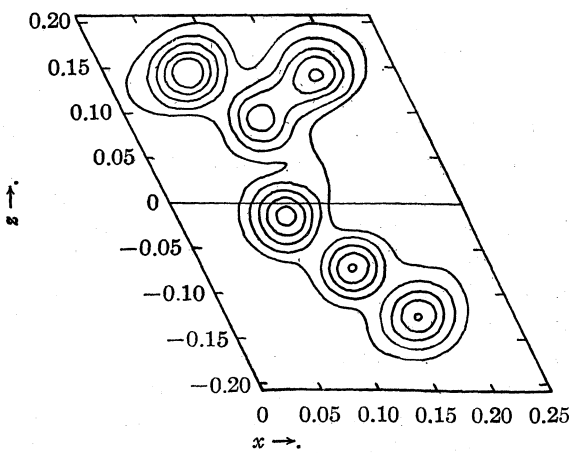

Fig. 3.—Projection of electron density on {010}. Contour intervals are approximately 2 electrons per sq. Å.

The summations of $\rho(x, z) = \Sigma_h\Sigma_l F_{h0l} \cos 2\pi (hx + lz)$ were carried out by Beevers–Lipson strips[5] at intervals of $1/120$ a and $1/120$ c. One-eighth of the final projection, which included all observed F's, is shown in Fig. 3. All atoms are satisfactorily resolved. The x and z coördinates were read from this plot to the nearest 0.0005 and are recorded in Table IV. The structure factors calculated from them are included in Table I and are seen to be in satisfactory agreement with the observed values.

TABLE IV

	C_1	C_2	N_3	N_4	N_5	N_6
x	0.1285	0.1145	0.1635	0.0920	0.1795	0.0705
y	.103	.171	−.037	.251	−.061	.334
z	−.0725	.0935	−.1265	−.0150	.1430	.1450

No assumption has been made so far with regard to the nature of the symmetry element at the origin of the Fourier plot. It may be a symmetry center at $y = 0$, one at $y = 1/4$ (lying between the c glide planes), a twofold axis or a twofold screw axis. A molecular model of average expected dimensions, adjusted in orientation to project exactly onto the Fourier peaks, was now moved along the y direction, assuming in succession each of the possible symmetry elements, and the interatomic distances to atoms in surrounding molecules produced by the symmetry elements were calculated as a function of the y coördinate of one of the atoms. It was found that satisfactory packing could not be obtained using symmetry axes at the origin. Nor did the center of symmetry between the glide planes give acceptable distances. Only when the origin was taken at a symmetry center in a glide plane did a structure with reasonable atomic separations result. In this way approximate y coördinates were obtained.

It was obvious at once from this approximate structure that there was no possible Fourier projection which would resolve any atom in such a way as to fix its y parameter. The six y coördinates had to be refined by the arduous trial and error procedure, using $hk0$ and $hk\pm1$ intensities. It seemed highly improbable that the four atoms of the guanidine group could be non-coplanar, or that the cyanimino group could be non-linear. The projection of the latter was in fact linear in the Fourier synthesis to the accuracy with which the plot could be prepared and read. Consequently, in refining the y parameters the trial adjustments were always made in such a way as to maintain the stated configurations. A survey of the final results indicates that even without these constraints the two groups would not have deviated from the expected shapes by more than the experimental errors.

(7) Pauling and Sherman, *Z. Krist.*, **81**, 1 (1932).

In comparing the calculated and observed structure factors no weight was given to those spectra believed to be influenced by absorption. The final accepted values are recorded in Table IV and the structure factors calculated from them (and the previously fixed x and z parameters) for $hk0$ and $hk\pm1$ are in Tables II and III. The agreement with observed values, while not as good as for the $h0l$ spectra, is satisfactory if one allows for the reduced reliability of the data.

Discussion

The resulting molecule is shown, as viewed parallel to and perpendicular to the plane of the guanidine group, in Fig. 4(a) and (b). The interatomic distances and bond angles are recorded on the figure (see also Table V). The underscored numbers give the heights of the atoms above the plane of the drawing in ångströms. The exact planarity of the guanidine group and the linearity of the cyanimino group have been imposed as described above, but the calculations indicate that unadjusted results would differ from these configurations by displacements not greater than the experimental errors. The probable error in the position of an atom is estimated to be about ±0.015 Å. and the probable error of a bond length consequently about ±0.02 Å. It is not very likely that any bond length is in error by more than ±0.04 Å.

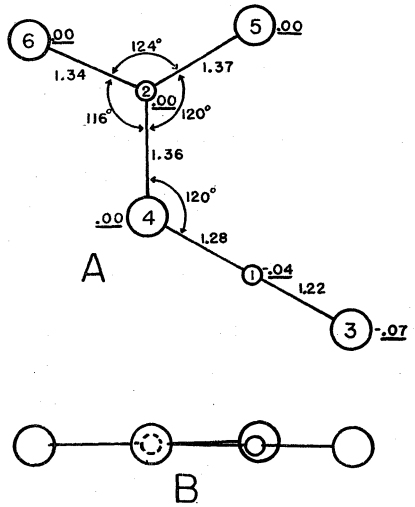

Fig. 4.—(a) View of the molecule perpendicular to plane of guanidine group. Underscored numbers are heights in ångströms of atoms above plane. (b) View of molecule parallel to same plane.

In a recent discussion[8] of double bond lengths it has been suggested that some of the double bond radii in common use recently have been too long. The present work supports this view. The previously accepted value for N=C was 1.28 Å. On this basis the 1.28 Å. bond of the cyanimino group would be a pure double bond and the corresponding structure $:\dot{N}=C=\dot{N}:$. This would require in turn that the other bond also be 1.28 Å. (or longer if one allows for the formal charge effect), whereas the observed value is 1.22 Å. If we accept the new constant for estimating double bond lengths, the theoretical C=N bond becomes 1.47 − 0.21 = 1.26 Å. and this value permits a satisfactory interpretation of both bond distances. If the cyanimino group resonates between the structures $:N\equiv C-\dot{N}:$ (25%) and $:\dot{N}=C=\dot{N}:$ (75%) the calculated bond lengths[9] become 1.22 Å. and 1.28 Å. in agreement with the observed values. These values differ from those previously predicted[10] for the cyanimino group, 1.20 Å. and 1.32 Å., respectively, partly because

of the revision in the C=N value but chiefly because in the earlier calculation it was assumed that the two resonating structures contribute about equally to the normal state. There is a special reason for the larger contribution of $:N{=}C{=}\ddot{N}\diagdown$ in the present structure. As we shall see below, the terminal nitrogen atom has three hydrogen bonds directed toward it. The structure $:N{\equiv}C{-}\ddot{N}\diagdown\!\!\diagdown$ has only one unshared electron pair to divide among these bonds which would therefore be weak, as in ammonia where a similar situation prevails.[11] But the alternative structure provides two unshared pairs and would permit much stronger hydrogen bonds. It consequently makes a larger contribution to the normal state, the final result being that the loss in resonance energy is more than made up by the gain in energy of the three hydrogen bonds. The structure $^{-2}\!:\!\ddot{N}{-}C{\equiv}N{-}$ which would provide even more electron pairs is probably of little importance because of the unfavorable bond angle, C—N—C = 120°. But the structure $^{-2}\!:\!\ddot{N}{-}\overset{+}{C}{=}N\diagdown$ may make a small contribution.

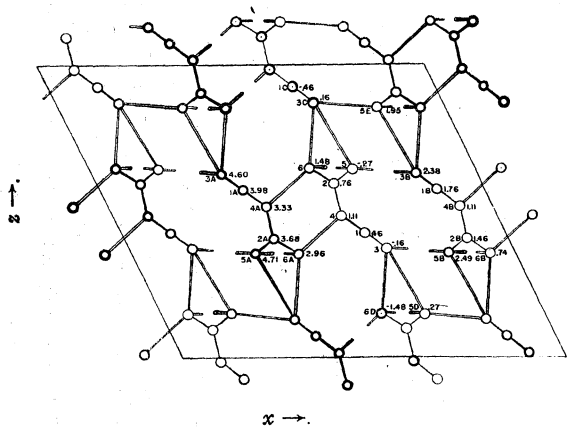

Fig. 5.—View of unit cell projected parallel to b. Numbers to right of atoms give heights in ångströms above {010}. Origin is at center of figure. Tubes represent hydrogen bonds.

In the guanidine group the double bond resonates to a certain extent into all possible positions.

$$-\ddot{N}\diagdown\!\!\diagdown C{-}NH_2, \quad =\ddot{N}\diagdown C{=}\overset{+}{N}H_2 \quad \text{and} \quad =\ddot{N}\diagdown C{-}NH_2.$$

The observed bond lengths 1.37, 1.36 and 1.34 Å. correspond to 23, 27, and 35% of double bond character, respectively, and the sum of these, 85%, comes fairly close to 100%. Moreover, the structure $=\ddot{N}\diagdown C^{+}{-}NH_2$ which involves no double bond is probably of some importance. Ordinarily we should expect the two amino groups to be equivalent and in fact the difference between their C–N bond lengths is of the order of the experimental error and may be without significance. This, however, will be discussed further in connection with the hydrogen bonds. The bond angles, which have a probable error of about ± 2½°, are compatible with the structures proposed. The deviation of the cyanimino group from the plane of the guanidine group, although probably exceeding experimental error, is quite small, corresponding to a rotation about the $\diagup\!\!\diagup N{-}C\diagdown\!\!\diagdown$ bond of only 2°.

The arrangement of the molecules in the unit cell is shown in Fig. 5. Here the atoms have been projected along the b axis, which is normal to the diagram, onto the {010} plane which is in the plane of the diagram. Numbers to the right of an atom give its height in ångströms above {010} while numbers and letters to the left identify the atoms. Numbers 1 to 6 indicate the atoms corresponding to the coördinates of Table IV, the origin being at the center of the figure. The suffix A, B, C, D or E indicates a molecule derived from the first by one of the symmetry operations of the space group. Primes, which occur in Table V, indicate atoms b(= 4.44 Å.) above or below corresponding unprimed atoms.

If one singles out sections of crystal parallel to (001) and one molecule thick all the molecules in alternate sections are approximately parallel to (310) while those in the interleaving sections are approximately parallel to (3$\bar{1}$0). These related planes make angles of about ± 45° with the horizontal and thus about 90° with each other. Within a section the molecules form strips, the atoms of the molecules of a strip all lying within ± 0.15 Å. of a plane parallel to (310) or (3$\bar{1}$0), depending upon what section the strip is in.

The arrangement about a single molecule is further shown in Fig. 6. Here the crystal has been projected onto the plane parallel to (310) which passes through symmetry centers at 0, ½, 0; ¼, ¼, 0; etc. Three of the molecules shown, which form part of a strip, lie almost in this plane, as indicated by underscored numbers

(11) Mark and Pohland, *Z. Krist.*, **61**, 532 (1925); de Smedt, *Bull. Acad. Roy. de Belgique*, **10**, 655 (1925).

which are the heights of the atoms above the plane in question. Portions of molecules in adjacent sections which are parallel to $(3\bar{1}0)$ are seen here edgewise at the top and bottom of the figure. Also are shown one molecule from each of the strips parallel to (310) but one layer above and below the plane of the drawing. The separation of these layers is 3.16 Å. Most of the interatomic distances between different molecules are 3.34 Å. or greater as shown in Table V, and correspond satisfactorily to expected van der Waals distances.[12] Five pairs of distances however are much shorter than van der Waals radii sums and these are indicated by dotted lines on Fig. 6 for the central molecule of the group. The lengths are also recorded there and in Table V. These are interpreted as hydrogen bonds and are represented in Fig. 5 by double lines or "tubes." Where one of these tubes ends before reaching a second atom it is generally directed at an atom b (= 4.44 Å.) above or below the atom at which it is directed but in some instances $2b$ (= 8.88 Å.) above or below.

These hydrogen bond distances are comparable with those found in ammonium azide,[13] 2.94 Å. and 2.99 Å.

Although the positions of the hydrogens cannot be found by X-ray diffraction effects, we may infer their positions from the arrangement of these short bonds. A hydrogen atom is to be placed, in accord with accepted stereochemical principles, on an atom at one end or the other of each short distance in such a way that there are four hydrogens per molecule. But in this case we have five pairs of bonds and only four hydrogens so we must assume that we have here another example of the so-called "bifurcated hydrogen bond" first reported in glycine.[14] In such a bond a hydrogen is attached to one atom with bond angles so arranged that it is directed equally well toward two other "acceptor" atoms on adjacent molecules. Because of this division of attraction the bonds are expected to be longer and in fact in glycine the two bonds of this type are on the average about 0.20 Å. longer than the other N–H...O bonds, but still definitely shorter than van der Waals approaches. This suggests that in dicyandiamide the two longest pairs of

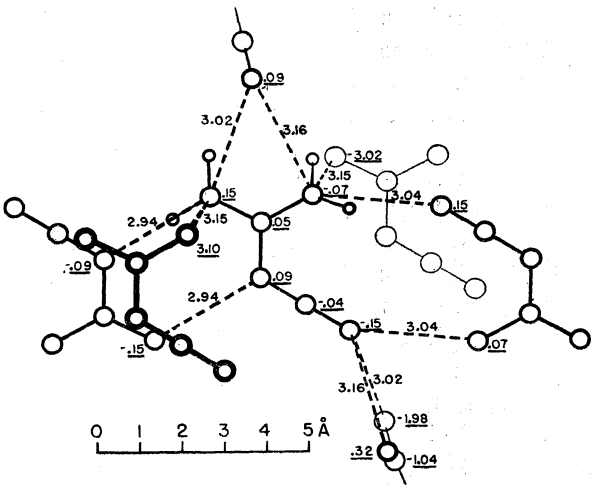

Fig. 6.—A normal projection of a portion of the structure onto (310). Small circles show probable positions of hydrogens. Underscored numbers are heights of atoms in ångströms above plane of diagram. Dotted lines indicate hydrogen bonds.

length 3.15 Å. and 3.16 Å. are the split bond and since they converge on atom 5 we place one hydrogen on it with the NH bond bisecting the angle between the two short distances. It was then found possible to distribute the three remaining hydrogens among the three remaining pairs of short distances in only one way without bringing hydrogen atoms on different molecules too close to one another. This way corresponds to the formation of two amino groups from atoms 5 and 6. The proposed positions thus found for the hydrogens are indicated (for the central molecule only) on Fig. 6 by small circles.

The N—H bonds were made to make angles of 120° with the C—N bonds (trigonal hybridization). The NH_2 group 6 is coplanar with the guanidine group and directs one of its hydrogens very nearly along (10°) the shortest hydrogen bond (2.94 Å.) while the other makes an angle of about 20° with the medium bond (3.02 Å.). The plane of NH_2 group 5 makes an angle of about 30° with the plane of the guanidine group. One of its hydrogens forms the bifurcated bonds (of lengths 3.15 Å. and 3.16 Å.) while the other makes an angle of about 25° with the second medium bond (3.04 Å.). The rotation of this NH_2 group out of the plane of the guanidine group would tend to force the resonating double bond somewhat out of this $\rangle C—NH_2$ bond and consequently more into the other. The observed C—NH_2 distances differ in the right direction for this

(12) Reference 9, p. 187.

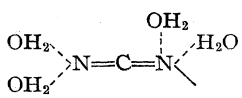
effect and this small difference may therefore well be real. The loss in resonance energy would be compensated for by the energy of forming the second half of the split hydrogen bond. The excess in length of the medium bonds (3.02 and 3.04 Å.) over the short ones (2.94 Å.) is to be accounted for partly by the fact that the hydrogen is more exactly directed along the short bond but probably the chief source of weakness in the medium bonds is the fact that they both converge, along with one half of the split bond, upon a single nitrogen atom which, as already noted, does not have enough unshared electron pairs to provide one pair per hydrogen bond. This is not the case for the short bond. The 3.15 Å. component of the split bond is directed at the p_z orbital of an amino group 6′ of another molecule. This electron pair is involved in double bond formation only to the extent of 35% as indicated above. It thus provides about as good a terminus for a hydrogen bond as the end nitrogen of the cyanimino group.

The proposed structure satisfactorily accounts for the cleavages. The crystal may be cleaved parallel to {100} by breaking only four hydrogen bonds per cell (see Fig. 5), or 0.069 per (Å.^{2}). For the poorer cleavage on {001} the corresponding figures are eight per cell and 0.120 per (Å.^{2}). Any other cleavage will break even more bonds per unit area.

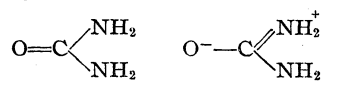
In water solutions the water molecules can form hydrogen bonds in equal numbers to both ends of the cyanimino group



Consequently, unlike in the crystal, the two contributing structures are probably of nearly equal energy and the resonance stabilization large. The addition of a proton at either end to form a cation would disturb this equality and so inhibit the resonance and decrease the stability. Moreover, the addition of a proton to an amino group would completely exclude the resonating double bond of the guanidine group from that atom and so would also cause a considerable decrease in stability. Consequently it is not surprising that the substance shows no basic properties whatever.

On the other hand, the removal of a proton from one of the amino groups to form an anion would destroy the equivalence of these two groups and although the effect would not be as drastic as that caused by adding a proton, the molecule would be destabilized to some extent by loss of resonance energy. It has been found that the acid properties are almost negligible. K_A is of the order[15] of 10^{-13} and the sodium salt, prepared in alcohol from sodium ethylate, is 95% hydrolyzed in 0.1 M solution in water. In liquid ammonia solution the conductivity of dicyandiamide reported[16] is exceedingly small so it would seem that even here there is very little dissociation despite the fact that some salts of dicyandiamide can be prepared in this solvent by reactions with metals or metal amides.

One may consider dicyandiamide to be an internal salt or zwitter ion in the same sense that urea may be so regarded. In urea the resonance of the double bond from oxygen to the amino groups transfers charges in such a way as to produce a high dipole moment:



In dicyandiamide the cyanimino group behaves like the oxygen of urea. In the crystal the hydrogen bonds from positive to negative groups tend to neutralize the charges and in fact the formal charge correction[17] has been ignored in calculating interatomic distances above. But in solution the substance would be expected to behave physically much like urea, producing an increase in the dielectric constant of the solution. This salt-like nature and the hydrogen bonds explain the high melting point (205°), low solubility in non-polar solvents, and high temperature coefficient of solubility in water and alcohol.

Crystals from alcohol were too poorly formed for goniometry but yielded a powder picture identical with that from crystals from water.

The dimensions found for the guanidine group are in good agreement with the C—NH_2 distance of 1.37 Å. found[18] in the closely related urea. But they do not agree with the corresponding distances reported[19] for the guanidinium ion, 1.20 Å. in guanidinium bromide and 1.18 Å. in the iodide.

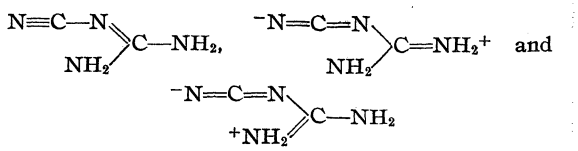
Summary

The crystal structure of dicyandiamide has been investigated. The monoclinic unit cell has $a = 15.00$ Å., $b = 4.44$ Å., $c = 13.12$ Å. and $\beta = 115° 20'$. The space group is $C2/c$ and there are eight molecules of $C_2N_4H_4$ per cell. The positions of the atoms have been found and correspond to a molecule which is a resonance hybrid, chiefly between structures



The packing of the molecules was found to be dominated by hydrogen bonds, one of which is of the rare bifurcated type. The properties of the compound have been discussed briefly in relation to the structure.

An Electron Diffraction Investigation of the Molecular Structure of Tellurium Tetrachloride

BY D. P. STEVENSON AND VERNER SCHOMAKER

Introduction

It has been remarked by Pauling[1] that it is not known whether or not the unshared electron pair in molecules and complexes such as $SeCl_4$, TeC_4l, and $[AsCl_4]^-$ is stereochemically inert as it is in the compounds M_2SeBr_6, or stereochemically active as in ammonia-like compounds. From a discussion of the properties of the solid and dielectric constant measurements on dilute benzene solutions, Smyth, Grossman and Ginsburg[2] conclude that $TeCl_4$ has a large dipole moment. But this conclusion is insufficient to fix the structure of the molecule or to determine the steric effect of the unshared electron pair. Through the kindness of Professor J. H. Hildebrand, a pure sample of $TeCl_4$ which had been used for heat capacity determinations[3] was made available to us for the study of the structure of the molecule in the gas phase. The results of our study are reported in this paper.

Experimental

The apparatus used in this investigation has been described by Brockway.[4] The wave length of the electrons determined in the usual manner from transmission photographs of gold foil ($a_0 =$ 4.070 Å.) was 0.0618 Å. The photographs were taken with a camera distance of 10.86 cm.

The low volatility of the compound (b. p. 390°) necessitated the use of the high-temperature nozzle[5] in order to obtain sufficient gas pressure. The photographs were taken with the sample in the boiler at 250–350°. We believe that the material actually present in the diffracting jet of gas was monomolecular tellurium tetrachloride. Simons[6] has shown that tellurium tetrachloride vapor is not appreciably dissociated (into tellurium dichloride and chlorine) up to 500° and that below this temperature the vapor is unassociated. There is the possibility that some of the tellurium tetrachloride reacted with the various metallic parts of the boiler. The only probable volatile product of such reactions is tellurium dichloride. Moderate amounts of tellurium dichloride would have little effect on our determination inasmuch as the tellurium–chlorine distance[7] (2.36 ± 0.03 Å.) in tellurium dichloride is nearly the same as the value found here for tellurium tetrachloride, while the chlorine–chlorine scattering is small compared to the chlorine–chlorine scattering of tellurium tetrachloride.

The photographs show seven rings, two of which are asymmetric. Curve D of Fig. 1, to be dis-

cussed below, gives a good representation of the appearance of the photographs. The observed values of $s\left(s = \frac{4\pi}{\lambda}\sin\frac{\Theta}{2}\right)$ for the maxima and minima as well as the visually estimated relative intensities, I, are given in Table I.

Interpretation.—The radial distribution function[8] was calculated using the formula

$$D(l) = \sum_n C_n \frac{\sin ls_n}{ls_n} \qquad (1)$$
$$C_n = f(I_n, s_n)$$

The values of C_n were calculated in accordance with the recommendations of Schomaker[9] and are given in column 4 of Table I. The plot of $D(l)$ *vs.* l is given in Fig. 1, curve A. The strong peaks at 2.33 and 3.37 Å. undoubtedly correspond to interatomic distances in the molecule. The rather pronounced shoulder at 2.75 Å. is probably spurious, since the value 2.75 Å. does not correspond to an interatomic distance in any reasonable molecular model for tellurium tetrachloride. The 2.33 Å. peak corresponds to the Te–Cl distance (covalent radius sum, 2.36 Å.), while the other maximum at 3.37 Å. corresponds to a Cl–Cl distance. This interpretation leads to a bond angle of slightly more than 90° ($2.33\sqrt{2} = 3.30$). It is to be emphasized that there is only one maximum corresponding to a Cl–Cl distance. Several molecular models can now be eliminated from consideration. The molecule cannot have a regular tetrahedral structure, since for such a structure the Cl–Cl distance would be $2.33 \times \sqrt{8/3} = 3.82$ Å., while the radial distribution function gives 3.37 Å. for this distance. Models that can be derived by distortion of the regular tetrahedron with retention of the symmetry elements of the group C_{3v} would also be unsatisfactory. For example, a model with equal Te–Cl distances would have two equally important Cl–Cl distances, one greater than and the other less than 3.82 Å., in disagreement with the radial distribution function. A model having all equal Cl–Cl distances, three Te–Cl distances at the radial distribution function value, and one very much shorter Te–Cl distance (at about 1.7 Å.) would agree satisfactorily with the radial distribution function, but would be extremely improbable for structural reasons.

The radial distribution curve is compatible with models having equal or nearly equal Te–Cl distances, about four bond angles at 93°, and no more than one or two bond angles at any other value. Models satisfying these conditions can be

(9) Verner Schomaker, A. C. S. Meeting, Baltimore, Md., April, 1939.

derived by unsymmetrical distortion of a regular tetrahedron retaining the symmetry elements of D_{2d} or C_{2v}. A very flat tetrahedron D_{2d} or C_{2v} (limiting case: the coplanar square) is such a model. A slightly distorted trigonal bipyramidal model (C_{2v}) in which the unshared electron pair occupies one of the equatorial positions is another. In these models the two Cl–Cl distances at values other than 3.37 Å. contribute little to the scattering, especially if different from each other, and might be expected not to appear on the radial distribution curve.

Theoretical curves were calculated for a variety of molecular models based on the interpretation of the radial distribution function given above, and are shown in Fig. 1, curves B-F. Average values of $Z_i - f_i$ were used in place of the more commonly used Z_i in the scattering formula

$$I(s) = \sum Z_i Z_j \frac{\sin l_{ij} s}{l_{ij} s} \qquad (2)$$

because of the great disparity in the functions $(Z - f)/Z$ for tellurium and chlorine. The effect of the variation of $(Z - f)_{Cl}/(Z - f)_{Te}$ with s was found to be negligible. The various symbols in equation (2) have their usual significance.[2] The values of f were obtained from the tables of Pauling and Sherman.[10] The intensity curves for the various models, except curve B, were all found to be satisfactory with regard to the qualitative features of the photographs, although none of the curves reproduces the unusually sharp appearance of the inner edge of the first maximum. Although we are unable to advance a satisfactory explanation of this discrepancy, we are quite sure that it is not due to our not having found the correct model for the structure of the molecule. Some of the curves were found to give more satisfactory quantitative agreement than others. Thus it was found that the models which had four of the bond angles equal to 93° gave curves for which the quantitative agreement was much better than those for which the angles were 90°. It was further found impossible to distinguish between models with two pairs of Te–Cl distances (2.27 and 2.40 Å.) from the corresponding models with all four Te–Cl distances equal to 2.33 Å., or between the flattened tetrahedral and the trigonal bipyramidal models of symmetry C_{2v}. The best quantitative agreement was attained when a temperature factor ($a = 0.003$) was introduced into the coefficients of the Cl–Cl terms as is suggested by the greater width of the Cl–Cl peak of the radial distribution function. The quantitative comparison with the most satisfactory curve (curve E, Fig. 1) is given in Table I.

The results of our electron diffraction study of $TeCl_4$ may be summarized as follows. The average Te–Cl distance is 2.33 ± 0.02 Å. The only important Cl–Cl distance is 3.37 ± 0.06 Å., corresponding to a bond angle of 93 ± 3°. The molecule cannot have a structure with symmetry C_{3v}. It may have any of a number of structures with symmetry D_{2d}, C_{2v}, or lower symmetry. The coplanar square structure seems unlikely because in it the important bond angles are at 90°. The value of a used in the effective temperature factor is comparable to the values found for other similar molecules investigated at high temperatures.

Discussion.—Among the possible configurations for $TeCl_4$ discussed above as being compatible with the electron diffraction photographs, only those of the "trigonal bipyramidal" type would be expected to lead to the large dipole moment (2.5 D)[2] found by Smyth, Grossman and Ginsburg. We accordingly believe that $TeCl_4$ molecules have a configuration derived from the trigonal bipyramid, one of the equatorial positions being occupied by the unshared electron pair. According to our electron diffraction investigation, the equatorial–axial bond angles are about 93°; the equatorial bond angle is probably considerably less than 120° but greater than 90°, as is suggested by the arguments given below; and the axial–axial bond angle is accordingly about 170°.

Our first argument regarding the equatorial bond angle is based on Pauling's theory of directed valence[1] and the assumption that the structure is based on the trigonal bipyramid with no significant distortion of the axial straight angle. If the four bond orbitals and the orbital occupied by the unshared pair are formed from the configuration sp^3d_z, as seems likely because of the greater stability of s and p, the equatorial bond angle will be 120° provided that p_x and p_y are distributed equally among the equatorial bonds and the unshared pair. It seems likely that the unshared pair orbital will have more than $1/3$ (s,d_z) character and less than $2/3$ p character because of the greater coulombic stability of s, and in spite of the lesser coulombic stability of d. This situation leads to an equatorial bond angle

(10) L. Pauling and J. Sherman, *Z. Krist.*, **81**, 1 (1932).

lying between 90 and 120°. On the other hand, the dipole moment (2.5 *D*) of $TeCl_4$ in benzene solution may be attributed to the free molecule also, and interpreted as the sum of four Te–Cl bond moments each having the value 2.3 *D* estimated by Smyth, Grossman and Ginsburg. For an axial–axial bond angle of 170° in the trigonal bipyramidal structure this interpretation leads to an equatorial bond angle of 102°.

The structure for $TeCl_4$ discussed here is in agreement with the prediction made by Pauling.[2] Kimball[11] suggested that $TeCl_4$ should have an "irregular tetrahedral" configuration of symmetry C_{3v}. This configuration is certainly incompatible with the results of our electron diffraction investigation; moreover, it would probably lead to a dipole moment much smaller than that found by Smyth, Grossman and Ginsburg. Kimball apparently assumed that in $TeCl_4$ the unshared pair occupies a pure *s* orbital. This assumption apparently is incorrect.

The Te–Cl distance, 2.33 Å., is but slightly less than 2.36 Å., which is the sum of the covalent radii.

(11) G. E. Kimball, *J. Chem. Phys.*, **8**, 194 (1940).

Summary

An electron diffraction study of gaseous $TeCl_4$ leads to the values 2.33 ± 0.02 Å. for the average Te–Cl distance, 3.37 ± 0.06 Å. for the only important Cl–Cl distance, and 93 ± 3° for the corresponding important bond angle. A distorted trigonal bipyramidal configuration with the unshared pair in one of the equatorial positions is compatible with these results and the known large dipole moment of the molecule. The equatorial bond angle is probably considerably less than 120°, but greater than 90°.

On the Molecular Structure of Sulfur Dioxide

BY VERNER SCHOMAKER AND D. P. STEVENSON

In the course of investigating the electron diffraction patterns of a number of simple molecules, we have obtained photographs of sulfur dioxide which are better than those previously obtained by Cross and Brockway,[1] in these Laboratories. Inasmuch as the interpretation of the new photographs leads to slightly different and probably more reliable values for the interatomic distances than those found by Cross and Brockway, we are reporting our results.

The apparatus and technique used in this investigation have been described by Brockway.[2] The camera distance was 10.85 cm. and the electron wave length 0.0611 Å. (a_0 = 4.070 Å. assumed for gold). The photographs showed seven rings of which six could be measured easily. The resulting *s* values $\left(s = \frac{4\pi}{\lambda}\sin\frac{\Theta}{2}\right)$ are given in Table I.

The radial distribution function,[3] curve A of the figure, was calculated according to the modified procedure recommended by Schomaker,[4] using the coefficients C_K given in Table I. The function has two peaks corresponding to an S–O distance of 1.435 Å., an O–O distance of 2.49 Å., and a bond angle of 121°.

TABLE I

Max.	Min.	C_K	s_0[a]	s_0[b]	s_c[c]	s_0/s_0[a]

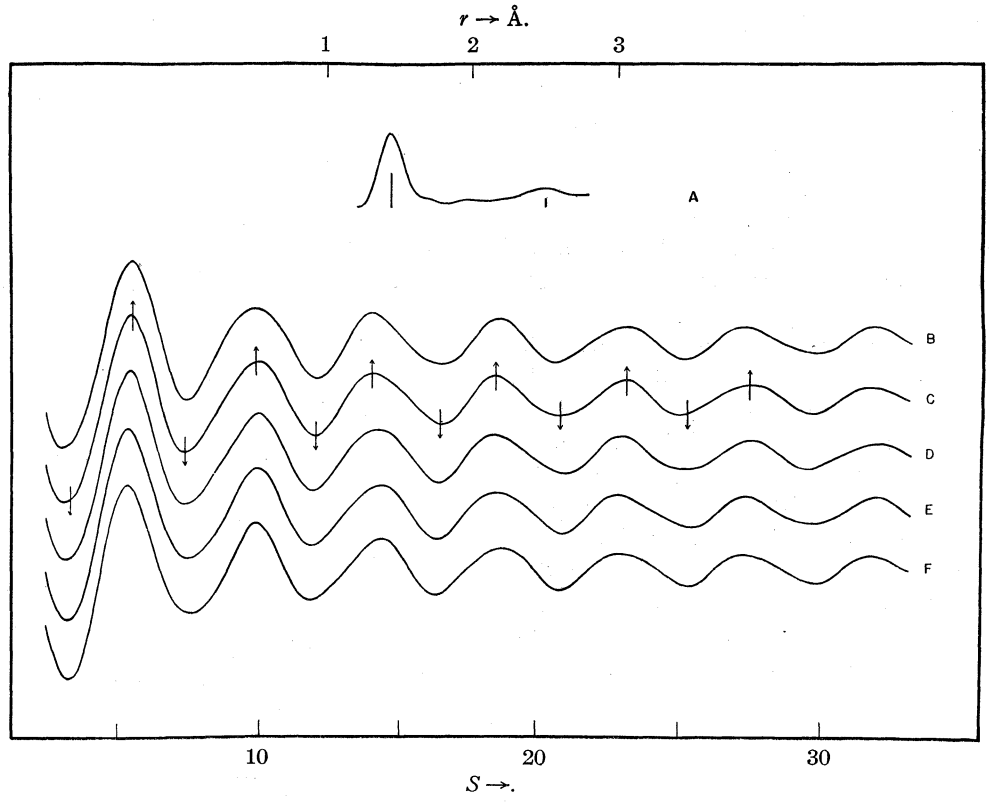

Fig. 1.—Theoretical intensity curves for sulfur dioxide: Curve A, radial distribution function; Curves B, C, D, E, F, simplified theoretical intensity curves with bond angles of 115, 120, 125, 130, 135°, respectively, and S–O = 1.43 Å. Observed s_0 values indicated by arrows.

Theoretical intensity curves, B–F of the figure, were calculated for five symmetrical models in which the bond angle was varied from 115 to 135°. It was found that the molecule could be regarded as rigid for the purposes of this investigation, and that the atomic numbers form satisfactory coefficients (Z_iZ_j) for the simplified intensity function. The curve for the 120° model (C) is the most satisfactory. Indeed, all of the other curves can be eliminated because of their appearance with respect to some or all of the following features: the width of the second maximum, the shape of the third maximum, the width and shape of the fourth maximum, and the width of the fifth maximum. Because the fifth, sixth and seventh rings of the photographs are quite faint, it is impossible to make any definite statements regarding the finer details of their appearance. The quantitative comparison of the observed and calculated s values is most consistent for the 120° model. This quantitative comparison for the 120° model is given in Table I and leads to the value 1.433 Å. for the S–O distance. The radial distribution function, and the qualitative and quantitative comparisons of the correlation method are thus in excellent agreement, giving for the S–O distance and the bond angle the values 1.433 ± 0.01 Å., and 120 ± 5°, respectively.

In previous electron diffraction investigations of sulfur dioxide Wierl,[5] whose pictures showed only one ring, found 1.37 Å. for the S–O distance, Cross and Brockway[1] found 1.46 ± 0.02 Å., and Pauling and Brockway,[3] interpreting the data of Cross and Brockway by the radial distribution method, found 1.43 Å.[6] for the S–O distance and 124 ± 15° for the bond angle. The observed s values of Cross and Brockway also are given in Table I. We feel that our s values, each of which is based on 20 to 30 measurements of a ring diameter, are the more reliable because our photographs (commercial ortho film) are much "cleaner" and show six more measurable features

(5) R. Wierl, *Physik. Z.*, **31**, 1028 (1930).

(6) The s value reported by Cross and Brockway for the first maximum of the sulfur dioxide photographs is too large, leading to a too small value for the interatomic distance. The discrepancy between the values (1.46 and 1.43) obtained from the same data by the two methods of interpretation arises largely because the first maximum was excluded from the average in the correlation procedure (C and B) but was given (excessively) great weight in the radial distribution function (P and B).

than the older photographs (X-ray film). (These differences are only typical, however, of the more or less gradual improvement which has occurred since 1933 in the electron diffraction technique employed in these Laboratories.) Moreover, it so happened that this investigation was undertaken concurrently with a very satisfactory series of check measurements on diatomic molecules[7] using the same technique and the same wave length calibrations.

There is some further information regarding the configuration of the sulfur dioxide molecule. Cross and Brockway[1] report the surprisingly consistent value 122 ± 5° as the bond angle obtained on fitting the three vibrational frequencies of the sulfur dioxide molecule to a two-constant, valence-force potential function. Much more important is the entropy determination of Giauque and Stephenson[8] which leads to the value (10.58 ± 0.99) × 10^{-116} g. cm.^{2} for the product of the three principal moments of inertia of the molecule. This value and our S–O distance give 121° as a fairly precise value for the bond angle, substantiating our electron diffraction determination. A variation of 0.1 cal. mol.$^{-1}$ deg.$^{-1}$ in the entropy (corresponding to the uncertainty in the product of the moments of inertia given above), or of 0.02 Å. in the bond distance, would produce a change of 4° in the value calculated for the bond angle. In the calculations leading to the results reported in this paragraph the current values[9] of N, h, and k were used. A correction of +0.2% was applied to our bond distance in order to compare it with the results of the entropy calculations based on the "new" constants. When the "old" values of the fundamental constants are used, the correlation of the entropy of sulfur dioxide with our bond distance leads to a bond angle value of 123°.

Summary

The structure of sulfur dioxide has been reinvestigated by the electron diffraction method, with the following results: S–O = 1.43$_3$ ± 0.01 Å., and ∠ O–S–O = 120 ± 5°. This value for the bond angle is in excellent agreement with the value, 121 ± 5°, derived from the bond distance and the entropy.

Aldehyde Complexes of Copper Salts

BY TENNEY L. DAVIS AND WALTER P. GREEN, JR.

As part of an investigation of the ability of compounds containing the carbonyl group to enter into coördinative combination, we have found that acetaldehyde and butyraldehyde combine with certain copper salts, and have prepared the compounds listed below and have determined their dissociation pressures at 0°.

TABLE I

DISSOCIATION PRESSURES AT 0° (MM. AT 20°)

$CuNCS \cdot CH_3CHO$	65.6
$3CuNCS \cdot 2C_3H_7CHO$	30.0
$2CuI \cdot CH_3CHO$	6.3
$3CuI \cdot C_3H_7CHO$	5.6
$Cu(OCOCH_3)_2 \cdot CH_3CHO$	89.9

For comparison with these dissociation pressures, we have determined the vapor pressure at 0° of pure acetaldehyde, 333.0 mm., and of pure butyraldehyde, 32.3 mm.

The formulas of the complexes show several interesting relationships. Cuprous thiocyanate combines (to form a complex which is fairly stable at 0°) with twice as many molecules of either aldehyde as cuprous iodide does. Two molecules of butyraldehyde are equivalent to three molecules of acetaldehyde in respect to the capacity of the aldehydes to combine with the cuprous salts.

When samples of the cuprous salts were exposed at 0° in closed vessels to atmospheres saturated with the vapors of the aldehydes, they absorbed the aldehydes rapidly in quantities much greater than correspond to the complexes listed above. Cuprous thiocyanate actually deliquesced in either aldehyde, and the crystals became covered with a layer of liquid. Cuprous iodide showed the same behavior with acetaldehyde, but

on exposure to butyraldehyde vapor it assumed a moist appearance but showed no distinct liquid phase after fifteen days. Different samples of the cuprous salts exposed to aldehyde vapors in the same vessel during the same interval of time absorbed different amounts of aldehyde, probably because of the formation of crusts. The results made it evident that pure complex compounds could not be produced conveniently by this procedure.

Cupric acetate absorbed acetaldehyde vapor more slowly than the cuprous salts; it remained dry in appearance but took on a deeper green color and absorbed about half a molecule of the aldehyde after five days.

Since the aldehydes attack mercury, the dissociation pressures could not be determined in an apparatus in which the vapors were allowed to come in contact with the mercury of a manometer. A torsion apparatus was used in which the pressure to be measured, within a spiral of very thin fused quartz tubing (without hysteresis), was balanced exactly by an external pressure measured with an ordinary manometer. The technique which had been used successfully in earlier researches[1] in this Laboratory, namely, that of adding to the dry salt an excess of the volatile component, pumping in the manometric apparatus, reading the equilibrium pressure, again pumping for a short time, again reading the equilibrium pressure, and so on until the equilibrium readings after successive pumpings were found to be the same, was satisfactory for determining the vapor pressures of the aldehydes but was found to be inapplicable to the complex compounds. The apparatus failed to come to equilibrium after standing for four or five days, evidently because dense, practically impervious crusts were formed which prevented the evaporation of the aldehyde from the interior of the mass.

The compositions of the complexes were determined by measurements of the weights of aldehyde retained by the dry salts. An excess of aldehyde was added to a weighed amount of the salt and the mixture was allowed to stand for several days at 0° in a closed container. The cuprous salts formed heavy, clay-like masses, while the complex of cupric acetate retained a granular texture. The materials were broken up and stirred over while the aldehyde evaporated freely at room temperature, until a complete change in the rate of evaporation of the aldehyde was noted, and dry, friable, meal-like masses were obtained. These were weighed, with the results indicated in Table II. The samples resulting from these experiments were used for the determinations of dissociation pressures. In the manometric apparatus they showed constant successive maximum equilibrium pressures after being successively pumped and allowed to stand. The pressures found in this way are reported in Table I.

6.1460	3.5703	1.4465	.972 *i. e.* 1:1	CH_3CHO

The aldehydes used in this work were purified from Eastman Kodak Co. "pure" materials. The acetaldehyde was treated with a small amount of 33% aq. sodium bisulfite solution for the removal of peroxides, allowed to stand six hours, and distilled through a Davis column; the upper fraction was dried with a mixture of sodium bicarbonate and anhydrous calcium sulfate, allowed to stand five hours, again distilled, and the middle fraction was taken. The butyraldehyde was distilled through a 3-foot (90-cm.) Podbielniak column to remove most of the acid and other high-boiling impurities; the middle fraction, b. p. 74.7–75.0°, was treated with sodium bisulfite for the removal of peroxides, washed with water, dried with anhydrous sodium and calcium sulfates, allowed to stand for two days at the temperature of dry-ice, and filtered clear from the impurities which had frozen out.

The vapor pressure of butyraldehyde at 0° has not been measured heretofore. The vapor pressure of acetaldehyde has been measured by de Leeuw[2] and by Emeleus,[3] whose data do not give straight lines on a semi-logarithmic chart,

(1) Davis and Batchelder, THIS JOURNAL, **52**, 4069 (1930); Davis and Ou, *ibid.*, **56**, 1061, 1064 (1934); Davis and Logan, *ibid.*, **58**, 2153 (1936).

(2) De Leeuw, *Z. physik Chem.*, **77**, 296 (1911).

(3) Emeleus, *J. Chem. Soc.*, 1735 (1929).

and by Gilmour,[4] who reported twenty-one values between +16.91° and −24.15°, and these values give a straight line on a semi-logarithmic chart which cuts the zero axis at a point corresponding to a value of 331.0 mm. for the vapor pressure of acetaldehyde at 0°. From Gilmour's data a writer in the "International Critical Tables"[5] has deduced a mathematical equation according to which we calculate the vapor pressure of acetaldehyde at 0° as 333.1 mm., in close agreement with our experimental value of 333.0 mm. Burton, Ricci and Davis[6] have recently reported the values 335.6 and 334.6 mm.

Summary

Complex compounds of cuprous thiocyanate and iodide with acetaldehyde and butyraldehyde, and of cupric acetate with acetaldehyde, have been prepared.

The dissociation pressures of the complexes at 0° and the vapor pressures of the pure aldehydes at 0° have been determined.

Cuprous thiocyanate at 0° forms a stable complex with twice as many molecules of aldehyde as does cuprous iodide.

Two molecules of butyraldehyde are equivalent to three molecules of acetaldehyde in respect to the capacity of the aldehyde to combine with cuprous salts.

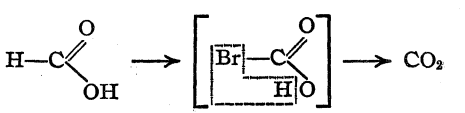
A New Reaction of Formic Acid

BY TENNEY L. DAVIS AND WALTER P. GREEN, JR.

If formic acid exists in the tautomeric form of dihydroxy divalent carbon, as has been suggested,[1] then it is possible that the reaction of formic acid with bromine might yield a certain amount of material produced from the tautomer, differing from any material which is likely to be produced from formic acid in its usual form. We find that the interaction of bromine and anhydrous formic acid produces a material (perhaps bromophosgene (carbonyl bromide) or, more probably, the hydrated form of bromophosgene, namely, dibromodihydroxy-methane) which reacts with aniline to form derivatives of urea, namely, carbanilide and brominated carbanilides, and conclude that the facts indicate with considerable probability that formic acid contains material of the formula $>C(OH)_2$.

The action of bromine on formic acid in dilute aqueous solution has been studied by Hammick, Hutchinson and Snell,[2] who concluded in 1925 that the reaction is of the second order and is essentially a reaction between bromine molecules and formate ions. They found that the influence of various reagents on the reaction is explained satisfactorily by a consideration of their effects upon the concentrations of the reacting molecules in accordance with the law of mass action. Jozefowicz[3] confirmed their results in 1929. Hell and Mühlhauser,[4] much earlier, in 1878, had studied the apparent catalytic effect of carbon disulfide on the rate of reaction of bromine with strong, but not anhydrous, formic acid. They postulated an intermediate compound but did not isolate it or assign any formula to it. In all these cases carbon dioxide was the product of the reaction, and the net result was as if the formic acid had been oxidized to carbonic acid.

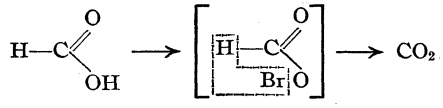
Formic acid in its usual structure may perhaps brominate by a mechanism which involves the primary substitution of either of its hydrogen atoms. If the hydrogen attached to the carbon is replaced by bromine, then the resulting intermediate compound will contain bromine and hydroxyl attached to the same carbon atom; and this is an arrangement which commonly splits off hydrogen bromide spontaneously: carbon dioxide will result.



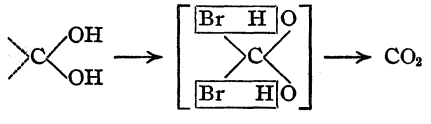
If, on the other hand, the hydrogen of the hydroxyl group is replaced by bromine, then an intermediate hypobromite will result which would

(1) Baly, Heilbron and Hudson, *J. Chem. Soc.*, **121**, 1080 (1922); Edith H. Ingold (Usherwood), *ibid.*, **125**, 1530 (1924); Scheibler, *Z. angew. Chem.*, **40**, 1072 (1927).
(2) Hammick, Hutchinson and Snell, *J. Chem. Soc.*, **127**, 2715 (1925).
(3) Jozefowicz, *Roczniki Chem.*, **9**, 309 (1929).
(4) Hell and Mühlhauser, *Ber.*, **11**, 241 (1878).

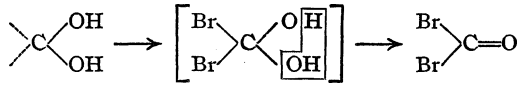
be expected to break up in the same manner that ethyl hypobromite breaks up, by the loss of hydrogen bromide from the bromine of the hypobromite group and the hydrogen attached to the same carbon atom: and again carbon dioxide will result.



The mechanism of the action of bromine on the tautomer of formic acid may perhaps involve first the addition of bromine to the two free valences, in the same way that bromine adds to carbon monoxide. The resulting intermediate dibromo-dihydroxy-methane may behave in three ways. (1) It contains bromine and hydroxyl on the same carbon atom, and would be expected to lose hydrogen bromide with the formation of carbon dioxide. This seems the most likely mode of its behavior, and the previously known comportment of formic acid with bromine may indeed occur through the intermediacy of this compound; and the formula of the tautomer explains the facts as conveniently as the more usual formula.



(2) There is however some chance, though a slight one, that this intermediate containing two hydroxyl groups on the same carbon atom, may lose the elements of water to form bromophosgene.



Since the other mode of decomposition seems more probable, and since bromophosgene is known to react readily with water, it is unlikely that more than traces of bromophosgene would be formed by the splitting out of water from a considerable amount of the intermediate. Bromophosgene reacts with aniline to form carbanilide; and a trace of bromophosgene indicates the probable presence in the original formic acid of at least some of the tautomer. (3) The intermediate itself would react with aniline to form carbanilide. There is also the possibility that the intermediate may not decompose at all to yield bromophosgene, but that while decomposing into hydrogen bromide and carbon dioxide, it may actually exist for a time in the presence of an excess of bromine with which it is probably in equilibrium.

When bromine and anhydrous formic acid were allowed to stand together at room temperature, and the mixture, still containing free bromine, was treated at room temperature or below[5] with an excess of aniline, a small quantity of carbanilide and of brominated carbanilide was formed. When a similar mixture was allowed to stand until the color of the bromine had disappeared, and was then worked up in the same way, no detectable carbanilide or brominated derivative of it was found. The substance from which the carbanilide was produced was therefore probably not bromophosgene but rather dibromo-dihydroxy-methane formed by the addition of bromine to the tautomeric form of formic acid.

Experiments

Anhydrous formic acid, m. p. 8.20°, was prepared by distillation with boric anhydride according to the method of Schlesinger and Martin,[6] who reported the melting point 8.26°.

6.9 Grams of bromine and 17.9 g. of anhydrous formic acid were allowed to stand together for thirteen days in a test-tube closed with a loosely fitting glass stopper. The mixture, which still consisted of two phases, was then frozen in dry-ice; 40.5 g. of purified and freshly distilled aniline was frozen in another tube; both tubes were allowed to warm somewhat, and the materials, partly frozen, were mixed with stirring and cooling. The temperature did not rise at any time above that of the room. The material was treated with aqueous sodium hydroxide in excess, and steam distilled for the removal of the aniline and of as much of the brominated aniline as possible. During the last part of the distillation a precipitate appeared in the flask. Precipitate and solution were extracted with ether, and the residue from the evaporation of the ether was recrystallized from alcohol, white crystals melting at 257–258° with some sintering at 230° (copper block). When this material was sublimed in the molecular still[7] it left about one-third of its mass behind in the form of tar. The sublimate, recrystallized from alcohol, yielded 0.0641 g. of material which melted at 260–265° dec., after another vacuum sublimation m. p. 278–281° dec., after another recrystallization from alcohol m. p. 279–281° dec., and further recrystallization did not raise the melting point. 2,4,2′,4′-tetrabromocarbanilide is reported[8] to melt at 281° dec. when heated rapidly. The purified product, now very small in amount, was heated with alcoholic ammonia in a sealed tube for twenty hours at 160°. The liquid on evaporation gave a tarry residue, the aqueous extract of

(5) The production of formanilide by the interaction of formic acid and aniline *in the cold* seems extremely unlikely, and hence unlikely the hypothesis that the carbanilide is formed from phenylisocyanate resulting from the action of bromine on formanilide.

(6) Schlesinger and Martin, THIS JOURNAL, **36**, 1589 (1914).

(7) Morton, Mahoney and Richardson, *Ind. Eng. Chem., Anal. Ed.*, **11**, 460 (1939), Fig. 2.

(8) Chattaway and Orton, *Ber.*, **34**, 1080 (1901).

which, acidified with hydrochloric acid, gave with xanthydrol solution a white precipitate insoluble in alcohol, evidently dixanthylurea.

Another experiment with 5.7 g. of bromine and 7.9 g. of anhydrous formic acid, twenty-four days of standing, 25.7 g. of aniline, etc., yielded 0.4 g. of material. This was extracted with cold concd. hydrochloric acid in an effort to remove the last portions of brominated aniline, then with alcohol and the residue from the evaporation of the alcohol was sublimed in the molecular still. The several fractions of the sublimate, recrystallized from alcohol, appeared to consist of mixtures of 4,4'-dibromo- and 2,2',4,4'-tetrabromocarbanilide. They were brought together and heated with alcoholic ammonia for five hours at 140–150°. The residue from the evaporation of the alcohol was extracted with water, and the aqueous solution, acidified with hydrochloric acid, gave with xanthydrol a white precipitate, insoluble in alcohol, m. p. 260° dec., showing the same behavior alone and in mixed melting point as a known sample of dixanthylurea prepared according to the directions of Werner and Fearon.[9]

Twelve grams of bromine and 30.7 g. of anhydrous formic acid were allowed to stand together for two days. The mixture, bromine being at the bottom, was allowed to run slowly from a dropping funnel into a solution of 108.3 g. of aniline in 300 cc. of benzene which was stirred vigorously with a mechanical stirrer. There was no considerable heating. A large amount of white precipitate appeared but this did not impede the stirring. The mixture, made alkaline, steam distilled, extracted with ether, etc., as described, yielded 0.2644 g. of crude product. Calculated as pure carbanilide this corresponds to 1.73% of the bromine. Fractional sublimation in vacuum and fractional crystallization yielded one fraction which consisted of impure carbanilide and another which consisted largely of brominated carbanilides. The first of these, recrystallized several times from alcohol, from dilute alcohol, and from water, and twice micro-recrystallized from alcohol, yielded carbanilide, m. p. 233.5–234.0°, identified by mixed m. p. 234.0–234.5° with a known sample, m. p. 234.5–235.0°. The other principal fraction was refluxed gently for forty-five minutes with 2 cc. of aniline in order that the brominated carbanilides by a "urea dearrangement" might be converted into carbanilide. The excess aniline was driven off by steam distillation, and the residue, dissolved out by ether, weighed 0.0341 g. In the molecular still it yielded 0.0199 g. of sublimate, light brown in color, and 0.0074 g. of residual tar. The sublimate, which evidently contained some brominated aniline, after several recrystallizations yielded carbanilide, m. p. 234.0–234.5°, mixed m. p. 234.5–235.0°, known m. p. 234.5–235.0°.

(9) Werner and Fearon, *J. Chem. Soc.*, **117**, 1360 (1920).

Summary

Bromine reacts with formic acid to produce a substance which, in the presence of an excess of bromine, reacts with aniline to form derivatives of urea, namely, carbanilide and brominated carbanilides.

The intermediate substance, evidently capable of existence only in the presence of free bromine, is probably dibromo-dihydroxy-methane formed by the addition of bromine to dihydroxy divalent carbon, the tautomeric form of formic acid.

Metal Pyridine Complex Salts. VI. Cobaltous and Nickelous Dipyridine Salts of Fatty Acids

BY TENNEY L. DAVIS AND ALBERT V. LOGAN

In the preceding paper of this series[1] experiments were reported which showed that the pyridine in the pyridine complex cupric, cobaltous and nickelous cyanates is held by greater forces of affinity than the pyridine in the corresponding complex thiocyanates. The greater forces of chemical affinity are evident both from the lower dissociation pressures of the complex cyanates and from the greater shrinkages which occur when the complex cyanates, as compared with the complex thiocyanates, are formed from their component salts and pyridine. The thiocyanate radical to a greater extent than the cyanate radical exhausts the total affinity of the metal atom and leaves less of it available for coördinative combination with pyridine. The effect is due solely to the difference between a sulfur and an oxygen atom at the far end of the acid radical which is attached to the metal by an electrovalent linkage.

In the present paper we wish to report experiments on the dipyridine cobaltous and nickelous salts of acetic, propionic, butyric, isobutyric and valeric acids. We have determined their dissociation pressures over the temperature interval between 15–20° and 85–90° and the volume changes which occur at 25° when the complexes are formed by the combination of their compo-

nent salts with pyridine. The results show the effect, upon the residual affinity of the metal atoms, of additional —CH_2— groups successively introduced into the acid radical.

Experimental Procedure

The dissociation pressures of the complexes were determined in the same way as in the earlier experiments of this series.[2]

Preparation of Compounds.—Cobaltous or nickelous carbonate was refluxed for several hours with the pure fatty acid, a small quantity of water was added, the solution was filtered and evaporated to dryness, and the crystalline residue was powdered and dried in vacuum over caustic potash for the removal of moisture and excess acid. When analysis showed that the material was the pure anhydrous salt, it was taken for the preparation of the complex.

The dry salts were converted into the complexes by treating them with chloroform and adding pyridine until everything went into solution. The lower members of the series of complex salts were found to be much less soluble in chloroform than the higher members, and a considerable excess of pyridine was found to be necessary to make them dissolve. The filtered solutions were allowed to evaporate in the hood, and the resulting crystals, dried between filter papers, were placed in a desiccator over caustic potash. The complex acetates and propionates were allowed to come to equilibrium with pyridine in an open vessel in the desiccator. When the same procedure was tried with the complex butyrates, isobutyrates and valerates, the crystals deliquesced and became wet with pyridine. The crystals of these complexes therefore were allowed to come to equilibrium, over caustic potash, with the pyridine which still adhered to their surfaces after they had been pressed between filter papers.

Cobalt was determined as sulfate, nickel as sulfate and sometimes by titration with potassium cyanide, and pyridine by the method of A. C. Houghton,[3] which we have used in earlier work and have found to be accurate to about 1%.

The five nickelous dipyridine complex salts consisted of bright greenish blue crystals. Cobaltous dipyridine acetate consisted of rose pink crystals, the propionate, butyrate and isobutyrate were more deeply colored, and the valerate crystallized in ruby red prisms.

Density Determinations.—The densities of the cobaltous and nickelous salts were determined by weighing in specific gravity bottles with dry benzene at 25°. Since it was expected that organic liquids would dissolve pyridine from the complexes, the densities of the latter were determined by using saturated solutions of the complexes in pyridine for the pycnometer liquids. The large effect of temperature on the solubility of the complex butyrates, isobutyrates and valerates in pyridine is probably the principal source of error in the determinations.

Experimental Results

The experimental data for the dissociation pressures, corrected for the expansion of mercury from 20°, are summarized in Table I. If these data are plotted on a semi-logarithmic chart, along with the data for the vapor pressure of pyridine (from our earlier experiments), they give good straight lines for the cobaltous complexes, lines which approach slowly at the higher tem-

peratures toward the straight line which represents the vapor pressure of pyridine. The data for the nickelous complexes yield straight lines which bend in the neighborhood of 60° and resume their straightness with a different slope, lines which approach the pyridine line both at the higher and at the lower temperatures. The dissociation pressures at 25°, estimated from the graphs, are shown in Table II.

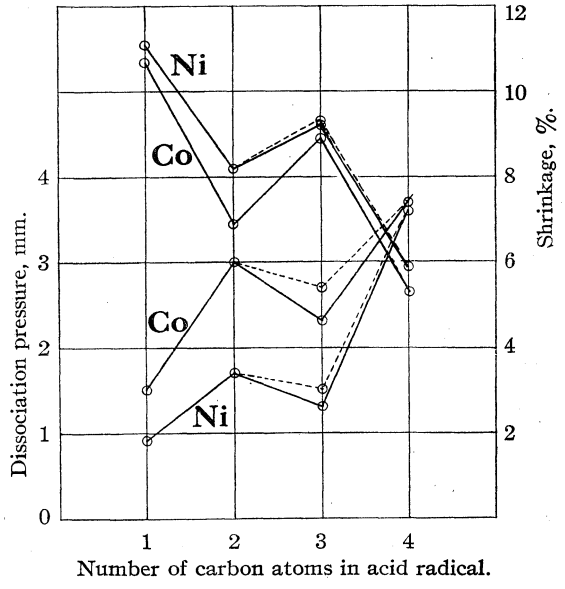

Fig. 1.—Dissociation pressures at 25° (lower), and shrinkages (upper) which occur at 25° during the formation of the complexes of cobaltous and nickelous dipyridine salts of fatty acids. (Dotted lines indicate isobutyrates.)

The results of analyses and of density determinations are summarized in Table III. In two cases the analytical figures represent single determinations; in all others they are averages of two check values.

The values reported for the densities are averages of two or of three determinations, and the "error" is the mean deviation from the average. From the densities and from our earlier data on the density of pyridine,[1] the molecular volumes were calculated and the contractions which occur when the simple salts combine with pyridine at 25° to form the dipyridine complexes were inferred. The decreases of volume per mole of complex are indicated in the last two columns of Table III.

Discussion of Results

From the positions of the dissociation pressure lines on a semilogarithmic chart (not reproduced), it is possible to conclude that, within the temperature range in which we have worked, the cobaltous dipyridine salts of the fatty acids are less stable at the higher temperatures. The nickelous compounds have a point of maximum stability in the neighborhood of 60°, and tend to decompose when they are warmed or cooled from that temperature. All of the nickelous and zinc pyridine complex salts which we have studied earlier have the remarkable property that they tend to decompose at low temperatures.

The greater forces of affinity which produce the greater decreases of volume during the formation of the complexes also result in the pyridine being more strongly bound to the metal and produce the lower dissociation pressures. The relationship is exhibited in the chart, Fig. 1, where the dissociation pressures at 25° and the volume–

decreases during formation at 25° are plotted as functions of the number of the carbon atoms in the acid radicals. Both curves show the sawtooth pattern which is a characteristic representation of many of the properties of fatty acids.

The acid radicals which contain two and four carbon atoms use less of the total affinity of the metals than do the acid radicals which contain three and five carbon atoms, and the corresponding complexes hold their pyridine more firmly, having lower dissociation pressures, their formation being accompanied by greater shrinkages.

Except for the effect of odd and even numbers of carbon atoms, the general effect of increasing the number of carbon atoms in the acid radical appears to be to reduce the residual affinities of the metal atoms and to leave less available for combination with pyridine.

The effect of a fork in the carbon chain is small.

The nickel atom has greater chemical forces available for coördinative combination with pyridine at 25° than has the cobalt atom, for the nickelous complex salts are formed with greater volume decreases, and have lower dissociation pressures, than the cobaltous compounds.

Summary

The dissociation pressures of cobaltous and nickelous dipyridine acetate, propionate, butyrate, isobutyrate, and valerate have been determined over the temperature range from 15–20° to 85–90°.

The densities at 25° of the complexes and of their component salts have been determined, and the volume changes which occur at 25° during the combination of the simple salts with pyridine have been calculated. The complexes of which the formation is accompanied by the greater shrinkages have the lower dissociation pressures.

The effect of groups upon the residual affinities of the metal atoms is discussed.

Alkanolamines. IX. Reducing and Hydrolyzing Action of the Ethanolamines on the Dichloronitrobenzenes

BY CHESTER B. KREMER AND AARON BENDICH

In a preceding article of this series,[1] an account was given of the reactions occurring between the isomeric dichloronitrobenzenes and monoethanolamine as carried out in neutral solvents. When these reactions are carried out in the absence of neutral solvents, the course followed is quite different, the condensing ability of the amino alcohol is considerably decreased and there is substituted the tendency toward reduction, hydrolysis and the formation of addition compounds. The finding of a combination of these tendencies, together with condensation, in a single run, is not infrequent. Insofar as the reductions involved, not only are the starting materials reduced to various stages, but there is also noted the reduction of an expected end-product. Under certain circumstances, it is found that when a dichloronitrobenzene is treated with monoethanolamine in the presence of anhydrous sodium carbonate, there can be isolated from the reaction mixture: (1) the condensation product, (2) a reduced product of the dichloronitrobenzene, either the azo or amino derivative, (3) the reduced condensation product, (4) an hydrolysis product of the dichloronitrobenzene, and in some cases (5) addition compounds of the type $x C_6H_3NO_2Cl_2 \cdot y NH_2CH_2CH_2OH$ where x and y are usually 1 or 2.

In order to make this survey more complete, the action of diethanolamine and triethanolamine upon the isomeric dichloronitrobenzenes was also studied. The ability of these ethanolamines to reduce, hydrolyze and form addition products with the isomers is, in most cases, greater than that of monoethanolamine. While condensations are possible in the case of diethanolamine, there was no instance of such reaction during the course of this work. Condensations involving this amino alcohol do occur when the reaction takes place in a neutral solvent; but even here the tendency is not great.

The fact that good yields of amino products can be obtained in these reactions is of interest since mononitro compounds are not generally re-

(1) Kremer and Bendich, THIS JOURNAL, 61, 2658 (1939).

duced to this stage in alkaline media. In this research, the reductions yielded only azo or amino compounds as final products, usually a mixture of the two. In only one or two instances was there any indication of the azoxy state and in no case were hydrazo compounds indicated.

Of the possible azo compounds derived by reduction of the dichloronitrobenzenes, only the 2,2′,5,5′-tetrachloroazobenzene is reported in the literature. This article reports the formation of two others, namely, 3,3′,4,4′-tetrachloroazobenzene and 3,3′,5,5′-tetrachloroazobenzene. It was not possible to isolate the azo compounds of the other isomers, tars being the main products in these cases. The presence of the azoxy state was suspected in several instances, but no satisfactory isolation was effected. The azo compounds obtained were orange solids, recrystallizable from benzene or petroleum ether–benzene mixtures.

Experimental

The isomeric dichloronitrobenzenes were prepared as previously described.[1] The ethanolamines were obtained from the Union Carbide and Carbon Corporation.

The experimental procedure followed in the major portion of this work can be summarized as follows. The apparatus used was a three-necked, round-bottom flask equipped with mechanical stirrer, reflux condenser and dropping funnel. The dichloronitrobenzene was introduced into the flask, along with any added alkali, and the whole gently warmed until the dichloronitrobenzene was melted. The ethanolamine was then added dropwise and the mixture refluxed for several hours. After refluxing, the reaction mixture was steam distilled until the distillate was clear. The latter was then freed of any solid or oil materials and extracted with ethyl ether and the ether extracts dried over anhydrous magnesium sulfate. The aqueous layers were made acid with hydrochloric acid and extracted with ethyl ether and these extracts were likewise dried.

The residue in the steam distillation flask was filtered from any resulting solid and alkaline and acid ether extracts made of the filtrate following the procedure described above.

The various extracts and residues were then systematically investigated and the results are summarized in Table I. All reactants are expressed in molar ratios although the actual amounts involved were usually fractions of those indicated.

Preparation of Azo Compounds. 3,3′,5,5′-Tetrachloroazobenzene.—In one run, monoethanolamine, 2,5-dichloronitrobenzene and anhydrous sodium carbonate in molar ratios were refluxed for approximately four hours. The reaction mixture was then subjected to steam distillation. 3,5-Dichloroaniline was detected in the steam distillate in a yield of about 20%. There remained in the distillation flask a very dark red solid which was filtered off. This was washed twice with hot alcohol and then recrystallized from benzene. The resulting product was orange in color and melted at 158.5° (cor.). Calculated % N for 3,3′,5,5′-tetrachloroazobenzene, 8.76; % N found, 8.88. The product was further identified by reduction with tin and hydrochloric acid. This yielded a white crystalline substance giving a primary amine test and melting at 51° (the melting point of 3,5-dichloroaniline). A mixed melt-

ing point with a known sample of 3,5-dichloroaniline showed no deviation.

In another run, diethanolamine was employed without added alkali. No attempt was made here to identify other products than azo which was present in about 40% yield.

Preparation of 3,3′,4,4′-Tetrachloroazobenzene.—The 3,4-dichloronitrobenzene was, in most cases, refluxed with either di- or triethanolamine. The experimental procedure was the same as described above. The amount of 3,4-dichloroaniline recovered was small, usually under 10%. The azo product was recrystallized from a petroleum ether–benzene mixture giving a light orange product melting at 195.5° (cor.). Analyses indicated a persistent impurity, difficult to remove through successive recrystallizations: calculated % N for 3,3′,4,4′-tetrachloroazobenzene, 8.76; N found, 9.15, 9.07. Further identification was furnished by reducing the product with tin and hydrochloric acid. A white product giving a primary amine test and melting at 71° was obtained. A mixed melting point with a known sample of 3,4-dichloroaniline was unchanged.

Discussion

That reduction of the dichloronitrobenzenes occurs in definite stages is clearly borne out by some of the experiments. The one involving the action of diethanolamine on 3,4-dichloronitrobenzene is representative. When the two are refluxed together for a period of two hours, the only reduction product isolated is the azo compound; if heating is continued for four hours, no tetrachloroazobenzene can be identified, but reduction to the amino state is found to have taken place.

In previous work,[1] it was established that the 2,4-, 3,4- and 2,5-dichloronitrobenzenes were the most reactive of the isomers insofar as condensation reactions were concerned, while the 2,3- and 2,6- were much less reactive. When we examine the reducing tendency of the ethanolamines upon the various isomers, this general division still holds. The latter two compounds were much given to tar formation, from which tars little of interest could be extracted. For this reason most of the reported work dealt with the reactions of the 2,5-, 3,4- and 3,5-isomers, the 2,5- especially having been studied at length.

Hydrolysis of one of the chloro groups of 2,5- and 3,4-dichloronitrobenzenes was found to occur in certain of the reactions. That the chloro groups of these compounds are more active than the corresponding chloro groups of the other isomers already has been amply demonstrated.

Summary

1. Reduction to the amino and azo condition is found to occur when the isomeric dichloronitrobenzenes are reacted upon by the ethanolamines in the absence of a neutral solvent.

2. Condensation, hydrolysis and addition reactions are also found to occur.

3. Two new azo compounds, 3,3′,4,4′- and 3,3′,5,5′-tetrachloroazobenzene, are reported.

Ketene Acetals. V. The Reaction of Ketene Diethylacetal with Various Compounds Containing an Active Hydrogen[1]

BY HARRY M. BARNES,[2] D. KUNDIGER AND S. M. MCELVAIN

In the fourth paper[3] of this series the unusual hetero-enoid system that is present in ketene diethylacetal was discussed, particularly as it affected the polymerization of the compound. It was to be expected that the reaction of a compound having such a strong nucleophilic center as does ketene acetal with other substances containing an active hydrogen would be of considerable interest. The present paper is a report of the results obtained from a study of the reactions of a variety of compounds, in which hydrogen is found attached to halogen, oxygen, carbon and nitrogen, with ketene acetal.

At the time that the preparation of ketene acetal was first reported,[4] the vigorous reaction of both water and ethyl alcohol with it was noted. These reactions produce ethyl acetate and ethyl orthoacetate, respectively. The formation of the former compound probably, and the latter obviously, involves addition across the carbon to carbon double bond of ketene acetal, thus

$$CH_2{=}C(OEt)_2 + HOEt \longrightarrow CH_3C(OEt)_3$$

Secondary alcohols (*i*-propyl and *s*-butyl) react similarly, but *t*-butyl alcohol does not appear to

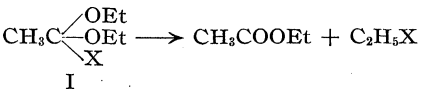
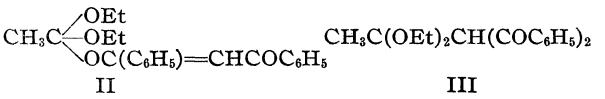
(4) Beyerstedt and McElvain, *ibid.*, **58**, 529 (1936).

react even after several hours of refluxing with the acetal. In a similar manner the halogen acids, carboxylic acids and phenol appear to add to ketene acetal. The reaction takes place at room temperature with the liberation of considerable heat. The addition product (I), however, is



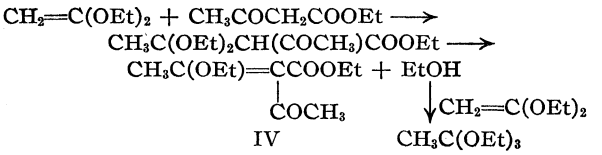
unstable and decomposes into ethyl acetate and C_2H_5X(X is —Br, RCOO—, or C_6H_5O—). In the case of the phenol reaction a small amount of I decomposes into phenyl acetate and ether.

In contrast to the behavior of phenol, the highly enolic dibenzoylmethane gives a stable addition product, (O-(α,α-diethoxyethyl)-dibenzoylmethane, (II) with ketene acetal. Reaction occurs at



25° and is practically quantitative. The reaction product melts at 87° (m. p. of dibenzoylmethane, 78°) and was shown to have the structure II by the fact that it reacted to only a small extent (16%) with a standard ethereal solution of sodium triphenylmethyl. The enolizable alternative addition product III, which would result from the addition of the dibenzoylmethane as H and CH(COC_6H_5)$_2$ to ketene acetal, would be expected to react quantitatively with this reagent as does dibenzoylmethane. When the product II is heated at 140° it decomposes into its components, dibenzoylmethane and ketene acetal. This is the same type of decomposition of an ortho-ester into a ketene acetal as that reported by Staudinger and Rathsam.[5] Indeed, II slowly decomposes at room temperature; a sample after standing in a vacuum desiccator over calcium chloride for three months was found to have reverted entirely into dibenzoylmethane.

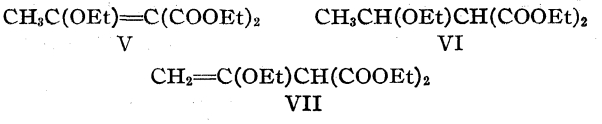
Acetoacetic ester, which contains a relatively small amount (7%) of the enolic form, shows an entirely different behavior with ketene acetal. While each of the reactants described above reacts with the acetal in the molecular ratio of 1:1, each mole of acetoacetic ester that reacts consumes two moles of the acetal. No apparent reaction occurs at 25° but after nine hours at 85° a 12% yield of ethyl (α-ethoxyethylidene)-acetoacetate (IV) and an equivalent amount of ethyl orthoacetate may be isolated. The product IV is probably formed by the addition of the keto-ester as H and CH($COCH_3$)COOEt to ketene acetal followed by the loss of alcohol from the addition product. This liberated alcohol then reacts with another equivalent of ketene acetal to produce the ortho-ester. These reactions are



The yield of IV from the above reaction may be increased to 55–60% of the theoretical by the addition of 1 mole per cent. of sodium ethoxide to the reaction mixture. A corresponding increase in the yield of ethyl orthoacetate also is obtained.

The structure of the ester IV was established by (a) carbon, hydrogen and ethoxyl analyses, (b) partial hydrolysis to ethyl diacetoacetate and (c) partial hydrolysis into alcohol, acetoacetic ester and acetic acid.

In the absence of sodium ethoxide malonic ester does not react with ketene acetal even after several hours of heating at temperatures as high as 200°. With 1 mole per cent. of this catalyst, however, a 55% yield of diethyl (α-ethoxyethylidene)-malonate (V) and the corresponding amount of ethyl orthoacetate may be obtained after sixteen hours at 125°. The structure of V was established by (a) analyses, (b) partial hydrolysis to diethyl acetomalonate and (c) catalytic reduction to diethyl (α-ethoxyethyl)-malonate (VI).



Differentiation between structure V and the alternative structure VII was made by ozonolysis.[6]

Methyl malonic ester could not be caused to react with ketene acetal under conditions that were effective for the reaction of malonic ester. The use of sodium ethoxide, in quantities of 1–50 mole per cent., or sodium triphenylmethyl as condensing agents together with temperatures

(5) Staudinger and Rathsam, *Helv. Chim. Acta*, **5**, 646 (1922).

(6) This ozonolysis was carried out by Mr. Howard Burkett of this Laboratory. He has found that a considerable amount of VII generally accompanies V as a product of this reaction. The combined yields of the two amount to about 80% of the theoretical. Their structures have been established by (a) ozonolysis and (b) alkylation of each to the same malonic esters, CH_2=C(OEt)C(R)(COOEt)$_2$, a series of which is being prepared and converted into the corresponding barbituric acids. This work will be reported in a future paper.

as high as 200° gave no appreciable reaction and in each case most of the starting materials could be recovered.

bis-(Phenylsulfonyl)-methane contains an acidic hydrogen, as shown by its solubility in alkali, but, presumably, is incapable of enolization. This disulfone gives no indication of reaction when treated with two equivalents of ketene acetal at 25°. When these reactants were heated together at 100° in dioxane solution for twelve hours and the solvent then removed by distillation, a glass-like residue remained. From this residue a considerable amount (42%) of the starting disulfone was separated, but no ketene acetal was recovered from the distilled solvent. The reaction product could be neither crystallized nor distilled. These facts indicate that this reaction was complicated by the polymerization of the ketene acetal. Similar results were obtained with these reactants when sodium ethoxide was used.

The nitrogen compounds used in this study were ammonia, aniline, ethylaniline and piperidine. In contrast to the vigorous reaction of water, ammonia shows no reaction with ketene acetal at 25°. At 100°, however, reaction between acetal and an excess of ammonia appears to be complete in three hours. For each mole of ketene acetal used, 1.68 moles of alcohol, 0.55 mole of acetonitrile (XI), 0.22 mole of acetamidine (X) and 0.02 mole of ethyl orthoacetate were isolated as reaction products. These products indicate that the following reactions occur

$$CH_2{=}C(OEt)_2 + NH_3 \longrightarrow \underset{\text{VIII}}{[CH_3C(OEt)_2NH_2]} \longrightarrow EtOH + CH_3C(OEt){=}NH$$

$$CH_3C(OEt){=}NH + NH_3 \longrightarrow EtOH + \underset{\text{X}}{CH_3C(NH_2){=}NH} \xrightarrow[-NH_3]{\text{IX}} \underset{\text{XI}}{CH_3CN} \quad (-EtOH)$$

The low yield of the ortho-ester suggests that the addition product VIII is sufficiently stable not to decompose into alcohol, which would convert the ketene acetal into the ortho-ester, until the ammonia has reacted with most of the acetal. The other alternative, *viz.*, that the imino-ether (IX) is formed from the ortho-ester and ammonia seems unlikely since some ortho-ester does remain in the reaction mixture in the presence of a large excess of ammonia.

Aniline reacts quite readily with ketene acetal at 25°. The main reaction product is ethyl N-phenyl iminoacetate (XIII) which is obtained in an 81% yield. An amount of alcohol equivalent to that required in the reactions below and a 7% yield of N,N'-diphenylacetamidine (XIV) is also obtained. No ethyl orthoacetate was isolated. The reactions that take place are

$$CH_2{=}C(OEt)_2 + H_2NC_6H_5 \longrightarrow \underset{\text{XII}}{[CH_3C(OEt)_2NHC_6H_5]} \longrightarrow \underset{\text{XIII}}{CH_3C(OEt){=}NC_6H_5} + EtOH$$

$$CH_3C(OEt){=}NC_6H_5 + H_2NC_6H_5 \longrightarrow \underset{\text{XIV}}{CH_3C(NHC_6H_5){=}NC_6H_5} + EtOH$$

Ethylaniline reacts with ketene acetal, slowly at 25°, but quite readily at 100° to give N-ethyl-N-(α-ethoxyvinyl)-aniline (XV) and ethyl orthoacetate. When the reactants are used in equivalent molecular quantities, one-half of the ethylaniline is recovered, indicating the following reaction course

$$2CH_2{=}C(OEt)_2 + C_2H_5NHC_6H_5 \longrightarrow \underset{\text{XV}}{CH_2{=}C(OEt)N(C_2H_5)C_6H_5} + CH_3C(OEt)_3$$

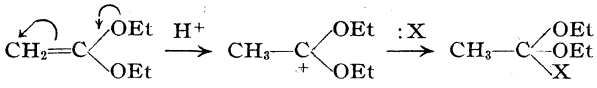
Whether or not an intermediate addition product of the type of VIII and XII is a precursor of XV is not known. The product XV was characterized by (a) analyses and (b) hydrolysis to ethylaniline, alcohol and acetic acid. It was not possible to partially hydrolyze XV to N-ethylacetanilide.

Piperidine shows no reaction with ketene acetal at 25°. When a mixture of a five-fold excess of the base with the acetal is refluxed for two hours, reaction takes place and 0.43 mole each of 1,1,1-tripiperidinoethane XVI and ethyl orthoacetate for each mole of ketene acetal used in the reaction may be isolated. The formation of these compounds is illustrated as follows

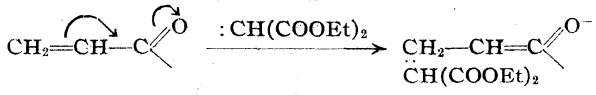
$$2CH_2{=}C(OEt)_2 + 3HNC_5H_{10} \longrightarrow \underset{\text{XVI}}{CH_3C(NC_5H_{10})_3} + CH_3C(OEt)_3 + EtOH$$

From the foregoing reactions it is seen that acids and, in general, compounds containing a replaceable hydrogen attached to oxygen (water, primary and secondary alcohols, enols, etc.) react readily with ketene acetal at ordinary temperatures. The reactivity appears to be related to the acidity of the compound. The same seems to be true for ammonia and its derivatives; the relatively strong bases (*i. e.*, weak acids), ammonia and piperidine, are decidedly less reactive than

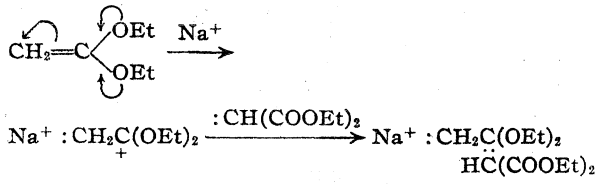
the very much weaker bases, aniline and ethylaniline. All of these reactions follow the course that would be expected, *viz.*, the attack of a proton on the nucleophilic center of a polarized molecule of ketene acetal, followed by the attachment of the negative portion of the addendum, :X, to the other carbon with an open sextet



The reactivities of the active methylene compounds, acetoacetic ester, malonic ester and methylmalonic ester, also decrease with the acidity of the ester but in these cases the reaction, when it occurs, is decidedly different in that it is catalyzed by sodium ethoxide and a new carbon to carbon bond is formed. It seems likely that the addenda in a case such as malonic ester are Na^+ and $:CH(COOEt)_2$, but whether the sodium cation or the anion is the attacking portion of the addendum is a matter of speculation. This reaction has some resemblance to a Michael reaction. The latter also involves the addition of an active methylene compound to a carbon to carbon double bond through the catalytic influence of sodium ethoxide. In this reaction it seems likely that the polarization of the carbonyl group of the unsaturated compound creates a center of low electron density at the carbon to which the addendum anion becomes attached



The hetero-enoid polarization of ketene acetal, however, is such that neither of the carbons acquires an electron deficit. It seems necessary to suppose, therefore, that the alkaline catalyst functions through the ability of the sodium cation to hold the electron increment that is built up on the methylene carbon until the anion portion of the addendum becomes attached to the other carbon which, after depolarization, would have the requisite electron deficit, thus



Another molecule of malonic ester could substitute a proton for the sodium cation, or a molecule of sodium ethoxide could be eliminated from the addition product, and the reaction continue through repetition of the steps above indicated. This formulation is similar to that used to explain the catalysis of cadmium chloride for the polymerization of ketene acetal.[3]

Since it has been shown[7] that active methylene groups in sulfones undergo the Michael reaction it was thought that *bis*-(phenylsulfonyl)-methane would behave similarly to malonic ester with ketene acetal. However, this was not the case. Even though it was not possible to isolate any product (except considerable of the starting disulfone) from this reaction it was quite obvious that it had taken a different course than that of the other active methylene compounds that were studied.

Experimental

The Reaction of Ketene Acetal with Acids and Enols

Hydrobromic Acid.—A solution of 18.6 g. (0.23 mole) of hydrogen bromide (from the bromination of xylene) in 200 g. of di-*n*-butyl ether was cooled to about 0° and treated dropwise, with vigorous stirring, with 26.7 g. (0.23 mole) of ketene acetal.[3] A yellow precipitate, which redissolved, was formed when each drop of the acetal entered the solution. A considerable amount of heat was evolved. After about one-fifth of the acetal had been added a red oil separated to the bottom of the reaction flask. This did not seem to increase in quantity during the reaction. After all of the acetal had been added, titration of the solution showed that 17% of the starting hydrogen bromide still was present. Distillation of the ether solution yielded 24 g. (85%) of the ethyl bromide and 12.7 g. (72%) of ethyl acetate.

3,5-Dinitrobenzoic Acid.—To 2.17 g. (0.01 mole) of 3,5-dinitrobenzoic acid, suspended in 30 ml. of ether, was added 1.7 g. (0.015 mole) of ketene acetal. The solution was evaporated on the steam-bath and recrystallized from alcohol. A yield of 1.8 g. (74%) of ethyl 3,5-dinitrobenzoate, m. p. 94–95°, was obtained.

Phenol.—To 47.0 g. (0.5 mole) of phenol in a flask attached to a condenser carrying a drierite tube, 58.0 g. (0.5 mole) of ketene acetal was slowly added with shaking. The temperature quickly rose to 80°. After standing for an hour, the reaction mixture was fractionated: 20.9 g. (59%) of ethyl acetate, b. p. 72–79°; 38.2 g. (78%) of phenetole, b. p. 162–169°, and 11.6 g. (17%) of phenyl acetate, b. p. 189–194°, were obtained.

Dibenzoylmethane.—To 14.0 g. (0.06 mole) of dibenzoylmethane, m. p. 77–78°, contained in a flask attached to a condenser carrying a drierite tube was added, with shaking, 14.5 g. (0.12 mole) of ketene acetal. In about thirty minutes the temperature of the solution had risen to 40°. After standing five to six hours the solution changed to a crystalline mass. The flask was then placed in an oil-bath at 60° and the excess of ketene acetal (6–7 g.) removed under 0.5 mm. pressure and collected in a cold trap.

(7) Connor, *et al.*, THIS JOURNAL, **58**, 1386 (1936).

The remaining 22 g. of residue was triturated in a mortar with 45 ml. of cold petroleum ether (60–68°) for ten minutes and then filtered by suction. The crystalline product so obtained was similarly washed with three other 18-ml. portions of petroleum ether and dried *in vacuo* to constant weight. The yield of product (II), melting at 86–87°, was 20.3 g. (95%). Its melting point remained unchanged after recrystallization from petroleum ether (60–68°); mol. wt. (cryoscopic in benzene), 335; calcd., 340.

Anal. Calcd. for $C_{21}H_{24}O_4$: C, 74.08; H, 7.11; OC_2H_5, 26.47. Found: C, 73.95; H, 7.06; OC_2H_5, 26.50.

The O-(α,α-diethoxyethyl)-dibenzoylmethane was characterized by the following reactions, (a) hydrolysis with 5% sulfuric acid converted it into ethyl alcohol, acetic acid and dibenzoylmethane; (b) pyrolysis of 20 g. of this product at 140° (38 mm.) under nitrogen produced 2.1 g. (31%) of ketene acetal as a distillate and left a rather tarry residue which, after washing with petroleum ether, and two recrystallizations from methanol yielded 8.3 g. (61%) of dibenzoylmethane, m. p. 77–78°; (c) simultaneous titration under nitrogen of a 1.2014 g. sample of the reaction product and a 0.4994 g. sample of dibenzoylmethane with a 0.0982 *N* solution of sodium triphenylmethyl[8] showed that the product used only 16% of a molecular equivalent while dibenzoylmethane used 100% of a molecular equivalent of the sodium triphenylmethyl before the red color of the solution of the latter compound persisted.

Ethyl (α-Ethoxyethylidene)-acetoacetate (IV).—To 22.8 g. (0.18 mole) of acetoacetic ester containing 1 mole per cent. of sodium ethoxide in a flask attached to a reflux condenser carrying a drierite tube was added 40 g. (0.36 mole) of ketene acetal. After heating for nine hours in an oil-bath at 85° the reaction mixture was fractionated. The following fractions were obtained, (a) 5.1 g. of a mixture of ethyl acetate and ethyl alcohol, (b) 21.8 g. (78% based on one-half of the ketene acetal used) of ethyl orthoacetate, b. p. 100–102° (200 mm.), (c) 1.5 g. of an intermediate fraction, and (d) 23.9 g. of a fraction boiling at 96–103° (1 mm.). Refractionation of fraction (d) gave 22.8 g. (68%) of IV, b. p. 96–98° (1 mm.); mol. wt. (cryoscopic in benzene), 208; calcd., 200.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 59.97; H, 8.06; OC_2H_5, 45.0. Found: C, 59.62; H, 8.02; OC_2H_5, 44.7.

When the above experiment was carried out in the absence of sodium ethoxide, a yield of only 12% of the theoretical amount of IV was obtained, even after twenty-four hours of heating at 85°.

Hydrolysis of 10 g. (0.05 mole) of IV with 1.8 g. (0.1 mole) of water in dioxane gave, after five hours of refluxing, 92% of the theoretical quantity of acetic acid (titration) and 2.0 g. of acetoacetic ester, b. p. 175–178°. Hydrolysis of 11.2 g. of IV with only one equivalent (0.95 g.) of water in 20 g. of dioxane gave, after thirty minutes of refluxing followed by fractionation, 3.7 g. of diacetoacetic ester,[9] b. p. 102–104° (15 mm.), the copper salt of which melted at 149–150°.[10]

(9) Claisen, *Ann.*, **277**, 172 (1893).

(10) James, *ibid.*, **226**, 212 (1884).

Diethyl (α-Ethoxyethylidene)-malonate (V).—A mixture of 23.2 g. (0.2 mole) of ketene acetal, 16 g. (0.1 mole) of diethyl malonate and 0.1 g. of sodium ethoxide was heated in an oil-bath at 125° for sixteen hours, after which time the reaction mixture was fractionated. A yield of 13.2 g. (81%) of ethyl orthoacetate and 19 g. of a fraction boiling at 100–102° (1 mm.) were obtained. This fraction was cooled to −15° and rapidly filtered through a cold filter. The crystals so obtained amounted to about 70% of the weight of the fraction boiling at 100–102° (1 mm.). The crystalline product (V) weighed 12.7 g. (55%) and melted at 26–27°.[11] Mol. wt. (cryoscopic in benzene), 219; calcd., 230.

Anal. Calcd. for $C_{11}H_{18}O_5$: C, 57.37; H, 7.88; OC_2H_5, 58.7. Found: C, 57.62; H, 7.86; OC_2H_5, 58.6.

A mixture of 11 g. of V and 10 ml. of 2 *N* hydrochloric acid was heated, with intermittent shaking, for ten minutes on a steam-bath. The mixture was cooled and extracted with ether. The ethereal solution, after washing with sodium carbonate solution, was dried and distilled. A yield of 6.8 g. of diethyl acetomalonate, b. p. 65–70° (0.55 mm.); $n^{25}D$ 1.4435; d^{25}_{25} 1.0906, was obtained. Its copper derivative melted at 124–125° and showed no depression in melting point when mixed with the copper derivative of a known sample of diethyl acetomalonate prepared by the procedure of Nef.[12]

Diethyl (α-Ethoxyethyl)-malonate (VI).—A solution of 9.4 g. (0.04 mole) of diethyl (α-ethoxyethylidene)-malonate (V) in 15 ml. of absolute alcohol was hydrogenated at 100° under an initial hydrogen pressure of 2800 pounds in the presence of 1 g. of Raney nickel. Hydrogen absorption ceased in forty-five minutes after about 0.05 mole had been absorbed. Careful fractionation of the alcoholic solution, after filtering off the nickel catalyst, yielded 5 g. of VI, b. p. 66–67° (0.4 mm.); $n^{25}D$ 1.4198; d^{25}_4 1.0120; M_D calcd., 57.95; found, 58.0; saponification equivalent, calcd., 116; found, 118.

Anal. Calcd. for $C_{11}H_{20}O_5$: C, 56.68; H, 8.68; OC_2H_5, 58.2. Found: C, 56.84; H, 8.97; OC_2H_5, 56.1.

Attempted Reaction of Diethyl Methylmalonate with Ketene Acetal.—A mixture of 19 g. (0.11 mole) of diethyl methylmalonate, 12.8 g. (0.11 mole) of ketene acetal and 0.1 g. of sodium ethoxide was heated in an oil-bath under a reflux condenser at 125° for sixteen hours. Upon fractionation of the reaction mixture, 10.7 g. of ketene acetal, b. p. 80–85° (200 mm.), and 18.2 g. of diethyl methylmalonate, b. p. 86–87° (13 mm.), were recovered.

Reaction of *bis*-(Phenylsulfonyl)-methane with Ketene Acetal.—To 6.4 g. (0.025 mole) of the disulfone dissolved in 45 g. of dioxane was added 5.8 g. (0.05 mole) of ketene acetal and the resulting solution refluxed for twelve hours. The solvent was then allowed to evaporate spontaneously from a crystallizing dish in a vacuum desiccator, with the last traces of the dioxane being removed at 80° under 1 mm. pressure. The liquid removed by this evaporation was collected in an acetone–carbon dioxide snow cold trap.

(11) Diethyl (α-ethoxyethylidene)-malonate has been reported by Sah, THIS JOURNAL, **53**, 1836 (1931), as a product (yield 4%) of the reaction of ethyl orthoacetate and diethyl malonate in the presence of acetic anhydride at 140°. He describes it as a red, glycol-thick liquid, the color of which could not be removed by redistillation.

(12) Nef, *Ann.*, **266**, 105 (1891).

Upon distillation it was found to be dioxane with small amounts of materials boiling above ketene acetal but lower than the disulfone. No ketene acetal was found. The glassy residue remaining after the evaporation was extracted with three 20-cc. portions of ether. These extractions left a quantity of the original disulfone as a white powder, which after recrystallization from dilute alcohol weighed 2.7 g. (42%) and melted at 118–119°. Evaporation of the ether used to extract the reaction product left a thick oil which changed to a dark non-volatile tar on attempted distillation under 0.01 mm. pressure.

The use of 5 mole per cent. of sodium ethoxide in a reaction similar to that described above gave practically the same results.

Reaction of Ketene Acetal with Ammonia and Amines. Ammonia.—Into 28.4 g. of ketene acetal contained in a bomb tube, prepared for sealing and cooled in an acetone–carbon dioxide snow bath, 14 g. of dry ammonia was distilled and the tube sealed off. The two liquids are immiscible. The bomb tube then was heated for three hours at 110°, after which time it was cooled and opened. The ammonia was allowed to distil off at room temperature and collected in a cold trap; 9 g. was recovered. Fractionation of the remaining liquid through a Widmer column yielded the following fractions: (a) 23.5 g. of a mixture of ethyl alcohol, ammonia and acetonitrile, b. p. 71–76°; (b) 6.2 g. in receiver and cold trap boiling below 40° (8 mm.); (c) 2 g. of a residue of acetamidine. The residue (c) could be sublimed but was best purified by dissolving in a mixture of anhydrous alcohol and ether and precipitating as the hydrochloride with hydrogen chloride. After filtration and recrystallization this hydrochloride melted at 177–178°.

Anal. Calcd. for $C_2H_7N_2Cl$: N, 29.65; Cl, 37.6. Found: N, 30.2; Cl, 36.3.

This amidine hydrochloride was further characterized as follows. A 0.6667-g. sample was treated with a solution of 5 g. of sodium hydroxide in 200 cc. of water and the ammonia distilled into a standard solution of sulfuric acid. The solution remaining in the boiling flask was treated with 2 g. of silver oxide and 30 cc. of 6 *N* sulfuric acid. The acetic acid was distilled out and titrated. Yields of 0.234 g. (97.5%) of ammonia and 0.415 g. (97.8%) of acetic acid were obtained.

Redistillation of fraction (b) gave 2.1 g. of material boiling at 73–76°, which was added to fraction (a), and 1.0 g. of ethyl orthoacetate boiling at 130–145°. A 3.60-g. sample of fraction (a) was titrated with 0.5 *N* sulfuric acid to neutrality with a methyl red–methylene blue indicator; this titration showed 0.031 g. of ammonia to be present. The acetonitrile was hydrolyzed by boiling with a sodium hydroxide solution as described above and the total ammonia collected in standard sulfuric acid. The acetic acid was determined in the remaining solution, from which the ammonia had been distilled, by acidification with sulfuric acid followed by distillation. Yields of 0.365 g. of ammonia and 1.19 g. of acetic acid were obtained from the 3.60-g. sample of fraction (a). After deduction of the free ammonia that was present in this sample, the molecular ratio of the ammonia to the acetic acid from the hydrolysis was 1:1.010. These values indicate that 5.6 g. (56%) of acetonitrile was formed in the reaction.

Aniline.—The addition of 5 g. of ketene acetal to 4 g. of aniline caused a considerable evolution of heat. After heating the mixture on a steam-bath for two hours in order to assure a more complete reaction, it was distilled. The following fractions were collected, (a) 1.7 g. (86% of the theoretical) of ethyl alcohol, b. p. 75–80°, (b) 5.7 g. of ethyl N-phenyliminoacetate, b. p. 93–94° (9 mm.), and (c) 0.6 g. of residue. Fraction (c), which was N,N'-diphenylacetamidine, solidified on cooling and after recrystallization from 70% alcohol, melted at 132–133°.[13] Fraction (b) was characterized by conversion into N,N'-diphenylacetamidine according to the procedure of Lander.[14]

Ethylaniline.—A mixture of 7.3 g. (0.06 mole) of ethylaniline and 7.0 g. (0.06 mole) of ketene acetal was heated on a steam-bath for five hours. After this time the reaction mixture was fractionated and the following fractions collected, (a) 1.25 g. (0.01 mole) of ethyl orthoacetate, b. p. 30–50° (22 mm.), (b) 3.7 g. (0.03 mole of ethylaniline, b. p. 100–105° (22 mm.), (c) 0.53 g. of an intermediate fraction boiling at 105–125° (22 mm.), (d) 5.47 g. (0.029 mole) of N-ethyl-N-(α-ethoxyvinyl)-aniline (XV), b. p. 128–130° (22 mm.). Redistillation of fraction (d) gave a product that boiled at 129–130° (22 mm.); $n^{25}D$ 1.5232; d^{25}_{25} 0.9750.

Anal. Calcd. for $C_{12}H_{17}ON$: N, 7.32; OC_2H_5, 23.6. Found: N, 7.28; OC_2H_5, 23.0.

The N-ethyl-N-(α-ethoxyvinyl)-aniline on treatment with 0.2 *N* sulfuric acid evolves considerable heat, but careful attempts to isolate N-ethylacetanilide from a partial hydrolysis of it were unsuccessful. All attempts at hydrolysis resulted in complete cleavage into alcohol, acetic acid and ethylaniline.

Piperidine.—Addition of 5 g. (0.043 mole) of ketene acetal to 19.5 g. (0.230 mole) of carefully dried piperidine produced no indication of reaction. The mixture, therefore, was refluxed for two hours. After this time it was fractionated into (a) 13.4 g. of a mixture of alcohol and piperidine, b. p. 45–55° (200 mm.), (b) 3.0 g. (43%) of ethyl orthoacetate, b. p. 45–50° (19 mm.) and (c) 5.2 g. (43% based on the acetal used) of 1,1,1-tripiperidinoethane, b. p. 113–115° (1 mm.); $n^{25}D$ 1.5042; d^{25}_{25} 0.9520.

Anal. Calcd. for $C_{17}H_{33}N_3$: N, 15.0. Found: N, 15.2.

Hydrolysis of a 1.77-g. sample of the tripiperidinoethane was carried out by refluxing it for twenty-four hours in 10 cc. of 6 *N* sulfuric acid solution. On making this hydrolysis solution alkaline, 83% of the theoretical quantity of piperidine could be distilled out. Acidification of the remaining alkaline solution with sulfuric acid followed by distillation gave 110% of the calculated quantity of acetic acid.

Summary

The reactions that take place between ketene acetal and a variety of compounds, in which an active hydrogen is attached to halogen, oxygen, carbon and nitrogen, are reported. In most of these cases the primary reaction involves the addition of the hydrogen to the methylene

(13) *Cf.* Biederman, *Ber.*, **7**, 540 (1874).

(14) Lander, *J. Chem. Soc.*, **77**, 737 (1900).

carbon of the acetal followed by the attachment of the remainder of the addendum to the carbon carrying the ethoxyl groups. This primary reaction may be followed by one or more subsequent reactions.

In the cases of acetoacetic ester and malonic ester the reaction takes a different course. These compounds do not add as H and O—C(R)=CHCOR, as does dibenzoylmethane, but rather as H and $CH(COR)_2$ and the addition is strongly catalyzed by small amounts of sodium ethoxide. The function of the catalyst in this reaction is discussed.

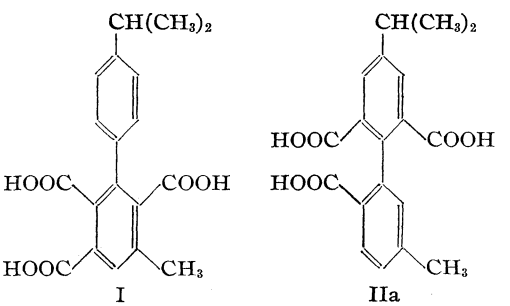
Acetylretene and 6-Retenol

BY WILLIAM P. CAMPBELL AND DAVID TODD

Acetylretene was first prepared by Bogert and Hasselstrom[1] and was shown[2] to have the acetyl group in the same position as the hydroxyl group of the β-retenol of Komppa and Wahlforss[3] by conversion into that substance. Evidence based on the coupling reaction, reduction potential data, and the Dimroth test, indicating that the β-retenol is either the 3- or the 6-derivative had been presented by Fieser and Young[4] and their view that the substituent probably is in the 6-position has been accepted in subsequent literature even though conclusive evidence was lacking. More recently there appeared a paper by Nyman[5] on acetylretene presenting evidence resulting mainly from oxidation experiments which he interprets as indicating that the acetyl group (and, therefore, the hydroxyl group of the β-retenol) occupies the 4- instead of the 6-position.

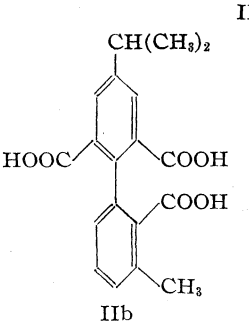
In the present research the possibility that these groups occupy the 6-position is definitely eliminated[6] by the preparation of 6-retenol (VII) of proven structure, which is different from the β-retenol. A careful study and reinterpretation of the results of Nyman[5] and of Fieser and Young[4] led us to the conclusion that the acetyl and hydroxyl groups must be in the 3-position in these compounds, and this view has been proven to be correct.

All of the arguments by which Nyman eliminated the various possible positions for the acetyl group in acetylretene seem valid with the exception of those regarding the 3-position. The point in question involves a distinction between I which would result from 3-acetylretene and IIa or b



I

IIa



IIb

which would result from the 4-isomer. The evidence presented in favor of II was that the substance melts at a high temperature (277°) without apparent loss of water, and fails to form an anhydride on heating with acetyl chloride, although heating with acetic anhydride does produce the anhydride. There is ample contradictory evidence in the literature which can lead only to the conclusion that it is not possible to decide between these compounds on the basis of such evidence. For example, trimellitic acid, which is analogous to I, melts at 238° without apparent loss of water

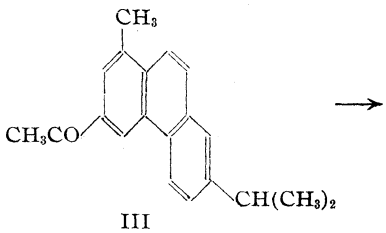
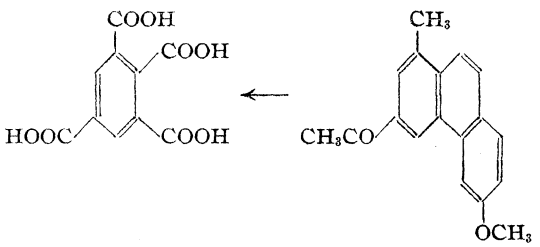
(6) In a publication which reached us after this paper was written, Ruzicka and St. Kaufmann (*Helv. Chim. Acta*, **23**, 288 (1940)) arrived at this same conclusion by a comparison of the melting points of 6-ethylretene (prepared by way of 6-acetyldehydroabietic ester) and two of its derivatives with those reported by Bogert and Hasselstrom[1] for their ethylretene obtained from acetylretene. In the present paper, a direct comparison of the corresponding retenols by mixed melting point has been made.

and is only partially converted into the anhydride by three-hour boiling with acetyl chloride or acetic anhydride.[7] On the other hand retene diphenic acid, similar to IIa and b, forms an anhydride[8,9] with acetyl chloride at room temperature. Thus the work of Nyman indicates only that the acetyl group is in the 3- *or* 4-position.

The reduction potentials of retenequinone and the quinones from 2- and β-retenol as determined and interpreted by Fieser and Young[4] provide evidence that the hydroxyl group of β-retenol is either 3 or 6.[10] With the 6-position now eliminated the compounds of the β-series would on this evidence be the 3-derivatives. Proof of this structure was accomplished by the isolation of mellophanic (1, 2, 3, 5) acid (IV) as an oxidation product of acetylretene (III). That Nyman[5] was



III



IV V

unable to isolate this degradation product may be because he used a different method of oxidation.

On the basis of this structure for acetylretene, the cyclopenteno- and benzo-retenes prepared by Adelson and Bogert[11] must be written as the 2,3- or 3,4- instead of the 5,6-derivatives. By analogy with similar work on phenanthrene, the 3,4-position is most probable.

That the retene molecule directs the entering groups to the 3-position in the Friedel and Crafts reaction and to the 2-[4] and 3-positions in sulfonation is interesting in view of the similar behavior of phenanthrene.[12] In addition, dihydroretene undergoes sulfonation in the 2- and 3-positions.[13] Thus it appears that there is some orienting influence inherent in the ring system which overcomes any directive effect of the alkyl groups. On this basis one would expect the acetyl derivative of dihydroretene, which Nyman[14] showed not to be the 3-isomer, to be the 2-derivative.[15]

In the course of this work we had occasion to carry out a Friedel and Crafts condensation of acetyl chloride with 1-methyl-6-methoxyphenanthrene, and in this case also we obtained the 3-acetyl derivative, V. The structure was proved by oxidation to IV, and the compound was characterized by oxidation to the corresponding 3-carboxy derivative. This orientation is in contrast to the results of Burger and Mosettig[16] with derivatives of 6-(or 3-)phenanthrol. The 6-methoxyphenanthrene was converted into the 10-acetyl derivative under conditions similar to those used above. The acetyl group, however, entered the 3-position when the reaction was carried out on 6-acetoxyphenanthrene.

The 6-retenol (VII) was obtained in good yield (68%) by selenium dehydrogenation of methyl 6-hydroxydehydroabietate[17] (VI, R=H), and it has been characterized by the preparation of several derivatives.

The 6-retenol corresponds in its melting point and the melting point of seven of its derivatives with a retenol obtained by Brandt and Neubauer[18] from ferruginol and considered by them to be the 8-isomer. These authors placed the hydroxyl group in the 8-position because of the non-identity of their compound with the β-retenol (3-retenol) previously regarded as the 6-compound, and because the corresponding hydroxyquinone gave a positive Dimroth test. The same retenol has been obtained from hinokiol.[18,19] Table I gives a comparison of the melting points of 6-retenol and its derivatives with those of the retenol obtained from ferruginol and hinokiol. Although a direct comparison by mixed melting point determination

has not been made, the close correspondence of the melting points of all of the derivatives adequately establishes the identity of the substances.

TABLE I

MELTING POINTS

Compound	6-Retenol	Retenol from ferruginol and hinokiol
Retenol	179–180	179–180[19b]
Picrate	177.5–178	176–177[18,19a]
Acetate	91–92	90–91,[18] 94[19]
Methyl ether	78.5–79	80[19b]
Acetoxyquinone	186–189	188–189[18]
Hydroxyquinone	303–304 d.	285 d.,[18] 307[19]
Hydroxyquinoxaline	225–226	223[19a]
Acetoxyquinoxaline	195–196.5	194[19]

The hydroxyl group of 6-retenol is rather highly hindered since the substance is only slightly soluble in aqueous alkali and apparently methylates with difficulty.[18,19] After treatment with diazomethane in ether at 0° for three hours, the retenol was recovered quantitatively unchanged. In one experiment, no ether was obtained on treating the chloromagnesium salt with dimethyl sulfate in ether solution.

A positive Dimroth test, as reported by Brandt and Neubauer for the quinone corresponding to their retenol, was also obtained with the quinone from 6-retenol. This test consists of a comparison of the color of a solution of the hydroxyquinone in acetic anhydride with that of a similar solution containing added boro-acetic anhydride. If the hydroxyl group is ortho to the quinone carbonyl as in 1-hydroxyphenanthrenequinone the highly colored complex, X, is formed; otherwise simple acetylation takes place. As far as is known, the only example of an anomalous test is that reported by Fieser,[20] who found that morpholquinone (XI) gave a positive test. Two possible explanations were offered for this observation. The first postulated a reaction of the boro-acetic anhydride with the tautomeric form, XII, producing the complex, XIII. The second explanation involved the formation of a boron complex of the type  , with the two adjacent hydroxyl groups.

A comparison, made in the present work, of the colors produced when a series of hydroxyphenanthrenequinones were subjected to this test has given results (Table II) which favor the first of the two explanations and permit a slight extension of the idea. The colors were divided roughly into three groups, faint, medium, and intense, which are widely different and easily discernible, although the difference between those listed as "faint" and those

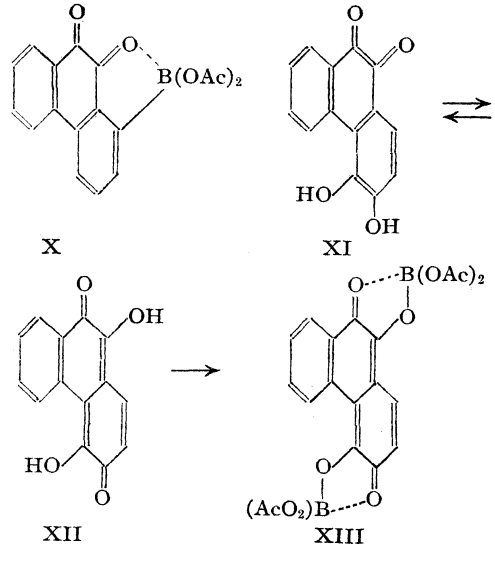

TABLE II

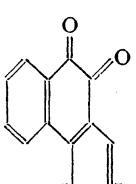
DIMROTH TEST ON HYDROXYQUINONES

Quinone from	Color
2,6-Dihydroxyphenanthrene[a]	None
3-Retenol[a]	None
3-Phenanthrol[a]	Faint
1-Methyl-6-phenanthrol	Faint
6-Retenol	Medium
Morphol[a]	Intense
1-Phenanthrol[a]	Intense

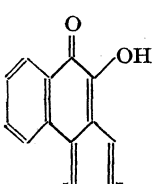
[a] Samples of these compounds were supplied by Professor L. F. Fieser.

(20) Fieser, THIS JOURNAL, 51, 2471 (1929).

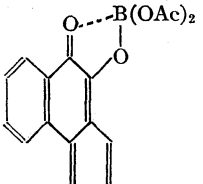
giving no color is not considered significant. If the development of color by the 3- and 6-hydroxyquinones is the result of the reaction of boro-acetic anhydride with the tautomeric form, the variation in the color produced can be qualitatively explained. An alkyl group substituted in the 5- or 7-position of XIV would exert only a negligible



XIV



XV



XVI

effect on the potential of the 9,10-quinone. The same substitution would, however, cause considerable lowering of the potential[21] of the tautomeric amphi-quinonoid form XV. The net effect would be an increase in the quantity of XV available for conversion into the colored complex, XVI, as a result of the increased stability of this form. Thus the quinone from 6-retenol (1-methyl-7-isopropyl-XIV), as would be expected, gives a deeper color than that from 1-methyl-6-phenanthrol. A hydroxyl group in the 5- or 7-position would produce an even greater lowering of the potential (roughly twice[21]) than an alkyl group, and the intense color obtained with morpholquinone (5-hydroxy-XIV) is in line with this view.

The results indicate that neither two ortho hydroxyl groups nor a hydroxyl group ortho to the quinone carbonyl is necessary for the production of color with boro-acetic anhydride, and that the reaction very probably takes place with the tautomeric amphi-quinonoid structure.

During the earlier stages of this research our first attempts to prepare 6-retenol by dehydrogenation of methyl-6-hydroxydehydroabietate met with little success. We sought, therefore, for a more productive source of the retenol and investigated the possibility of preparing the compound from podocarpic acid. In a recent investigation, Sherwood and Short[22] found that the resin acid could be dehydrogenated in good yield to 1-methyl-6-hydroxyphenanthrene, identified by synthesis. The formation of this phenanthrol on dehydrogenation locates all of the carbon atoms in the molecule except the methyl and the carboxyl groups which are eliminated in the reaction. Sherwood and Short considered formulas VIIIa and VIIIb (R=H) for podocarpic acid, favoring VIIIb because the carboxyl group is considerably more hindered than in the abietic acid series where the structure is similar to VIIIa.

Our plan for preparing 6-retenol from this substance involved the introduction of an isopropyl group into the 7-position and subsequent dehydrogenation. This was accomplished without difficulty by introducing an acetyl group into the 7-position by a Friedel and Crafts reaction. The reaction of the 7-acetyl compound with methylmagnesium chloride followed by dehydration and catalytic hydrogenation produced methyl O-methyl-7-isopropylpodocarpate (IXa). Dehydrogenation followed by cleavage of the methoxy group with hydrobromic acid yielded the same retenol (VII) as was obtained from 6-hydroxydehydroabietic ester. This latter reaction, in addition to confirming the location of the hydroxyl group, proved that the acetyl group entered the podocarpate molecule in the 7-position.

In connection with a suggestion advanced by Fieser and Campbell[17] concerning the structure of podocarpic acid, we were interested in comparing methyl O-methyl-7-isopropylpodocarpate (IXa) with methyl 6-methoxydehydroabietate (VI, R=CH_3). If podocarpic acid has the structure VIIIa, the two substances should be identical, providing the configuration in both molecules is the same. The melting points of the two compounds, however, are widely different and the mixed melting point showed considerable depression. The two substances, therefore, are either position- or stereo-isomers.

The methylation of methyl 6-hydroxydehydroabietate presented some difficulty. The hydroxyl group is highly hindered by the *o*-isopropyl group, since methylation of podocarpic acid proceeds with great ease. The phenol-ester is practically insoluble in aqueous alkali. In one experiment a small amount of the methyl ether was obtained by the action of dimethyl sulfate in alcoholic alkali but this could not be repeated. Attempts to prepare the ether by reaction with silver oxide and methyl iodide, with diazomethane (alone or with aluminum tertiary butylate), or by treating the sodium or potassium salt with dimethyl sulfate were all unsuccessful. The compound was unaltered by heating with potassium carbonate and dimethyl

(22) Sherwood and Short, *J. Chem. Soc.*, 1006 (1938).

sulfate in boiling xylene, although this method was used successfully[18] for the methylation of ferruginol. The ether was obtained in good yield, however, by the action of dimethyl sulfate on the chloromagnesium salt, prepared by treating the phenol with methylmagnesium chloride.

The authors wish to thank Professor L. F. Fieser for suggesting some of this work and for his helpful advice in connection with the interpretation of the results of the Dimroth test.

Experimental Part[23]

3-Acetylretene (III).—In this preparation nitrobenzene, instead of carbon disulfide,[1,2] was used for the solvent. To a solution of 25 g. of retene and 15 cc. of acetyl chloride in 100 cc. of nitrobenzene at −5° was added 29 g. of aluminum chloride. When about half of this material had been added, a deep red, finely divided complex separated accompanied by a slight rise in temperature. After stirring for five hours at −5° and standing at 5° for forty hours, the reaction mixture was poured into ice and 70 cc. of concentrated hydrochloric acid. The black residue remaining after steam distillation was treated with Norit in ether and crystallized from this solvent yielding 13.5 g. (45%) of pure acetylretene, m. p. 99.5–100° (cor.). From the mother liquor, 4.5 g. of product melting at 85–89° and 9.8 g. of a picrate melting at 127–132° were obtained. These materials are being investigated.

Oxidation of 3-Acetylretene to Mellophanic Acid.—A mixture of 0.5 g. of 3-acetylretene, 1 cc. of concentrated nitric acid and 2 cc. of water was heated for thirty-three hours in a sealed tube at 190–200°. Twice, during this time, the tube was opened and 1 cc. of concentrated nitric acid was added. The yellow sirup obtained by evaporation of the solution solidified on stirring with fuming nitric acid. The solid was removed by filtration and washed well on the filter with fuming nitric acid. This product was esterified with diazomethane and the ester was crystallized from methanol, m. p. 108–109°. Recrystallization from methanol raised the melting point to 108.5–109.5° (cor.). The melting point of a mixture of this material with an authentic sample of the tetramethyl ester of mellophanic acid (m. p. 110.5–111°) was 109–110.5° (cor.).

1-Methyl-6-phenanthrol.—This substance (m. p. 160–161°) was prepared by dehydrogenation of podocarpic acid (see below) by the method of Sherwood and Short.[22] It was also obtained from its methyl ether by boiling for four hours with hydrobromic-acetic acid.

1-Methyl-3-acetyl-6-methoxyphenanthrene (V).—This reaction was carried out in the same manner as the preparation of 3-acetylretene, above, using 0.95 g. of 1-methyl-6-methoxyphenanthrene,[22] 0.45 cc. (50% excess) of acetyl chloride, and 1.14 g. of aluminum chloride in 25 cc. of nitrobenzene. The time of reaction was sixty-five hours. The product was washed in ether solution with alkali and after drying the solvent was removed. The residue could not be induced to crystallize and was treated with 0.87 g. of picric acid in ethanol. The orange *picrate* which separated melted at 146–148.5° after two crystallizations from ethanol. Decomposition of the picrate by warming with aqueous sodium carbonate and crystallization of the resulting material from ethanol gave 0.25 g. (21%) of light feather-like crystals melting at 126.5–127°.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10. Found: C, 81.90; H, 6.07.

For characterization the acetyl derivative (0.34 g.) was treated in dioxane–sodium hydroxide solution with iodine–potassium iodide solution until the iodine color persisted for two minutes at 60°. The **1-methyl-3-carboxy-6-methoxyphenanthrene** was obtained in a pure, crystalline condition after two precipitations from aqueous alkaline solution by hydrochloric acid, m. p. 233–235°. Recrystallization from aqueous ethanol did not change the melting point.

Anal. Calcd. for $C_{17}H_{14}O_3$: neut. equiv., 266. Found: neut. equiv., 266.

For proof of the structure, 0.07 g. of the acid was heated with 1 cc. of concentrated nitric acid and 2 cc. of water at 100° for one hour and at 180–200° for thirteen hours. The product obtained on evaporation of this solution to dryness was esterified in ether with excess diazomethane. The mellophanic tetramethyl ester, crystallized from aqueous ethanol, melted at 107–108° (cor.). Mixed with an authentic sample (m. p. 108.5–109.5°) it melted at 107–109° (cor.).

6-Retenol (VII).—A mixture of 2 g. of methyl 6-hydroxydehydroabietate and 2.1 g. of selenium powder was heated at 280–285° for twenty-four hours and then at 335° for four hours. The mixture was stirred continuously by passing a slow stream of nitrogen through it. The product was extracted with ether, washed with 5% sodium hydroxide, and dried. On concentrating the nearly colorless solution and adding hexane, 0.71 g. of 6-retenol, m. p. 177–178°, separated as thin, colorless flakes. A second crop of 0.27 g., m. p. 173–175°, separated from the concentrated mother liquor. Recrystallization from ether–hexane raised the melting point to 179–180°; yield 68%. In another run under the same conditions but without the nitrogen stirring, the yield was 43%. This product, mixed with the β(3)-retenol (m. p. 158–161°) melted below 138°.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.37; H, 7.25. Found: C, 86.58; H, 7.18.

6-Methoxyretene.—Dehydrogenation of 1.75 g. of methyl O-methyl-7-isopropylpodocarpate was carried out as described above using 1.85 g. of selenium. The ether solution, after clarification with Darco, was evaporated and the residue was taken up in methanol. One crop of crystalline material (m. p. 72–74°) was obtained from this solution. Recrystallization from methanol yielded 0.30 g. (22%) of 6-methoxyretene, m. p. 75–77°. By repeated crystallization from methanol the melting point was raised to 78.5–79°.

The non-crystalline residue from the first methanol mother liquor was refluxed for seven hours with 20 cc. of glacial acetic acid and 5 cc. of 48% hydrobromic acid. The product was washed and dried in ether and, after clarification with Darco, was purified by crystallization from ether–hexane. In this way 0.38 g. (30%) of 6-retenol, m. p. 172–175°, was obtained. Recrystallization from ether–

(23) The melting points are uncorrected unless otherwise specified.

hexane gave a product, m. p. 179–180°, which did not depress the melting point of the 6-retenol prepared from methyl 6-hydroxydehydroabietate.

Derivatives of 6-Retenol.—With the exception of the methyl ether, the derivatives of 6-retenol listed in Table I were prepared by methods previously described.[18,19] For the oxidation of 6-acetoxyretene to the quinone the conditions used by Fieser[20] for oxidation of diacetoxyphenanthrenes were found to be most suitable.

Podocarpic Acid (VIII, R = H).—This substance was prepared from "rimu" resin from *Dacrydium cupressinum*.[24] Two crystallizations of the crude resin from aqueous alcohol according to Sherwood and Short[22] gave acid melting at 193–200° in 85% yield. Methylation with methyl sulfate[22] of the material remaining in the mother liquors yielded an additional quantity of product as the more easily purified methyl O-methyl ester, bringing the total yield from the resin to more than 90%.

Methyl O-Methyl-7-acetylpodocarpate.—To a solution of 18 g. of methyl O-methylpodocarpate[22] and 9 cc. of acetyl chloride in 200 cc. of nitrobenzene at 0°, 16.2 g. of aluminum chloride was added over a half-hour period. After stirring at 0° for four hours the clear solution was let stand at 5° for one hundred hours, then at room temperature for five hours. The nitrobenzene was removed by steam distillation, after hydrolysis with ice and hydrochloric acid, and the residue was separated by filtration. The product was decolorized with Darco in hot ethanol solution and on cooling 16.3 g. (80%) of the acetyl derivative melting at 109–117° was obtained. A sample, after several crystalizations from ethanol melted constantly at 119–119.5°, $[\alpha]^{25}D$ + 142° (1.8% in ethanol.)

Anal. Calcd. for $C_{21}H_{28}O_4$: C, 73.23; H, 8.19. Found: C, 73.08; H, 8.26.

The oxime (m. p. 190–193° from ethanol) was prepared by treating the acetyl compound (0.1 g.) with a filtered solution of hydroxylamine hydrochloride (0.1 g.) and excess sodium bicarbonate in ethanol. Hydrolysis with dilute hydrochloric acid yielded the original ketone.

Methyl O-Methyl-7-(α-hydroxyisopropyl)-podocarpate.—A solution of 5 g. of the 7-acetyl derivative (m. p. 109–117°) in dry ether was added slowly to excess methylmagnesium chloride in ether and, after refluxing for one-half hour, hydrolysis was brought about by the addition of saturated ammonium chloride solution. The ether layer was washed, dried and evaporated and the residue was crystallized from hexane, yielding 4.6 g. of thick prisms melting at 146–150°. An additional 0.5 g. of product (m. p. 143–147°) was obtained from the mother liquor bringing the yield to 97%. Recrystallized from hexane, the product melted at 148–150°, $[\alpha]^{25}D$ + 119° (2.4% in ethanol).

Anal. Calcd. for $C_{22}H_{32}O_4$: C, 73.28; H, 8.96. Found: C, 73.15; H, 8.78.

(24) Samples of this resin for this and other investigations were very kindly supplied by Dr. John R. Hosking of Kent, England, and by Dr. H. J. Hardon, Buitenzorg, Java, to whom we are greatly indebted. We are also indebted to Dr. C. L. Mantell of the American Gum Importers Association, and to Dr. Jakobs, Buitenzorg, Java, for their courtesy in locating sources of material.—L. F. FIESER.

Methyl O-Methyl-7-isopropenylpodocarpate.—Dehydration of the hydroxyisopropyl derivative was accomplished by boiling 2 g. of the compound in 20 cc. of acetic acid for a few minutes. The residue remaining after evaporation of the solvent was washed and dried in ether and crystallized from hexane; yield, 1.5 g., m. p. 120–121°. A sample, recrystallized from hexane, melted at 120.5–121.5°, $[\alpha]^{25}D$ + 136° (2.1% in ethanol).

Anal. Calcd. for $C_{22}H_{30}O_3$: C, 77.16; H, 8.82. Found: C, 76.97; H, 8.85.

Methyl O-Methyl-7-isopropylpodocarpate (IXa).—Hydrogenation of 0.5 g. of the 7-isopropenyl derivative in 95% ethanol with 15 mg. of Adams catalyst proceeded to completion in thirteen minutes. After removal of the catalyst, water was added to the concentrated solution to incipient turbidity, and crystallization took place on cooling. The product (0.49 g.) melted at 109–109.5° and the melting point was not changed on further crystallization; $[\alpha]^{25}D$ + 124° (1.2% in ethanol).

Anal. Calcd. for $C_{22}H_{32}O_3$: C, 76.68; H, 9.38. Found: C, 76.78; H, 9.28.

Methyl 6-Methoxydehydroabietate (VI, R = CH_3).—Methyl 6-hydroxydehydroabietate (0.5 g.) was refluxed for one hour in dry ether with 2.3 cc. of 0.69 *N* methylmagnesium chloride solution. A solution of 10 cc. of freshly distilled dimethyl sulfate in dry ether was added slowly and refluxing was continued for eighteen hours. After decomposing the excess dimethyl sulfate with alkali, the ether solution was evaporated and the product was crystallized from aqueous ethanol. On recrystallization from the same solvent, there was obtained 0.32 g. (61%) of broad flakes melting at 65.5–66.5°, $[\alpha]^{25}D$ + 87° (1.6% in ethanol).

Anal. Calcd. for $C_{22}H_{32}O_3$: OCH_3, 18.01. Found: OCH_3, 17.82.

Summary

1. Acetylretene and β-retenol are shown to be the 3- instead of the 6-derivatives.

2. The preparation of 6-retenol is described and this substance is shown to be identical with the retenol, reported to be the 8-isomer, obtained from ferruginol and hinokiol.

3. The preparation and proof of structure of 1-methyl-3-acetyl-6-methoxyphenanthrene, and the corresponding 3-carboxy derivative are reported.

4. It is shown that suitably substituted 3-hydroxyphenanthrenequinones give a positive Dimroth test and a satisfactory explanation for this anomalous action is offered.

5. The 7-isopropyl derivative of podocarpic acid is not identical with 6-hydroxydehydroabietic acid.

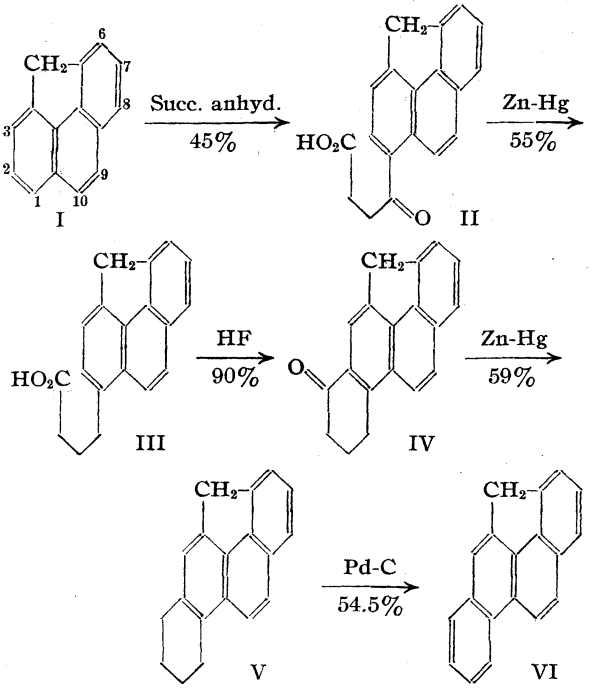
Synthesis of 4,5-Methylenechrysene and 1',9-Methylene-1,2-benzanthracene from 4,5-Methylenephenanthrene

BY LOUIS F. FIESER AND JAMES CASON[1]

4,5-Methylenephenanthrene (4,5-phenanthrylenemethane) was isolated in small amounts from coal tar by Kruber[2] in 1934 through the sodio and carboxy derivatives but has not as yet been made available by synthesis. We were interested in utilizing the substance as a starting point for the synthesis of higher hydrocarbons of possible carcinogenic activity and also in studying the orientation in a molecule combining special features of both the phenanthrene and the acenaphthene structures. An investigation along these lines has been possible through the courteous coöperation of Dr. O. Kruber, who kindly placed at our disposal a generous supply of the rare hydrocarbon.

In an initial study of the succinoylation of 4,5-methylenephenanthrene (I), it was found that with nitrobenzene and aluminum chloride at 5° there is produced a mixture of keto acids from which one isomer could be isolated in 45% yield and obtained in a completely pure form through the ester. On the basis of evidence to be presented below this substance is assigned the structure of the 1-acid (II). The same product was obtained by succinoylation in the presence of anhydrous hydrogen fluoride[3] but the reaction was less smooth and gave more tar. The reduced acid III was prepared by the Clemmensen reaction and purified by a novel and convenient method consisting in crystallization of the trinitrobenzene derivative and recovery of the acid by extraction with soda solution. By this means satisfactory material was easily obtained starting with partially purified keto acid. After cyclization with hydrogen fluoride[3] to the ketone IV, we tried aluminum isopropylate reduction to the carbinol and treatment with palladium charcoal, but in contrast to Bachmann and Struve's[4] experience with a tertiary carbinol, the results were unpromising. Clemmensen reduction and dehydrogenation proceeded more satisfactorily and gave a highly fluorescent hydrocarbon isomeric with the known 1',9-methylene-1,2-benzanthracene[5] and melting at 172.4–172.9°. The ultraviolet absorption spectrum, which will be reported later by Dr. R. N. Jones, closely resembles those of chrysene and 5-methylchrysene, indicating that the substance is 4,5-methylenechrysene as formulated (VI), and in view of the confirmatory chemical evidence to be presented there can be no doubt on this score. The hydrocarbon bears a certain resemblance to 3,4-benzpyrene in its chrysenoid form[6] and is being assayed for carcinogenicity.



Since the saturation of the 9,10-double bond of phenanthrene leads to homogeneous succinoylation in the 2-position,[7] this expedient was investigated. 9,10-Dihydro-4,5-methylenephenanthrene (VII) was first prepared in this Laboratory by R. C. Clapp and was found to correspond in spectrum to 9,10-dihydrophenanthrene. As with the parent hydrocarbon,[8] hydrogenation over copper chromite catalyst proceeds at a low

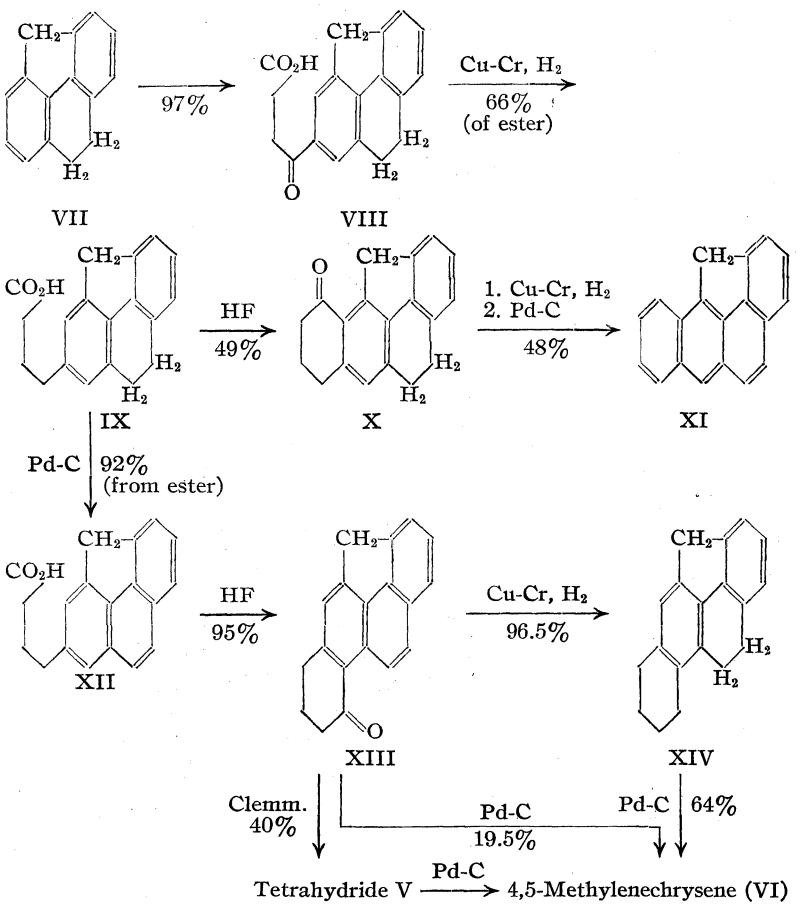
temperature and affords VII in 85% yield. Succinoylation of the dihydride gave a single keto acid (VIII) in almost quantitative yield and this was reduced most satisfactorily by hydrogenation of an aqueous solution of the sodium salt over copper chromite catalyst. The resulting acid (IX) on cyclization afforded a ketone mixture from which a pure isomer (X) was isolated in only poor yield,



and since either the 1- or the 3-isomer could cyclize in only one direction this is an indication that the compound in question is probably the 2-acid (IX). Reduction of the ketone X by high pressure hydrogenation to a hexahydride followed by dehydrogenation, gave an aromatic hydrocarbon identical with the previously described 1′,9-methylene-1,2-benzanthracene[5] (XI), which proves that the dihydro acid (IX) is either the 2- or the 3-isomer. After this dihydro acid had been dehydrogenated in the form of the ester the aromatized acid (XII) underwent cyclization in a different direction, for the resulting ketone (XIII) on reduction and dehydrogenation afforded a fully aromatic hydrocarbon isomeric with 1′,9-methylene-1,2-benzanthracene. If the acidic side chain were located at the 3-position, cyclization could proceed in only one direction regardless of the degree of hydrogenation, and hence the chain must be attached at the alternate 2-position, as in formulas IX and XII. Since ring closure of the aromatized 2-acid XII does not occur in the 3-position, with the formation of a benzanthracene derivative, the reaction must involve the alternate 1-position and give 4,5-methylenechrysene (VI). The product obtained in this series of experiments was identical with that resulting as the end-product in the first series reported, and the chemical evidence of the structure of the hydrocarbon thus coincides with that derived from spectroscopy. A further inference can be drawn from the fact that the aromatized 2-acid XII of the second series is isomeric and not identical with the acid obtained by the succinoylation of 4,5-methylenephenanthrene and reduction. Since this acid gives rise to the 1,2-ring compounds, V and VI, identical with those from the 2-acid, it can only be the 1-acid (III).

The most practical route to the new 4,5-methylenechrysene is that starting with 9,10-dihydro-4,5-methylenephenanthrene and proceeding through VIII, IX, XII, XIII and XIV, and indeed the reactions all proceed so well that the over-all yield in the six-step synthesis from the hydrocarbon isolated from coal tar is 30%. In the next to last stage of this process the reduction of the carbonyl group of the ketone XIII is accomplished very satisfactorily by hydrogenation over copper chromite catalyst, and under the conditions required for effecting this change the 9,10-double bond is likewise attacked and the resulting hydrocarbon is a hexahydride (XIV). 4,5-Methylenechrysene was also obtained directly by heating the ketone XIII with palladium charcoal, as in a comparable case reported by Fieser and Joshel,[9] but the yield was quite poor.

The orientation of 4,5-methylenephenanthrene

(9) Fieser and Joshel, THIS JOURNAL, 61, 2958 (1939).

in the Friedel and Crafts reaction is quite different from that of the parent hydrocarbon. While phenanthrene is substituted chiefly at the 3-position (50–60%), with the formation of small amounts of the 2-isomers,[10] the 4,5-methylene derivative is attacked chiefly at the 1-position, a difference clearly attributable to the strong para directing influence of the 4-methylene group. This influence is similar to that operative in acenaphthene.

The exclusive 2-substitution of 9,10-dihydro-4,5-methylenephenanthrene parallels exactly the behavior of 9,10-dihydrophenanthrene,[7] the substituent in each case entering an unhindered para position in the diphenyl ring system. The direction of ring closure under the influence of hydrogen fluoride, however, is different in the two series. While γ-(2-phenanthryl)-butyric acid is cyclized largely (78%) in the 3-position,[11] the 2-acid XII undergoes reaction exclusively at the 1-position para to the methylene bridge, and while γ-(9,10-dihydro-2-phenanthryl)-butyric acid is cyclized by hydrogen fluoride solely at position 3,[12] the corresponding acid IX suffers ring closure at the 3-position only to the extent of 49% and evidently much substitution again occurs para to the methylene group. The 4,5-methylene bridge thus constitutes a dominant factor in directing the course of both the inter- and intramolecular acylations of 4,5-methylenephenanthrene.

Experimental Part[13]

β-(4,5-Methylene-1-phenanthroyl)-propionic Acid (II).—A solution of 8 g. of aluminum chloride in 40 cc. of nitrobenzene was cooled in ice and treated with 2.65 g. of powdered succinic anhydride followed by 5 g. of 4,5-methylenephenanthrene, the hydrocarbon being added in half-gram lots with swirling and cooling in ice after each addition. After standing at 5° for seventy-two hours the dark, opaque solution was treated with dilute hydrochloric acid and the solvent was removed with steam. The crude acid, obtained after washing and drying as a brown solid, was treated with Norit in 500 cc. of acetone and crystallized first from 125 cc. of this solvent and then from 150 cc., giving 2.85 g. of almost colorless needles, m. p. 203.5–205° dec. An additional 0.60-g. crop of the same quality was obtained from the mother liquor (total yield 45.4%).

This material consists almost entirely of the 1-acid but contains a trace of isomeric product which could not be separated by direct crystallization. Conversion to the methyl ester with diazomethane or methanol–hydrogen chloride gave material melting at 119–122°, and after four crystallizations from benzene–hexane (1:3) the pure 1-ester was obtained as slender, colorless prismatic needles, m. p. 124.8–125.5°. On systematic working of the mother liquors the yield of pure ester was brought to 60%.

Anal. Calcd. for $C_{20}H_{16}O_3$: C, 78.93; H, 5.29. Found: C, 78.99; H, 5.46.

On saponification of the pure ester and decoloration of the greenish hydrolyzate with Norit, the free acid crystallized from acetone in the form of colorless blades, m. p. 207–208°, dec.

Anal. Calcd. for $C_{19}H_{14}O_3$: C, 78.61; H, 4.86. Found: C, 78.80; H, 4.91.

Attempts to isolate another isomer by crystallization of the residual material as acid, ester, or salt were unsuccessful. The most nearly homogeneous material melted as the ester at 100–103° and as the acid at 178–184°.

On treating the hydrocarbon (1 g.) and succinic anhydride (0.53 g.) with hydrogen fluoride at room temperature for twenty hours there was recovered from the highly tarry reaction mixture 0.07 g. of the 1-acid, m. p. 203–204.5° dec. (no depression with above product), and very little additional acidic material.

γ-(4,5-Methylene-1-phenanthryl)-butyric Acid (III).—This was prepared most conveniently from the crude keto acid II, purification being accomplished more easily after reduction than before. The use of the methyl ester in the Clemmensen reduction was tried without success, the product being non-distillable. The most satisfactory procedure was essentially that of Martin[14]; a small amount of acetic acid[14] seemed better than a large quantity[4] or than none at all.

One gram of keto acid, m. p. 203.5–205° dec., was refluxed for twenty-four hours with 20 g. of amalgamated zinc, 15 cc. of water, 1 cc. of acetic acid, 20 cc. of toluene and a total of 65 cc. of concentrated hydrochloric acid. The crude acidic material was distilled at 2 mm. and converted in benzene solution into its stable **trinitrobenzene derivative.** Three or four crystallizations of this complex gave satisfactory material, m. p. 183.5–184.5°, whereas the free acid could be obtained pure only after seven to ten crystallizations. The recrystallized analytical sample formed yellow blades, m. p. 183.8–184.8°.

Anal. Calcd. for $C_{25}H_{19}O_8N_3$: N, 8.59. Found: N, 8.82.

By systematically working the mother liquors a total of 1.1 g. of pure trinitrobenzene derivative was obtained. This was dissolved in warm benzene and shaken out with sodium carbonate solution. After washing the carbonate extract three times with benzene the acid was precipitated, dried and crystallized from benzene, when it formed colorless plates, m. p. 176.6–177.6°; yield 0.52 g. (55%).

Anal. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.83. Found: C, 82.80; H, 6.00.

4,5-Methylene-7-keto-7,8,9,10-tetrahydrochrysene (IV).—The pure acid III (0.5 g.) was mixed with hydrogen

(13) All melting points are corrected. Microanalyses by Lyon Southworth. The 4,5-methylenephenanthrene employed (total used, 22 g.) was that supplied by Dr. O. Kruber of the Gesellschaft für Teerverwertung and melted at 114.4–115.2°.

(14) Martin, THIS JOURNAL, **58**, 1438 (1936).

fluoride (20 g.) and after twenty-two hours the residual reagent was largely removed in a stream of air and the residue was shaken with soda solution and benzene. The collected ketone crystallized from alcohol (Norit) as nearly colorless blades, m. p. 167.5–168.5° (0.42 g., 90%). Two further crystallizations gave a sample forming iridescent flat needles, m. p. 168–169°.

Anal. Calcd. for $C_{19}H_{14}O$: C, 88.34; H, 5.46. Found: C, 88.53; H, 5.43.

On reducing the ketone with aluminum isopropylate and heating the resulting carbinol for one hour with palladium charcoal at 300–320°, a dark product resulted from which only a small amount of impure 4,5-methylenechrysene could be isolated.

4,5-Methylene-7,8,9,10-tetrahydrochrysene (V). (a) From the 7-Ketone IV.—The ketone was reduced by the Clemmensen–Martin method and the product distilled at 2 mm. and crystallized once from alcohol, giving a 59.5% yield of the tetrahydride, m. p. 127.5–128.5°. This did not depress the m. p. of the purified sample described below.

(b) **From the 10-Ketone XIII.**—Following the same procedure, the yield of once crystallized hydrocarbon, m. p. 124–126°, was 40.5%, the lower yield possibly being due to greater hindrance. Six recrystallizations were required to give material of the constant m. p. 129–129.4° (colorless plates).

Anal. Calcd. for $C_{19}H_{16}$: C, 93.40; H, 6.60. Found: C, 93.37; H, 6.76.

The dehydrogenation of V is described below.

4,5-Methylene-9,10-dihydrophenanthrene, VII (with R. C. Clapp).—Fifteen g. of 4,5-methylenephenanthrene was hydrogenated at high pressure over copper chromite catalyst (KAF) at 160° without solvent, one mole of hydrogen being absorbed in about two and one-half hours. The product was separated from catalyst in benzene solution and then treated with Norit in alcohol and crystallized from this solvent. The first crop (12.2 g.) separated as large, colorless plates, m. p. 138–140° and the mother liquor afforded 0.7 g. of satisfactory material (yield 85%). The analytical sample after two more crystallizations from alcohol melted at 140.5–141.2°.

Anal. Calcd. for $C_{15}H_{12}$: C, 93.70; H, 6.30. Found: C, 93.67; H, 6.38.

β-(4,5-Methylene-9,10-dihydro-2-phenanthroyl)-propionic Acid (VIII).—The succinoylation was conducted as described for I, using 6.5 g. of the dihydride VII. A solution of the crude acid in warm sodium carbonate solution was clarified with Norit; the precipitated product was light gray and melted at 218–221°, dec.; yield 9.7 g. (99%). Three crystallizations from acetone gave colorless needles, m. p. 224–224.5°, dec.

Anal. Calcd. for $C_{19}H_{16}O_3$: C, 78.07; H, 5.51. Found: C, 77.99; H, 5.66.

It was found most convenient to isolate the acid in the form of the sodium salt as required for hydrogenation to IX. The carbonate solution obtained as above was treated at the boiling point with saturated sodium chloride solution until crystallization commenced, and the salt which separated on cooling was washed with 10% sodium chloride solution and with acetone. After recrystallization in the same manner the yield of almost completely colorless salt was 10 g. (95%).

The **methyl ester,** prepared by Fischer esterification of the crude acid and crystallized three times from methanol, formed colorless needles, m. p. 137.1–137.4°.

Anal. Calcd. for $C_{20}H_{18}O_3$: C, 78.42; H, 5.91. Found: C, 78.51; H, 6.03.

γ-(4,5-Methylene-9,10-dihydro-2-phenanthryl)-butyric Acid (IX).—A steel pressure bomb was charged with 7.5 g. of the sodium salt of VIII, 1 g. of copper chromite catalyst, 50 cc. of water, and a few drops of dilute sodium hydroxide. Hydrogenation was conducted at high pressure and 200° until two moles of hydrogen had been absorbed (five to ten hours). The product was extracted with warm water and the solution filtered with Super-cel, then with Norit, and the clear tan filtrate acidified, giving 5.0 g. of crude acid, m. p. 145–149°. Distillation at 2 mm. gave satisfactory material, and the analytical sample obtained by one crystallization from benzene–hexane (1:1) consisted of colorless blades, m. p. 154.5–155°.

Anal. Calcd. for $C_{19}H_{18}O_2$: C, 82.00; H, 6.50. Found: C, 81.98; H, 6.70.

Clemmensen–Martin reduction of the keto acid VIII proved less satisfactory, the yield of distilled product being 44%.

The **methyl ester,** prepared by Fischer esterification of the crude acid, was obtained on vacuum distillation as an almost colorless distillate which crystallized immediately on cooling to a solid, m. p. 53–57°; yield 4.6 g. (66% from the keto acid). Four crystallizations from methanol gave colorless plates, m. p. 59.3–60°.

Anal. Calcd. for $C_{20}H_{20}O_2$: C, 82.17; H, 6.88. Found: C, 82.15; H, 7.01.

8-Keto-1′,9-methylene-3,4,5,6,7,8-hexahydro-1,2-benzanthracene (X).—Cyclization of 0.5 g. of IX with hydrogen fluoride was conducted as described for the preparation of IV and the crude ketone was treated with Norit in 50 cc. of alcohol and crystallized from 25 cc. of this solvent. There separated 0.35 g. of large, colorless, feathery plates, m. p. 186–197° dec., which on fractional crystallization afforded 80 mg. of X, m. p. 201–203° dec., and 150 mg., m. p. 196–200° dec.; yield 49%. The m. p. of the top fraction was not altered by recrystallization; the fairly broad m. p. range apparently is due to decomposition.

Anal. Calcd. for $C_{19}H_{16}O$: C, 87.67; H, 6.19. Found: C, 87.54; H, 6.42.

1′,9-Methylene-3,4,5,6,7,8-hexahydro-1,2-benzanthracene was prepared by hydrogenation of 150 mg. of ketone X at high pressure as described below for ketone XIII. Distillation of the crude hydrocarbon gave a nearly colorless crystalline solid, m. p. 78–80°; yield 135 mg. (94.5%). Three crystallizations from alcohol gave 75 mg. of colorless, iridescent blades, m. p. 83–83.5°.

Anal. Calcd. for $C_{19}H_{18}$: C, 92.65; H, 7.35. Found: C, 92.78; H, 7.71.

1′,9-Methylene-1,2-benzanthracene (XI).—The mother liquors from the crystallization of the above hexahydride were evaporated to dryness and the residue, together with 50 mg. of pure material, was heated with 15 mg. of palladium charcoal for thirty minutes each at 220–265° and at 265–300° and finally for ten minutes at 300–320°.

After distillation, the pinkish material was converted to the picrate and this was crystallized twice from alcohol in the presence of excess picric acid and then decomposed by passage in benzene through a tower of alumina and Super-cel. Crystallization from alcohol then gave 50 mg. of 1′,9-methylene-1,2-benzanthracene, m. p. 120–121°, which formed a brilliant orange trinitrobenzene derivative, m. p. 161.5–162°. These two substances gave no depression when mixed with authentic samples.[5]

γ-(4,5-Methylene-2-phenanthryl)-butyric Acid (XII).—A mixture of 5.25 g. of the distilled methyl ester of γ-(4,5-methylene-9,10-dihydro-2-phenanthryl)-butyric acid (IX) and 0.60 g. of palladium charcoal was heated at 200–240° for thirty minutes, at 240–250° for thirty minutes, and at 250–265° for thirty-five minutes. The catalyst was removed by filtering a solution of the product in benzene and the ester was distilled at 2 mm., giving 5.05 g. of colorless distillate which soon solidified, m. p. 32.5–34.5°. A sample of this **methyl ester** when crystallized twice from methanol formed colorless, iridescent plates, m. p. 36.3–37.3°.

Anal. Calcd. for $C_{20}H_{18}O_2$: C, 82.74; H, 6.23. Found: C, 82.81; H, 6.56.

For saponification the ester was refluxed for forty-five minutes with 25 cc. of 1 *N* alcoholic potassium hydroxide and the solution was poured into 500 cc. of water (clear solution) and acidified. The light tan precipitated product (4.7 g.; m. p. 164–166°) was clarified in benzene and crystallized from 75 cc. of benzene and 50 cc. of hexane. After collecting a first crop of 4.4 g. of plates, m. p. 167–167.6°, the mother liquor afforded material which after two recrystallizations melted at 164–165.5° (0.10 g.); total yield 92%, from the dihydro ester. A sample crystallized twice more from benzene–hexane formed colorless blades and plates, m. p. 167.7–168.0°.

Anal. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.83. Found: C, 82.84; H, 6.10.

10 - Keto - 4,5 - methylene - 7,8,9,10 - tetrahydrochrysene (XIII).—Cyclization of 4.4 g. of the acid XII was conducted in hydrogen fluoride (120 g.) for sixteen hours and the product was isolated as described for the isomeric ketone IV, giving 3.70 g. of pale yellow plates, m. p. 171.5–173°, and 0.19 g., m. p. 169.5–171°; yield 95%. Two more crystallizations from alcohol gave highly iridescent plates with a yellowish reflex, m. p. 173–174°.

Anal. Calcd. for $C_{19}H_{14}O$: C, 88.34; H, 5.46. Found: C, 88.18; H, 5.69.

4,5 - Methylene - 7,8,9,10,11,12 - hexahydrochrysene (XIV).—One gram of the 10-ketone XIII in 7 cc. of absolute alcohol was hydrogenated at 160° under high pressure in the presence of 0.10 g. of copper chromite catalyst. The reaction proceeded rapidly and in less than one hour three moles of hydrogen had been absorbed; the absorption then became quite slow and the reaction was stopped. Distillation of the collected product gave 0.92 g. (96.5%) of almost colorless material which softened at 105° and melted at 110–115°. After three crystallizations from alcohol, the hydrocarbon formed clusters of colorless blades, m. p. 116.6–117.2°.

Anal. Calcd. for $C_{19}H_{16}$: C, 92.65; H, 7.35. Found: C, 92.63; H, 7.52.

4,5-Methylenechrysene (VI). (a) From the Hexahydride XIV.—The hexahydride (920 mg.) was heated with palladium charcoal (100 mg.) in a bath initially at 220°. The temperature was gradually raised to 265° in the course of one hour and held at 265–270° for fifty minutes. After separation from the catalyst the hydrocarbon was conveniently isolated as the trinitrobenzene derivative. Two crystallizations from alcohol gave 1.21 g. of complex, m. p. 193.5–194.5°, which was decomposed by reduction with stannous chloride. An initial crystallization of the recovered hydrocarbon from alcohol gave 480 mg., m. p. 172.4–172.9°, and 90 mg., m. p. 170–170.8°; total yield 64%. The compound crystallizes in highly iridescent colorless plates, many of them diamond shaped. Both the solid and its solutions show a violet fluorescence in daylight and give a particularly intense violet in ultraviolet light.

Anal. Calcd. for $C_{19}H_{12}$: C, 94.96; H, 5.04. Found: C, 95.10; H, 5.09.

The **trinitrobenzene derivative** crystallizes from alcohol in bright orange needles, m. p. 194–195°.

Anal. Calcd. for $C_{25}H_{15}O_6N_3$: N, 9.27. Found: N, 9.08.

The **picrate** forms bright red, flat needles from alcohol but is rather unstable.

(b) From the Tetrahydride V.—Dehydrogenation of 150 mg. of V with 20 mg. of palladium charcoal at 250–265° for one hour gave, after distillation of the product and crystallization from alcohol, 45 mg. of VI, m. p. 171.5–172.3°, and 12 mg., m. p. 169–170.2° (54.5%, no depression with above sample).

(c) From the 10-Ketone XIII.—A sealed Pyrex tube containing 200 mg. of XIII and 25 mg. of palladium charcoal was heated at 275–285° for six hours. (The yield was slightly lower on heating at 315° for three hours or at 265° for two hours.) The material was dissolved in benzene and the filtered solution passed through a column of alumina and Super-cel (1:1). In ultraviolet light the filtrate was brilliantly fluorescent and a yellow zone appeared at the top of the column, followed by a blue zone. The product recovered from the filtrate on distillation at 2 mm. gave 80 mg. of colorless crystalline distillate. Two crystallizations from alcohol afforded 45 mg. of hydrocarbon, m. p. 167–168.5°, which was combined with similar material from other runs and recrystallized four times. By systematic working of the mother liquors, with use of the trinitrobenzene derivative, there was obtained in all a 19.5% yield of pure 4,5-methylenechrysene, m. p. 172–172.5°, which gave no depression when mixed with the above samples.

Summary

By the Friedel and Crafts condensation of 4,5-methylenephenanthrene with succinic anhydride the 1-keto acid is obtained in 45% yield and affords a suitable intermediate for the synthesis of the new 4,5-methylenechrysene. 9,10-Dihydro-4,5-methylenephenanthrene undergoes succinoylation exclusively in the 2-position, and after reduction ring closure can be effected at the 3-position, providing in moderate yield a ketone

which can be converted into the known 1′,9-methylene-1,2-benzanthracene. γ-(4,5-Methylene-2-phenanthryl)-butyric acid is obtained in good yield by dehydrogenating the dihydro intermediate as the ester and it cyclizes exclusively at position 1, affording a very satisfactory route to 4,5-methylenechrysene in which the over-all yield from 4,5-methylenephenanthrene is 30%.

The structures of the different products are fully established by the transformations indicated.

In all of the inter- and intramolecular acylations observed in the 4,5-methylenephenanthrene series a strong para directive influence of the 4-methylene group is discerned.

Certain Trialkylated Benzenes and their Compounds with Aluminum Chloride and with Aluminum Bromide

BY JAMES F. NORRIS AND JOHN N. INGRAHAM[1]

In a recent paper[2] methods were described for the preparation, with high yields, of mesitylene and *s*-triethylbenzene by the Friedel–Crafts reaction. By the use of similar conditions toluene and *m*-xylene were ethylated and methyldiethyl- and dimethylethylbenzene were prepared. It seemed highly probable that these hydrocarbons had the symmetrical structure, although the properties of some of their derivatives were not in accord with those recorded in the literature for the symmetrical hydrocarbons.[3]

The ethyldimethylbenzene has been restudied and additional evidence is presented in favor of the symmetrical structure of the hydrocarbon.

In the paper by Norris and Rubinstein results were given of the study of the product formed from toluene, aluminum bromide and hydrogen bromide. Since Gustavson[4] has reported that the compound containing *s*-triethylbenzene and aluminum bromide is a crystalline solid, the investigation of this substance was undertaken. It was formed by passing hydrogen bromide into a solution of aluminum bromide in the hydrocarbon. Heat was generated and a light red oil separated from the excess of hydrocarbon. When cooled the compound formed yellow crystals which melted at 64–66°. Analyses of the crystals gave results which checked with the formula proposed by Gustavson: $Al_2Br_6 \cdot 2C_6H_5(C_2H_5)_3 \cdot HBr$. The complex was held at 0.002 mm. pressure at room temperature. When it came to constant weight the residue was shown by analysis to contain the Al_2Br_6 and hydrocarbon in the ratio of 1 to 1.

When the crystalline complex was treated with acetyl chloride, the yield of methyltriethylphenyl ketone was 67%.

An attempt was made to prepare a compound having the formula $Al_2Br_6 \cdot 2C_6H_3(C_2H_5)_3 \cdot HCl$ by passing hydrogen chloride into a solution of the bromide in the hydrocarbon. Analyses of the product from time to time showed that the bromine in aluminum bromide was being replaced by chlorine. When aluminum chloride and the hydrocarbon were treated with hydrogen bromide, the chlorine was replaced and the complex containing aluminum bromide was formed.

A crystalline complex having the formula $Al_2Cl_6 \cdot 2C_6H_3(C_2H_5)_3 \cdot HCl$ was isolated. The complex prepared from mesitylene had the formula $Al_2Br_6 \cdot 3C_6H_3(CH_3)_3 \cdot HBr$ (m. p. 47–48°). When held at 0.002 mm. to constant weight the residue contained Al_2Br_6 and $C_6H_3(CH_3)_3$ in the molecular ratio 1:1.

The complex with pseudocumene contained three moles of hydrocarbon. The complex with benzene and aluminum bromide was very unstable. When held at 12 mm. pressure, nearly all the benzene was lost.

The complex prepared from toluene and aluminum bromide when held at 12 mm. to constant weight left a residue which contained one mole of the hydrocarbon to one of Al_2Br_6. When held at 0.002 mm., it lost nearly all the hydrocarbon. The compounds containing trimethyl and triethyl benzene (ratio to Al_2Br_6 1:1) were stable at this

pressure. The results show that the stability of the complexes increases as the number of alkyl groups present increases.

Details of Experiments

Dimethylethylbenzene.—The hydrocarbon was prepared by the method of Norris and Rubinstein except that *m*-xylene, furnished by the du Pont Company, which contained less than 1% of isomers was used instead of commercial "metaxylene." The product, after fractionation only, boiled at 184–184.6°. The crude tribromo derivative melted at 86.5–88°, and after repeated recrystallization at 87–89°. Distillation in a molecular still did not change the melting point. The trinitro compound melted at 114–116° (uncor.). Oxidation of the hydrocarbon gave a mixture of acids from which the monobasic acid was recovered by steam distillation; it melted at 161–162° (uncor.). The melting point of 3,5-dimethylbenzoic acid is 165° (cor.) and that of the 2,4-isomer is 124°.

A sample of the crude hydrocarbon was sulfonated, hydrolyzed and distilled. There were obtained 6 cc. at 182–184°, 21 cc. at 184.0°, and 6 cc. at 184–185.6°. The fraction boiling at 184.0° (total immersion thermometer, pressure, 752 mm.) was redistilled without change in boiling point. The index of refraction taken of the distillate, from time to time, remained constant. The tribromo derivative melted at 89–89.5° and the trinitro derivative at 117–117.6°. The hydrocarbon was analyzed. Calcd.: C, 89.55; H, 10.45. Found: C, 90.35, 90.18, 89.66; H, 10.47, 10.46, 10.23.

A sample of the hydrocarbon was converted into the sulfonamide, which was crystallized; it melted at 123.0–123.6° (literature 126°). The hydrocarbon was recovered from the sulfonamide by hydrolysis and converted into the tribromo derivative, which melted at 88.0–88.5°, and the trinitro derivative which melted at 115–116°.

1,3-Dimethyl-4-ethylbenzene.—This compound has been prepared by a number of investigators, but the constants of its derivatives are not in good agreement. We prepared it by condensing pure *m*-xylene with acetyl chloride at 0° with aluminum chloride in the presence of carbon disulfide, and subsequent reduction of the ketone formed.

The hydrocarbon boiled at 187.8° (total immersion thermometer) and gave a tribromide derivative (m. p. 81–82°) and a trinitro derivative (m. p. 119–120°). The monobasic acid formed by oxidation melted at 123.5–124.0° (uncor.), the melting point of 2,4-dimethylbenzoic acid. The boiling points given in the literature for the hydrocarbon vary from 183 to 187°; the melting points of the tribromo derivative from an oil to 135° and of the trinitro derivatives from 119–127°. The sulfonamide was found by four investigators to melt at 148°. It was evident that our hydrocarbon was not 1,3-dimethyl-4-ethylbenzene.

Complexes Containing Aluminum Halides and *s*-Triethylbenzene.—In the preparation and manipulation of the complexes precautions were taken to exclude moisture. The aluminum bromide used was distilled in an all glass vessel into the tube in which the complex was made. The tube was then sealed off from the distilling apparatus. The compounds were manipulated, when necessary, in a stream of dry nitrogen.

Analyses of a complex were made by melting the latter, and drawing up a sample into a pipet. The liquid was run into a small flask of known weight, which was weighed again. The weight of complex used was about 1.5 g. Water and ice were added and the flask stoppered. During the decomposition of the complex the flask was kept in cold water. The aqueous solution was diluted to a definite volume, a part of which was titrated with standard alkali, using phenolphthalein as indicator, for the determination of acid. It was shown that the bromine in aluminum bromide could be accurately determined in this way. The solution was next treated with a slight excess of ammonia and heated. The aluminum hydroxide was separated and ignited. The amount of hydrocarbon in the complex was determined by decomposing it in a small Babcock bottle. Enough water was added to bring the hydrocarbon into the graduated neck of the bottle, which was then placed in a centrifuge to ensure complete separation of the two liquids. The volume of the hydrocarbon measured on the standardized scale gave results from which could be calculated the weight. In most of the analyses the complex was decomposed in the Babcock bottle and the same sample used for the determination of aluminum, halogen, and hydrocarbon. The total of the percentages obtained served as a check on the accuracy of the analysis. With the samples that contained both chlorine and bromine the halogens were determined, in separate portions of the solution, by precipitation with silver nitrate and by neutralization with an alkali.

The Complex $Al_2Br_6 \cdot 2C_6H_3(C_2H_5)_3 \cdot HBr$. Preparation and Analysis.—About 25 cc. of the complex was made by passing hydrogen bromide into a solution of aluminum bromide in *s*-triethylbenzene. Heat was generated and a red oil began to separate at once. When precipitation was complete the product changed to a mass of yellow crystals which melted at 64–66°. Without further treatment two samples were analyzed (Sample 1). The complex was washed with petroleum ether, the excess of the latter removed and the product held under diminished pressure (15 mm.) for five minutes (Sample II). A complex was made by forming it from a mixture of equal volumes of petroleum ether and the hydrocarbon. It separated as a fluffy precipitate, from which the liquid was poured off. It was washed with petroleum ether, dried by evacuation and analyzed (Sample III). The results are given in Table I. The duplicate analyses of each sample were made on different samples.

TABLE I

Sample	Al, %	Br, %	Hydrocarbon, %	Molecular ratios Al	Br	Hydrocarbon
I	5.94	61.23	32.13	1	3.46	0.9
	5.99	61.23	32.48			
II	5.97	61.23	32.64	1	3.45	.9
	6.03	61.28	32.52			
III	5.54	59.23	34.01	1	3.56	1.0
	5.75	59.60	34.55			
Calculated for $Al_2Br_6 \cdot 2C_6H_3(C_2H_5)_3 \cdot HBr$				1	3.5	1

Behavior under Reduced Pressure.—A sample of the complex which weighed 7.547 g. was held at room temperature and 0.002 mm. pressure of mercury, and weighed

at intervals. At the end of two hours the loss in weight was 0.273 g. Constant weight was reached in forty-five hours, when the loss was 1.775 g. The theoretical loss in weight should have been 1.823 if the residue had the compostion $Al_2Br_6 \cdot C_6H_3(C_2H_5)_3$. The residue was analyzed. The molecular ratio found was Al, 1, Br, 3.06, $C_6H_3(C_2H_5)_3$, 0.48.

Reaction of the Complex with Acetyl Chloride.—A mixture of 19.6 g. of complex and 6 cc. of acetyl chloride (molecular ratio 1 to 2) was allowed to stand in an ice-bath for two hours. After decomposition with water the oil was dried and distilled. The product solidified when cooled and melted at −17°. The yield of the mono-acetyl derivative of *s*-triethylbenzene was 5.5 g. (67%).

Reaction of the Complex with Ethyl Bromide.—A cold saturated solution of the complex in ethyl bromide was treated with petroleum ether; an oil was formed which crystallized when cooled with dry-ice. The oil was separated, held at 15 mm. pressure to remove solvent and analyzed. The sample used melted at about −20°. Bromine and aluminum were determined in the usual way. The liquid formed by decomposition with water was a mixture of triethylbenzene and ethyl bromide. To determine the amount of ethyl bromide present, the index of refraction of the mixture was determined and compared with a plot of the indexes of known mixtures of ethyl bromide and the hydrocarbon. The molecular ratios found were Al 1, Br 3.7, triethylbenzene 1.17, ethyl bromide 0.46. These results have led to further study. If the complex containing ethyl bromide is heated slightly above room temperature it decomposes with the evolution of hydrogen bromide.

Reaction of the Complex with Hydrogen Chloride.—An attempt was made to prepare a complex with the formula $Al_2Br_6 \cdot 2C_6H_3(C_2H_5)_3 \cdot HCl$ by passing hydrogen chloride into a solution of aluminum bromide in the hydrocarbon. At the end of ten minutes, when the reaction appeared to be complete, the product was washed and the vessel containing it was evacuated. The molecular ratios found were Al 1, Br 2.4, Cl 1.25, $C_6H_5(C_2H_5)_3$ 1.01. The result showed that bromine was being replaced by chlorine. The preparation was repeated and hydrogen chloride passed through the mixture for five hours. The product melted at 48–49° and an analysis gave the ratios: Al 1, Br 0.4, Cl 3.3, $C_6H_5(C_2H_5)_3$ 0.99. Repeated efforts failed to obtain a product free from bromine. It appears probable that the bromine of the aluminum bromide alone is replaced and not that in the hydrogen bromide in the complex. The molecular ratios in such a compound are: Al 1, Br. 0.5, Cl 3, $C_6H_5(C_2H_5)_3$ 1.

The product obtained as above was treated with hydrogen bromide. The mole ratios found were Al 1, Br 3.6, Cl 0, $C_6H_5(C_2H_5)_3$ 0.9. All the chlorine that had replaced bromine was removed from the compound.

Purity of the Triethylbenzene Recovered from Complexes.—It was found that the hydrocarbon recovered from complexes which had stood for not longer than two days had the correct index of refraction. In the case of the evacuation experiments which continued for several days, the index was about 0.0050 too high. Samples of the hydrocarbon from these experiments were combined and fractionated (180 cc.). A small amount of low- and high-boiling hydrocarbons was obtained along with 145 cc. of *s*-triethylbenzene which boiled at 215.4°.

The Complex $Al_2Cl_6 \cdot 2C_6H_3(C_2H_5)_3 \cdot HCl$.—Freshly sublimed aluminum chloride was covered with the hydrocarbon and hydrogen chloride was passed into the mixture. An oil was formed rapidly and on cooling changed to crystals that melted at 48–49°. The compound on analysis gave the following results: Al 8.66, 8.55%; Cl 40.33, 39.78%; $C_6H_5(C_2H_5)_3$ 52.85, 52.78. Calcd.: Al 8.60, Cl 39.66, $C_6H_5(C_2H_5)_3$ 51.69. The mole ratios found were Al 1, Cl 3.54, $C_6H_5(C_2H_5)_3$ 1.01.

The Complex Containing Mesitylene.—Experiments showed that apparently more than one complex was formed from mesitylene. Products were obtained in which the molecular ratios of the constituents changed when varying amounts of aluminum bromide and the hydrocarbon were used. When a large excess of the hydrocarbon was used the crystalline material obtained after cooling the reaction product was washed with petroleum ether and the vessel containing it was evacuated. The molecular ratios found were Al 1, bromine 3.6, $C_6H_3(CH_3)_3$ 1.6. These results are in fair agreement with the formula $Al_2Br_6 \cdot 3C_6H_3(CH_3)_3 \cdot HBr$. There was evidence of the formation of a complex which contained less of the hydrocarbon. The problem will be considered in a later paper.

The complex was treated with hydrogen chloride; a large percentage of the bromine was replaced by chlorine. The vessel containing a sample of the complex (10.22 g.) was evacuated to constant weight at 0.002 mm. in one hundred thirty-six hours. The loss in weight was 50%. If the residual compound had the composition $Al_2Br_6 \cdot C_6H_3(CH_3)_3$ the loss in weight would have been 52%. The hydrocarbon recovered from the complex after evacuation had the index of refraction $n^{14.7}D$ 1.5059 (literature for mesitylene at this temperature 1.4966 and for pseudocumene 1.5072). It was evident that on long standing the hydrocarbon had undergone a change.

Complex Containing Pseudocumene.—This was prepared in the usual way from the pure hydrocarbon. It separated as a red oil, which lost about one-fourth of its volume when washed with petroleum ether. When cooled in running water crystals were formed. The analysis gave the ratios Al 1, Br 3.44, $C_6H_3(CH_3)_3$ 1.5, which is in good agreement with the formula $Al_2Br_6 \cdot 3C_6H_3(CH_3)_3 \cdot HBr$.

Complex Containing Toluene.—The amounts of hydrogen bromide required to precipitate the complex containing aluminum bromide and toluene were determined. When the amounts of hydrogen bromide and aluminum bromide (Al_2Br_6) were in the ratio 1:1, precipitation was complete. With smaller amounts of hydrogen bromide the amount of precipitated oil decreased as the hydrogen bromide decreased. In these cases the addition of more hydrogen bromide brought about complete precipitation. The experiments confirm the view that the toluene complex contains aluminum bromide (Al_2Br_6) and hydrogen bromide in the ratio 1:1.

Complex Containing Benzene.—The complex was evidently very unstable and the analyses made did not fit accurately any definite molecular ratios. The precipitated oil gave the molecular ratios Al 1, Br 3.2, C_6H_6 3.05. An analysis of a second preparation gave 1:3.2:3.15.

These results indicate that the ratio of Al_2Br_6 to C_6H_6 is 1:6 and that the complex contains some hydrogen bromide.

When the oil was shaken with petroleum ether it decreased in volume. The residual oil gave on analysis the ratios Al 1, Br 2.9, C_6H_6 0.63. It appeared that the product contained Al_2Br_6 and C_6H_6 in the ratio 1:1.

The vessel containing a sample of the original oil was evacuated at 12 mm. Crystals soon appeared. This behavior is different from that of the complexes formed from the other hydrocarbons which gave no crystals but left a product containing the bromide and the hydrocarbon. The crystals appeared to be aluminum bromide. When 18.2 g. of the complex was held under diminished pressure, in about three hours the residue weighed 8.8 g., which is very close to the weight of the aluminum bromide in the complex.

In a second experiment the complex was held at 12 mm. for four hours and then at 0.002 mm. The loss at the latter pressure was 0.01 g. The residue was slightly impure aluminum bromide. The sum of the percentages of aluminum and bromine was 94.4%.

Summary

1. The ethyldimethylbenzene prepared by the Friedel and Crafts reaction from ethyl bromide and *m*-xylene has been restudied and evidence given that the hydrocarbon has the symmetrical structure.

2. The preparation and properties of complexes of certain aromatic hydrocarbons and aluminum bromide or aluminum chloride are described.

CAMBRIDGE, MASS. RECEIVED FEBRUARY 10, 1940

NOTES

Reaction between a Highly-Substituted Bromopyridine and Lithium

BY C. F. H. ALLEN AND G. F. FRAME

In view of the increasing interest in organometallic heterocyclic compounds[1] it seems advisable to record that lithium reacts slowly with the highly-substituted 2-bromo-3,4,6-triphenylpyridine. The resulting suspension does not seem to react with carbon dioxide, aldehydes, or ketones. Upon decomposition by acids, a 20–25% yield of 2,4,5-triphenylpyridine can be secured by distilling in a high vacuum. No conditions were found under which the highly-substituted 2,3,5-triphenyl-4-bromofuran would react with lithium. Neither of these substances reacts with magnesium.[2]

In the usual apparatus, swept by nitrogen, a mixture of 50 cc. of dry ether, 0.5 g. of lithium, and 13.8 g. of 2-bromo-3,4,6-triphenylpyridine was refluxed with stirring for four hours. A slow reaction was noted and the solution became a deep reddish-brown. After standing for several days practically all the metal had disappeared. The ether layer, which separated after adding iced hydrochloric acid, was removed, washed, dried, and the solvent evaporated. After efforts to induce crystallization had failed, the thick oil (1.2 g.) was distilled at 1.2–2 microns; a black tarry residue remained. The clear distillate (1.8 g.) crystallized when rubbed with alcohol. 2,4,5-Triphenylpyridine crystallizes in glistening, slightly iridescent rods, m. p. 112°, readily soluble in alcohol, ether and benzene.

Anal. Calcd. for $C_{23}H_{17}N$: N, 4.6. Found: N, 4.5.

The Carbonation of Organoalkali Compounds

BY HENRY GILMAN AND H. A. PACEVITZ

The kind and ratio of products obtained by carbonation of organometallic compounds are influenced markedly by the rate and temperature of carbonation. With organolithium compounds,[1] in particular, low temperature together with a large excess of carbon dioxide (conditions realized by pouring RM compounds jet-wise on crushed solid carbon dioxide) give predominantly the acid and little of the ketone or tertiary alcohol. Furthermore, carbonation by solid carbon dioxide depresses markedly the formation of malonic acids from benzylmetallic types. This is strikingly illustrated in studies submitted recently[2] with compounds like benzylsodium, benzylpotassium and 3,5-dimethylbenzylpotassium. These RM compounds when carbonated by solid carbon dioxide give almost exclusively the corresponding carboxylic acids; however, carbonation by gaseous

(1) Gilman and Van Ess, THIS JOURNAL, **55**, 1258 (1933). See, also, Gilman and Parker, *ibid.*, **46**, 2816 (1924).
(2) Gilman, Pacevitz and Baine, *ibid.*, **62**, June (1940).

carbon dioxide gives, in addition to the expected carboxylic acids, significant quantities of the malonic acids. The malonic acids probably owe their formation largely to a secondary metalation reaction of the active methylene group by the unused RM compound present in slow carbonation. The typical transformations may be illustrated by the studies of Ivanoff and Spassoff[3] with benzylmagnesium chloride.

$$C_6H_5CH_2MgCl + CO_2 \longrightarrow C_6H_5CH_2CO_2MgCl$$

$$C_6H_5CH_2CO_2MgCl + C_6H_5CH_2MgCl \longrightarrow [C_6H_5CHCO_2MgCl][MgCl] + C_6H_5CH_3$$

$$[C_6H_5CHCO_2MgCl][MgCl] + CO_2 \xrightarrow{[H_2O]} C_6H_5CH(CO_2H)_2$$

Our carbonation experiments with benzylalkali types[2] raise a question concerning benzylidene-dialkali compounds like $C_6H_5CHM_2$. If such compounds are formed in one way or another incidental to the several procedures[2] for the preparation of benzylalkali compounds, then it is possible, but somewhat unlikely, that they are not carbonated by solid carbon dioxide. We are at present of the opinion that they are either not formed or are formed to a subordinate extent, incidental to the preparation of benzylalkali types.

Of more immediate interest are the aliphatic types, $RCHM_2$, like amylidene-disodium.[4] From the experiments now reported, we find that the organosodium compound or compounds formed by interaction of *n*-amyl chloride and sodium give largely caproic acid with very little *n*-butylmalonic acid when carbonation is effected by solid carbon dioxide; and a mixture of caproic acid with large amounts of *n*-butylmalonic acid when gaseous carbon dioxide is used. Additional experiments may provide an answer to the question as to whether secondary metalations or other transformations, some of which have been reported,[4] are responsible for the reactions of compounds of benzylidene-dimetallic and amylidene-dimetallic types.

Experimental Part

In a typical experiment, a solution of 16.5 g. (0.155 mole) of freshly distilled *n*-amyl chloride (b. p., 107–108°) in 15 cc. of petroleum ether (b. p. 85–100°) was added dropwise over a one-hour period to 8.75 g. (0.38 g. atom) of sodium sand in 75 cc. of petroleum ether. The mixture was stirred at room temperature for four hours, after which it was carbonated by pouring jet-wise on solid carbon dioxide, the addition being completed within ten seconds. The products obtained (by isolation and weighing) were 6.9 g. or 38.5% of caproic acid and less than 1% of impure *n*-butylmalonic acid. In a check experiment on this carbonation by solid carbon dioxide the yield of *n*-caproic acid was 7.3 g. or 40.8%; and the yield of impure *n*-butylmalonic acid was again less than 1%. In a parallel experiment in which carbonation was effected by admitting gaseous carbon dioxide to the surface of the reaction mixture over a five-hour period at 27–28° and with stirring, the yield of *n*-caproic acid was 2.72 g. or 15.2%; and the yield of *n*-butylmalonic acid was 2.1 g. or 16.9%.

Again using the same quantities of reagents, two parallel experiments were carried out by first stirring at 27–28° for one hour and then at 42° for two hours. Rapid carbonation (solid carbon dioxide, ten seconds) yielded 6.52 g. or 36.4% of *n*-caproic acid, and less than 1% of impure *n*-butylmalonic acid. Slow carbonation (gaseous carbon dioxide, five hours) yielded 3.53 g. or 19.5% of *n*-caproic acid, and 1.83 g. or 14.8% of *n*-butylmalonic acid.

Acting on the suggestion that low boiling petroleum ether might give different results, parallel experiments were carried out with purified petroleum ether distilling over the range 28–38°. Rapid carbonation (solid carbon dioxide, five to ten seconds) yielded 51.5% of caproic acid and less than 2% of *n*-butylmalonic acid. Slow carbonation (gaseous carbon dioxide, four hours) yielded 17.3% of caproic acid and 31.4% of *n*-butylmalonic acid.

Agaric Acid and the Donnan Theory of Membrane Equilibrium

BY R. J. HARTMAN, E. W. KANNING AND J. E. WEBER[1]

The electromotive force of the following cell was measured at 25°.

Calomel electrode	Satd. KCl	Outside solution: dilute HCl	"Parlodion" membrane	Inside solution: agaric acid, 1.25%; $Ca(OH)_2$ or HCl, in varying quantities	Satd. KCl	Calomel electrode

The agaric acid was prepared by electrodialyzing "Noble Difco" agar agar for twenty-four hours under a potential of 110 volts according to the procedure of Hoffman and Gortner.[2] The procedure followed in making the electromotive force measurements was essentially the same as that used by Loeb.[3] After about twenty-four hours a true membrane equilibrium was established as

is shown in Table I where the observed P. D. (Measured Potential) is found to be in reasonably good agreement with the hydrogen electrode potential calculated from the pH values of the two solutions (measured at the end of the experiment). The membrane potential thus obtained arises from the unequal distribution of H^+ and Cl^- on opposite sides of the membrane. Tests of the hydrogen chloride solution revealed that neither Ca^{++} nor agarate ions passed through the membrane in detectable quantities.

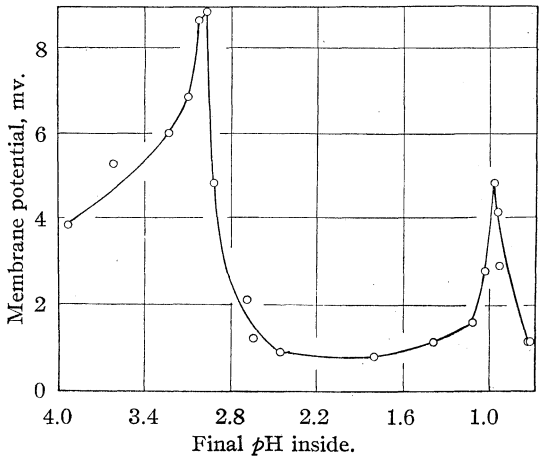

Fig. 1.—Relationship between pH and membrane potential.

When the final pH inside is plotted against the measured membrane potential, two maxima are found at pH values of approximately 3.0 and 1.0 (see Fig. 1). The second maximum is attributed to the hydrolytic decomposition of the agar. Since the membrane potential of such systems is a colligative property depending upon the number of discrete discontinuities of the dissolved constituent present, it is to be expected that the membrane potential will vary as a function of the concentration of the osmotically active particles. Agaric acid, a polyuronide, yields uronic acid units and reducing sugars.[4] Therefore, a second equilibrium is to be expected at pH values of approximately 1.0 where the agar complex is known to hydrolyze into simpler units.

Melting Points of the p-Bromoanilides of Solid Fatty Acids[1]

BY DAVID F. HOUSTON

The melting points of the p-bromoanilides of certain solid fatty acids recently prepared in this Laboratory differ greatly from those in the literature.[1a] Several of our results agree with those previously ascribed to higher homologs. A graph of our values has the general form of the melting-point curves of aliphatic series; that of

A sample of their material showed a melting point of 113.1° when determined by the writer by means of the Francis and Collins method.

the literature values has an opposite convexity. Hence it has seemed wise to publish our results.

The reagent quality acids were first recrystallized from concentrated sulfuric acid[2] until no further discoloration of the solvent occurred, and they were then repeatedly recrystallized interchangeably from acetone, benzene, and glacial acetic acid until no further change in melting point occurred. The acids were converted into their acid chlorides with thionyl chloride.

The *p*-bromoaniline was prepared (a) by the reduction of *p*-nitrobromobenzene (m. p. 126.3°), (b) by hydrolysis of *p*-bromoacetanilide (m. p. 168.6°) according to Vecchiotti,[3] and (c) by recrystallization of a commercial product from chloroform and then from aqueous alcohol to remove colored matter[4] and tribromoaniline, respectively. The three preparations of *p*-bromoaniline thus obtained had melting points between 63.5 and 64.0°, and gave products with palmitic acid which had identical melting points.

The chlorides were treated with a benzene solution of *p*-bromoaniline according to the procedure of Kuehn and McElvain,[5] with the single modification of first crystallizing the product directly from the benzene solution instead of evaporating the benzene. In the case of the long chain acids, this affords a more rapid purification.

The melting points were determined with a partial-immersion thermometer (calibrated at this Bureau) by the improved capillary-tube method of Francis and Collins.[6] This procedure, which maintains an extremely slow rate of temperature rise at the melting point, gives values that are somewhat lower than those usually obtained by capillary-tube methods (see footnote *d* of table). The results are, however, in better agreement with those obtained by equilibrium measurements on larger amounts of material.

The Separation of Hydroxy from Non-hydroxy Fat Acids by Means of a Dibasic Acid Anhydride[1]

BY FLOYD E. KURTZ[2] AND P. S. SCHAFFER[2]

The methods used for separating hydroxy from non-hydroxy fat acids have been based for the most part on differences in physical properties of the acids or of the derivatives formed with the carboxyl group. When the fat acid mixture contains acids in which these differences are small, it becomes difficult to secure a separation by such methods. This is particularly true if one of the similar acids is present as a minor constituent while the other is present in a high concentration.

In the method proposed here, the mixed esters are heated with a dibasic acid anhydride, the reaction mixture is dissolved in petroleum ether, and the derivative formed with the hydroxy esters is extracted with alkali. Since this method consists in the separation of an alcoholic from a non-alcoholic compound rather than upon the separation of two acids, its efficiency is not affected by a similarity in the physical properties of the acids.

Of the most readily available dibasic acid anhydrides, phthalic anhydride was considered unsuitable because of the difficulty of freeing the recovered fat acids from phthalic acid. Maleic anhydride was thoroughly investigated. It formed derivatives with methyl ricinoleate and with 12-hydroxymethylstearate which could be extracted readily from petroleum ether solutions, less readily from ether solutions, by means of dilute potassium hydroxide. Since ricinoleic acid and 12-hydroxystearic acid represent two hydroxy acids with quite different physical properties, it is considered likely that similar results could be ob-

(1) The part relating to maleic anhydride was presented before the Division of Biological Chemistry at the 97th meeting of the American Chemical Society, April 3–7, 1939, at Baltimore, Maryland. (Not subject to copyright.)

tained with a large variety of hydroxy fat acids. Maleic anhydride is sufficiently soluble in esters, so that the reaction mixture can be made homogeneous by the addition of only a small proportion of dioxane and often without any solvent. Pyridine is not suitable as a solvent because of the formation of large amounts of a tarry precipitate. A disadvantage in the use of maleic anhydride was found in an unexpected side reaction which takes place to a certain extent between methyl oleate and maleic anhydride to form a saturated compound. Succinic anhydride does not have this disadvantage but because of its lower solubility in the higher esters a solvent is necessary. With dioxane low yields are obtained. With pyridine better yields are obtained, but on prolonged heating considerable quantities (though much less than with maleic anhydride and pyridine) of a tarry precipitate are formed. It is recommended that when the separation involves only saturated acids, maleic anhydride be used, and that when unsaturated acids are present, succinic anhydride be used.

Table I summarizes the results of some typical experiments. It is obvious from the data that, in most cases, more than one application of the separation would be necessary to secure the one type of acid free from the other. In the case of the castor oil acids, which contain about 85% of hydroxy acids, it was found that by two applications of the separation the hydroxy acids were obtained practically free from non-hydroxy acids.

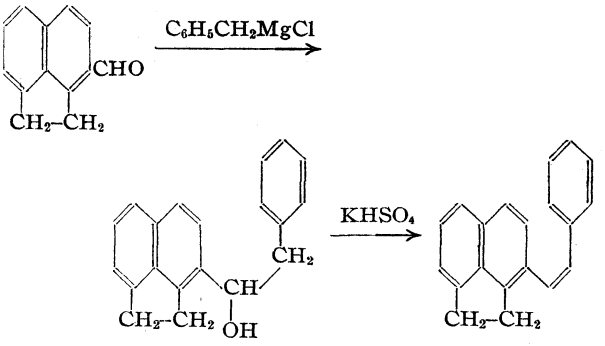
1-(β-Styryl)-acenaphthene

BY E. B. HERSHBERG[1] AND LLOYD M. JOSHEL[2]

The hydrocarbon mentioned in the title seemed of interest because in the *cis* form it constitutes an "opened" model of the carcinogenic cholanthrene from which it differs merely by the absence of one linkage connecting the benzenoid rings. The substance was synthesized by condensing 1-acenaphthaldehyde[3] with benzylmagnesium chloride and dehydrating the resulting carbinol. The hydrocarbon is crystalline and shows fluorescence in ultraviolet light.



Experimental Part[4]

1-Acenaphthylbenzylcarbinol.—A solution of 3.7 g. of 1-acenaphthaldehyde in benzene was added to the Grignard reagent from 3.5 cc. of benzyl chloride and 0.8 g. of magnesium in ether and after refluxing for one and one-half hours the mixture was decomposed with ammonium chloride and the solvents removed with steam. The product was taken up in ether and after washing and drying was obtained from ether–ligroin as needles, m. p. 107–109.5°, sufficiently pure for the next step; yield 4.9 g. (88%). A sample recrystallized for analysis from ether–ligroin (Norit) formed colorless needles, m. p. 109–110°.

Anal. Calcd. for $C_{20}H_{18}O$: C, 87.55; H, 6.61. Found: C, 87.62; H, 6.82.

1-(β-Styryl)-acenaphthene.—A mixture of 1.5 g. of the carbinol and about 0.1 g. of fused potassium bisulfate was heated at 200° until the evolution of water had ceased (ten minutes) and the product was then vacuum distilled and crystallized from absolute alcohol. The yield of twice crystallized hydrocarbon, m. p. 91.5–93°, was 1.0 g. (71%), but further recrystallizations were required to give material of the constant m. p. 93.2–94.0° (0.6 g.), possibly because

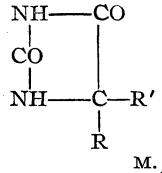
Some New 5,5-Disubstituted Hydantoins

BY DAVID MARSH AND C. L. LAZZELL

It appears desirable to record data obtained on some six new 5,5-disubstituted hydantoins which have been prepared in this Laboratory following Bucherer's[1] method incidental to some other investigations. These substances were all recrystallized from 50% alcohol and were dried for five days at 85°. Except for the di-(*p*-dimethylaminophenyl) analog, which was yellow and soluble in benzene, they were all white crystalline solids, readily soluble in such organic solvents as acetone and 95% alcohol, but only moderately soluble in water.

TABLE I



—R	—R′	M. p. °C. (cor.)	Yield, %	Molecular weight Calcd.	Molecular weight Found	% Nitrogen Calcd.	% Nitrogen Found
Methyl	Cyclohexyl	204–205	48	199.31	200	14.1	14.1
Methyl	Styryl	217 d.	12	216.26	214	13.07	13.1
p-Dimethylaminophenyl	*p*-Dimethylaminophenyl	136–137	3	338.50	344	16.63	16.6
Methyl	2-Methylpropenyl	209–210	18	168.26	168	16.73	16.8
Methyl	*p*-Aminophenyl	100–101	36	205.33	202	20.57	21.0
Methyl	2-Methyl-2-hydroxypropyl	180–181	10	186.27	188	15.12	15.0

The yields obtained were rather low, but since it was only desired to obtain a pure sample of each hydantoin, no effort was made to improve them.

The Addition of Hydrogen Bromide to Methyl Methacrylate

BY CHARLES C. PRICE AND EUGENE C. COYNER

It has been found that methyl methacrylate adds hydrogen bromide to form methyl β-bromoisobutyrate exclusively. Only the β-bromo ester was produced even in pentane solution with peroxide catalysis, the conditions most favorable for reversing the mode of addition of hydrogen bromide to a double bond.[1]

This is in agreement with similar experiments with acrylic and crotonic acids and ethyl crotonate reported by Walling, Kharasch and Mayo and by Grimshaw, Guy and Smith[2] since the initiation of this investigation.

Since only the boiling points of the two possible addition products have been recorded, the two isomeric methyl bromoisobutyrates have been carefully characterized.

Methyl β-Bromoisobutyrate.—When redistilled methyl methacrylate[3] (10 g.) in hexane or carbon tetrachloride solution (50–100 cc.) was treated with hydrogen bromide at 0 or 25° in the presence of 1% of hydroquinone, benzoyl peroxide or "Lucidol"[4] or while exposed to direct sunlight in a quartz flask, nearly quantitative yields of methyl β-bromoisobutyrate were obtained; b. p. 67° (17 mm.),[5] $n^{20}D$ 1.4551; d^{20}_4 1.426; $M^{20}D$ (calcd.) 34.71; $M^{20}D$ (found) 34.47.

Anal. Calcd. for $C_5H_9O_2Br$: Br, 44.15. Found[6]: Br, 44.38.

No other product could be detected; even the first few drops of distillate had properties in agreement with those above. When methanol was used as a solvent no addition occurred at room temperature.

The hydrogen bromide was generated by dropping bromine into tetralin; it was bubbled through tetralin to free it from bromine vapor.

Methyl α-Bromoisobutyrate.—For comparison, the α-bromo ester was prepared by the Hell–Volhard–Zelinsky method. Bromine (102.5 g.) was added to 29.5 g. of

(4) Lucidol Corporation, Buffalo, New York.

(5) Vocke (*Z. physiol. Chem.*, **191**, 83 (1930)) reported the boiling point as 65–67° (12 mm.).

(6) Method described by Rauscher, *Ind. Eng. Chem., Anal. Ed.*, **9**, 296 (1937).

isobutyric acid and 5 g. of red phosphorus at 70–80°. The excess bromine was removed by evaporation under diminished pressure and the residue cooled in ice while 20 cc. of methanol was added. On fractional distillation, 14.4 g. (25%) of methyl α-bromoisobutyrate was obtained; b. p. 52° (19 mm.),[7] $n^{20}D$ 1.4410; d^{20}_4 1.331; $M^{20}D$ (calcd.), 34.71; $M^{20}D$ (found), 35.01.

Anal. Calcd. for $C_5H_9O_2Br$: Br, 44.15. Found[6]: Br, 43.14.

The physical properties of this ester changed appreciably on standing for a few hours since hydrogen bromide is evolved with extreme ease. This accounts for the low bromine content of the product. The physical properties recorded above were observed immediately after distillation.

The Identity of Obaculactone, Evodin and Dictamnolactone with Limonin[1]

BY MILTON S. SCHECHTER AND H. L. HALLER

Several investigators[2,3] have isolated from the extractives of the bark of the amur cork tree (*Phellodendron amurense* Rupr.) a colorless, crystalline, optically active compound, which melts with decomposition at 292–293° and possesses the properties of a dilactone. The compound was named "obaculactone" by Fujita and Wada,[2] who were the first to describe it. On the basis of combustion analyses and molecular weight determinations they assigned the formula $C_{15}H_{16}O_6$ to obaculactone, but subsequent studies have shown this formula to be in error. The molecular formula $C_{26}H_{30}O_8$ is now generally accepted as correctly representing the composition of the compound.

In 1934 Fujita, Kaku and Kutani[4] showed that obaculactone is identical with evodin and with dictamnolactone. Evodin was first isolated by Keimatsu[5] in 1902 from the benzene extractives of the fruit of *Evodia rutaecarpa* Hook. f. and Thoms., and subsequently by several investigators from the fruits of other species of *Evodia*. Dictamnolactone was first described by Thoms and his co-workers[6] who obtained it from the extractives of white dittany (*Dictamnus albus* L.). The latter workers surmised that evodin and dictamnolactone were identical but were unable to make a direct comparison. The identity of the three compounds was established[4] by mixture melting point determinations and specific rotations in neutral and alkaline solution. In acetone all three compounds are levorotatory; $[\alpha]_D$ about −123°. In ethanolic potassium hydroxide solution they are dextrorotatory; $[\alpha]_D$ about +30°.

None of the early formulas assigned to the lactone were correct. In 1933 Chen and Chen[7] proposed the formula $C_{26}H_{30}O_8$. Mayeda[8] confirmed this and suggested that some of the previous difficulties in the determination of the molecular formula may have been due to the fact that the lactone crystallizes from acetic acid with one mole of acetic acid of crystallization. The lactone melts with decomposition, and melting points ranging from 280 to 293° have been reported for obaculactone, evodin and dictamnolactone by the several investigators.

A recent communication by Higby[9] describes the isolation of limonin from the pulp and seeds of the Valencia orange. This colorless, crystalline compound was first obtained by Bernay[10] in 1841 from the seeds of several varieties of citrus. Limonin has been shown to be an optically active dilactone, and combustion analyses and molecular weight determinations indicate it to possess the formula $C_{26}H_{30}O_8$. Koller and Czerny[11] have reported that limonin melts with decomposition at 280° (uncor.), whereas Higby found 292° (cor.). Citrolimonin, which is considered by Feist and Schulte,[12] by Koller and Czerny, and by Higby as being identical with limonin, is reported to melt with decomposition at 304° (Kofler micro melting point apparatus) by the first-mentioned workers.

In the course of our studies on the insecticidal properties of the fruit of the amur cork tree, the results of which will be reported elsewhere, obaculactone has been obtained from the ether and the acetone extracts of the fruit. The compound, when recrystallized by solution in acetone followed by the addition of ethanol, melted with decomposition at 299–300° (cor.).[13] When recrystallized from glacial acetic acid, it melted with decomposition at 297–298° (cor.). An aqueous

Fig. 1.

ethanol solution of the lactone has an intensely bitter taste. It is insecticidally inert.

Some of the chemical properties recorded for obaculactone have been confirmed by us. It is a dilactone, dissolves in concentrated sulfuric acid with the formation of an intense red brown color, and does not absorb bromine in chloroform solution. It does not possess alkoxyl groups, or reactive carbonyl or hydroxyl groups. Contrary to the statement of Fujita and Wada,[2] it has been found that obaculactone absorbs hydrogen slowly on catalytic hydrogenation with the formation of a mixture of products. A study of these products will form the subject of a future communication.

Obaculactone recrystallized from a mixture of ethanol and acetone and then dried in an Abderhalden drier at 100° gave the following analytical data:

Anal. Calcd. for $C_{26}H_{30}O_8$: C, 66.35; H, 6.43; mol. wt., 470. Found: C, 66.39, 66.20; H, 6.52, 6.50; mol. wt. (Rast), 445; equiv. wt. (sodium hydroxide titration), 240. *Optical rotation:* 0.0888 g. in 10 cc. of acetone at 20.5° rotated −2.29°; l = 2.0 dm.; $[\alpha]^{20.5}D$ −129°. 0.0844 g. in 5 cc. of 0.5 N ethanolic potassium hydroxide and 5 cc. of water at 20.5° rotated +0.55°; l = 2.0 dm.; $[\alpha]^{20.5}D$ +32.6°.

The melting point, the rotation in neutral solution, the behavior toward alkali, and the identity of the molecular formula of obaculactone and limonin led us to believe that the two were the same. Through the courtesy of Dr. M. B. Matlack, Food Research Division, Bureau of Agricultural Chemistry and Engineering, U. S. Department of Agriculture, we obtained a sample of limonin isolated by him from orange seed. When recrystallized from ethanol or from glacial acetic acid the compound melted with decomposition at 297–298° (cor.). A mixture of equal parts of limonin and obaculactone also melted with decomposition at 297–298° (cor.).

The optical rotations of limonin in acetone solution and in 0.25 N aqueous ethanol potassium hydroxide solution were practically identical with the values obtained for obaculactone in these solvents.

Obaculactone and limonin recrystallized from ethanol consisted of colorless, micaceous, six-sided plates and were found to be identical microscopically.[14] Refractive indices (determined by immersion in oily liquids): n_α = 1.563; n_β = indet.; n_γ = 1.582; both ±0.002. In parallel polarized light (crossed nicols) the birefringence is moderate, usually first-order grays being shown. There appears to be no definite elongation. In convergent polarized light (crossed nicols) the plates were found to extinguish sharply, indicating that the plane of the optic axes is approximately parallel to the broad face of the plates so that interference figures could not be expected. Therefore, the refractive indices were determined by a variation of the statistical method, plates showing maximum double refraction for obtaining n_α and n_γ being selected.

The foregoing results indicate clearly that obaculactone and limonin are identical.

Since obaculactone, evodin, dictamnolactone, limonin, and citrolimonin are the same compound, it would appear desirable to retain one name and discard the others. As the compound was first

(14) We are indebted to George L. Keenan, of the Food and Drug Administration, U. S. Department of Agriculture, for the photomicrographs and for the optical crystallographic data reported here.

obtained by Bernay, who designated it "limonin," we suggest that this name be retained.

Mechanism of Nuclear Isomer Separation Process

BY G. T. SEABORG, G. FRIEDLAENDER AND J. W. KENNEDY

It has been shown that the energy released during the radioactive transition from an upper to a lower isomeric state of an atomic nucleus can be used to effect a chemical separation of two genetically related nuclear isomers and this discovery has provided a powerful method for the study of nuclear isomerism.[1,2,3,4] These so-called *isomeric transitions* have been the source of activation energy for many interesting chemical reactions and offer a unique method for a study of chemical activation.[1-6] We wish to report briefly some experiments which we have performed for the purpose of elucidating the mechanism of the chemical separation process.

The small amount of recoil energy, about 5.6 kcal. per mole,[7] acquired in the majority of the cases by the Br^{80} atom as the result of the emission of an internal conversion electron during an isomeric transition in a Br^{80} nucleus, seemed to be too small to account for the bond rupture and activation experiments (sometimes 100% efficient[1]) observed with bromine compounds. We have performed experiments with the isomeric transitions[3] in radioactive Te^{127} and Te^{129}, where the recoil energies are again very small. Internal conversion electrons are emitted in these cases and the recoil energies[3] of the tellurium atoms are 9.2 and 6.6 kcal. per mole for Te^{127} and Te^{129} respectively. We made a quantitative study of the change of telluric acid to tellurous acid which occurs when the radioactive Te^{127} or Te^{129} nucleus in the telluric acid undergoes a transition from its upper to its lower isomeric state. The experiments show, for both Te^{127} and Te^{129}, that the isomeric transitions effect reduction of telluric to tellurous acid with approximately 100% yield in aqueous solution at room temperature or even when frozen to the temperature of liquid air.

These experiments suggest, in view of the very small recoil energies involved, that the bond rupture and activation occurs, not as a result of the recoil energy, but as a consequence of the high state of electronic excitation which results from the vacancy in the K- or L-shell created by the emission of the internal conversion electron. A direct test of this view could be obtained by determining whether or not bond rupture could be initiated by an isomeric transition in which the transition gamma-ray undergoes very little internal conversion. Just such a case[8] is radioactive Zn^{69}, where the transition gamma-rays are largely *unconverted* and are of such an energy as to impart 40 kcal. of energy to the recoiling zinc atoms. We compared the effectiveness of the Zn^{69} transition in producing bond rupture with that of Te^{127} and Te^{129} under comparable conditions, namely, with the zinc and tellurium in the form of their gaseous diethyl compounds at 110°. The separation of the radioactivity corresponding to the lower isomeric state, as shown by its presence on the walls of the containing vessel (where fragments of the ruptured molecules collected), made it evident that again the isomeric transitions in Te^{127} and Te^{129} had been effective in producing an isomer separation process, while in the case of the zinc diethyl no separation was observed. The tellurium isomers were separated either in the presence or absence of electrically charged plates while the zinc isomers were not separable in any case. It is difficult to see how the isomer separations observed in tellurium compounds can be attributed to the recoil energy involved, since the recoil energy in the case of zinc is roughly five times greater and yet produces no separation in a similar molecule with similar bond energies.

These results lead to the not unexpected[6] conclusion that the state of high electronic excitation which exists after the loss of an internal conversion electron is responsible for the accompanying isomer separation process. For example, the tellurium atom is excited after K-shell conversion to the extent of 32 Kev. (740,000 kcal. per mole) or after L-shell conversion to 4.9 Kev. (110,000 kcal. per mole). During the electronic rearrangement which follows, the molecule should have ample opportunity to dissociate by reaching

either a repulsive state or an attractive state with sufficient vibrational energy (due to the operation of the Franck–Condon principle).

In some cases activation of a chemical reaction by an isomeric transition may follow from the formation of an undissociated molecular residue which, either before or after it regains an electron, is itself in a sufficiently reactive state. The irradiation of solutions by X-rays, wherein the same type of molecular excitation is produced, has also led to the observation of chemical decomposition and activation processes.[9]

Reaction of Sulfur with Mercuric Acetate in Glacial Acetic Acid

BY RICHARD E. VOLLRATH

When sulfur is heated with mercuric acetate in glacial acetic acid, no mercuric sulfide is formed but instead mercurous acetate. Quantitative experiments in which the reduction product was estimated as mercurous chloride and the oxidation product as barium sulfate indicate that the chief process taking place corresponds to

$$6Hg(C_2H_3O_2)_2 + S \longrightarrow 6HgC_2H_3O_2 + 6HC_2H_3O_2 + H_2SO_4$$

By carrying on the reaction in a sealed tube at 135°, over 90% of the mercury can be recovered as mercurous acetate. No more than a trace of mercuric sulfide was obtained after prolonged heating.

Prolonged heating of the mixture gives some mercurated acetic acid or related compound, as indicated by the fact that addition of sodium iodide no longer gives a precipitate of red mercuric iodide but instead a pale yellow iodide having the characteristics of an organic mercury compound. Further work is being done on this phase of the problem.

Statistical Method from the Viewpoint of Quality Control. By WALTER A. SHEWHART, Ph.D., Member of the Technical Staff, Bell Telephone Laboratories, New York, with the editorial assistance of W. EDWARDS DEMING, Ph.D., Senior Mathematician, The Department of Agriculture, Washington. The Graduate School, The Department of Agriculture, Washington, 1939. ix + 155 pp. Illustrated. 16.5 × 24.5 cm.

Based on four lectures delivered in March, 1938, this book is a critique of statistical quality control, for readers who already have some acquaintance with the elements of statistical theory, and are more interested in applying than in developing it. Chemists and physicists will be interested in the analysis of the data on basic physical and chemical constants, in the light of which the incompatibilities pointed out by R. T. Birge may be evidence that statistical sins, even in high places, do not go forever unpunished. "When a scientist makes a mistake in the use of statistical theory, it becomes a part of 'scientific law'; but when an industrial statistician makes such a mistake, woe unto him for he is sure to be found out and get into trouble." The discussion of the specification of accuracy and precision will be a disappointment to readers who are looking for easy answers, "...neither the physical nor the numerical aspect of an operation by itself can be taken as a complete description of the operation." The table of contents by sections goes far toward atoning for the lack of an index, and the typography reflects credit on the Lancaster Press.

ELLIOT Q. ADAMS

Theoretical Qualitative Analysis. By J. H. REEDY, Associate Professor of Analytical Chemistry, University of Illinois. McGraw-Hill Book Co., Inc., 330 West 42d St., New York, N. Y., 1938. ix + 451 pp. 34 figs. 14.5 × 21 cm. Price, $3.00.

Most present-day Qualitative Analysis texts consist of companion sections on the theory of the processes of precipitation and separation, and on the characteristic reactions of the various ions, with the detailed analytical procedures. The author has followed this plan, presenting first some 150 pages of theory dealing with solutions, colloids, mechanics of precipitation, analytical operations, equilibrium, mass law, ionization and its applications, sulfide behavior, amphoterism, complex ions, hydrolysis, cell potentials, and the handling and balancing of equations. This list is a comprehensive and ambitious one for the space allotted; the treatment of each item is matter-

of-fact and necessarily brief, too much so at times, since many concepts and mathematical statements have to be introduced, considered and dismissed with little or no introductory background or explanation.

The qualitative analytical part of the book occupies the remaining 270-odd pages, consisting of the usual descriptive paragraphs on cations and anions (much more extensive than in most texts), the systematic procedures for the various groups, and short sections on dry (blowpipe) analysis and the dissolving of solid substances. The systematic cation procedure handles the silver group in the customary way, and the copper and tin group sulfides are divided with ammonium polysulfide. In the large iron–nickel family the whole group is precipitated as hydroxides and sulfides, and these are divided either with sodium hydroxide–peroxide, or by solution of all except cobalt and nickel in hydrochloric acid, followed by separation of the soluble members with sodium hydroxide (the phosphate–oxalate interference procedure also is given in some detail). The alkali earth cations are precipitated as usual with hot ammonium carbonate and then analyzed by a choice of methods: chromate–sulfate–oxalate, chromate–ferrocyanide–sulfate, chromate–chromate–oxalate, or the alcohol separation of the nitrates and chlorides. The Mg–Na–K group ions are identified by several methods, the phosphate–perchlorate–zinc uranyl acetate, and phosphate–perchlorate–fluosilicate (incorrect flow-sheet) methods being suggested. The anion analysis treatment is quite detailed, the radicals being classified on behavior into six groups: (I) insoluble silver salts (8), (II) slightly soluble silver salts (4), (III) silver and barium salts insoluble in dilute acid (11), (IV) soluble silver and barium salts (7), (V) barium salts insoluble in acids (3), (VI) silicates.

Every book contains factual and typographical faults or arguing points; in this text there might be mentioned: the use of certain unattractive (to the reviewer) plural and compound words, such as, mediums, equilibriums, deionization, saltlike, noncorrodible, nonoxidizing, timesaving, glycerin (glycerol preferred), nonionizing, nonaqueous, subreaction, semichemical, etc.; the unorthodox definition of molal solutions (p. 11); the unusual concept of "solid concentrations" (p. 50); the slightly severe treatment of the Arrhenius theory (pp. 72 ff.) (John Dalton has fared much better; did Arrhenius ever propose that ions actually existed as free simple atoms or groups?); the typographical oversight which has allowed the signs on anions to join end-to-end (preferably spaced or set up as $^{--}$ $^{=}$ or $^{---}$).

ALLEN D. BLISS

General Chemistry. Theoretical and Descriptive. By THOMAS P. MCCUTCHEON, Ph.D., Professor of Inorganic Chemistry, University of Pennsylvania, HARRY SELTZ, Ph.D., Professor of Physical Chemistry, Carnegie Institute of Technology, and J. C. WARNER, Ph.D., Professor of Chemistry, Carnegie Institute of Technology. Third edition. D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, N. Y., 1939. xiii + 685 pp. Illustrated. 14 × 22 cm. Price, $3.75.

This is a book which will appeal to the instructors who wish to give a full course in General Chemistry for the able student who has already had work in physics and chemistry. Hearing so much about the necessity of making chemistry simple arouses one's fears that teachers may choose texts which leave out the meat and that the chemical soup will be too dilute to satisfy the strong student. It is therefore encouraging to find another text, thorough in its presentation and accurate in detail, meet with sufficient support to warrant a third edition.

The subject matter is divided into two parts, following the plan of former editions. Part I, entitled "Chemical Principles and Theories," is complete in itself and would be received with favor for some uses if it were bound separately. This part is written with the viewpoint of the physical chemist and includes a good deal of the material ordinarily found in elementary physical chemistry texts. Nevertheless, the presentation is not too mathematical and a student who has had or is taking his first college mathematics, should comprehend fully any of the material presented.

Part II, entitled "Descriptive Chemistry," contains the usual factual information about the elements and their compounds. Following an introductory chapter on "Acids, Bases and Salts. Metals and Non-Metals," there are several chapters in which the non-metals and their compounds are presented in the conventional order. The metals are discussed in families following the order of the Periodic Table, two chapters on Organic Chemistry being included after group IVb.

The book has eight full-page portraits, about seventy-five excellent drawings, some seventy references (most of which are to more advanced texts) in Part I, no references in Part II, and a twenty-two-page two-column index.

It is the opinion of the reviewer that the text should have several fields of usefulness, such as: (1) a textbook for sincere and able students who have had some previous training in science; (2) a review for the upperclassman who wishes a logical presentation of chemical theory, which is not cluttered up with factual data about individual substances; (3) reading for teachers in related fields of Biology, Physics, Geology, and Mathematics, as well as Elementary Chemistry teachers, who for any of various reasons wish to be brought up to date in chemical thought and terminology.

C. R. CONARD

The Nature of the Atom. 115 pp. Illustrated. By G. K. T. CONN, M.A. (Aberdeen), B.A., Ph.D. (Cambridge). **The Wave Nature of the Electron.** 78 pp. Illustrated. By G. K. T. CONN. **The Nature of Crystals.** 114 pp. Illustrated. By A. G. WARD, B.A., Scholar of Trinity College, Cambridge. All three volumes published by Chemical Publishing Company, 148 Lafayette Street, New York, N. Y., 1939. 12.5 × 19 cm. Price, each, $1.50.

This series of little books is intended for the intelligent lay reader who desires a somewhat more thorough exposition of modern conceptions of the structure of matter than is to be found in the ordinary popular book on general physical science. Though the volumes belong naturally together, each is complete in itself, containing a carefully developed presentation of its subject. The ap-

proach is historical, in order to show why it has so frequently been necessary to abandon naive conceptions in favor of difficult and at first sight apparently fantastic abstractions. Assuming no special knowledge of mathematics on the part of the reader, the authors have been at pains to present their material in a way which should enable him to obtain, at the cost of a few hours of careful reading, some real comprehension and appreciation of the trends of recent Physics. The volume on crystals contains excellent illustrations and diagrams of the simpler lattice types, with directions for the construction of models which will undoubtedly, if followed, aid the reader to grasp the elementary theory of the crystal lattice. There is considerable discussion of modern views of different kinds of binding forces between molecules, atoms and ions. The volumes on the atom and the electron present what are now the standard results of wave mechanics.

A. S. COOLIDGE

A Short History of Chemistry. By J. R. PARTINGTON, M.B.E., D.Sc., Professor of Chemistry in the University of London, Queen Mary College. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1937. xiv + 386 pp. 124 figs. 13.5 × 20.5 cm. Price, $2.50.

This Short History of Chemistry by Partington comes as a welcome addition to our somewhat meager list of really readable histories of chemistry. In the first portion the author has traced the beginnings of chemistry through the alchemical, iatrochemical and phlogiston periods in a most delightful manner, and has brought a fresh viewpoint on pre-Lavoisierian chemistry. His own investigations into original sources add a personal touch and the profuse illustrations are indeed refreshing. It is pleasing to note the emphasis and recognition given to that pioneer, van Helmont. The work on the discovery of gases by the group of British chemists is well described.

The main portion of the book, exactly one-half of the entire contents, is devoted to the period from Lavoisier down through the establishment of the valence theory. In giving account of the advances made and theories proposed during this badly confused period in the development of our science, the author has been only moderately successful. In the opinion of the reviewer, more definition might have been given to the interpretation of prevailing theories, in order to clarify the concepts, notations and viewpoints as they gradually evolved. In using this text with a class in the history of chemistry, the reviewer's students encountered this difficulty of interpretation. Yet, it might be said in justice to the author, that other histories of chemistry covering this epoch are likewise difficult to read and harder to understand; the authors are not entirely to blame, the period itself was chaotic.

The period of expansion following 1860, in which Inorganic Chemistry became definitely etsablished, Organic Chemistry greatly expanded and Physical Chemistry became differentiated as a separate branch of the science, is covered rather briefly by the author. For this brevity the author states in the preface "... this part of the subject is dealt with in the ordinary lecture courses on Chemistry, and need not be repeated in a book of this kind." For one seeking a concise (57 page) account of the development of chemistry from 1860 to relatively recent times, he will find it here.

On the whole, this book is one of the finest short histories of chemistry ever written. The reviewer commends it and congratulates the author in his accomplishment.

C. J. ENGELDER

Introduction to Practical Organic Chemistry. By FREDERICK GEORGE MANN, Sc.D. (Cantab.), D.Sc. (Lond.), F.I.C., Fellow and Lecturer, Trinity College, Cambridge, University Lecturer in Chemistry, and BERNARD CHARLES SAUNDERS, M.A., Ph.D. (Cantab.), B.Sc. (Lond.), Fellow and Charles Kingsley Lecturer, Magdalene College, Cambridge, University Demonstrator in Chemistry, Sometime Assistant Master, Eton College. Longmans, Green and Co., 114 Fifth Avenue, New York, N. Y., 1939. ix + 191 pp. Illustrated. 14.5 × 22.5 cm. Price, $1.50.

This book is "essentially a severely abridged version" of "Practical Organic Chemistry" by the same authors (*cf.* THIS JOURNAL, **61**, 1297 (1939)), and has been designed "to cover the essential requirements for the organic chemistry of the 1st M. B. examination at Cambridge and most other British universities, the various Higher School Certificate Examinations, the Chemist and Druggist Qualifying Examination of the Pharmaceutical Society, and examinations of a similar type. It is, therefore, directed at a specific group in Britain.

Inasmuch as the larger book has been competently reviewed, it seems that it remains only to point out the extent of abridgment. The section on methods and manipulation has been cut from 37 to 27 pages; preparations occupy 64 pages compared to 164 in the larger book; the section dealing with reactions and identification of organic compounds has been shortened from 79 to 57 pages; 24 pages instead of 77 are devoted to quantitative analysis, and the section on simple enzyme reactions has been deleted.

The use of a great deal of fine print does not increase the readability of the book, but if one desires a laboratory text in which preparations, reactions and identification of organic compounds and quantitative organic analysis are treated in the brief space of 172 pages, the text can be recommended. The exposition is clear and concise, and the choice of material good.

NATHAN L. DRAKE

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) **Aluminiumlegierungen.** (Aluminum Alloys.) Collection of Patents. Edited by G. APEL, Regierungsrat in the Patent Office. First Supplement, Parts I–III. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 35, Germany, 1939. VI + 1877 pp. Price, RM. 72 + 49.50 + 31.50.

This is a First Supplement to the Collection of Patents on Aluminum Alloys published in 1936 as an Addendum to the volume on Aluminum in Gmelin's Handbook. It covers all the patents on aluminum alloys which have appeared in England, France, Germany, Switzerland and the

United States during the succeeding three-year period, that is, from the beginning of 1935 to February, 1938. The same convenient system is followed as before, namely, listing the foreign constituents of each alloy alphabetically and putting all the alloys with the same final constituent in a single group arranged in the order of increasing complexity.

A list of the trade names of recognized aluminum alloys with their percentage composition and the name of the inventor or manufacturer is also provided.

The present collection, in spite of the short interval of time covered must include more than twice as many alloys as the original volumes. This is an indication of the extraordinary activity in this field.

ARTHUR B. LAMB

Rheological Memoirs. Volume I, Number 1, January, 1940. EUGENE C. BINGHAM, Editor. Experimental Investigations upon the Flow of Liquids in Tubes of Very Small Diameter. By Dr. JEAN LEONARD MARIE POISEUILLE, translated by WINSLOW H. HERSCHEL. Published by Rheological Memoirs, Easton, Pennsylvania. 101 pp. 10 figs. 15.5 × 23 cm. Price, $2.00; bound in cloth, $2.50.

The preface says in part: "There is no gainsaying that an adequate library is one of the most important of tools, even granting that research is highly dependent upon the laboratory. Even with the deployment of our scientific journals to cover every field, there still are memoirs which are not readily available. There are works which need to be made more accessible, not because of an existent demand and a probable financial return or for reasons of patriotism or other allegiance. There are some classical researches which are needed as tools of research and in education....

"It is now proposed, under the title of Rheological Memoirs, to publish in inexpensive form certain classical memoirs in rheology in the English language which are not only important but inaccessible to the majority of readers. For the rheologist, such a paper would be that of Poiseuille published in the *Mémoirs présentés par divers savants à l'Institut de France* in 1846. This paper was the one which brought to the world the knowledge of viscous flow and the data there given are still regarded as among the best available for the absolute determination of the viscosity of water....

"The attempt will be made to publish rheological memoirs from time to time in unbound numbers, exactly as are the journals. When a suitable number of these are published, it is proposed to bind them in book form. Subscriptions may be placed with the Rheological Memoirs, Lafayette College, Easton, Pa., or with the Secretary of the Society of Rheology in care of the American Institute of Physics, 175 Fifth Avenue, New York, N. Y. The publication is edited by Dr. Eugene C. Bingham, and each paper is passed upon by the Publications Committee of the Society of Rheology.

"A fund has been collected to initiate this project. The response of the public will determine whether this type of publication will support itself and be continued."

This monograph by Poiseuille, which was originally published in 1846, should be read by every chemist or physicist interested in the flow of liquids. Poiseuille, a man trained as a physician and physiologist who was primarily interested in the circulation of the blood in the human body, boldly challenged the accepted formulas of the hydraulic engineers and demonstrated that flow of liquids in narrow tubes obeys different laws than the flow in wide pipes. In addition to the great historical interest of this paper in opening a new branch of science, it is remarkable that nearly one hundred years ago Poiseuille evidently attained a precision in his experimental results which would be difficult to surpass at the present time even with the aid of modern equipment.

The translation has been done splendidly. A brief biography of Poiseuille and many critical notes add to the interest and value of the pamphlet. Our thanks are due to Eugene C. Bingham and to Winslow H. Herschel for making this masterpiece available.

Other memoirs on plasticity and lubrication are foreshadowed.

GRINNELL JONES

Molecular Spectra and Molecular Structure. I. Diatomic Molecules. By GERHARD HERZBERG, Research Professor of Physics, University of Saskatchewan. Translated with the Co-operation of the Author by J. W. T. SPINKS, Professor of Physical Chemistry, University of Saskatchewan. Prentice-Hall, Inc., 70 Fifth Avenue, New York, N. Y., 1939. xxviii + 592 pp. 181 figs. 16 × 23.5 cm. Price, $6.50.

The German edition of this book has been reviewed in the February, 1940, number of THIS JOURNAL. The English edition does not differ in any essential respect from the German, though some improvements have been made. The translation is adequate. The book provides an accurate and up-to-date account of the theory of diatomic molecules, especially those portions of immediate applicability to spectral analysis; some of the more difficult details and certain more complex portions of the theory are omitted. The theory is illustrated by many examples, a large number of which are discussed in detail. Table 36 summarizes the data on the ground states of the known diatomic molecules, including isotopic molecules, and has been revised as of July, 1939. The new values of the physical constants are used, instead of Birge's table of 1929. As most calculations in the literature are based on the older values, the reader using the data in the present volume will need to exercise some care in order not to introduce inconsistencies. The book is furnished with an excellent subject index. Altogether, it is a work which is indispensable to anyone who has a serious interest in the field covered.

O. K. RICE

Quantitative Biological Spectroscopy. By ELMER S. MILLER, Assistant Professor, Department of Botany, University of Minnesota. Burgess Publishing Company, Minneapolis, Minn., 1939. 213 pp. Illustrated. 21 × 27 cm. Price, $3.50.

This manual contains eighteen chapters. A brief history of optics and a summary of the theory of molecular spectra is given in chapters one and two. Chapter three

deals with thermopiles, photoelectric cells and amplifiers and chapter four with spectrophotometric instruments. In chapter five spectrophotometric methods for the determination of the absorption in the ultraviolet, visible and infrared regions of the spectrum are described and chapter six is devoted especially to photoelectric spectrophotometry. After having presented in chapter seven the basis of absorption spectroscopy including calibration and standards, the author has discussed in chapter eight the sources of error which may influence the accuracy of measurements. These chapters, which give a survey of the various types of spectroscopic apparatus and discuss the performance of absorption measurements represent a valuable collection of information otherwise obtainable only by wearisome search through scattered literature. They are enriched by fine illustrations.

The following chapters may be considered as a second part of the manual dealing with the applications of absorption spectroscopy: to chemistry (chapter nine); to the determination of molecular structure (chapter ten), and chapter eleven emphasizes the importance of infrared absorption spectroscopy for chemistry. Furthermore, chapters twelve to seventeen include the application of absorption spectroscopy to important biological material, such as absorption spectra of vitamins, cytochrome and other pigments; spectrophotometric studies of hemoglobin derivatives; absorption spectra applied to lipids and lipid metabolism; analysis of binary, ternary and quaternary mixtures (with special reference to chlorophylls and carotenoids); application of quantitative spectral analysis to plant pigment inheritance studies. The last chapter presents selected annotated references of spectrophotometric studies.

The compilation of these various applications of absorption spectroscopy will be of great value not only for those who intend to become acquainted with this field but also to those already familiar with the subject, especially with respect to the critically and clearly stated precautions which must be observed in investigations of this kind. It is unfortunate that the selected references given in the last chapter are not accompanied by a compilation of the references on these subjects for the past five years, particularly since many of them are given in the chapter bibliographies. Considering the significance of the application of absorption spectroscopy to biological problems this manual, written by a competent author, is welcome.

ADOLPH STERN

Thermodynamics for Chemical Engineers. By HAROLD C. WEBER, Associate Professor of Chemical Engineering, Massachusetts Institute of Technology. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1939. vii + 264 pp. Illustrated. 15 × 23.5 cm. Price, $3.25.

The author states in the preface that it is his purpose to present the more important thermodynamic relations in a manner particularly useful to the chemical engineer. The preliminary preparation expected of the students is indicated by the statement "Familiarity with the fundamentals of physics will be useful, and the simultaneous study of physical chemistry, as practiced in many schools, will be helpful." In the reviewer's opinion practically all of the book can be readily understood by most students without any previous or simultaneous study of physical chemistry. One exception is the chapter IV on phase relations which would be quite difficult for any student who had not made some study of the temperature–pressure–composition diagrams for binary systems. Many other sections of the book would involve unnecessary repetition for students who have taken a course in physical chemistry which even approximately covers the material in any standard text. As examples of this type of material may be cited portions of Chapters V, VI, VIII, and XVI.

In the preface it is suggested that the first fourteen or fifteen chapters include as much material as can be covered satisfactorily in a two semester course. Such a selection omits consideration of equilibrium constants, electrochemical effects, third law, and free energy as a function of temperature. The reviewer believes that these topics are of more importance in a course on thermodynamics than some other topics, such as fluid flow which is treated in considerable detail in chapter XI. Such topics are more suitable for a course in plant design than one in thermodynamics.

Objections to the material contained in the book are relatively few. Chapter XIX on electrochemical effects is probably the poorest in the book. In the first place the diagram on p. 241 does not even remotely resemble a workable cell. Then on p. 242 the author speaks of the cell reaction for a cell consisting of two hydrogen electrodes one in 0.1 molal hydrochloric acid and the other in 0.1 molal sodium hydroxide as being the transfer of hydrogen ion from a solution where its activity is a_1 to one where its activity is a_2. Actually the cell reaction is the formation of water from its ions. Later in the chapter the reader is left without any clear idea how to determine whether a given cell is functioning reversibly.

The numerous diagrams will be found an aid to the student. However, it is unfortunate that the author did not select a reaction for the figure on p. 27 which could be balanced at some pressure which can be contained by apparatus which is obtainable. Figure 9, p. 79 and Fig. 10, p. 81, both have entropy of vaporization as ordinates, it would be better to call it by this name rather than speak of an enthalpy function, especially since the term entropy is used elsewhere in the same chapter.

Those teachers who agree with Professor Weber as to the content of a course in thermodynamics for chemical engineers will probably be well satisfied with the book as it is. Those who believe more stress should be laid on the material covered in the last five chapters will have to amplify the book considerably.

G. K. ROLLEFSON

Colloid Chemistry. By ROBERT J. HARTMAN, Indiana University. Houghton Mifflin Company, 2 Park Street, Boston, Massachusetts, 1939. xxviii + 556 pp. 184 figs. 16 × 24 cm. Price, $4.75.

This textbook of colloid chemistry treats the subject under four general headings: surface chemistry (130 pages), lyophobic colloidal systems (225 pages), lyophilic colloidal systems (80 pages), and the biocolloids (100 pages). In the first section are treated the general char-

acteristics, theories, and applications of adsorption, including a chapter on contact catalysis. The second section is concerned primarily with the preparation, properties, and stability of sols, aerosols, emulsions, and foams. [Since a *sol* is by definition a colloidal system, the tautological expression *colloidal sol*, which the author uses frequently in this section, is not recommended.] The third section deals with lyophilic sols and with gels. The final section is devoted specifically to biocolloids and some colloidal aspects of organisms.

In the preparation of this book, the author has attempted "to present the important phases of colloid chemistry without overemphasizing one narrow phase of the subject at the expense of others which are to the average student and reader just as important." A specialist who writes a textbook is very likely to devote proportionately more space to the authoritative and critical analysis of that portion of the field in which he is directly interested; the remainder of the specialist's books will be less authoritative and is likely to be less critical. In this book the author has accomplished his worthy aim of avoiding overemphasis on some phase of colloid chemistry at the expense of others equally important; but unlike the specialist's book, this volume suffers throughout from the lack of a critical analysis on the part of the author of the large amount of material that he has compiled.

The book gets off to a good start with the section on adsorption phenomena. The survey of Langmuir's valuable contribution is especially good. Because of the space devoted to Langmuir, much less prominence could be given to the important work of Harkins, Bartell, and Adam.

For the purpose of "avoiding much possible confusion" the lyophobic and lyophilic colloidal systems are considered separately, although the author recognizes clearly that no exact line of demarcation can be drawn between them. On page 140, the author puts the oxide sols on the border line: "For example, the hydrosols of the oxides of such metals as iron, vanadium and chromium will tolerate the presence of more electrolytes than lyophobic colloids, such as suspended metals, before a state of instability is reached; and yet they are far more sensitive to electrolytes than lyophilic colloids such as protein suspensions." In the light of this statement the student unfamiliar with the various factors which influence the stability of sols, may be confused on finding on pages 260–261 that the precipitation value of sodium chloride, for example, is 28 for a certain gold sol and 9.25 for a certain ferric oxide sol. As a matter of fact, most of the oxide sols are not near the border line but are distinctly more lyophobic than lyophilic in their colloidal behavior. The gels are classified under lyophilic systems although dilute jellies of such lyophobic materials as platinum and cadmium have been prepared. In inorganic gels the capacity of the solid phase to form an interlacing structure may be much more important for gel formation than the lyophilic character of the solid phase.

The chapters dealing with the preparation and the physical, optical, and electrical properties of sols, are among the best in the book. The chapter on the stability of sols appears less satisfactory. Little attention is given to the constitution of colloidal particles and the discussion of the mechanism of the electrolyte coagulation process on which so many people have worked, is inadequate. No mention is made of the outstanding work of Verwey on this subject. The space devoted to biocolloids in this book is considerably greater than in most introductory treatises on colloid chemistry. For this reason it may be found of special use to students of biology and biochemistry.

The book is very attractively printed. The cuts include 40 excellent reproductions of photographs. The subject matter is well outlined by the generous use of section and paragraph headings. Throughout the book, distinctive terms appear in black face type. The interested instructor will be impressed by the good physical make-up of the book, but he will want to read it carefully to determine whether the choice and treatment of the subject matter are sufficiently critical to serve his purposes as a textbook for advanced undergraduate and graduate students.

HARRY B. WEISER

Die Ultrazentrifuge. Theorie, Konstruktion und Ergebnisse. (The Ultracentrifuge. Theory, Construction and Results.) By Prof. Dr. THE SVEDBERG and Dr. KAI O. PEDERSEN, Physical-Chemical Institute of the University of Upsala. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1940. xii + 433 pp. 154 figs. 15.5 × 23.5 cm. Price, RM. 35; bound, RM. 37.

This comprehensive monograph is a thorough description of ultracentrifuges as developed in Professor Svedberg's laboratory at Upsala and of the results obtained with these machines by Svedberg and his pupils. Svedberg's development of ultracentrifugation is from every standpoint —technical, theoretical and in fruitfulness—one of the great triumphs of physical chemistry. For that reason his description within the confines of one book is of the widest importance.

The monograph is a coöperative effort of Svedberg and his pupils. General and introductory sections have been written by Svedberg himself; most of the sections on theory and method have been prepared by Pedersen. Special topics in theory and results have been written by several of Svedberg's pupils, and Bauer and Pickels have contributed a detailed description of their type of the air-driven ultracentrifuge.

The four principal parts of the book are devoted (1) to the theory of sedimentation, (2) to the construction of ultracentrifuges, (3) to the various methods of measurement with ultracentrifuges and (4) to the summary of results obtained with Svedberg's ultracentrifuges. The last of these parts without a doubt holds most interest for the general reader. Svedberg has a number of times summarized the data from his laboratory but this review, being more detailed and comprehensive, is of correspondingly wider usefulness. It should be read by all biochemists and physical chemists. Active workers with ultracentrifuges will probably find especially valuable the two chapters dealing with methods of measurement and with general theory. There is much useful technical information on design and construction, particularly of rotors, in the chapter describing the oil-turbine ultra-

centrifuge. This description makes apparent the enormous amount of work that has gone into developing the instrument; after studying it one can readily understand why more have not been built.

The few workers with ultracentrifuges who are not directly a part of the Svedberg school will find the book largely a record of the point of view, as well as the accomplishments, of one group. There is, of course, the greatest justification for this in the overwhelming role that Svedberg has played in demonstrating the usefulness of centrifugation in the study of macromolecules. At the same time this physical technique will reach its full usefulness only when it can be widely and freely employed and its methods modified by many people of varied interests. There is thus a real need to have ultracentrifugation, and its still unrealized opportunities as a research tool, presented in such a way as to encourage others to try to use it. Very high centrifugal fields are useful, not only as a step in molecular weight estimation, but also as a tool for the isolation and purification of macromolecular substances. The centrifuges necessary for such preparative work as well as for accurate measurements of sedimentation rates on the heavier proteins can be much less costly and complicated than those described in this monograph. Many persons feel that the air-turbine ultracentrifuge is important for the very reason that it makes possible instruments the average laboratory is equipped to build and operate. From this standpoint it may be regretted that the treatment of air-ultracentrifugation is restricted to a detailed description of one excellent but still very complicated, and costly, instrument.

Sir William Jackson Pope

JOURNAL OF THE
AMERICAN CHEMICAL SOCIETY

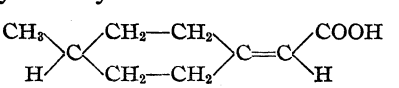
VOLUME 62 JUNE 8, 1940 NUMBER 6

SIR WILLIAM JACKSON POPE

1870–1939

William Jackson Pope was born on March 31, 1870 in London. He commenced the study of Chemistry in the Finsbury Technical College as one of the earliest students of the late Professor H. E. Armstrong, whom he followed in 1887 when the latter migrated to South Kensington. Ten years later he was appointed head of the Chemistry Department of the Goldsmiths Institute at New Cross. In 1901 he became Professor of Chemistry at the College of Technology in Manchester and seven years later was appointed to the Chair of Chemistry at Cambridge, where he remained until he died on October 17th, 1939.

Early as a student, Pope was attracted to the science of crystallography, and possessed the uncommon faculty of spatial visualization. At Manchester, in collaboration with Barlow, he published a series of interesting papers on the packing of atomic spheres as models of crystal structure. Whilst Pasteur, whose papers Pope studied with deep interest, in 1849, had clearly enunciated the fact that optically active substances, whilst not necessarily devoid of all elements of symmetry, were dissymmetric and possessed no plane of symmetry in their structure, this important generalization was in some danger of being forgotten in the attention given to the papers of van't Hoff and Le Bel in 1874. In these the concept of the asymmetric carbon atom, defined by van't Hoff as an atom to which four dissimilar groups were attached, as the criterion of dissymmetry and thus of optical activity, was somewhat unduly stressed. It is clear, however, that Van't Hoff visualised the possibility of optical dissymmetry in compounds such as allene derivatives which possessed no one asymmetric atom as defined by him. In collaboration with Perkin and Wallach, Pope prepared the first compound of such a type by synthesising and resolving 1-methyl-cyclo-hexylidene-4-acetic acid



He also showed that it was unnecessary for the asymmetric carbon atom to be attached to other carbon-containing groups for optical activity by preparing and resolving one of the simplest compounds possessing optical activity, *viz.*, HC(I)-(Cl)SO_3H. Up to 1899 optical activity had been associated with compounds which were either dissymmetric or contained an asymmetric atom of carbon, but in that year Pope opened what was virtually a new field in the chemistry of optical activity by preparing a compound in which the optical activity was due to an asymmetric atom of nitrogen by resolving benzylphenylallylmethylammonium iodide. In many of these resolutions he was assisted very materially by his discovery

and use with Kipping of the strong optically active acid α-bromocamphor sulfonic acid. This success was soon followed by the preparation of optically active compounds which owed their activity to asymmetric atoms of sulfur, selenium and tin.

At a later date there issued from the Cambridge Laboratories optically active compounds of arsenic, beryllium and zinc and still more recently compounds of platinum and rhodium. He was Longstaff Medalist of the Chemical Society in 1903 and Davy Medalist of the Royal Society in 1914; he was awarded the Dumas Medal of the Société de Chimie Industrielle in 1921 and the Messel Medal of the Society of Chemical Industry in 1932. He was elected an Honorary Member of the American Chemical Society at its 62nd General Meeting on September 7, 1921.

During the late war his breadth of knowledge and ability for getting things done resulted in a process for the direct synthesis of mustard gas and to drawing the attention of the authorities to a valuable source of toluene. For these services he was made a Knight of the British Empire in 1919. He was always keenly interested in the Goldsmiths Company, and attained high honor in this ancient Livery Company of the City of London. He took a lively interest in the metallurgical and chemical properties of the rare metals, gold, palladium and silver. After the late war his activity in research diminished although he still followed closely developments in dissymmetric molecular structure especially in the spirane configuration. Indeed, only a few weeks before his death he discussed with the writer the possible extension of a spirane configuration into a cyclol structure such as has recently been proposed by some as the basis of protein form.

The extent to which chemistry enters into the national economy impressed Sir William most forcibly during the period of the war, and it may be said that he devoted the rest of his life to rendering chemistry both more effective as a national asset, in the form of a Federal Council for Chemistry and as an important factor in international relations. It is generally recognized that the International Union of Pure and Applied Chemistry and the unique Solvay Chemical Conferences, in both of which he played a large part, owe much in vitality and mode of operation to Sir William Pope.

The criticism which has frequently been levelled at chemists that they are oblivious of other forms of culture could not be applied to Sir William, although it is true that this side of his life was presented only to his friends. His collections of pestles and mortars and of engravings of early alchemical discoveries are probably unique. He was also interested in ceramics and was no indifferent bibliophil. Whilst to some he appeared somewhat forbidding in aspect, to those who knew him and especially to those who had the privilege of being on his staff, he revealed himself as a man with a great sense of humour, of unusual kindness and generosity, possessed by an unexpected love of nature and withal somewhat shy. By his death International, British and Cambridge Chemistry have suffered a loss which will not easily be replaced.

Microtome Measurements of the Adsorption of Hydrocinnamic Acid in the Surface of its Aqueous Solutions*

BY J. W. MCBAIN, T. F. FORD AND G. F. MILLS

It has been demonstrated that the composition of a *moving* surface bears little relation to monomolecular adsorption or to the Gibbs theorem.[1] The microtome method[1,2] was developed for measuring adsorption at *static* air–water interfaces. In principle this method fulfills the Gibbsian requirement of equilibrium, and therefore can, theoretically, be made definitive as well as accurate. Results obtained with this apparatus are here reported for solutions containing 1.5 g. of β-phenylpropionic acid in 1000 g. of water. Humphreys,[2] Swain,[1] and two of the present authors (T. F. F. and G. F. M.) have each independently obtained a final value for the absolute adsorption per square centimeter of between 5.2 and 5.6 $\times 10^{-8}$ g.

It is disturbing to find that time appears to be a factor and that these equilibrium values appear to develop only on solutions that have been aged for several hours. However, it has been well established[3] by many methods and in several laboratories that the lowering of surface tension of these solutions likewise requires long periods of time for development. The Gibbs equation involves only quantities measured under equilibrium conditions. Hence, although it may be interesting that the final values for adsorption agree with the initial non-equilibrium values of surface tension obtained by the drop weight method,[3] they must properly be compared with the somewhat higher values obtained from the later more static measurements of surface tension.

Experimental

Apparatus.—The apparatus differs in a number of details from that previously used.[1,2] In order further to eliminate evaporation, both the inner and outer enclosures were rebuilt. In the inner enclosure the independent suspension of the trough was discarded. Instead, a silver sub-trough one inch (2.5 cm.) deep was set between the rails so as to seal the entire space and so designed that the trough rested directly upon it. The surface of the solution itself came into contact only with pure silver, except at the ends of the trough where the edges were coated with dicetyl. The glass side walls of the outer enclosures were replaced by brass ones heavily plated with silver, and all that space lower than the rails themselves was hermetically shut off from the outside by means of silver-plated aprons; the small cracks where the parts of the enclosure were fitted together were sealed on the inside with paraffin wax, and the glass covers were fitted on the cases with apiezon wax. After thus eliminating all leaks, it was found that, in the saturated atmosphere existing in the enclosure, water condensed in the guides in which the inner doors operate, and that capillary forces prevented their opening. The automatic feature of the doors as constructed had then to be discarded, and in these experiments the inner doors were operated manually by an assistant.

The sample of solution collected by the car was removed to the interferometer cell for analysis by means of a suitably shaped pipet, thus obviating the necessity of lifting the car from the tracks and reducing the evaporation loss. Also the whole length of the tracks beyond the outer enclosure was covered by a tunnel constructed of glass and of cardboard coated with shellac to make it possible for the car to be started and stopped in contact with a vapor similar to that inside the enclosures.

The silver stirrer previously used was replaced by one made of thin glass rods welded in the shape of a ladder with many rungs. This stirrer lies flat on the bottom of the trough and is manipulated through the holes in the covers of the outer and inner enclosures by means of a bent glass rod.

The tracks were surveyed and levelled where necessary, using a 15-inch (38-cm.) Pratt and Whitney gage, with which differences of 0.00005 inch (0.00127 mm.) per foot (30.5 cm.) may be estimated. Surveys were made before the experiments were started and again afterward to detect possible changes in level. The tracks within the enclosure were of pure block silver six feet long and were scraped true and level; the twenty-six feet of tracks outside the enclosure were of steel.

The microtome barrel in which the liquid skimmed off was caught was, like the trough itself, made of pure silver, burned together by autogenous welding to avoid contamination from solder. All fresh surfaces of solution were cut off many times to remove contamination. They were then very thoroughly stirred for several minutes and time was counted from the completion of stirring.

Experimental Procedure.—All apparatus was thoroughly washed and dried under cover before the experiment was started. No parts were handled more than could possibly be avoided. To prevent contamination being carried into the enclosure on the runners of the car, they and the tracks were washed with distilled benzene before each experiment.

A blank run, from which an approximate value of otherwise indeterminable experimental errors could be esti-

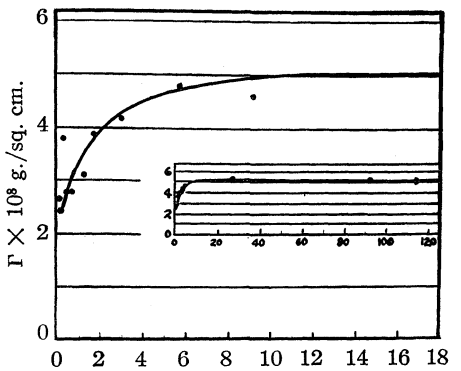

Fig. 1.—The measured adsorption of β-phenylpropionic acid in the surface of a solution containing 1.5 g./1000 g. water.

mated, was made by the usual procedure in which the sample placed in the microtome collecting chamber, or barrel, was of known original concentration. As a check the blank correction was divided into an evaporation and a dilution blank which were then added together. In the first, a known sample was poured into the barrel of the car after the car, wet with the same liquid, had been shot along the tracks; and this sample was then removed and analyzed. In the dilution blank the car was not shot at all, but a sample which differed by a known amount from the solution which had been used to rinse the barrel of the car was introduced into the barrel and removed again for analysis. The evaporation correction was −0.4, the dilution correction was +0.3, giving a composite blank correction −0.1 division of the interferometer dial for a 3-g. sample of 1.5 g./1000 g. hydrocinnamic acid. The corrections affect the final results by less than 4%. An 8-cm. Zeiss cell was used for analysis, reading to 0.1 division or 1.19×10^{-7} g. of hydrocinnamic acid to one gram of water.

A time schedule for a typical experiment was as follows. Three minutes after opening the inner doors only, the barrel of the car had been thoroughly rinsed with the stock solution. At 2, 3, 4 and 6 sec. later, respectively, the car was on the tracks, the outer doors opened, the car released, and the outer doors closed. At 21 and 51 sec., the sample had been placed in the interferometer cell and a sample of the liquid left in the trough had been removed and placed in the other compartment of the interferometer cell.

In the microtome measurements, the solutions were shielded from light or exposed during experiments only to the dimmest possible artificial light. Only dim indirect light was at any time permitted in the basement room in which the equipment was housed. This precaution was primarily to minimize temperature fluctuations, but it also guarantees the absence of light-induced polymerization of adsorbed solute. In the surface tension measurements in the same room, the solution was completely enclosed in an opaque box.

Results of Adsorption Measurements

The adsorption results for solutions containing 1.5 g./1000 g. water are collected in Table I and are shown graphically in Fig. 1. The table gives interferometer readings, Δ, for the surface liquid compared with that remaining in the trough from which the surface liquid had just been removed, and Γ the excess of solute found per square centimeter of the air–water surface over that corresponding to uniform concentration right up to the surface, where Γ = g./cm.^{2} = $\Delta Vk/A$, where k is the interferometer constant, V is the volume of shaving, and A is the area of surface removed by the microtome, 288 sq. cm. in every case.

TABLE I

13	116 hr.	1.65± .10	7.6	7.4	5.0

[a] Analyzed mixture with equal volume of standard solution.

Survey of the tracks before and after each set of experiments disclosed differences in level of less than 0.001 cm. throughout the length of the trough, so that complete films were certainly collected.

Effect of Evaporation.—Extensive tests of the effect of evaporation upon the experimental results were carried out both with solutions of hydrocinnamic acid and with more concentrated solutions of phenol, the latter being volatile. It was shown that a correct result can be obtained only when the solution in the trough is kept in such an atmosphere that its composition undergoes no change over long periods of time. This is in accordance with the Gibbs requirement of true equilibrium. For the experiments recorded in Table I, for example, the change in concentration of the solution in the trough was less than 1 division, or 1×10^{-6} g./cc. or 0.0006% of the original concentration, in a month.

Twelve measurements also were made upon solutions containing 5.2 g./1000 g. water. These data are not displayed here because at the low temperatures they were too near saturation. With the exception of two low values (including 0.14×10^{-8} g./cm.^{2} at age one minute), they averaged 6.6×10^{-8} g./cm.^{2}. The last four values obtained at ages from twenty-three to fifty-three hours averaged 7.7×10^{-8} g./cm.^{2}, which is still distinctly below the Gibbs value predicted from surface tension of aged solutions (see Table IV).

When the solution of hydrocinnamic acid in the trough was exposed to the atmosphere of the room, approximately 4 g. of water evaporated per hour, corresponding to an increase in concentration of 0.25 g./liter, and the value of apparent Γ found during this period was increased fivefold over the equilibrium value.

Phenol.—With Kahlbaum phenol solution (36 g./1000 g. solution in boiled out distilled water) the average equilibrium value of Γ was 8.3×10^{-8} g./cm.^{2}; and determinations during evaporation and condensation at known rates for this phenol solution gave an interpolated value of $\Gamma = 10 \times 10^{-8}$ at the point where both evaporation and condensation were suppressed. The Gibbs equation gives for phenol at this concentration $\Gamma = 4.7 \times 10^{-8}$, as calculated by Goard and Rideal.[4]

Experiments were made by L. A. Wood with pure water, at one hour and after two days, but no difference whatsoever could be observed in the interferometer, showing complete absence of contamination.

Surface Tension Determinations on Aqueous Hydrocinnamic Acid Solutions. Drop Weight Method.—It is commonly supposed that the static or final surface tension of a crystalloidal solution is established within a small fraction of a second.[5] In many cases, and especially for hydrocinnamic acid solutions, this certainly is not true. Nevertheless, it is generally felt that the few seconds required for drop weight determinations[6] represent a close enough approach to a static condition, and consequently such measurements have been universally used for calculation of adsorption by the Gibbs equation. In the two previous papers on the microtome apparatus[1,2] drop weight surface tension measurements were utilized for calculating Γ. The measurements were made independently by C. R. Bacon and R. C. Swain in 1932 and 1933, Dr. Bacon using a tip kindly furnished by Professor Harkins.

The effective radii of the tips were calculated from the drop weight of conductivity water (σ = 72.11 dynes at 24.6°). The radii, and the technique, were checked with repeatedly distilled benzene (density 0.879) dried over calcium chloride, and also with a solution of resublimed Kahlbaum "zur Analyze" *p*-toluidine (density 0.9983), containing 2.0 g. per 1000 g. of water. The results of these preliminary experiments are given in Table II; upper row by C. B., lower row by R. C. S.

TABLE II

CALIBRATION OF DROP WEIGHT

Tip radius cm. (calcd.)	Water drop wt., g.	Benzene Drop wt., g.	σ	*p*-Toluidine Drop wt., g.	σ
0.2955	0.08377 at 24.6°	0.03242 at 22.4°	28.54 28.56[a]	...	...
0.2932	0.08325 at 24.7°	0.03221 at 21.9°	28.50 28.63[a]	0.07300 at 22.1°	63.76[b]

[a] Calculated for check from values in "International Critical Tables, Vol. IV, p. 454.

[b] 65.34 at 20° obtained by Gans and Harkins[6]; 64.89 at 16° (in tap water) by Ferguson and Kennedy, *Proc. Phys. Soc.*, 44, 517 (1932); and 65.6 at 16.6° by Brown, *Phil. Mag.*, [7] 11, 689 (1931).

Solutions were prepared by Bacon and Swain from recrystallized Eastman Kodak Co. hydrocinnamic acid. The experimental results are given in Table III. The values of Γ are calculated by the approximate formula

$$\Gamma = -\left(\frac{c}{RT}\right)\left(\frac{d\sigma}{dc}\right)$$

TABLE III

DROP WEIGHT OF SOLUTIONS OF HYDROCINNAMIC ACID

(7) Harkins and Jordan, *ibid.*, **52**, 1751 (1930).

ance, by floating the large platinum dish containing the solution on water whose level can be exactly and smoothly adjusted. Since both glass and paraffin tend to contaminate the surface of water after long periods, Bakelite lacquer was used, twenty coats being applied, each baked on at 140°. This coating is not only completely impermeable, but has no tendency whatsoever to contaminate water even after a day or so. Both platinum dishes and Bakelite coated metal were used.

The arrangement of the apparatus is shown in Fig. 2. Evaporation was prevented by surrounding the solution with a closed dish (also floating) draped inside with cloth dipping into a surrounding reservoir of solution several centimeters deep, and with a small hole in the top of the vessel for the connection to the balance. This opening was closed except during the moments required for a measurement. After forty-five days a 2.5 g./liter solution of hydrocinnamic acid was found to be 2.46 g./liter.

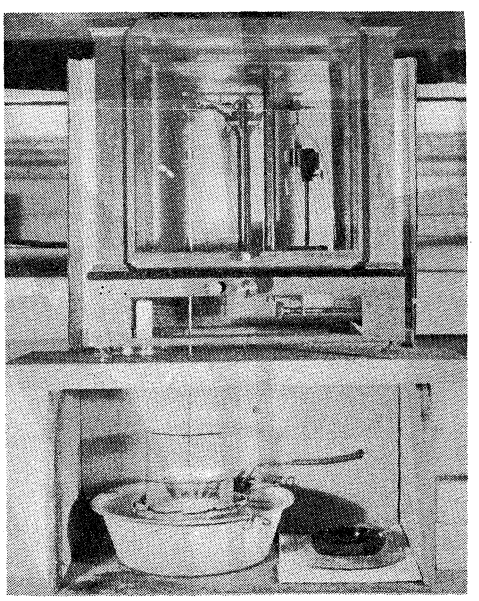

Fig. 2.—Modified ring method for measuring surface tension; outside container cut open to show interior, and wet draping also not shown.

In conducting an experiment, the solution dish was filled to overflowing and the surface twice swept with clean paper toweling, more solution added, the vapor chamber placed in position and the solution allowed to age for some hours. The du Noüy platinum ring was heated to white heat, the surface swept four or five times, the ring heated again in a clear alcohol flame, and then kept submerged beneath the surface except during measurements. A contact angle is observed when the ring approaches the surface from above, but not when it has been kept below. Conductivity water from a Barnstead still ($<0.4 \times 10^{-6}$ mhos) and specimens of hydrocinnamic acid purified by different methods were employed. It was shown that excess carbon dioxide, where permitted, did not affect the results, which are given in Figs. 3 and 4. The temperature was 22.5 ± 0.5°. The surface tension of water measured in the same apparatus remained completely constant for twenty-four hours. This may be contrasted with the changes found by du Noüy and by Klopsteg not using our precautions.

It is evident that the thirty seconds usually allowed in drop weight experiments is inadequate for the attainment of the static surface tension of such solutions. Actually the surface tension seems to change for days or weeks. This persistent time change agrees with observations by Adam and Shute,[8] studying 0.01% solutions of cetyltrimethylammonium bromide. They find big changes in surface tension with time by the sessile drop method, and Tartar and Reed and Cadle[9] find similar results for alkyl sulfonate solutions using capillary tubes. All these authors report changes persisting for periods of a week or more.

It is evident that ordinary processes of diffusion are almost infinitely faster than these surface tension effects. Application of the film balance to these solutions by McBain and Perry and Spencer[10] has shown that quite complicated phenomena occur in their surfaces. Measurements[3] with the PLAWM trough and pendant drop methods (at Stanford and at Massachusetts Institute of Technology) confirm this slow establishment of surface tension.

Discussion

The figures which have been given show that adsorption measured by the microtome method does not attain its final value immediately, but that several hours may be required. For solutions containing 1.5 g. of hydrocinnamic acid per kg. of water, the final or asymptotic value $\times 10^8$

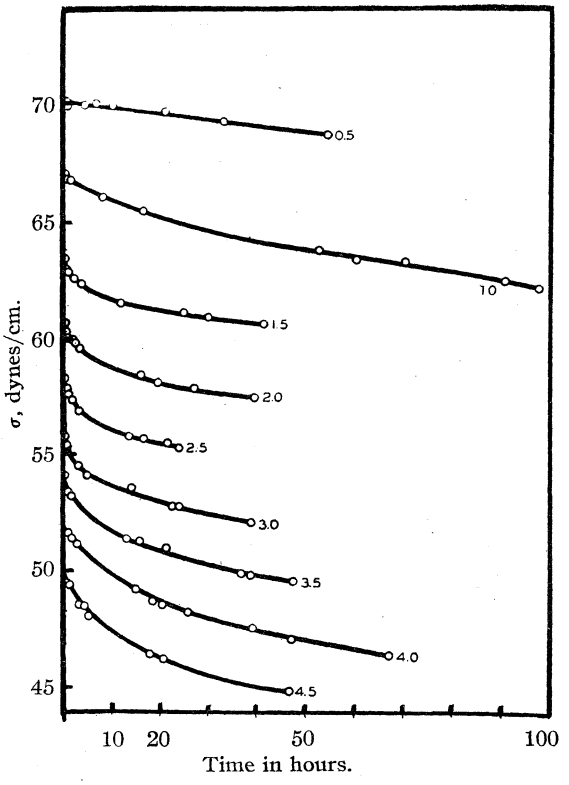

Fig. 4.—Change of surface tension of hydrocinnamic acid with time.

appears to be 5.2 ± 0.4, as compared with previous average values 5.2[1] and 5.6,[2] in experiments where time effects were not studied, and the apparatus had not been refined. Similarly, experiments with the interferometer[11] (by G. F. M.) have yielded a final value 5.2 attained after some hours. For solutions of 5.2 g./liter the final result appears to be at least 7.7×10^{-8} by the microtome method.

Having established the experimental values, the unexpected difficulty lies in finding what are the theoretical values predicted by the Gibbs theorem, since the surface tension changes so much and so slowly with time. Actually, although the surface tension falls for long periods, the slope of the surface tension–concentration curve and hence the predicted adsorption may change very little, and with the stronger solutions the amount of adsorption predicted from the Gibbs formula may even diminish with time, in contrast to the falling surface tension.

In Table IV are given data for the adsorption predicted for solutions containing 1.5, 4.0, 4.5 and 5.2 g./kg. of water, respectively, by the drop weight and by the ring method.

It appears that the actual equilibrium adsorption agrees very well with the value predicted from the non-equilibrium drop weight surface tensions, but is somewhat less than the proper values predicted from equilibrium surface tension.

TABLE IV

ADSORPTION, $\Gamma \times 10^8$ IN G./CM.², PREDICTED FROM GIBBS EQUATION, FOR SOLUTIONS OF HYDROCINNAMIC ACID OF DIFFERENT AGES OF SURFACES

Concentration g./1000 g. H_2O	Drop weight 30 sec.	Du Noüy 5 min.	Du Noüy 1 hr.	Du Noüy 9 hr.
1.5	5.2	5.9	5.9	6.3
4.0	7.3	9.0	8.8	8.8
4.5	7.7	10.2	9.1	9.1
5.2	7.6	..	..	..

In the adsorption experiments the solution was always thoroughly stirred before time was counted. The equations for ordinary diffusion are well known[5,12] and with the stirring employed the calculated time required for replenishment of the solution near the surface denuded by adsorption would be[12] about 10^{-1} second. The adsorption per square centimeter is 5×10^{-8} g., which comes from a solution which is 0.01 *N* and contains 1.5 g./liter. It therefore could deplete this to a depth of several Ångström units, and this would be restored to the extent of 90% in

(11) Ford and McBain, THIS JOURNAL, **58**, 378 (1936).

(12) Langmuir and Schaefer, *ibid.*, **59**, 2407 (1937); **60**, 2805 (1938).

0.003 sec. and to the extent of 99% in 0.3 sec. In only three experiments did we attempt a measurement until at least twenty minutes after stirring. As Doss has emphasized,[10,13] here the adsorption is delayed and therefore the diffusion "activated."

It is clear from all the phenomena referred to that the surfaces of ordinary solutions are far from being the simple structures commonly taken for granted. As was recently pointed out[10] the Gibbs equation is sometimes incompatible with their being monomolecular; for solutions of the simpler soluble fatty acids the Gibbs predicted adsorption remains constant with increase in concentration while the surface tension continues to drop. Much remains to be discovered about the depth, electrification and organization of surfaces of solutions.

(13) Doss, *Kolloid-Z.*, **86**, 205 (1939).

Summary

1. Even after efficient stirring, the experimentally determined adsorption of β-phenylpropionic acid in the surface of its aqueous solution as measured by the microtome method is not completed immediately, but may require several hours, whereas diffusion processes would require only about a tenth of a second.

2. The surface tension is not finally established until after much longer periods of time.

3. The final measured absolute adsorption seems to be slightly less than that calculated by the Gibbs theorem from surface tensions of comparable age and closest approach to equilibrium.

The Effects of Pressure, Temperature and Chemical Composition on the Absorption of Light by Mixtures of Aromatic Amines and Nitro Compounds

BY R. E. GIBSON AND O. H. LOEFFLER

Introduction

It has been known for a long time that, when pure aniline and pure nitrobenzene are mixed, the solution immediately develops a deep orange color.[1] This is an example of a very general phenomenon, similar color changes being observed whenever primary, secondary or tertiary aromatic amines are mixed with aromatic nitro compounds,[2] aliphatic nitro compounds such as tetranitromethane,[2,3] nitroso compounds, quinones[4] or liquid sulfur dioxide,[5] etc. These color changes are due neither to adventitious impurities nor to irreversible reactions; addition of dilute hydrochloric acid to aniline–nitrobenzene mixtures discharges the color immediately, and the deep orange or red solutions of aniline or dimethylaniline in nitrobenzene freeze to very pale yellow solids which are immediately stained red when melting begins.[6] Furthermore, in the solutions we have studied, phototropic effects are not obvious although the mixtures do not differ greatly from some phototropic compounds.[7]

A satisfactory discussion of the changes in light absorption which occur when amines are mixed with *mono-nitro* compounds does not seem to have been given. It has been assumed that the colors observed are due to the formation of small amounts of intermolecular compounds in the solutions[8] and this has received some support from the known existence of a wide variety of stable, colored, solid intermolecular complexes between polynitro compounds and amines or hydrocarbons, substances which have been studied extensively.[9]

(1) I. Ostromisslensky, *Ber.*, **44**, 268 (1911). The phenomenon must have been noticed much earlier than this by such workers as Hepp (1882) or Kremann, but we have not been able to find any specific discussion of it in the literature.

(8) See P. Pfeiffer, ref. 4, pp. 358 and 384; G. M. Bennett and R. L. Wain, *J. Chem. Soc.*, 1108 (1936). Further references to articles supporting this view are given by D. L. Hammick and G. Sixsmith, *ibid.*, 972 (1939). In this paper we shall follow the customary practice and use the term "compound formation in solution" to mean the formation of covalent bonds between atoms in unlike molecules of the original components, as contrasted with general intermolecular attractions that result from dipole interaction or other polarization effects. A definite criterion, *viz.*, a measurable reaction velocity, has been proposed for this type of "compound formation" by D. L. Hammick and G. Sixsmith, *ibid.*, 580 (1935). Unless such a restriction is placed on the term "compound formation," it becomes too broad to be useful in the present state of our knowledge.

Recent work, however, has shown that the stability of these solid addition compounds may be accounted for by the interaction energy arising from the mutual polarization of the molecules,[10] and their significance in supporting a theory of compound formation in the solution has consequently depreciated.

Furthermore, important differences in behavior indicate that the potential energy due to attractive forces between unlike molecules is less in systems containing mononitro compounds than in systems containing polynitro compounds, and that the former systems actually show positive deviations from ideality. For example, the freezing point curves of mixtures of aniline with (a) trinitrobenzene, (b) *m*-dinitrobenzene, (c) nitrobenzene indicate the formation of a congruently melting solid compound in case (a), of an incongruently melting compound in case (b) and no solid compound in case (c).[11] Linard's conclusion that a compound is formed in system (c) does not seem to be supported by his own diagram,[12] or by the disappearance of color when these solutions freeze. Tinkler[2] found a simple eutectic in the system *p*-chloronitrobenzene–diphenylamine, and, indeed, it has been stated categorically that no crystallized addition compounds of mononitro compounds are known.[13] The measurements of partition coefficients made by Moore, Shepherd, and Goodall[14] lead to the same conclusion. The fluidity–composition curves for mixtures of mononitro compounds and amines[15] show positive deviations from ideal behavior.[16] A small amount of heat is *absorbed* on the formation of aniline–nitrobenzene solutions[17] (132 cal./mole for a 50 mole per cent. solution at 14°) and we have already indicated that the volume changes on mixing at different pressures and temperatures make it unlikely that compound formation takes place in these solutions, and that if it did, the compound would be destroyed by rise of pressure.[18]

In this paper we give the results of some observations of the effects of pressure changes from 1 to 1500 bars and of temperature changes between 25 and 85° on the absorption of light by solutions of aniline, dimethylaniline, diphenylamine and triphenylamine in nitrobenzene, and by a number of solutions of related substances. The bearing of these observations on the problem of molecular interaction in solution, on the mechanism of the color changes to which we have referred, and on the role of intermolecular action in determining the color of organic compounds will be discussed.

Experimental

The effects of pressure and temperature on the absorption of light by the various solutions were measured in the same bomb and thermostat and with the same absorption cells that were used in our work on the determination of refractive indices under pressure.[19] Light from an incandescent tungsten strip filament entered the pressure bomb by one window, passed through the solution which was contained over mercury in the glass cell, and after emerging through the other window, impinged on the slit of a Hilger Type D2 constant deviation wave length spectrometer. The character of the incident light was varied to meet our requirements by adjustment of the filament temperature or by the use of suitable glass filters. The spectra of the transmitted light were photographed on Wratten panchromatic plates. An approximate scale of wave lengths was provided by similar photographs of the spectra of mercury and helium arcs, a spectrum of the mercury arc being superimposed on the transmission spectrum of each solution. The results of these experiments will be given in the form of microphotometer tracings of the photographs of the transmission spectra which were made on a Moll recording microphotometer.[20]

In these diagrams the abscissas give the approximate wave lengths and the ordinates are proportional to the logarithms of the intensity of the transmitted light over the ranges of intensity indicated by the vertical arrows in the right-hand margins.

The chief part of the experimental work consisted of comparing the transmission spectra at different pressures and temperatures with those at 25° and 1 bar, and care was taken to make the first and last photographs of any series with the solution under these standard conditions. In any pressure experiment the cell was filled with freshly prepared solution and the transmitted light was photographed

at different pressures in the following order, 1, 500, 1000, 1500 (in a few cases), 500 and 1 bar. All exposures to be compared were made on the same plate, the cell being left undisturbed whenever possible, and the exposure times were made long enough (30 to 60 sec.) to ensure adequate reproducibility. In the same way, when the effects of temperature changes were being studied, the exposures taken at the higher temperatures were bracketed between initial and final exposures at 25°. Except in rare cases when obvious causes were present, the photometer curves for exposures taken under the same conditions coincided within 2 mm. on a photographic record where the total possible excursion was 100 mm.

The Effect of Pressure on the Absorption of Light by Solutions of Amines in Nitrobenzene

The following observations were made on solutions of aniline, dimethylaniline, diphenylamine and triphenylamine in nitrobenzene, but it seems probable that conclusions drawn from them may be applied to solutions of any amine in a nitro compound. When the pressure is raised, the absorption of visible light by these solutions is increased much more than can be accounted for by the increase in the density of the solution. The effect is quite reversible and shows no time lag. Typical features of our results are to be seen in Fig. 1, which illustrates the results obtained with a 50% solution of dimethylaniline in nitrobenzene.

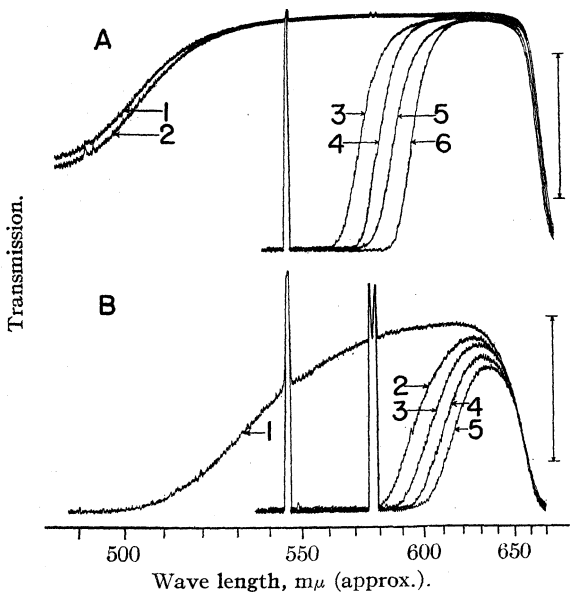

Fig. 1.—Transmission curves for a 50% solution of dimethylaniline in nitrobenzene at 45°: A1, aniline in 0.9-cm. cell; A4, solution in 0.9-cm. cell at 1 bar; A6, solution in 0.9-cm. cell at 1000 bars; A2, aniline in 0.5-cm. cell; A3, solution in 0.5-cm. cell at 1 bar; A5, solution in 0.5-cm. cell at 1000 bars; B1, same as A1; B2, solution at 1 bar; B3, solution at 500 bars; B4, solution at 1000 bars; B5, solution at 1500 bars.

Figure 1A shows the transmission spectra at 1 and 1000 bars with two different absorption cells: cell (a) 0.9 cm. thick and cell (b) 0.5 cm. thick. Curves 1, 4 and 6 refer to cell (a) and curves 2, 3 and 5 to cell (b). Curves 1 and 2 were taken with the cells full of pure aniline, no filter was used, the source of light being held at a low temperature in this series. Curves 3 and 4 were obtained at 1 bar and curves 5 and 6 at 1000 bars. The magnitude of the effect of pressure on the absorption of light by this solution may be estimated from a comparison of curves 3, 4 and 5, due allowance being made for the separation of curves 1 and 2. It will be seen that a 1.8-fold increase in the thickness of the absorbing layer does not increase the absorption by any means as much as an increase of pressure of 1000 bars even though the change in density due to the rise of pressure is less than 4%. In Fig. 1B, a systematic study of the effect of pressure on this system is given; cell (a) was used in this and in all the following experiments, and curves 2, 3, 4 and 5 give the transmission spectra at 1, 500, 1000 and 1500 bars, respectively. It will be noticed that at wave lengths where the solution is quite transparent at 1 bar, its absorption is considerable at 1500 bars, and that in the strongly absorbing regions on the short wave side of the transmission spectrum the logarithm of the intensity decreases linearly with rise of pressure.

Transmission curves for a 50% solution of aniline in nitrobenzene are given in Fig. 2A. The incident light (curve 1) passed through a filter of Corning Daylight Glass (5 mm.). Curves 2 and 3 represent different exposures at 25° and 1 bar and their reproducibility is typical. Curve 5 was obtained at 1000 bars. In one set of experiments with a photocell and galvanometer, it was found that the amount of light of wave length 546 mμ (mercury green line) transmitted by an aniline–nitrobenzene solution fell to 40% of its value at 1 bar when the pressure was raised to 1000 bars. From an examination of a series of mixtures of aniline and nitrobenzene over the whole range of concentration, it was concluded that there was no obvious influence of concentration on the effect of pressure on the absorption of light by these solutions.

The behavior under pressure of an 8.5% solution of triphenylamine in nitrobenzene is shown in Fig. 3A and that of an 8.5% solution of diphenylamine in Fig. 3B. The legend for the

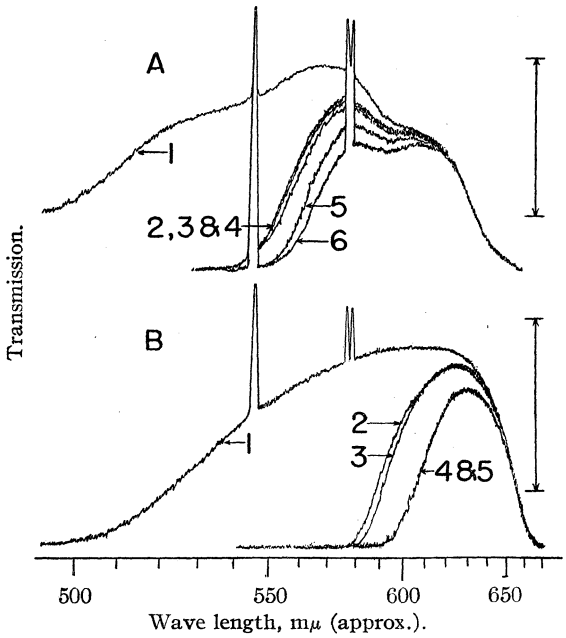

Fig. 2.—Transmission curves **A** for a 50% solution of aniline in nitrobenzene, **B** for a 49% solution of dimethylaniline in nitrobenzene: **A1** and **B1**, aniline in cell; **A2** and **A3**, solution at 25° and 1 bar; **A4**, solution at 85° and 1 bar; **A5**, solution at 25° and 1000 bars; **A6**, solution at 85° and 1000 bars; **B2**, solution at 85° and 1 bar; **B3**, solution at 25° and 1 bar; **B4** and **B5** (indistinguishable), solution at 25 or 85° and 1000 bars.

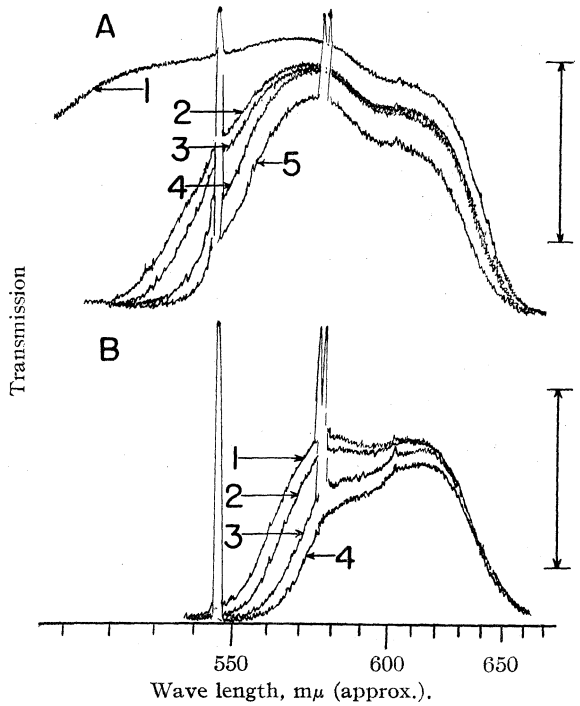

Fig. 3.—Transmission curves for 8.5% solutions of **A** triphenylamine in nitrobenzene, **B** diphenylamine in nitrobenzene: **A1**, aniline in cell; **A2**, solution at 85° and 1 bar; **A3**, solution at 25° and 1 bar; **A4**, solution at 85° and 1000 bars; **A5**, solution at 25° and 1000 bars; **B1**, solution at 85° and 1 bar; **B2**, solution at 25° and 1 bar; **B3**, solution at 85° and 1000 bars; **B4**, solution at 25° and 1000 bars.

figure identifies the curves. It will be noticed that as regards the effect of pressure on the absorption of light these solutions resemble those of the other amines in nitrobenzene. The transmission curve (A4) for the triphenylamine solution at 85° and 1000 bars is, however, anomalous in that it converges on the curve for 85° and 1 bar (A2) at a wave length of 580 mμ.

The Effect of Temperature on the Absorption of Light by Solutions of Amines in Nitrobenzene

We examined the transmission spectra of the solutions described in the previous section at 25, 55 and 85°. As the results at 55° were always intermediate between those at 25 and 85°, they are omitted from the published diagrams for the sake of clarity. The results are so diversified that each solution must be described separately. Figure 2A illustrates the results found with the aniline–nitrobenzene solution. At atmospheric pressure a rise of temperature from 25 to 85° produces a very small but reproducible *increase* in the absorption of light by this solution (curves 2, 3 and 4) which gains in significance when it is noticed that at 1000 bars the same rise of temperature causes a pronounced increase in the absorption of light by this solution, as a comparison of curves 5 and 6 will show. These observations apply to all the nitrobenzene–aniline solutions we have studied. The behavior of a 50% solution of dimethylaniline in nitrobenzene is shown in Fig. 2B. At 1 bar a rise of temperature from 25 to 85° causes a slight decrease in the light absorption particularly on the short wave edge of the transmission spectrum (curves 2 and 3). This change is reproducible and seems to be real. At 1000 bars the same rise of temperature produces no observable change in the absorption of light by the solution. As in the case of aniline–nitrobenzene mixtures, the effect of raising the pressure is to make the temperature coefficient of the absorption more positive. The curves given in Fig. 3 show that the absorption of light by the solutions of triphenylamine and of diphenylamine in nitrobenzene decreases quite significantly when the temperature is raised from 25 to 85° at both 1 and 1000 bars, and that there is no appreciable effect of pressure on the temperature coefficient.

At 85° and 1000 bars the specific volumes of all the solutions discussed in this section are approximately the same as at 25° and 1 bar. It will be seen from the diagrams, therefore, that rise of temperature at constant volume causes an increase in the absorption of light by all the solutions.

Miscellaneous Observations

In order to satisfy ourselves that the pressure effects just described were not due to some unexpected characteristic of our apparatus, we made similar observations on an 11% aqueous solution of potassium bichromate. No significant effect of pressure on the absorption of light by this solution was found (Fig. 4B). We also observed that the transmission of light by the apparatus, when the cell was filled with pure aniline, was not affected by pressure.

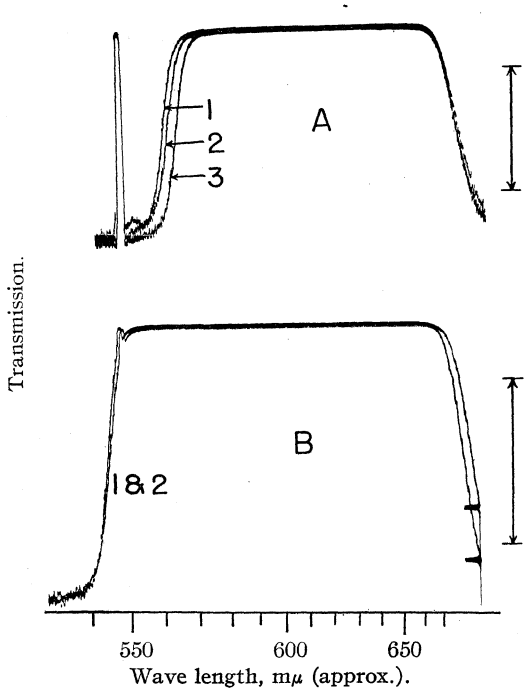

Fig. 4.—A. The transmission of light by a 3.1% solution of dimethylaminoazobenzene in benzene at 1 bar (1), 500 bars (2), and at 1000 bars (3). B. The transmission spectra of an 11% solution of potassium dichromate in water at 1 and at 1000 bars.

Solutions of *p*-nitrophenol in aniline absorb light less strongly in the visible than nitrobenzene–aniline solutions of the same molal composition, but their behavior under pressure changes is the same. On the other hand, the absorption of light by the *p*-nitrophenol solutions is notably increased by rise of temperature. The transmission curves at 25° (1) and 85° (2) for a 44% solution are given in Fig. 5, where it will be seen that the positive temperature coefficient is much larger than any other we have described.

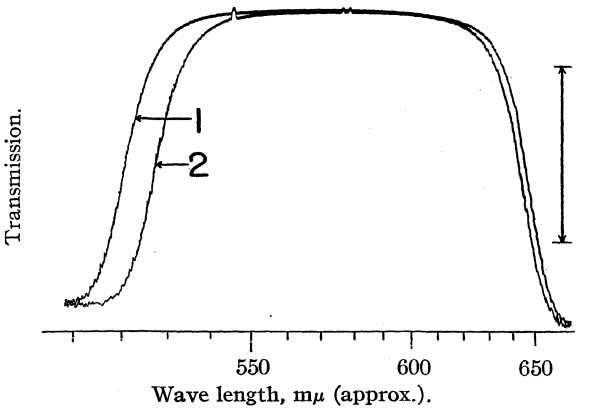

Fig. 5.—The effect of temperature on the transmission of light by a 44% solution of *p*-nitrophenol in aniline. Curve 1 was obtained at 25° and curve 2 at 85°, the pressure being 1 bar.

Solutions of nitrosobenzene in aniline and other amines are much more highly colored than the corresponding solutions of nitrobenzene. Figure 6A shows that rise of pressure increases the absorption of light by a dilute (1.1%) solution of nitrosobenzene in aniline. Similar results

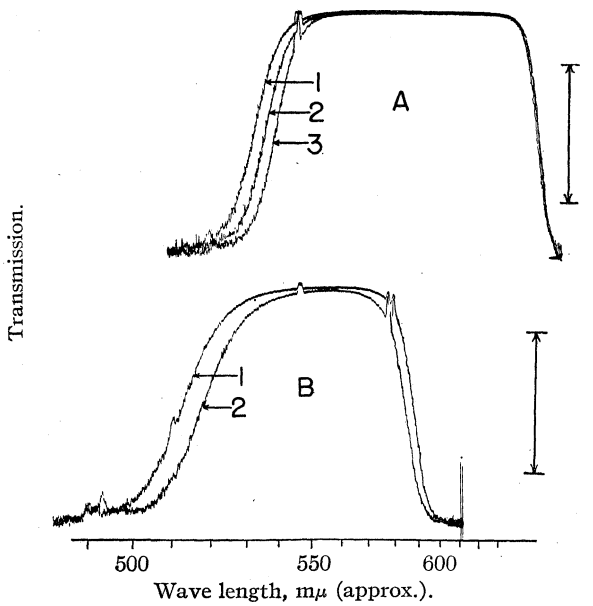

Fig. 6.—A. The transmission spectra of a 1.1% solution of nitrosobenzene in aniline at 1 bar (1), at 500 bars (2), and at 1000 bars (3). B. The effect of pressure on the transmission of light by an 18% solution of nitrosobenzene in benzene. Curve 1 was obtained at 1 bar and curve 2 at 1000 bars.

were obtained with solutions of nitrosobenzene in dimethylaniline. The absorption of light which gives rise to the well-known green color of solutions of **nitrosobenzene in benzene** also is influenced significantly by pressure changes (Fig. 6B).

We have observed an effect of pressure on the transmission curves of dilute solutions of **dimethylaminoazobenzene in benzene** (Fig. 4A) and of solutions of *o*- or *p*-nitroaniline in acetone (not illustrated). The pressure coefficients of the light absorption by these solutions are, however, not as large as those of solutions in which the NO_2 and NH_2 groups are on entirely separate molecules.

Solutions of *s*-Trinitrobenzene in Aniline.—These solutions absorb light much more strongly than any others we have discussed and it is known that a 1:1 solid addition compound is formed in this system.[21] Figure 7 shows that a 2.5% solution of trinitrobenzene in aniline behaves in the same way as mixtures of mononitrobenzene with amines under pressure changes and that the absorption of light is diminished by rise of temperature more rapidly than in the other cases we have studied. At constant volume, however, increase of temperature enhances the absorption of visible light by this solution. A comparison of Figs. 2, 3 and 7 shows that the stronger the absorption of visible light by the solution, the more negative is its temperature coefficient at atmospheric pressure.

Thermodynamic Discussion of Results

The experiments just described contribute strong evidence against the hypothesis that the colors of these solutions arise from the presence of small amounts of compounds that have been formed by the rearrangement of covalent bonds. A consideration of the temperature coefficients of the absorption of light by aniline–nitrobenzene solutions at different pressures, of the absence of time lag, of the data summarized in the introduction, and of the fact that the solutions all absorb more strongly when the temperature is raised at constant volume will show the improbability of such an assumption. On the other hand, the hypothesis that the colors of the solutions arise from the mutual polarizations of the unlike molecules when they are separated by distances which are short compared with the mean distance of separation, *i. e.*, during a collision, furnishes the basis for a fairly detailed account of our results.

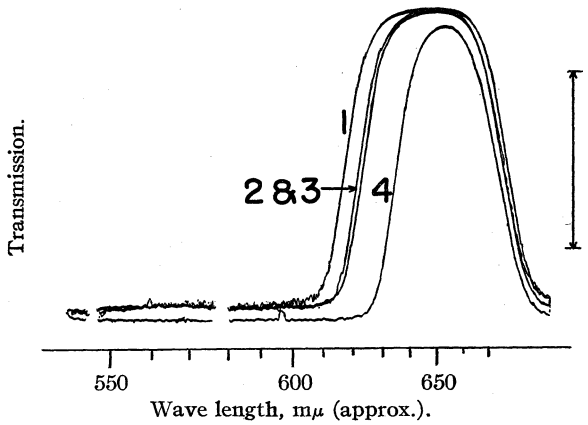

Fig. 7.—The effects of pressure and temperature on the transmission spectra of a 2.5% solution of *s*-trinitrobenzene in aniline. Curves 2 and 3 are from different photographs at 25° and 1 bar. Curve 1 gives the transmission at 85° and 1 bar, and curve 4 refers to 25° and 1000 bars.

We shall assume, therefore, that the absorption of visible light by the solution is proportional to the average time the active groups on unlike molecules spend very close to each other, *i. e.*, to the probability of finding two unlike molecules at very short distances apart and suitably oriented in the solution. The average time spent by the molecules at close distances may be correlated qualitatively with the pressure and temperature through the familiar model for liquids in which the thermal motion of the molecules is expressed in terms of the oscillations of a given molecule in a free volume, v_f, bounded by other molecules which are held stationary in their mean positions.[22] On the assumption that the potential energy of the molecule changes only during collisions, a formula for the oscillation frequency ν in such a system has been derived by Bradley and is essentially

$$\nu = Const.\ T^{1/2}/M^{1/2}V_f^{1/3} \qquad (1)$$

where T is the absolute temperature, M the molecular weight, and V_f the free volume per mole. From our thermodynamic data on aniline, nitrobenzene and their mixtures,[23] we can estimate V_f by means of a relation whose validity

(21) B. R. Hamilton and D. L. Hammick [*J. Chem. Soc.*, 1350 (1938)] have found that the absorption coefficients of solutions of aniline and *s*-trinitrobenzene in carbon tetrachloride diminish with rise of temperature.

Mott and R. W. Gurney, "Repts. on Progress of Physics," Vol. V, The University Press, Cambridge, 1939, p. 46; (d) J. Frenkel, *Trans. Faraday Soc.*, **33**, 58 (1937).

(23) R. E. Gibson and O. H. Loeffler, THIS JOURNAL, **61**, 2515, 2877 (1939).

has been made probable by Kincaid and Eyring[24] and which may be written in the form

$$V_f^{1/3} = 2R/V^{2/3}\,(\partial P/\partial T)_V \qquad (2)$$

At constant temperature we have found empirically that $V_f^{1/3}$ is inversely proportional to the pressure over a range of 1000 bars. By equation (1), therefore, the oscillation frequency of the molecules which determines the average time they spend in close proximity under these conditions should be directly proportional to the pressure, and, according to our hypothesis, the absorption of light of a given wave length should also vary directly with the pressure. This conclusion is in accord with the results given in Fig. 1A.

At constant volume we found empirically that the product $T^{1/2}(\partial P/\partial T)_V$ was constant over a range of 60° at least, whence it follows that $V_f^{1/3}$ is directly proportional to $T^{1/2}$ or to the mean square velocity of the molecules at their mean positions, and that the oscillation frequency is independent of the temperature (eqn. 1). This increase of free volume with temperature is due to the compressibility of the molecules,[25] their distance of closest approach during a collision depending on the velocity with which they collide, and on consequent changes in molecular distribution. As a result of this increasing interpenetration the molecules spend on the average a larger fraction of the time at very close distances as the temperature rises, even though the oscillation frequency computed from equations (1) and (2) remains constant, and the absorption of light of longer wave lengths increases. All the solutions we have studied show a marked increase in light absorption as the temperature is raised at constant volume.

The effect of increasing temperature at **constant pressure** is not so easy to predict, since the rapid increase in free volume reduces the probability that two unlike molecules will be close together, while the increase in the kinetic energy of the molecules and their closer approach on collision influences this probability in the opposite direction. It will be noticed that the influence of temperature at constant pressure on the absorption of light by all the solutions of amines in nitrobenzene is quite small, as might be expected when two opposing effects are at work. Calculations with equations (1) and (2) show that the oscillation frequency in aniline–nitrobenzene mixtures decreases when the temperature is raised at constant pressure, and that the decrease is slightly less rapid at 1000 bars than at 1 bar, owing to the fact that the thermal expansion of the solution diminishes with pressure. As the interpenetration effect may be presumed to be independent of pressure, the effects of pressure on the temperature coefficient of the light absorption shown in Figs. 2A and 2B are correlated with the thermodynamic properties of the solutions.

Another factor in determining the probability that two active groups on unlike molecules shall be in contact is the existence of short-range, specific attractive forces between groups in the respective molecules which will cause a temporary "sticking" when the molecule in our model collides with an appropriate spot on the walls of the "cage" of surrounding molecules. This effect is to be expected in systems showing negative deviations from ideality, especially those in which solid addition compounds are formed, and its importance decreases with rise of temperature according to the Boltzmann law.[26] In solutions where the mutually attracting groups are those intimately connected with the absorption of visible light this "sticking" effect will increase the absorption at low temperatures and produce a relatively large negative temperature coefficient of the light absorption. We consider this to be the state of affairs in solutions of *s*-trinitrobenzene in aniline and we shall refer later to the mechanism of the "sticking" effect in this system.

If, however, one or both of the mutually attracting groups is not directly connected with the absorption process, the probability of color-producing collisions will fall, the solution will absorb light to a less extent at low temperature (other things being equal) and the temperature coefficient of absorption will have a relatively large positive value. Solutions of *p*-nitrophenol in aniline provide, we think, an example of this effect, the strong specific attraction being between the OH and NH_2 groups. The behavior of these solutions suggests that a phenomenon akin to complex isomerism in some solid addition compounds[27] is appearing in the solutions. We recognize two separate intermolecular actions in these solutions: (a) interaction between the NO_2 and NH_2 groups giving rise to the color, and (b)

(24) J. F. Kincaid and H. Eyring, *J. Chem. Physics*, **6**, 620 (1938).

(25) For a definition of this term see R. E. Gibson and O. H. Loeffler, THIS JOURNAL, **61**, 2520 (1939), or ref. 22c.

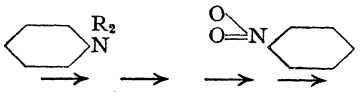
(26) The short-range attractions between groups on like molecules must not be overlooked in this discussion.

(27) E. Hertel and K. Schneider, *Z. physik. Chem.*, **A151**, 413 (1930); **B13**, 387 (1931).

interaction between the NH_2 and OH groups tending to inhibit (a) at lower temperatures and giving rise to solid addition compounds. It is well known that mixtures of phenol and aniline[28] and of *p*-nitrophenol and aniline[29] have relatively high viscosities, show large negative departures from Raoult's law, and deposit solid addition compounds at lower temperatures, but that these deviations from ideal behavior diminish rapidly as the temperature is raised.[30]

The Effect of Composition on the Absorption of Light by the Solutions

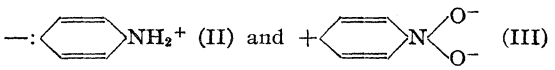
In the systems we have studied, reactions involving a transfer of electrons from the amino group of an *aromatic* amine[31] to the nitro or nitroso group of the other component (*e. g.*, oxidation–reduction or acid–base reactions) are possible, and, although they do not actually proceed under the conditions of our experiments, we suggest that the primary inductomeric or electromeric polarizations[32] associated with these reactions do occur and are responsible for the color changes. Kinetic studies of the reduction of nitrobenzene derivatives[33] have shown that the rate of reduction increases when the inductive and resonance[34] effects of the nuclear substituents tend to diminish the negative charge on the nitro group and hence to increase its attraction for external electrons. We shall assume, therefore, that a drift of electronic charge from the NR_2 group to the oxygens of the NO_2 group with consequent displacements of negative charge in the N:O bond and in the polarizable aromatic nuclei in the direction indicated by the arrows in formula I takes place when an aromatic amino group and a nitro group come very close together in the solution.



(I)

Hammick[35] and his collaborators already have suggested the same polarization mechanism in their assumption that the primary activation in the formation of solid addition complexes between polynitro compounds and aromatic hydrocarbons is a driving of electronic charge from the oxygen to the nitrogen of the NO_2 group.

In demonstrating from qualitative considerations of the inductive and resonance effects of substituents in either compound that the absorptions of the solutions are pushed to longer wave lengths (a) as the electron attraction power of the oxygen of the NO_2 group increases and (b) as the electron mobility in the aromatic amine increases, we should first note that the configurations



(II) and (III)

which, together with the orthoquinonoid forms, contribute significantly to the structure of aniline and of nitrobenzene,[36] actually oppose the polarization we have suggested. We should emphasize, therefore, that the electron drift in formula I is presumed to occur in aniline–nitrobenzene solutions only when the molecules are brought into very close contact by their thermal motion (*cf.* the discussion of the temperature coefficient).

Electron-attracting groups such as NO_2, Cl or CO_2CH_3 in the ring of the nitro compound promote the electronic drift by reducing the negative charge on the NO_2 group. This gives rise to short-range attractions and affords an explanation of the differences in behavior between solutions of polynitro compounds and those of mononitro compounds in amines or hydrocarbons mentioned in the introduction and accounts for the greater absorptions of the polynitro solutions. It will be recalled that dilute alkalies cause color changes in polynitrobenzenes but not in pure nitrobenzene.[37]

Electron-repelling groups such as NH_2 or CH_3 in the ring of the nitro compound reduce its ability to polarize the amino compound both by their inductive effects and, in *o*- and *p*-positions, by their resonance effects. We found from

(30) See, for example, the effect of temperature on the viscosity–composition curves of mixtures of phenol with amino compounds studied by A. Bramley, *J. Chem. Soc.*, **109**, 10 (1916).

(31) We have found that no significant color change occurs when α-phenylethylamine, a stronger base than aniline, is mixed with nitrobenzene. This observation suggests strongly that the amino group must be attached to the ring either directly or through a conjugated bond system, if a color change is to be produced.

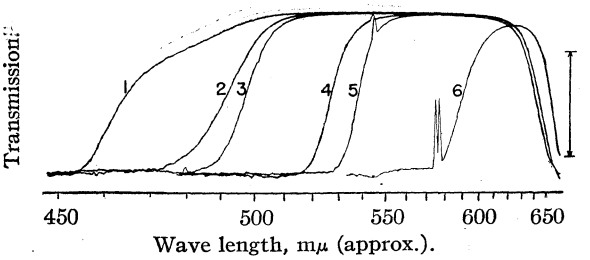

Fig. 8.—A comparison of the transmission of light by equimolecular solutions of (1) *p*-nitroaniline in nitrobenzene, (2) aniline in nitrobenzene, (3) *p*-nitroaniline in aniline, (4) diphenylamine in nitrobenzene, (5) dimethylaniline in nitrobenzene, and (6) *p*-phenylenediamine in nitrobenzene.

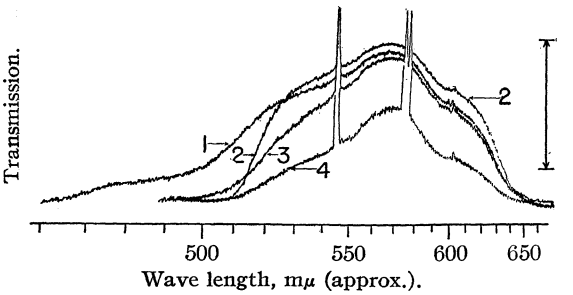

Fig. 9.—A comparison of the transmission curves of 0.22 molar solutions of *p*-nitroaniline (1), *o*-nitroaniline (2), aniline (3), and *m*-nitroaniline (4) in nitrobenzene.

curves similar to those in Fig. 9 that the absorption of visible light by 0.31 molar solutions in aniline increased in the order *p*-nitroaniline < nitrobenzene < *m*-nitroaniline. Quinonoid structures being impossible in *m*-nitroaniline,[38] this result shows that the inductive effect of the NH_2 group does not compensate for the loss of the resonance effect when nitrobenzene is changed to *m*-nitroaniline and that the resonance in nitrobenzene does diminish its interaction with aniline.[39]

As regards the effects of substituents in the amine nucleus, Fig. 9 shows that 0.22 molar solutions of the nitroanilines in nitrobenzene increase in light-absorbing power in the order *p*-nitroaniline ~ *o*-nitroaniline < aniline ≪ *m*-nitroaniline. The effect of an absence in the meta compounds of possible quinonoid configurations is again striking and indicates that resonance involving these configurations does reduce the interaction of aniline with nitro compounds as formula I suggests. A comparison of the transmission curves of equimolecular solutions of aniline, *m*-nitroaniline and *p*-nitroaniline in nitrobenzene, on the one hand, and of nitrobenzene, *m*-nitroaniline and *p*-nitroaniline dissolved in aniline, on the other, showed that absorptions of light are more influenced by the resonance effect of the NO_2 group than by that of the NH_2 group, a conclusion which is supported by the interaction dipole moments of aniline and nitrobenzene.[40] A transmission curve of a solution of *p*-nitroaniline in nitrobenzene is shown also in Fig. 8, curve 1. The sharp bend in this curve about 465 mμ is a feature of interest, because the absorption below this wave length is sensitive to pressure changes and hence of intermolecular origin, whereas the absorption at longer wave lengths is not sensitive to pressure changes, being due presumably to the nitroaniline itself. By their inductive effects, groups such as NH_2 or CH_3[41] increase the potential concentration of electronic charge on the amino group. This effect on the absorption of light is strikingly shown by the curve for a dilute solution of *p*-phenylenediamine (a much stronger reducing agent than aniline) in nitrobenzene in Fig. 8 (curve 6). The exposure from which this curve was made was four times as long as that of any of the other amines in this diagram.

In acetanilide and *p*-nitroacetanilide the configurations $C_6H_5NHC(CH_3)=O$ and $C_6H_5{}^+NH=C(CH_3)O^-$ contribute to the structure,[42] and the resonance introduced lowers the possibility of the formation of a double bond between the nitrogen and the ring and renders the NH group less polarizable. The interaction of the NH group with external or internal NO_2 groups is, therefore, reduced by the attachment of the acetyl group. We have observed, on the one hand, that acetanilide and *p*-nitroacetanilide (a *white* solid) dissolve in nitrobenzene without any appreciable color change, and, on the other, that the transmission spectra of *p*-nitroacetanilide–aniline solutions resemble closely those of nitrobenzene–aniline solutions, being quite different from the spectra of *p*-nitroaniline–aniline solutions of the same molar concentration.

The electron mobility in the N-substituted amines, as measured, for instance, by the interaction dipole moments (resonance contribution to the dipole moment) of their *p*-substituted

(41) B. R. Hamilton and D. L. Hammick (*op. cit.*) showed that the absorption coefficients of carbon tetrachloride solutions of *s*-trinitrobenzene and different amines decreased in the order *o*-toluidine > *m*-toluidine > *p*-toluidine > aniline > chloroaniline.

(42) See L. Pauling, ref. 34, p. 192.

derivatives, increases as the number of methyl groups on the nitrogen increases.[43] Our results show that the absorption of light by nitrobenzene solutions of these N-substituted amines is pushed to longer wave lengths as the solute changes from aniline to dimethylaniline (curves 2 and 5, Fig. 8). It is of interest to note that the heats absorbed on the formation of 50 mole per cent. solutions of nitrobenzene in aniline, ethylaniline and diethylaniline are, respectively, 132, 27 and −15 cal./mole.[17]

In accord with the well-known fact that nitrosobenzene is much more readily reduced than nitrobenzene,[33] we have observed that the colors of liquid mixtures of amines and nitrosobenzene are much more intense than those of the corresponding mixtures with nitrobenzene. Both these facts may be explained by the recognized existence of the NO_2 group itself as a resonating structure[44] to which several configurations stabilizing the electronic charge on the oxygen contribute. We conclude from our observations of the effect of pressure on the absorption of light by solutions of nitrosobenzene in benzene that part, at least, of this absorption is due to intermolecular action. The interaction of a polarizable benzene molecule with a nitroso group is apparently large enough to bring the light absorption into the visible region, whereas the action of benzene on a nitro group is apparently not large enough. The role of the amino group seems to be that of a liaison between the polarizable aromatic nuclei and the oxygen atoms of the NO_2, NO, SO_2, etc., groups, the amino group focussing the polarization, and the difference between the interactions of aromatic hydrocarbons and of aromatic amines with these oxygens is, therefore, only one of degree.

Without a quantum mechanical treatment, methods of which are, however, rapidly developing,[45] it is difficult to locate exactly the electron system responsible for the absorption of visible light by these solutions. The behavior of tetranitromethane shows that the aromatic part of the nitro compound is not essential to the phenomenon. Sklar[46] has shown theoretically that the weak 2500 Å. band in benzene is intensified and shifted toward the red when the symmetry of the ring is distorted by the resonance effects of substituents. It seems improbable, however, that any intermolecular polarization of the type we have discussed can cause distortions in the aromatic ring as large as those produced intramolecularly in nitrobenzene or nitroaniline, whose absorptions in the green or yellow are very much less than those of the solutions. Furthermore, the behavior of hydrocarbons suggests that the amino group is not absolutely essential, so that we are left with the N:O group as the most probable seat of the absorption. It will be seen from our picture in formula I that the proximity of the polarizable amine or hydrocarbon lowers the energy of a state in which an ionic binding such as $^{-}N—O^{+}$ exists in the N:O group.[47]

Our hypothesis that the colors of the solutions discussed in this paper arise from preliminary polarizations in oxidation–reduction reactions suggests comparison with other labile intermediate oxidation–reduction products such as quinhydrone, Wurster's salts, or semiquinones in general,[48] whose strong absorptions have been ascribed to charge-resonance involving odd electrons.[49] Nitrosobenzene and *p*-nitrosodimethylaniline are also relatively unstable, deeply colored intermediate steps in oxidation–reduction series, but they differ from the semiquinones in that they are diamagnetic[50] and have, presumably, no odd electrons. The apparent similarities in origin and behavior of the semiquinones, the nitroso compounds and the colored solutions are, however, sufficiently striking to merit further investigation, even though a theoretical picture embracing all these types of systems is not immediately obvious.

If our assumption that the changes in the absorption of light by these solutions are due to prereaction polarizations is substantiated, interesting possibilities of investigating reaction mixtures under different thermodynamic conditions by ultraviolet and visible absorption spectroscopy arise. Indeed, the large accelerating effect of pressure on reactions such as the addition of isopropyl iodide to dimethylaniline[51] is exactly

paralleled by the effects of pressure on the absorption of light by similar solutions.

Summary

We have found that the absorption of visible light by solutions of aromatic amines in nitro or nitroso compounds is pushed very significantly toward the longer wave lengths when the hydrostatic pressure over the solutions is raised at constant temperature, and also when the temperature is raised at constant volume. The absorption of light by these solutions may increase, decrease or remain constant as the temperature is raised at constant pressure. These results have been correlated into a consistent theory which avoids any assumption of the formation of colored compounds by the hypothesis that the colors of the solutions arise from the mutual polarizations of the molecules when appropriate groups are in close proximity, account being taken of the influence of pressure and temperature on the collision frequency, the distance of closest approach and the effect of short-range attractions between groups.

We have also shown from orienting experiments that substituents in the nitro compound and in the amine influence the absorption of light by the solutions in a way that parallels closely their effects on the reducibility of the NO_2 or NO group on the one hand, and the electron mobility in the amino compound on the other. It is suggested that the polarizations which give rise to the colors of the solutions may be regarded as primary steps in possible reactions, such as oxidation and reduction, involving transfer of electrons from the aromatic amine or hydrocarbon to the oxygen of the nitro or nitroso group.

Composition of Cottonseeds. III. Solubility of Proteins in Alkaline Solutions of Neutral Salts[1]

BY H. S. OLCOTT AND T. D. FONTAINE

Oil-free cottonseed meats contain approximately 8.5% nitrogen (50–55% protein). Water will extract 25–30% of the nitrogen compounds. Dilute solutions of neutral salts extract 75–85% of the total. The materials not dissolved by water but extracted by salt are the cottonseed globulins. Osborne and Vorhees[2] and Jones and Csonka[3] have recorded some of the properties of these proteins. Their extraction by salt and alkaline solutions has been described more recently.[4]

Methods were sought for isolating the globulin fraction on a large scale. Extraction with salt solutions was efficient but means of recovery therefrom did not appear to be practical. Dilution required relatively large amounts of water, and precipitation with acid, though easily effected, yielded an insoluble product. The cottonseed globulins, like several other vegetable globulins, are very readily denatured in acid solution.

Extraction with alkali at *p*H 10.0 and precipitation by the addition of acid to the isoelectric point (*p*H 6.5–7.0) was found to be a satisfactory procedure but suffered from the disadvantage that cottonseed pigments are easily oxidized in alkaline solution, yielding brown products which affect the color of the protein.

A consideration of the theories of protein solubility suggested that the globulin might be extracted at lower *p*H levels in the presence of low concentrations of salt; that is, that the two methods, salt peptization and alkali solution, would be mutually additive. Experimentally, however, it was found that the opposite was true; in the presence of low concentrations of salt, the solubility of the protein at a *p*H below the maximum for extraction was actually depressed. The phenomena observed were of sufficient interest to invite further investigation.

Experimental

Data were obtained in the following manner. Ether-extracted cottonseed meats[4,5] were used. A sample was

(5) The amount of nitrogen extracted under a given set of conditions varied for different preparations of cottonseed meal. With the two meals used in the present investigation, alkali at *p*H 9.0 extracted 83% of the nitrogen from one, 77% from the other.

shaken thoroughly with 40 times its weight of water containing sufficient salt and alkali (as indicated by preliminary titrations) to bring the mixture to the required *p*H and salt concentration. Several drops of chloroform were added to prevent spoilage and the mixtures were allowed to stand, with occasional shaking, for sixteen to twenty-four hours. To determine the amount of protein extracted, the suspension was centrifuged, filtered, and aliquots were analyzed for nitrogen by a modified Kjeldahl method. *p*H was determined with the glass electrode.[6]

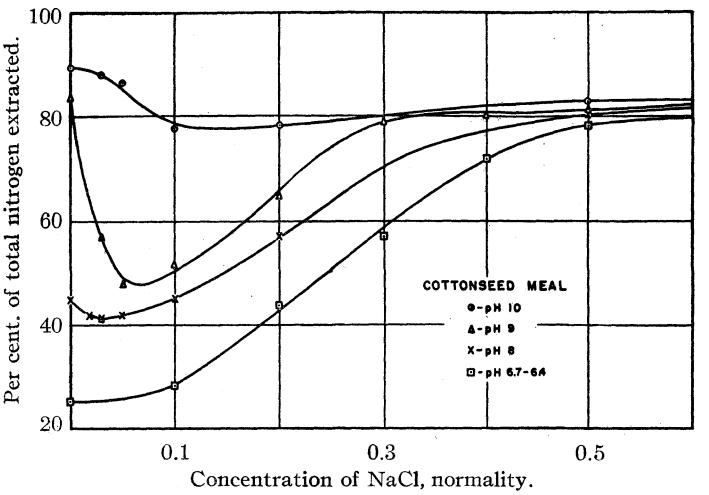

Fig. 1.—Effect of sodium chloride concentration on the extraction of cottonseed proteins from the meal at different *p*H levels. Sodium hydroxide was used to bring the mixtures to the proper *p*H.

The effect of sodium chloride on the extraction of the nitrogen compounds of cottonseed at various *p*H levels is indicated in Fig. 1. The solubility of the protein at *p*H 10 was depressed only slightly by the presence of salt. At *p*H 9, the amount of protein extracted reached a minimum in 0.05–0.07 *N* salt, the solubility again increasing with increasing concentration of salt. At *p*H 8, the antagonistic effect of the salt was only slightly evident. The lowest curve represents the extractability of the cottonseed proteins in solutions of salt to which no alkali had been added. The *p*H of such extracts varied from 6.7 in the absence of salt to 6.4 in 0.5 *N* solution.

That the behavior of cottonseed meal under the conditions described could be attributed specifically to the globulins was demonstrated by duplicating the experimental procedure with the isolated protein (Fig. 2). The material was prepared by leaching cottonseed meal with water to remove water-soluble constituents, then extracting the residue with 0.5 *N* sodium chloride. After centrifugation, the protein was precipitated by dilution with 5 volumes of water. The precipitate was repeatedly washed with distilled water to remove residual salts, separated each time by centrifugation, and finally dried in thin layers on a glass plate in a current of air. Sixty-four % of the product so obtained was soluble at *p*H 9.0, but only 22% could be peptized at the same *p*H in the presence of 0.05 *N* sodium chloride. A solution of the protein at *p*H 9.0 or 9.5 could be partially precipitated by the addition of the correct amount of salt.

The effect of several other inorganic salts on the solubility of the cottonseed proteins was investigated under similar conditions (Fig. 3). In the case of the sodium salts, the important part played by the anion was evident. In contrast to the chloride, the sulfate and iodide caused only a slight depression in the solubility curve. Sodium fluoride is a poor peptizing agent; whereas, in neutral solution, most inorganic salts (0.5 *N*) peptize 75 to 85% of the nitrogen of cottonseed meal, sodium fluoride peptizes only 57%. The results obtained with potassium chloride and sulfate were almost identical with those observed with the corresponding sodium salts (Table I).

The effect of alkaline earth salts was more pronounced. Inasmuch as water alone extracts 25 to 30% of cottonseed nitrogen, the 0.03–0.05 *N* solutions of calcium chloride and magnesium sulfate apparently suppressed entirely the solubility of the globulin. This fact was also demonstrated with the isolated protein. A quantitative method for the separation of the globulin from an alkaline extract of cottonseed meal is suggested, based upon the addition of calcium, magnesium, or barium salts in the correct concentration. The precipitation is not dependent upon a decrease in *p*H.

The data for experiments typical of those which have been plotted on the graphs are shown in Table I. Preliminary runs were used to determine how much alkali was necessary to bring the mixture to the required *p*H. It will be noted that increasing amounts of alkali were needed with increasing concentrations of salt.[7]

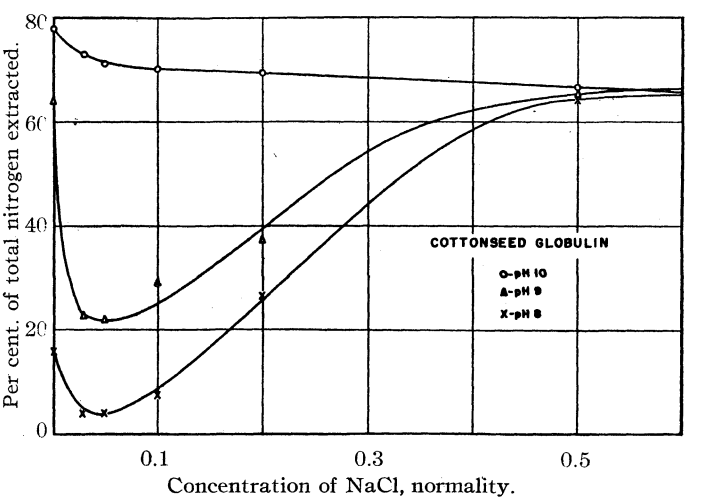

Fig. 2.—Effect of sodium chloride on the solubility of a cottonseed globulin preparation at different *p*H levels.

The effect of sodium and calcium chlorides, in the concentrations resulting in minimum solubility, on the extrac-

[a] Five g. of meal was extracted with 200 cc. of solution for sixteen to twenty-four hours. The amount of nitrogen contained in a filtered aliquot of the extract was calculated to 200 cc. to obtain the data. [b] Cottonseed meal contains 8% ash, more than half of which is soluble in water. The extractability of the protein is probably influenced somewhat by the presence of these salts of unknown nature.

tion of the nitrogenous compounds from cottonseed meal throughout the *p*H range 3 to 11 is shown in Fig. 4. For purposes of comparison, the curves showing the efficiency of extraction with 0.5 *N* sodium chloride and in the absence of salt are repeated from the earlier publication.[4] The specific antagonistic effect of 0.07 *N* sodium chloride is marked in the *p*H range between 8 and 10, while that of calcium chloride does not disappear until a *p*H of 11 is attained.

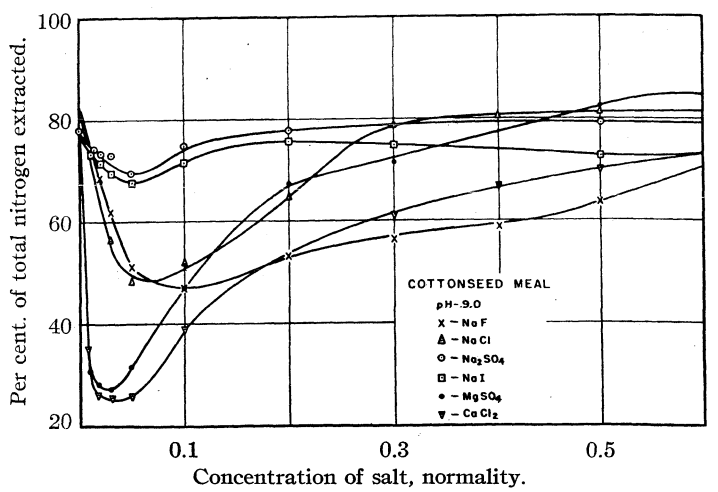

Fig. 3.—A comparison of the effect of several inorganic salts on the extraction of cottonseed proteins from the meal at *p*H 9.0.

The results shown graphically in Fig. 5 were obtained with ether-extracted hempseed meal under experimental conditions similar to those used with cottonseed meal. The absolute amounts of nitrogenous substances peptized differ from those observed with cottonseed meal but the shapes of the curves are somewhat similar. The antagonistic effect of sodium sulfate was more marked than in the case of cottonseed meal but was still less than that of sodium chloride.

Discussion

The phenomena of protein solubility have recently been reviewed by Edsall.[8] According to the investigators cited, neutral salts invariably *increase* the solubility of globulins on the alkaline side of the isoelectric point.

Sörensen and Sladek[9] concluded, from their carefully controlled experiments, that the solubility of casein varied directly with the concentration of sodium chloride in solutions alkaline to the isoelectric point. However, in the series in which the largest amount of alkali was used, a depression of solubility is recorded at a concentration of 0.025 *N* sodium chloride, as shown in Table II. This discrepancy is not commented upon in the original paper nor by Green[10] in her interpretation of the results. If the data are significant, they would indicate that, within a limited *p*H range, low concentrations of salt may antagonize rather than increase the solubility of casein in alkali. There is no suggestion in Green's[10] solubility determinations of hemoglobin in alkaline salt solutions of any parallelism with the phenomena described in this paper. The *p*H, how-

TABLE II

EFFECT OF SALT ON THE SOLUBILITY OF CASEIN IN ALKALI[a]
(Data of Sörensen and Sladek)[9]

ever, did not vary by more than 1 *p*H unit from the isoelectric point, nor were salts other than phosphate buffers investigated. In the case of the cottonseed globulin, the region of maximum

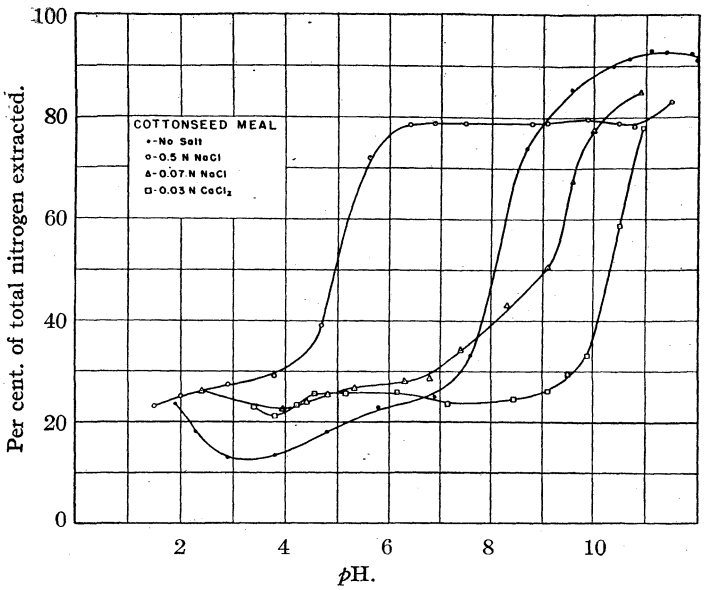

Fig. 4.—Extraction of proteins from cottonseed meal. Sulfuric acid and sodium hydroxide were used to adjust *p*H.

antagonism appears to be 2 *p*H units higher than the isoelectric point of the protein.

Edsall[11] observed that a clear gel of myosin in alkaline solution was precipitated by the addition of a small amount of salt. Upon the addition of further salt the precipitate dissolved. No quantitative data were recorded.

The data of Smith, Brother and Circle[12] can be interpreted as indicating a direct parallelism between soybean meal and cottonseed meal proteins (Fig. 6). More protein can be extracted from soybean meal with distilled water than with dilute salt solutions. Minimum solubility occurs at a concentration of 0.1 *N* sodium chloride (1 part meal:40 parts water). The isoelectric point of the principal soybean protein lies in the *p*H range 4.2–4.7; therefore the solubility behavior in neutral salt solutions (*p*H 6.7–6.0) was measured at approximately 2 *p*H units above the isoelectric point. While there was no attempt to maintain a constant *p*H level, the variations were probably not large enough to change essentially the character of the solubility curves.

(11) Edsall, *J. Biol. Chem.*, **89**, 289 (1930).

(12) Smith, Circle and Brother, THIS JOURNAL, **60**, 1316 (1938).

That the results obtained with soybean meal are a reflection of the behavior of the soybean globulin is indicated by the data shown graphically in Fig. 7. In this case the equilibrium was approached from the solution in dilute alkali.

A fresh precipitate of purified soybean globulin[13] was washed thoroughly with water, then dissolved by the careful addition of sodium hydroxide to *p*H 6.7. Upon the addition of different amounts of sodium chloride to aliquot portions, some cloudiness appeared but no precipitate could be removed by centrifugation. Quantities of acid sufficient to lower the *p*H to approximately 5.7 were then added to each aliquot, the several samples were centrifuged, and portions of the supernatant solution were analyzed for nitrogen. The sodium chloride concentration for minimum solubility appeared to be 0.1 to 0.15 *N*[14] or about twice that indicated by Smith, *et al.*,[12] for the meal. However, the solution contained approximately 3% protein, whereas with the meal, at maximum solubility, the protein was present to the extent of only 1.25%. The data for calcium chloride were obtained after the salt had been added to the solution at *p*H 6.7. In this case, no further addition of acid was necessary. The concentration of calcium chloride

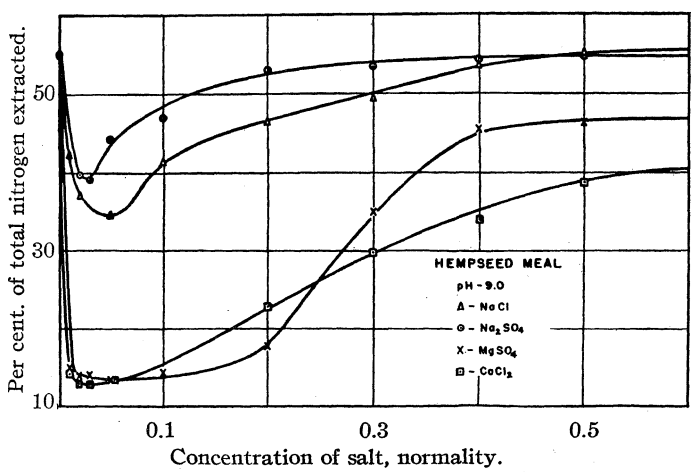

Fig. 5.—Effect of several inorganic salts on the extraction at *p*H 9.0 of the proteins from ether-extracted hempseed meal.

(13) Kindly supplied by Dr. N. J. Beaber, Mellon Institute.

(14) The salt concentrations are approximations. It was not determined how much of the sodium hydroxide used to bring the protein into solution had been required to neutralize adsorbed sulfuric acid.

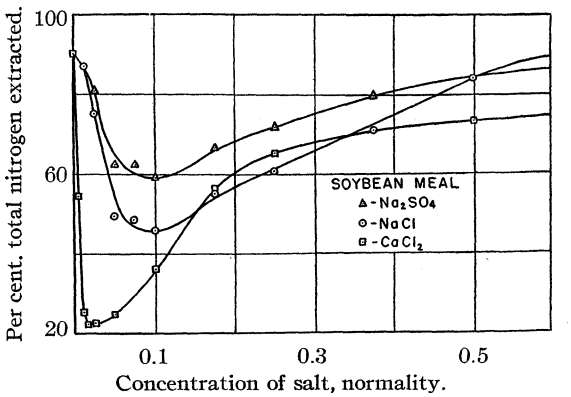

Fig. 6.—Data of Smith, Brother and Circle[12] on the extraction of soybean proteins by aqueous salt solutions. The *p*H was not held constant but probably varied from 6.7 to 6.3 with sodium chloride and from 6.7 to 5.2 with calcium chloride.

necessary to ensure minimum solubility was also approximately twice that required for the meal.

The solubility of cystine in water is increased in the presence of salt. Cystine is also soluble in dilute alkali. This resemblance to the behavior of globulins, which has been discussed by Cohn,[15] suggested that the antagonism might be observable with the amino acid. However, in a short series of determinations, in which the sodium chloride concentration was varied from 0.1 to 2.0 *N* and the *p*H maintained at 8.0, the solubility was found to vary directly with the salt concentration.

A complete interpretation of the physical and chemical reactions involved in the antagonism of small amounts of salts to alkaline extraction of the several globulins does not seem possible at present. In the case of the alkaline earth salts, the inference that metallic proteinates are precipitated appears justified. The insoluble proteinate either may again be peptized in the presence of higher concentrations of salt or may react to form more soluble compounds containing larger amounts of calcium, barium, or magnesium or consisting of double salts of the metallic proteinate and the salt.

In the case of the sodium and potassium salts, the anion plays an important role.[16] Thus the sodium proteinate which is insoluble in sodium chloride solution (0.05–0.1 *N* at *p*H 9.0), is soluble in sodium sulfate or sodium iodide when these salts are present at the same concentration.

(15) Cohn, *Chem. Rev.*, **19**, 241 (1936).

(16) It has been suggested that the results may be interpreted in terms of electrokinetic potential changes. However, in the simplest application of such an explanation, it would be expected that a divalent anion (sulfate) would be a more effective precipitant than a monovalent ion (chloride), which is contrary to the observations.

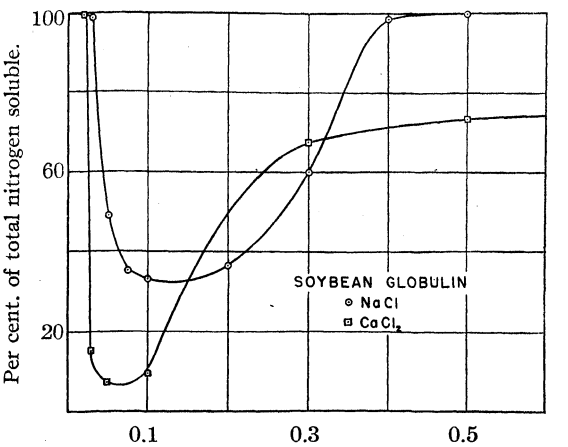

Fig. 7.—Effects of salts on the solubility of a soybean globulin preparation. The *p*H varied from 5.8 to 5.63 in the sodium chloride series and from 6.48 to 6.25 in the calcium chloride series.

As the proteins discussed in this communication, except myosin, are known to be mixtures of several individual entities, the possibility that the solubility phenomena observed with sodium chloride may be ascribed to a fractionation requires further investigation. A comparison of the physical and chemical properties of the precipitate and the soluble portion would be of interest. The data obtained with hempseed meal suggest that edestin would be a suitable purified protein for a more critical investigation of the phenomenon.

Inasmuch as it is not possible at present to continue this work, the attention of other investigators is invited to the possibilities for study of protein behavior suggested by these observations.

Summary

At *p*H 9.0 small amounts of sodium chloride markedly depress the solubility of cottonseed protein, as determined by extraction studies with cottonseed meal. Greater or smaller concentrations of salt permit the peptization of larger amounts of the total nitrogen. The alkaline earth salts are particularly effective precipitants; under the conditions used, 0.03–0.05 *N* calcium or magnesium salt solutions suppress the solubility of the globulin at *p*H 9.0 completely. The effects of several other salts on the solubility of the nitrogenous constituents of cottonseed meal have been determined. That the observed phenomena can be ascribed to the globulins and not to other constituents of the meal is shown in experiments with isolated globulin preparations.

Analogous results have been obtained with hempseed meal.

The data of Smith and co-workers[11] have been interpreted to indicate that the influence of salts on the solubility of soybean proteins in the neutral *p*H range is a parallel phenomenon.

The observations cited are exceptions to the hitherto-accepted generalization that the solvent action on proteins of salts and alkali is additive.

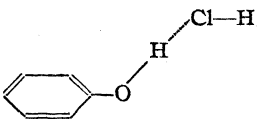
Increases in the Acid Strength of Hydrogen Chloride in Dioxane Brought about by Phenols and Alcohols

BY PAUL D. BARTLETT AND HYP J. DAUBEN, JR.

Some years ago Meerwein and his co-workers[1] showed that the metallic chlorides which catalyze the rearrangement of camphene hydrochloride into isobornyl chloride are all capable of forming complexes with hydrogen chloride which are stronger acids than hydrogen chloride itself. This property was demonstrated by a method introduced by Hantzsch.[2] A solution of hydrogen chloride in dry ether was made just too dilute (0.02 *N*) to redden the indicator butter yellow (*p*-dimethylaminoazobenzene). The addition of equivalent stannic chloride (which alone at this concentration did not redden the indicator) now turned the indicator red, and a dilution of 120-fold was necessary to restore the yellow color. This was clearly due to the fact that in ether an acid of the type H_2SnCl_6 is stronger than hydrochloric acid. Meerwein concluded that the catalytic activity of the chloride and its acid-strengthening power were closely related manifestations of its complex-forming ability.

By Hantzsch's method it can be shown that the phenols, which also catalyze the rearrangement of camphene hydrochloride, conform to this generalization in that they, too, increase the acid strength of hydrogen chloride in ethereal solution. The effect is much less than with stannic chloride, but quite definite. We are forced to the conclusion that phenols, like the complex-forming inorganic chlorides, can form complexes with hydrogen chloride in which the phenol is attached to the chlorine and encourages the separation of this as an ion. The only probable manner in which a phenol can form such an attachment is through hydrogen-bond formation at its hydroxyl group



and we thus have a method of making some quantitative measurements on the relative tendencies to hydrogen bonding by a series of hydroxyl compounds.

This subject is of particular interest at the present time in view of the attention directed by G. N. Lewis[3,4] to the general aspects of the acid–base relationship. Any molecular species X which can form a coördinate link with the chloride ion, $X:\ddot{\underset{\cdot\cdot}{Cl}}:^-$, is functioning as an "acceptor" center, in the terminology of Sidgwick,[5] while the chloride ion functions as a "donor." Lewis prefers to substitute the terms "acid" and "base" for "acceptor" and "donor," and says of the Sidgwick notation: "This expressive nomenclature I should be glad to adopt if I did not hope to show that his classification coincides absolutely with the classification of acids and bases, so that the need for new names disappears."[3,4]

Now in the present instance we have a substance, a phenol, which can function as an acid in the Brönsted sense by donating a proton to some acceptor; it can also function as an acid in the Lewis sense, as an acceptor, by forming a complex with the chloride ion or with hydrogen chloride through its chlorine. If these two kinds of acidity run completely parallel in a series of phenols, being governed by exactly the same structural features, then we have no need to differentiate between them. However, as we shall show, the Lewis

(5) Sidgwick, "The Electronic Theory of Valency," Oxford University Press, New York, N. Y., 1929.

acidity and the Brönsted acidity do not run completely parallel and much interest is attached to their separation and comparison. Therefore we cannot absorb the one class of acids completely into the other. Rather than to use a new term for proton-donors, which are now generally designated by the term "acid," it seems to us best to retain this term in its accepted sense and to adopt Lewis's second choice by calling the Lewis acids "acceptors." At least this practice will contribute to clarity in the present paper. Ingold's useful term, "electrophilic reagent," is of course synonymous with "acceptor."

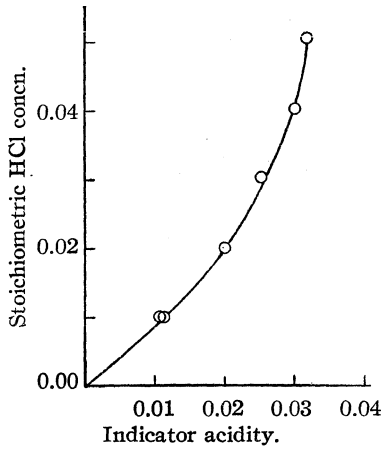

Fig. 1.

For exploring the relationship between acid strength and acceptor activity among the phenols it was desirable to have a quantitative method which should be sensitive to small differences in the latter property. Accordingly, series of colorimetric measurements were made using a one-color indicator, and comparing the specific color intensity of a standard solution of hydrogen chloride with those of weaker hydrogen chloride solutions containing progressively greater concentrations of a phenol. Because of its volatility, ether would be an objectionable solvent for this purpose, and we used carefully purified dioxane instead. As an indicator pentamethoxy red (2,2′,2″,4,4′-pentamethoxytriphenylcarbinol) proved well adapted to our purpose. This indicator turns from colorless to red at such a point that a 0.02030 *M* solution of hydrogen chloride in dioxane is a convenient standard. This standard solution, containing six drops of a 0.005 *M* solution of the indicator in 50 cc. of solution, was compared with series of solutions 0.001578 *M* in hydrogen chloride and from 0.05 to 4.0 *M* in the phenol containing the same amount of indicator. For each phenol–hydrogen chloride solution readings were taken at different times and with thermostatic control, so that temperature effects were eliminated and time effects could be shown to be absent. In each case we established the absence of color in solutions of the phenol and indicator more concentrated than any used in the work.

The expressing of our results in terms of a hydrogen ion activity or H_0 scale[6] is rendered undesirable by the fact that our indicator reaction forms water

$$\underset{\text{Colorless}}{ROH} + BH^+ \rightleftharpoons \underset{\text{Colored}}{R^+} + H_2O + B$$

Although our solvent and materials were as anhydrous as possible, it is unjustified to assume that the water formed as a result of this reaction is the only water present. Accordingly, no attempt is made to use a true measure of acidity. The quantity called "indicator acidity" in Fig. 1 is the molarity of hydrogen chloride in the standard solution multiplied by the ratio of color intensities in the test solution and the standard. Figure 1 shows the relationship of this indicator acidity to the stoichiometric concentration of hydrogen chloride in a series of solutions containing no phenol.

Figure 2 shows the plots of indicator acidity against phenol concentration for several phenols studied. These curves are not all the same shape, and do not appear to approach the same limiting value of the ordinate. This is not surprising since we are dealing with a solvent of dielectric constant only 2.2,[7] and adding to it relatively large amounts of substances which will raise the dielectric constant and probably alter the behavior of electrolytes. It can be seen that the early parts of the

phenol curves are very nearly linear and differ among themselves markedly in slope. This slope of the initial part of the curve of indicator acidity

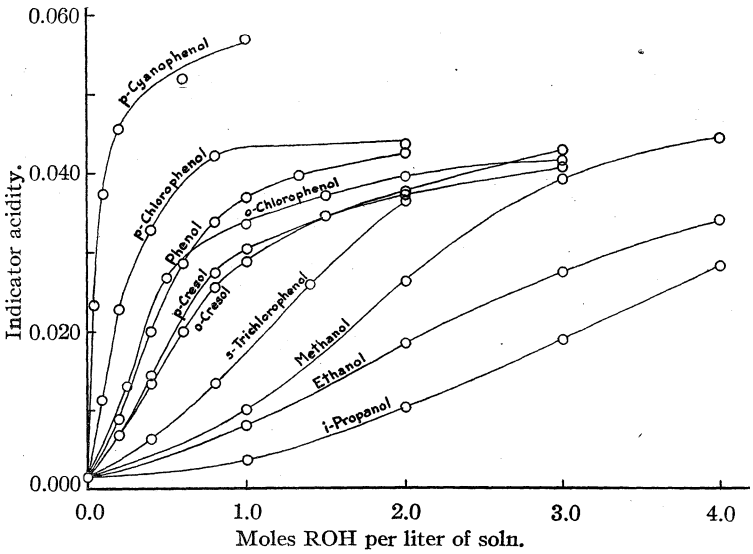

Fig. 2.

against phenol concentration seems about the best comparative measure of the acceptor activities of the different phenols. We have no way of determining to what extent the slope reflects the acid strength of the HCl–phenol complex as contrasted with the actual extent of conversion of the HCl molecule into the complex. Since these two effects are almost certain to run parallel in any series of closely related hydroxyl compounds, there is some justification in referring to the slope of our curve as a measure of the acceptor activity of the phenol.

In many instances the logarithms of the rate or equilibrium constants for two reactions shown by compounds containing the same series of radicals have been found to be linearly related.[8] Although we have no equilibrium constant for a reaction involving the phenols as acceptors, it is of interest to plot the logarithm of the slope, our measure of acceptor activity, against the logarithm of the acid dissociation constant of the same phenol. Figure 3 shows such a plot including points for all the hydroxyl compounds measured. The acid dissociation constants taken are those recorded for aqueous solutions.[9] It is not too much to expect that the phenols will fall in the same order of acid strength in dioxane as in water, in view of the fact that acids *of the same type* have been found to have the same order of acidity in solvents of quite different character.[10]

All the phenols measured except *o*-chlorophenol and 2,4,6-trichlorophenol yield points which fall on a straight line in the figure. These chlorophenols deviate largely from the linear relationship, especially the symmetrical trichlorophenol, which has a K_a of 2.6×10^{-8}, the highest of the series, but is definitely the weakest acceptor of the group. The mere fact that these ortho-substituted phenols are known to have intramolecular hydrogen bonds[11] is not sufficient to explain why the acceptor activity should suffer in comparison to the acid strength, for if free rotation of the hydroxyl group were possible any restraint against

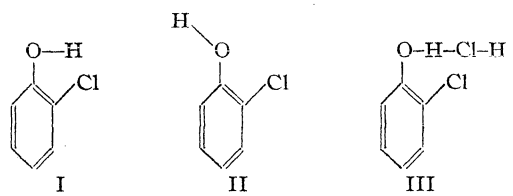
the formation of an outside hydrogen bond (limitation of acceptor activity) would be attended by an equal restraint against the complete donation of the proton to an outside base (acid activity). What needs to be explained is a *selective* operation of the ortho-effect against the acceptor activity of the phenol.

An attractive explanation is to be found based upon Pauling's interpretation[12] of the infrared absorption spectra of the chlorophenols.[13] The evidence is that *o*-chlorophenol exists as an equilibrium mixture of the two spectroscopically distinguishable forms, I and II



without detectable amounts of forms resulting from random rotation of the hydroxyl group about the C–O bond. The possibility of forming a hydrogen bond in the "*cis*" form, I, results in its predominance (estimated as 10 to 1) over the "*trans*" form, II, but the force restraining free rotation arises from the contribution of structures having carbon–oxygen double bond character, and hence requiring the hydroxyl group to lie in the plane of the ring. There is presumably no hindrance to acceptor activity in the *trans*-form. In the *cis*-form the breaking of the intramolecular hydrogen bond and forming of one outside results in a congested structure, III, for it amounts to placing the outside donor, in this case chlorine, on an extension of the O—H bond contiguous to the aromatically bound chlorine atom. We must suppose that this makes the formation of such a hydrogen bond less probable but not impossible. Trichlorophenol, which can have no "*trans*" form, still shows an acceptor activity about one-third as great as that of phenol, and one-fortieth of that to be predicted from its acid dissociation constant. *o*-Cresol, in which for obvious reasons the *trans*-form would be expected to predominate over the *cis*-, shows normal acceptor activity in terms of its acid strength.

Now, in the transfer of a proton to another base, the reaction whose equilibrium constant expresses the acidity of the phenol, a phenol must form a *transition state* resembling the phenol–hydrogen chloride complex, in its chemical and geometrical nature. In the case of the *o*-chlorophenols this transition state, too, would be hindered. If the acid dissociation were something whose rate we could measure, we should expect to find this rate retarded according to our present hypothesis of the ortho-effect. However, this reaction in normal cases proceeds too fast to measure, and as long as the hindrance to the formation of the transition state is not absolute, the equilibria of proton-transfer will continue to be established. Since the transition state appears on either side of the equilibrium, *the equilibrium of proton transfer should be exempt from this particular kind of ortho-effect.* Rates of acid-catalyzed reactions should not be exempt, for here any hindrance to a transition state in proton transfer will show itself in a lowering of the rate.

The work of Farinacci and Hammett[14] on the solvolysis of benzhydryl chloride in alcohol–water mixtures, and the interpretation of the work of Olson and Halford and of W. Taylor[15] in its light, make it seem highly probable that water, and to a lesser extent, alcohols, can also form hydrogen bonds with the chloride ion and so facilitate its removal from organic combination. We investigated methyl, ethyl and isopropyl alcohols with the results shown in Fig. 2. Here the initial rise is slow and not perfectly linear. In evaluating the slope use was made of the first point, but this is open to criticism since we do not know that this represents the true limiting slope. The points for methyl and ethyl alcohols have been included in Fig. 3. Here the assignment of abscissas is made on the basis of existing data[16] on the self-ionization of the pure liquids. It is, of course, difficult to compare these acid dissociation constants with the others determined in water solution. According to Faurholt,[17] the ionization constant of methanol in water solution is $10^{-15.5}$ at 18°, or 1.5 pK units greater than the figure we have plotted. This assignment is made in the belief that it cannot be far enough in error to bring the alcohol points onto the phenol line, and this is of some interest. It means that the alcohols are, in proportion to their acid strengths, far better acceptors than the phenols.

Meerwein found that benzoic and other organic acids had the ability to increase the acidity of ether–hydrogen chloride solutions. Acetic acid under our conditions shows an acceptor activity similar to that of the alcohols. A comparison with the phenols on the basis of acid strength in water may be misleading since if the acetic acid exists as double molecules in dioxane, then it is not present as the same species whose acid strength has been determined.

The results of Farinacci and Hammett indicate that water is a stronger acceptor than alcohol. Unfortunately, we are unable to demonstrate this with our present system, since water is a component of the indicator-equilibrium. The curve obtained with water is shown in Fig. 4. Its curious shape, which has been repeatedly checked, suggests a superposition of various effects. Among these we might expect to find the acceptor activity of water, its participation in the indicator-equilibrium, its basicity, and the fact that the addition of any quantity of it to dioxane multiplies the dielectric constant of the solution and accordingly greatly alters the state of ions in solution. The first and last of these effects might operate to give the curve a positive slope, while the two other effects would tend to make the curve descend as it does.

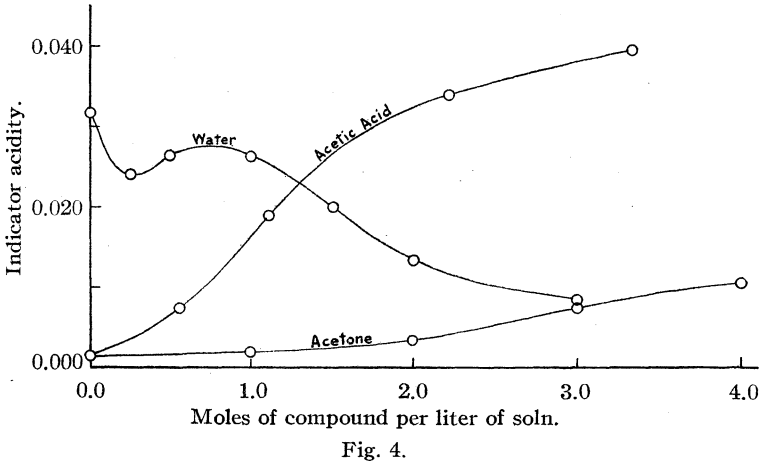

Fig. 4.

The carbonyl group has been demonstrated to have both donor and acceptor activity, arising out of its dipolar character. Toward the cyanide ion it functions as a pure acceptor,[18] while strong acids bring out its donor activity. In general, the reagent employed determines which type of activity will be displayed. Toward hydrogen chloride in dioxane the behavior of acetone is that of a feeble acceptor whose effect (Fig. 4) is so slight that it may be purely a solvent effect. Gordy[19] has presented data which indicate that acetone and dioxane are bases of about the same strength.

Several of the properties of dioxane as a solvent are worthy of comment for the way in which they determine the behavior of our system. In the first place, the basic strength of dioxane is sufficient to assure us that the hydrogen chloride occurs entirely chemically combined with the solvent, as dioxanonium chloride. This same basicity of dioxane causes phenol to be largely combined with the dioxane in which it is dissolved and not associated, as it would be in non-basic solvents of low dielectric constant.[20] When we speak of the phenols as if they were free, we refer to a small fraction which must be free in order to have acceptor activity, since there is no evidence that hydrogen can be attached to more than two other atoms at once.

The conductivity data of Chesterman[21] and Mounajed[22] show that in solutions of hydrogen chloride in ether the diethyloxonium chloride is only slightly dissociated into free ions. The dielectric constant of dioxane is still less (2.2) than that of ether (4.6) so that in our present system we may expect a great deal of ion association, not only into pairs but into clumps of greater size.[23]

The well-known "leveling" effect of a basic solvent, that of converting into its own conjugate acid all stronger acids which might be formed in solution, is important in bringing out the effects which we have observed. In a completely non-basic solvent, alcohols are known to behave as bases toward hydrogen chloride, and this effect, if present here, would completely conceal the acceptor properties of the alcohols. These acceptor properties appear here because there is practically no hydrogen chloride present, but only the much

weaker acid, dioxanonium chloride, from which methyl or ethyl alcohol is incapable of taking a proton.[19] Hence the acceptor properties of the alcohols are not overlaid. If these experiments were carried out in benzene, it would surely be impossible to detect the acceptor properties of the alcohols or of acetone, and we might even find phenols displaying basic character.

It is equally obvious that if any base is to be used as solvent which, like dioxane, combines completely with hydrogen chloride, the solvent must not be one which allows complete ionization of the resulting salt. Such ionization would mean that the maximum acidity of which the system was capable was already reached, and complex-formation by the acceptors would not be detectable by the indicator method.

It is of interest that the acceptor properties of phenol have been utilized[24] in promoting the elimination of hydrogen bromide from 9,10-dibromo-9,10-dihydroanthracene.

Experimental

Apparatus.—A Bausch and Lomb colorimeter (No. 2504) of the Dubosque type was used. Water-jacketed all-glass cups were clamped firmly in place and provided with machined brass caps with felt linings which fitted the plungers and minimized the entrance of moisture from the air. Water at 25.00 ± 0.05° from a thermostat was circulated through the jackets.

1,4-Dioxane.—The technical product was purified by refluxing for eight to fifteen hours with concentrated hydrochloric acid to destroy acetals, drying, refluxing with sodium until no reaction occurred, and distilling. The fraction used boiled at 101.1–101.3° and melted at 11.8°.[25] It was stored in a nitrogen atmosphere over sodium wire in a bottle closed with a paraffin-treated cork.

***p*-Dimethylaminoazobenzene** from the Eastman Kodak Co. was recrystallized three times from ethyl alcohol and carefully dried before use. It melted at 115–116°.

2,2′,2″,4,4′-Pentamethoxytriphenylcarbinol was prepared by the method of Lund.[26] Several recrystallizations from hot ethanol gave well formed white crystals of m. p. 145.5–146.5°.

Phenols.—With the exception of *p*-cyanophenol the phenols were prepared by the fractional distillation of good commercial grades. The *p*-cyanophenol[27] was synthesized and purified by crystallization from hot water and melted at 111.5–112.5° after careful drying. To obtain *p*-chlorophenol free from hydrogen chloride it was necessary to extract it with water, dry, and distil under diminished pressure. The fraction used boiled at 119.2–119.7° under 27 mm. pressure. The *o*-cresol boiled at 105.9–106.0° under 50 mm. pressure. The other phenols were fractionally distilled at atmospheric pressure. The phenol melted at 40.6° and boiled at 178.0–178.4°. The *p*-cresol boiled at 202.4–202.5° at atmospheric pressure. The *o*-chlorophenol boiled at 174.8–174.9° at 756 mm. The *sym*-trichlorophenol melted at 66.5–67.5°. All the phenols were stored in an atmosphere of nitrogen.

Methanol.—A commercially available "acetone-free" product was refluxed with sodium hydroxide and iodine, distilled, dried by refluxing with magnesium and a little iodine, and finally distilled. It gave no precipitate with aluminum ethoxide.

Ethanol (absolute, from the Commercial Solvents Co.) was refluxed with silver nitrate and potassium hydroxide for seven to eight hours, distilled, and finally dried by the magnesium method. It also gave a negative test with aluminum ethoxide.

Isopropanol was heated under reflux for thirty hours with its weight of quicklime and distilled. The middle fraction, which boiled at 82.2°, was used.

Acetone (alcohol-free) was refluxed with potassium permanganate and a little sodium hydroxide for a few hours and distilled. The middle fraction of the distillate was shaken with freshly dried potassium carbonate for about twelve hours. The product distilled at 56.2°.

Acetic acid, provided by Rolf Altschul, had been heated with chromic anhydride and a little acetic anhydride and distilled through a six-foot (1.8-meter) packed column. The fraction used boiled at 118.3° at 764 mm. and had a freezing point of 16.6° just before use.

Summary

Seven phenols and three alcohols have been investigated and all found to increase the acid strength (measured by an indicator) of solutions of hydrogen chloride in dioxane. This is interpreted as due to the formation of a hydrogen bond with the chlorine atom of the hydrogen chloride by the hydroxyl group of the phenol or alcohol. A composite quantitative measure of this effect is had from colorimetric determinations. The hydrogen bond formation appears to run parallel to the acid strength in the series of phenols except for phenols with ortho-substituents capable of intramolecular hydrogen bonding, which are far less efficient "acceptors" than would be expected from their acid strength. This deviation is regarded as an argument against the diversion of the term "acidity" to cover activity as an electron acceptor.

This property of hydroxyl compounds is correlated with the mechanisms of the Wagner–Meerwein rearrangement and the solvolysis of secondary and tertiary halides. Measurements on acetic acid and acetone are included for comparison.

Kinetics of the Reaction of *p*-Methoxybenzhydryl Chloride with Methanol in Dilute Nitrobenzene Solution

BY PAUL D. BARTLETT AND RICHARD WILSON NEBEL

Much of the kinetic work on the reaction of organic halides with hydroxyl compounds has been done with the hydroxyl compounds as solvents.[1] These conditions obscure the manner in which the hydroxyl compound participates in the rate-determining step, which has been the subject of much debate. The present work is an effort to obtain unambiguous evidence on this point by carrying out the alcoholysis of a suitable halogen compound in an inert solvent, in which the alcohol concentration can be kept low and varied, and in which the reaction can be freed from competing reactions and made irreversible. The first of these conditions has been met in a series of experiments described by W. Taylor[2] since the inception of our work.

The dielectric constant has been considered by some to be an important factor in the effect of changing medium on the rate of solvolysis of secondary and tertiary halides.[3] With this in mind we chose an inert solvent with approximately the same dielectric constant as the alcohol taking part in the reaction. Nitrobenzene ($E = 36.1$)[4] and methanol ($E = 33.7$)[5] were selected. Nitrobenzene has the further advantage of being thoroughly inert to the kind of substances expected to be present. It was necessary, however, to establish the limits within which methanol acts as a normal, unassociated solute in nitrobenzene. This was done by a series of vapor pressure measurements, by the dynamic method, of methanol–nitrobenzene solutions at 25°. Absorption of the alcohol vapor in sulfuric acid and weighing was found precise enough to give this information. The plot of partial pressure of methanol against its formal concentration, shown in Fig. 1, indicates constancy of the size of the dissolved unit up to 0.6 molar, which means that methanol is unassociated under these conditions.

Since in dilute alcohol solutions alcoholysis of a chloride is incomplete at equilibrium, it was desirable to make the reaction irreversible if this could be done without disturbing its course. The trials for the selection of a suitable chloride were therefore made in the presence of excess piperidine, which was converted into its hydrochloride as the reaction progressed and could be titrated as a means of following the reaction. After various trials, *p*-methoxybenzhydryl chloride was selected as a halide which reacted at a convenient rate with these low concentrations of methanol. It was found, however, that there was an appreciable rate of reaction with piperidine in the absence of any methanol, and piperidine accordingly was replaced by triethylamine, which was shown to be free from this difficulty. Only after standing for a matter of months was there appreciable reaction at room temperature between the chloride and triethylamine in nitrobenzene. This great preference on the part of a secondary chloride for reacting with the weakly basic methanol rather than the more strongly basic triethylamine or even piperidine emphasizes the difference in mechanism of reaction between secondary and primary chlorides to which Ingold and Hughes have repeatedly directed attention.

In view of recent results and discussions of sol-

volysis it seemed possible that, even though the chloride did not react directly with triethylamine, the reaction in the presence of both triethylamine and methanol might lead to a substantial fraction of the quaternary ammonium salt. To test this, the following experiment was performed. A solution was prepared of 0.953 g. of *p*-methoxybenzhydryl chloride with two equivalents of methanol and 1.25 equivalents of triethylamine in 50 cc. of nitrobenzene, and this solution was allowed to stand overnight. The precipitate (triethylamine hydrochloride) was filtered off and the solution was extracted three times with 10% hydrochloric acid. Then 10 cc. of the solution was concentrated under 2 mm. pressure to about 0.5 cc. and the last of the solvent removed by steam distillation. The oily residue crystallized on seeding and standing at 0°, yielding 0.195 g. of crystals melting at 19–20°, identified as impure *p*-methoxybenzhydryl methyl ether by mixed melting point with a pure sample, m. p. 27–28°. The theoretical yield was 0.189 g. of the ether. If any quaternary ammonium salt had been formed it would have passed into the water extract and the quantity of ether isolated would have been correspondingly diminished. We conclude that in titrating the amine we are following the rate of reaction between *p*-methoxybenzhydryl chloride and methanol, no reaction being involved between the chloride and the amine.

Runs carried out in the presence of only the chloride, the alcohol and the amine did not at first show good second order kinetics. The liberation of hydrogen chloride was at first excessively rapid, and the bimolecular plots did not become linear until the run was well under way. It was noted that the point of straightening of the curve in each case coincided approximately with the time at which triethylamine hydrochloride began precipitating from the solution. Apparently the building up of salt concentration was attended by a slowing of the specific reaction rate. This was confirmed by saturating the solvent in advance with triethylamine hydrochloride, which resulted in the second order plots being linear over the entire measurable reaction (in some cases more than 90%). The runs reported in this paper were all made in solutions saturated with triethylamine hydrochloride.

The solubility of triethylamine hydrochloride in nitrobenzene is markedly dependent upon the methanol concentration, even when this is small. Table I shows the solubility under the conditions of the kinetic runs.

TABLE I

SOLUBILITY OF TRIETHYLAMINE HYDROCHLORIDE IN NITROBENZENE CONTAINING METHANOL AND TRIETHYLAMINE AT 25.0°

Concentrations in moles per liter		
Methanol	Triethylamine	Triethylamine hydrochloride
0	0	0.0157
0	0.101	.0147
0.0833	.102	.0236
.167	.102	.0356
.250	.102	.0468

The slight effect of 0.1 molar triethylamine upon the solubility of triethylamine hydrochloride suggests that the large effect in the case of methanol is due to its chemical union with one of the ions of the salt, presumably with the chloride ion, to give a new and more soluble molecular species. The solubility in the solutions containing triethylamine is well expressed by

$$0.0145 + 0.1086[CH_3OH] + 0.0854[CH_3OH]^2$$

This is consistent with the idea of practically constant solubility for the molecular species $C_6H_{15}N\cdot HCl$ and the appearance of soluble $C_6H_{15}N\cdot HCl\cdot CH_3OH$ and $C_6H_{15}N\cdot HCl\cdot(CH_3OH)_2$ in amounts governed by the methanol concentration. From the solubility data we can estimate equilibrium constants

$$K_1 = \frac{[S][CH_3OH]}{[S\cdot CH_3OH]} = 0.119, \text{ and}$$

$$K_2 = \frac{[S\cdot CH_3OH][CH_3OH]}{[S(CH_3OH)_2]} = 1.27$$

where S represents triethylamine hydrochloride. This would mean that at all concentrations of methanol in nitrobenzene saturated with triethylamine hydrochloride, about 11% of the methanol is bound to the salt in a mono-alcoholate, while in the most concentrated solution about a further 4% of the methanol is bound in a di-alcoholate. This fits with the other observations made in this work and offers a satisfactory interpretation of the effect of low concentrations of methanol on the solubility of the salt.

Despite the apparent bimolecular nature of the reaction in individual runs, the bimolecular velocity constant varied markedly as the concentration of methanol was altered. A change of the methanol concentration from 0.0737 to 0.2129 caused a change in the bimolecular rate constant from 0.153 to 0.233. From the experimental results of Farinacci and Hammett[6] and the calcula-

(6) Farinacci and Hammett, *loc. cit.*

tions of Winstein,[7] it seemed possible that there might be, superposed upon the bimolecular reaction, a trimolecular reaction involving the attack of two molecules of alcohol upon one of the chloride. The trimolecular reaction, if simultaneous with the bimolecular one, would gain in importance at higher alcohol concentrations. An equation for such superposed reactions has been derived and found to fit the present results.

If the chloride is present at a concentration x and the alcohol at a concentration $(x + c)$, and the chloride is disappearing irreversibly by a bimolecular and a trimolecular path, then

$$-dx/dt = k_2x(x + c) + k_3x(x + c)^2$$

If the ratio k_2/k_3 be denoted by r, the integrated equation is

$$k_2t = \frac{1}{c} \ln \frac{x + c}{x} - \frac{1}{(c + r)} \ln \frac{x + c + r}{x} + \text{constant} \quad (1)$$

Two tests of this equation are possible. A value of r should exist such that the same values of k_2 and k_3 are obtained from all the runs, and the plots of Equation (1) should be linear in all cases. By successive approximations we arrived at the value $r = 0.221$, which meets these conditions. Table II summarizes the results of applying this equation to our kinetic data.

TABLE II

BIMOLECULAR AND TRIMOLECULAR VELOCITY CONSTANTS FOR THE REACTION OF *p*-METHOXYBENZHYDRYL CHLORIDE WITH METHANOL IN NITROBENZENE AT 25°, ASSUMING $k_2/k_3 = 0.221$

Initial concentrations of Chloride	Methanol	Triethylamine	k_2	k_3	% reaction covered
0.0712	0.0737	0.0908	0.131	0.593	82

.0780	.2129	.0851	.127	.575	77
		Average	.133	.599	

The values of the rate constants, in parentheses, for the runs containing 0.1736 and 0.2352 M triethylamine, are not included in the average, since these large increases in the amine concentration appreciably diminish the rate of the alcoholysis. This fact and the slightly reduced solubility of triethylamine hydrochloride in the presence of tenth molar triethylamine in nitrobenzene (for which no "common ion effect" can be responsible) both suggest a slight association between methanol and triethylamine to give some such species as

$$(C_2H_5)_3N \ldots HOCH_3$$

in which the hydroxylic hydrogen is not available for hydrogen bonding and hence unable to promote either the solution of the hydrochloride or the rate of the alcoholysis.

From the average values of k_2 and k_3, we conclude that with 0.1 M methanol the reaction is proceeding 69% by the bimolecular and 31% by the trimolecular path. In this same case when the reaction is 75% complete, these percentages become 90 and 10, respectively. It is not surprising that the simple bimolecular formulation seems to fit these runs, since in the later stages of the reaction, when the distinction between orders of reaction is easiest to draw, the deviation from bimolecular kinetics is slight.

For reasons which have been reviewed recently,[8] we favor the interpretation of the solvolysis of secondary and tertiary halides given by Farinacci and Hammett[6] in that the rate-determining step is the removal of halogen by the alcohol or water as a solvated anion. Our present results are in harmony with this mechanism. If the solvation of a halide ion is regarded as a chemical process, there is a series of possible solvated ions involving one, two, three, etc., molecules of alcohol. The alcohol can be attached by a hydrogen bridge through any or all of the electron pairs of the halogen ion, and polymeric clusters of alcohol molecules can take the place of single alcohol molecules. By our solubility and kinetic measurements on dilute solutions we seem to have detected the ions with one and two molecules of alcohol of solvation. There is reason to suppose that at somewhat higher concentrations, where association of the alcohol becomes important, the formation of more highly solvated ions will introduce terms of higher order into the rate equation. The "polymolecular" reaction of Farinacci and Hammett would then be the predominant one in the pure alcohols and in alcohol–water mixtures.

Experimental

***p*-Methoxybenzhydryl chloride** was prepared according to Norris and Blake.[9] After purification by distillation it solidified and was recrystallized from benzene–hexane solution. It melted at 62–63°.

(7) Winstein, THIS JOURNAL, **61**, 1635 (1939).

(8) Bartlett and Knox, *ibid.*, **61**, 3187, 3188 (1939).

(9) Norris and Blake, *ibid.*, **50**, 1811 (1928).

Nitrobenzene, m. p. 5.7°, was freshly distilled from phosphorus pentoxide immediately before each run. It was very light yellow in color.

Triethylamine, b. p. 89°, was kept over magnesium sulfate and distilled before each run from zinc and sodium.

The **methanol** used was an analytical grade giving no precipitate with aluminum ethoxide.

Triethylamine hydrochloride was prepared by passing hydrogen chloride gas into an ethereal solution of triethylamine. The product was recrystallized from alcohol, washed with ether, and dried for several days in a vacuum desiccator over calcium chloride.

Vapor Pressure Measurements.—Solutions of methanol in nitrobenzene were prepared by breaking weighed ampoules of methanol into weighed amounts of nitrobenzene. The solutions so prepared were placed in absorption towers filled with glass beads. The amount of solution used was such that in removing enough methanol for a vapor pressure determination the concentration of the methanol was not altered by more than 2%. Dried air was drawn through the absorption towers immersed in a thermostat at 25°, and then through a U-tube filled with glass beads wet with sulfuric acid. Pure nitrobenzene gave a gain in weight of the absorption tube of 0.0011 g. per 100 cc. of air passed, and a proportional blank correction was applied to each run to determine the methanol absorbed. Seventeen runs were made, at molar concentrations of methanol from 1.015 down to 0.117. Table III summarizes the results.

While these results are not very precise, the plot in Fig. 1 shows clearly the linear relationship between concentration and partial pressure of methanol up to 0.6 molar.

The solubility determinations were made by stirring the solutions of methanol and triethylamine in nitrobenzene with finely powdered triethylamine hydrochloride for several hours in the thermostat, extracting measured portions of the solution with water and titrating with standard silver nitrate. The solid phase present at saturation was identified as the original triethylamine hydrochloride, without any solvent of crystallization.

Technique of Velocity Determinations.—The titrations of triethylamine were satisfactorily carried out in acetone as a titration medium using a standard solution of hydrogen chloride in ether and brom phenol blue as indicator. A solution of triethylamine was freshly prepared by adding about 0.77 cc. of it to 60 cc. of nitrobenzene and mixing. Then 55 cc. of this solution was delivered into a 125-cc. glass-stoppered Erlenmeyer flask and a weighed ampoule of methanol was broken into it. Excess solid triethylamine hydrochloride was added and the solution was shaken for several hours at 25° to attain saturation with the salt. A 5-cc. sample was then pipetted out and titrated in 50 cc. of acetone with 0.025 *N* hydrogen chloride–ether solution. The reaction was started by the addition of a weighed quantity (about 0.9 g.) of *p*-methoxybenzhydryl chloride to the 50 cc. of solution which had been brought to temperature in the thermostat. The solid dissolved rapidly, and the stop watch was started at the time of complete solution. Samples of 5 cc. were withdrawn at successive times with a pipet and titrated. The end-points were sharp and showed no tendency to drift. One 5-cc. sample was sealed in a tube and heated at 100° for several hours to get the titer corresponding to complete reaction. This provided a check on the purity of the chloride, which

TABLE IV

RUN G-14

0.3787 g. of methanol and 0.9154 g. of *p*-methoxybenzhydryl chloride in 50 cc. of nitrobenzene containing excess triethylamine and saturated with triethylamine hydrochloride. Samples of 4.99 cc. titrated with 0.02740 *N* ether–HCl solution.

Minutes	Titer	x	$x + c$	D	Per cent. reaction
0	15.50	0.0780	0.2129	0.1541	0
2.42	13.57	.0674	.2023	.1749	12
5.75	11.94	.0584	.1934	.1973	25
8.83	10.60	.0511	.1860	.2195	34

37.17	4.55	.0179	.1529	.4312	77

proved to be better than 95%, and also on the consistency of the other measurements.

We present in Table IV the data for a typical run. The quantity D in the table is

$$\log_{10}\frac{x+c}{x} - \frac{c}{c+r}\log_{10}\frac{x+c+r}{x}$$

which, according to the kinetic equation used, is expected to be proportional to time. Figure 2 shows the plot of this quantity against time.

Summary

The rate of the reaction between methanol and *p*-methoxybenzhydryl chloride in dilute nitrobenzene solution under irreversible conditions has been studied as a function of the methanol concentration from 0.07 to 0.21 *M*. There is a bimolecular reaction involving one molecule of the chloride and one of methanol and at the same time a trimolecular reaction involving one molecule of chloride and two of methanol. It is suggested that mechanisms of higher order appear as the alcohol is made more concentrated, as seems probable also from the work of Farinacci and Hammett.

Vapor pressure measurements have been made, showing that methanol is not associated in nitrobenzene solutions of the strength used.

The solubility of triethylamine hydrochloride in nitrobenzene is altered markedly by small concentrations of methanol. A series of solubility measurements are interpreted as giving evidence of specific solvation of the chloride ion by one and by two molecules of methanol.

Triethylamine is inert toward *p*-methoxybenzhydryl chloride in nitrobenzene solution, at least in comparison to like concentrations of methanol. This makes it possible to use triethylamine to combine with hydrogen chloride liberated in the alcoholytic reaction and thus to make the reaction effectively irreversible.

CAMBRIDGE, MASSACHSETTS RECEIVED MARCH 27, 1940

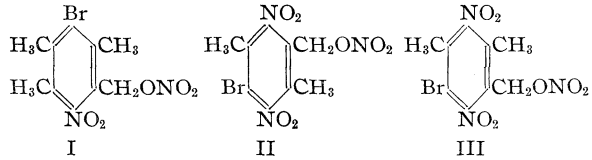
Polymethylbenzenes. XXVI. The Nitration of Bromopentamethylbenzene

BY LEE IRVIN SMITH AND JAMES W. HORNER, JR.[2]

When bromodurene is nitrated under certain circumstances, the product is 6-nitro-3-bromo-2,4,5-trimethylbenzyl nitrate, I.[3] Similarly, 5-bromopseudocumene or its 3,6-dinitro derivative can be attacked at the side chain by nitric acid,[4] and the product has been shown to consist of an inseparable mixture of two benzyl nitrates, II and III.[5]



These nitrates usually can be converted into aromatic nitro compounds by action of sulfuric acid. Peculiar orientation effects frequently are observed when polyalkylbenzenes are converted into substitution products by reactions in which an alkyl group is simultaneously removed or replaced.[6] The most striking of these effects is perhaps that shown by the nitration of pentamethylbenzene[7] and of pentaethylbenzene[8] to dinitrotetraalkylbenzenes in yields of over 70%, and with an ortho orientation of the nitro groups in the methyl derivative and a para orientation in the ethyl derivative. The easy decomposition of benzyl nitrates to nitro compounds indicates that these substances may well be intermediates in those reactions in which alkyl groups are replaced by nitro groups and that the peculiar orientation effects observed in such reactions are due to factors which determine which one of several alkyl groups will be attacked.

In order to study further these effects, the nitration of bromopentamethylbenzene (IV) has been examined. When fuming nitric acid was added to a solution of IV in chloroform, there resulted an oily solid from which was isolated a mixture of two isomeric bromotetramethylbenzyl nitrates, V

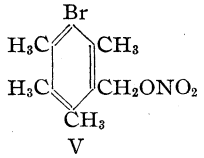
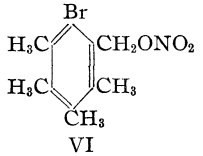
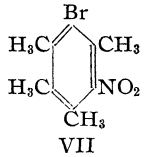
and VI, and a substance A, melting at 66.5–70° containing halogen but no nitrogen. The two benzyl nitrates formed an inseparable mixture and like the inseparable mixture of II and III, the mixture of V and VI could not be converted into any separable mixture of isomers. When the



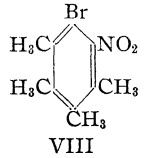
V



VI



VII



VIII

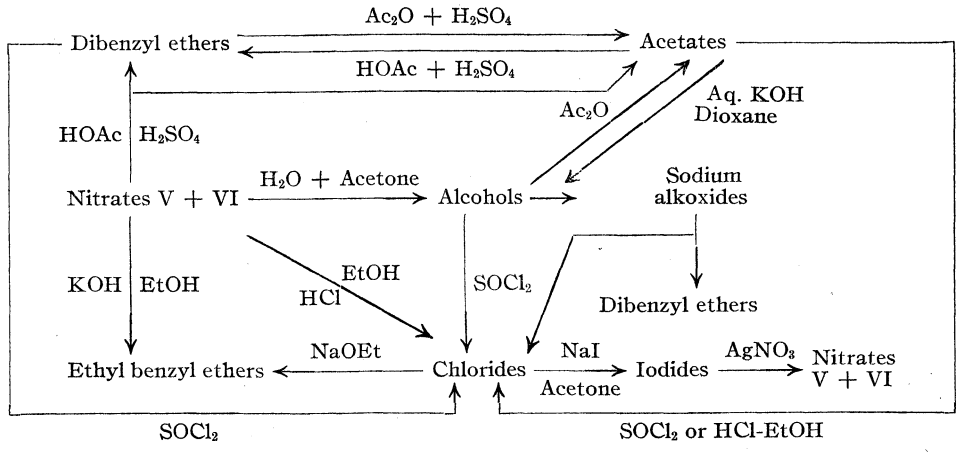
nitrates were subjected to the action of sulfuric acid, there resulted an inseparable mixture of bromo nitro tetramethylbenzenes, VII and VIII. When this mixture of nitro compounds was reduced by tin and hydrochloric acid, the product was a mixture of bromoaminoisodurene (IX) and aminoprehnitene (X), the halogen having been removed from the *o*-halo nitro compound, and not from the *m*-isomer.[9] The two amines produced in this way were separated; the mixture yielded approximately 0.6 mole of IX and 0.4 mole of X. No trace of any derivative of durene could be obtained from the mixture of amines. It followed, therefore, that the mixture of bromo nitro compounds contained about 60% of VII and 40% of VIII, and, in turn, that the nitration of bromopentamethylbenzene gave, as one of the products, a mixture of the nitrates V and VI containing about 60% of V.

The reactions of the nitrates and their derivatives are summarized in the chart. It is particularly noteworthy that these nitrates, in contrast to I, II and III, never produced any aldehydes upon hydrolysis.[10]

Substance A was obtained from the mother liquors after the crude nitration product was crystallized from methanol. Acetylation of A produced the same acetate mixture as that obtained from V + VI. This fact made it possible to prepare all the benzyl derivatives described above directly from the entire solid nitration product rather than from the purified nitrates only. These properties of A, together with the low melting point and the analysis, indicated that A was a mixture of the benzyl methyl ethers derived from V and VI.

The complete series of compounds (chlorides, iodides, acetates and nitrates) derived from each of the bromotetramethylbenzenes, was synthesized. In every case, the melting point of the derivative from bromopentamethylbenzene was not depressed by addition of the synthetic derivative from either prehnitene or isodurene, but a marked change in the melting point resulted when the durene derivative was added.

REACTIONS OF THE BENZYL NITRATES V + VI



Experimental Part[11]

Nitration of Bromopentamethylbenzene.—Fuming nitric acid (d. 1.52, 22 cc.) was added over a period of fifteen minutes to a vigorously stirred solution of bromopentamethylbenzene (10 g.) in chloroform (150 cc.) at −11°.

(9) Nicolet, *et al.*, THIS JOURNAL, **43**, 2081 (1921); **49**, 1796, 1801, 1806, 1810 (1927).

(11) Microanalyses by J. W. Opie and E. E. Renfrew.

During the reaction, the temperature rose to −1°; the mixture was poured immediately into cold water. The chloroform layer was removed and washed with carbonate (5%) and then with water. Removal of the solvent left a yellow oily solid (13 g.) which was crystallized from methanol (80 cc.) at room temperature. Succeeding crops of crystals were obtained by evaporating the filtrates to half their volume and cooling in ice. In this way the following material was obtained: first crop, 3.56 g., m. p. 69–83°; second crop, 3.00 g., m. p. 53–59°; third crop, 0.77 g., m. p. 55–56°; fourth crop, 0.41 g., oily, m. p. 50–67°; residue, 3.73 g., orange oil. The first crop was principally V + VI. This could be recrystallized from methanol, ethanol, ether, acetic acid, ethyl acetate or petroleum ether. After the two crystallizations from petroleum ether, it melted at 78–84°. Further crystallization sometimes gave a product with a slightly higher melting point, but the melting point range was not decreased.

Anal. Calcd. for $C_{11}H_{14}O_3NBr$: C, 45.83; H, 4.90. Found: C, 46.00; H, 4.90.

After three crystallizations of the fourth crop from methanol, the substance A, m. p. 66.5–70°, was obtained. This substance was most likely a mixture of benzyl methyl ethers. It was not a mixture of the alcohols (m. p. 170°) and bromopentamethylbenzene (m. p. 160°) because a mixture of these two substances melted at 160–164.5°.

Anal. Calcd. for $C_{12}H_{17}OBr$: C, 56.03; H, 6.61. Found: C, 55.57; H, 6.11.

The nature of the nitration product depends greatly upon the amount of acid used, and upon the time allowed for the reaction. More vigorous conditions yield a very oily product from which only the product of exhaustive nitration, 4-bromo-5,6-dinitrohemimellithene, can be isolated. As an example, the following may be cited: pentamethylbromobenzene (29.3 g.) in chloroform (130 cc.) was added slowly (two hours) to a well-stirred mixture of sulfuric acid (381 cc.), fuming nitric acid (d. 1.52, 88 cc.) and chloroform (500 cc.) at 25–31°. The product (34 g.), isolated as in method 1, consisted of 4-bromo-5,6-dinitrohemimellithene, m. p. 201–202° (5.9 g.) and an oil (27.7 g.) which on standing in sulfuric acid slowly deposited more of the bromo dinitro compound. The solid was identified by comparison with an authentic specimen of 4-bromo-5,6-dinitrohemimellithene,[12] and by analysis.

Anal. Calcd. for $C_9H_9O_4N_2Br$: C, 37.38; H, 3.12. Found: C, 37.74; H, 3.49.

The Dibenzyl Ethers.—The nitrates (3.43 g.) were refluxed in acetic acid (50 cc.) containing water (50 cc.) and sulfuric acid (2 *N*, 5 cc.) for four hours. The cooled reaction mixture deposited a white solid (2.27 g.) melting at 80–165°. Extraction of this material with hot ethanol left a residue of the ether mixture (0.83 g.) melting at 202–218°. Crystallization of this material from chloroform–ethanol or benzene did not give a product with a sharper melting point. This mixture of dibenzyl ethers had the widest melting point range of any of the derivatives of the nitrates; since it is derived from two molecules of V and VI, three benzyl ethers probably are present.

(12) Smith and Moyle, THIS JOURNAL, **58**, 9 (1936).

Anal. Calcd. for $C_{22}H_{28}OBr_2$: C, 56.40; H, 6.03; active H, 0; carbonyl, 0. Found: C, 56.44, 56.45; H, 5.79, 6.33; active H, 0; carbonyl, 0.

The alcoholic extract, when concentrated and cooled, deposited the acetates (0.86 g.) melting at 72–78°.

The Acetates. (a) The **benzyl ethers** (0.55 g.) were allowed to stand for seventeen hours in acetic anhydride (10 cc.) and sulfuric acid (5 drops). The solution was poured into water and the solid (0.65 g., 100%) was removed and crystallized from petroleum ether. It then melted at 82–83.5°.

Anal. Calcd. for $C_{13}H_{17}O_2Br$: C, 54.73; H, 6.01. Found: C, 54.92; H, 6.27.

(b) The **alcohols** (0.19 g.), after the above treatment, gave the same acetate, m. p. 77.5–83.5° after one crystallization from methanol.

(c) The **chlorides** were largely unchanged when treated as above, but the **iodides** (0.15 g.) were readily converted into the acetates by refluxing in acetic acid (5 cc.) with potassium acetate (0.21 g.) for two hours. The product melted at 81–86°.

When the acetates (0.21 g.) were refluxed for eleven hours in acetic acid (4 cc.) containing water (3 cc.) and sulfuric acid (5 drops), the product (0.17 g.), m. p. 140–170°, was the **dibenzyl ether** mixture. After two crystallizations from chloroform–ethanol, it melted at 211–219°.

(d) Substance A (0.63 g.) was allowed to stand for thirty-five minutes in acetic anhydride (5 cc.) and concentrated sulfuric acid (5 drops). The mixture was poured into water and the solid was removed and crystallized three times from methanol. It weighed 0.21 g., melted at 78–82°, and gave no depression in m. p. when mixed with the acetates prepared in other ways. Similarly, substance A (0.18 g.), hydrolyzed with acetic acid (2 cc.), water (2 cc.) and sulfuric acid (2 *N*, 0.2 cc.) gave an impure product which melted at 60–120°. Acetylation of this material produced the acetates (0.13 g.) melting at 77.5–81.5° without any purification.

(e) The entire nitration product, consisting of the nitrates and substance A, was subjected to successive hydrolysis and acetylation as described under (d). The acetates were obtained in good yield, although apparently there was an impurity present throughout which was best removed by steam distillation before the final acetylation. Further, the crude hydrolysis product could be converted into the alcohols in good yield by the dioxane–potassium hydroxide method, but again the rather persistent impurity was best removed by steam distillation before the final hydrolysis to the alcohols.

The Alcohols.—(a) The acetates (0.67 g.) were refluxed for six hours in dioxane (10 cc.) and potassium hydroxide (25%, 10 cc.). The solution was diluted with water and the solid was removed and crystallized first from ethanol and then from methanol. It weighed 0.35 g. (61%) and melted at 168–171°. It crystallized sometimes as brittle glassy rods, sometimes in clumps of heavy white needles.

Anal. Calcd. for $C_{11}H_{15}OBr$: C, 54.31; H, 6.22; active H, 1 mole; carbonyl, 0. Found: C, 54.30; H, 6.08; active H, 1.0 mole; carbonyl, 0.

(b) The **nitrates** (0.52 g.) were heated with acetone (9 cc.) and water (4 cc.) to 200–240° in a sealed tube for

twenty-three hours. The product, after crystallization first from benzene and then from methanol, melted at 168.5–170°.

The chlorides. (a) The **alcohols** (0.97 g.) were refluxed with thionyl chloride for fifteen minutes. Excess reagent was pumped off and the residue (1.04 g., 100%), if it melted below 110–113°, was crystallized from methanol or ethyl acetate.

Anal. Calcd. for $C_{11}H_{14}ClBr$: C, 50.48; H, 5.40. Found: C, 49.88, 50.12; H, 5.47, 5.59.

(b) The **acetates** (0.20 g.), heated with thionyl chloride (3.2 cc.) in a sealed tube at 112° for twenty hours, gave the **chlorides,** m. p. 109–110.5°. When a solution of the acetates (0.40 g.) in ethanol (12 cc.) and hydrochloric acid (4 cc.) was refluxed for five hours, the **chlorides,** m. p. 108–112.5°, were produced.

(c) The **dibenzyl ether** (0.14 g.) was heated for forty-two hours at 122° in a sealed tube with thionyl chloride (3 cc.). The product (0.097 g., 62%) was the chloride. After crystallization from ethanol it melted at 105–110.5°.

(d) The **nitrates** (1.51 g.) were refluxed for a day in ethanol (24 cc.) and hydrochloric acid (8 cc.). The solution was poured into water and the solid (0.18 g.) was removed and crystallized from ethanol. It was the chloride, m. p. 111–112°. The aqueous filtrate contained 1.21 g. of orange oil from which some solid material, m. p. 75–100°, could be isolated, but it could not be purified further. The oil gave an immediate precipitate with silver nitrate.

When the chloride (0.25 g.) in toluene (5 cc.) was refluxed for five hours with the sodium derivative of the alcohols (prepared by refluxing the alcohols (0.23 g.) with sodium (0.023 g.) in toluene (5 cc.) until the white sodium derivative was formed), the product was the **dibenzyl ether.** The reaction mixture was filtered, water was added to the filtrate and the toluene was removed by steam distillation. The residue was extracted with chloroform and crystallized from methanol or benzene. The product melted at 200.5–211°.

The Iodides.—The chlorides (1.04 g.) were warmed briefly with an acetone solution of sodium iodide (10%, 20 cc.) and the solution was then allowed to stand for an hour. Addition of water precipitated a solid (1.34 g., 95%) which was removed and crystallized from acetone or ethyl acetate. It then melted at 133.5–136°.

Anal. Calcd. for $C_{11}H_{14}BrI$: C, 37.40; H, 4.00. Found: C, 37.25; H, 3.97.

The Benzyl Ethyl Ethers.—The nitrates (1.00 g.) were refluxed for eighty-five minutes with ethanol (25 cc.) containing potassium hydroxide (2.19 g.). The inorganic precipitate contained 1.8% of nitrite. The alcoholic filtrate was diluted with water and the solid was removed and crystallized twice from aqueous methanol. It melted at 51–53.5°.

Anal. Calcd. for $C_{13}H_{19}OBr$: C, 57.55; H, 7.06. Found: C, 56.70; H, 7.30.

When the chlorides (0.11 g.) were refluxed for seven hours with sodium ethoxide in ethanol (0.21 g. of sodium, 10 cc. of dry ethanol), the product was the benzyl ethyl ether, m. p. about 50°.

The Bromonitrotetramethylbenzenes, VII + VIII.—Sulfuric acid (8.3 cc.) was added slowly at room temperature to a vigorously stirred solution of the nitrates (0.72 g.) in chloroform (7 cc.). The chloroform layer was removed at once (seven minutes after starting the reaction), washed with carbonate (5%), then with water, and evaporated to dryness, pumping off the last traces of the solvent. The residue, after crystallization from ethanol (charcoal), weighed 0.14 g. (22%) and melted at 163–174.5°. Recrystallization from petroleum ether gave a product melting at 174–177°.

Anal. Calcd. for $C_{10}H_{12}O_2NBr$: C, 46.51; H, 4.69. Found: C, 46.38; H, 4.81.

The mixture of VII + VIII (0.57 g.) in acetic acid (6 cc.) was refluxed for ten hours with granular tin (1.25 g.) and hydrochloric acid (5.5 cc.). The reaction mixture was made strongly alkaline and was steam distilled. The solid (0.25 g.) was removed from the distillate and was sublimed *in vacuo*, first at 100° and then briefly at 150°. The first portion of the sublimate (0.05 g.) melted at 57–62°; the second portion (0.06 g.) melted at 115–136°, and the residue (0.09 g.) melted at 144–147°. The first sublimate, after crystallization from petroleum ether, melted at 64.5–67.5°, gave no depression in m. p. when mixed with aminoprehnitene (m. p. 66–68°), but did give a depression when mixed with aminodurene (m. p. 71.5–74.5°). The residue from the sublimation, after crystallization from petroleum ether, melted at 146–148°. It gave no depression in m. p. when mixed with bromoaminoisodurene (m. p. 145.5–147°). Considering the first sublimate to be pure aminoprehnitene, and the residue to be pure bromoaminoisodurene, and assuming that the midpoint (125°) of the melting range of the second sublimate is a linear function of the mole fractions of aminoprehnitene (m. p. *ca.* 70°) and bromoaminoisodurene (m. p. *ca.* 147°) present, then the mole fractions of these two amines in the second sublimate are 0.286 and 0.714, respectively, and their respective weights are 0.012 g. and 0.048 g. Hence the total weights of aminoprehnitene and bromoaminoisodurene in the reduction product were 0.062 and 0.138 g., which corresponds with 0.107 g. (41%) of bromonitroprehnitene and 0.156 g. (59%) of bromonitroisodurene in the original mixture of VII + VIII.

The Pure Isomers.—The preparations are described in detail for one set of isomers; other results are given in Table I.

TABLE I

DATA ON PREPARATION OF PURE BROMOTETRAMETHYLBENZYL DERIVATIVES

TABLE II

MELTING POINTS (°C.) OF BROMOTETRAMETHYLBENZYL DERIVATIVES

	Chloride	Iodide	Acetate	Nitrate
1. Durene series	105.5–107.5	118.5–120	119.5–122	113–114.5
2. Isodurene series	114–114.5	132.5–134	88.5–90	105–106.5
3. Prehnitene series	114–116	142–143.5	96.5–98	90–92.5
4. Mixture from bromopentamethylbenzene	110–113	133.5–136	82–83.5	78–84
1 + 2	96–101	114–128	89–116	111–114.5
1 + 3	94–100	118–133	97.5–109	84–110
2 + 3	111.5–113	134.5–136	81–92	78–85
1 + 4	Below 99	115–127	83–116	82–110
2 + 4	110–114	134–134.5	83–86	80–91
3 + 4	112.5–114.5	136.5–137	80–94	81–89

Chloromethylations.—The bromohydrocarbon (2.5 g.), hydrochloric acid (10 cc.) and formalin (10 cc., 40%) were stirred vigorously and heated on a water-bath for thirty-two hours while a stream of dry hydrogen chloride was passed through. Occasionally during the reaction, more formalin (total 10 cc.) was added in 2–3 cc. portions. The reaction mixture was extracted with chloroform and the organic layer was washed with water. Removal of the solvent left the solid reaction product, which was crystallized once or twice (charcoal if the product was colored) from ethyl acetate.

Iodides.—The chloride (1.28 g.) was dissolved in a solution of sodium iodide in acetone (20 cc., 10%) and allowed to stand for forty-five minutes to one hour. The solution was poured into water and the solid was removed by filtration or chloroform extraction and crystallized from acetone.

Acetates.—The iodide (0.30 g.) was refluxed for three to five hours in acetic acid (12 cc.) containing potassium acetate (0.50 g.). The mixture was poured into water and the precipitate was removed and crystallized from ethanol.

Nitrates.—The iodide (0.30 g.) was refluxed in dry dioxane (10 cc.) containing powdered silver nitrate (1.50 g.). The reaction mixture was poured into water and the solid was isolated by filtration or, better, by chloroform extraction. It was crystallized from petroleum ether (b. p. 60–68°).

In Table II are given the melting points of the pure substances and their binary mixtures (approximately 50–50) with each other and with the corresponding derivatives (mixture) from bromopentamethylbenzene. It is apparent that many of the mixtures do not show great depressions in melting points, but in all cases the melting points of mixtures of the isodurene and prehnitene derivative are almost identical with, and do not depress, the melting points of the corresponding mixture obtained from bromopentamethylbenzene.

Bromonitrodurene.—A mixture of chloroform (3.5 cc.) and fuming nitric acid (d. 1.57, 1.3 cc.) was added rapidly (4.5 minutes) to a cooled (0°) and well-stirred mixture of chloroform (17 cc.) sulfuric acid (5.5 cc.) and bromodurene (5 g.). The reaction mixture was immediately poured into water, the chloroform layer was removed and partially evaporated. Ethanol was added to replace the chloroform until the hot solution began to crystallize, after which the mixture was chilled. The product (4.03 g., 66%) consisted of light yellow needles which melted at 179–180° after crystallization from chloroform–ethanol.

Anal. Calcd. for $C_{10}H_{12}O_2NBr$: C, 46.51; H, 4.69. Found: C, 46.19; H, 5.14.

Bromonitroisodurene was prepared as above from bromoisodurene (4 g.). The product (2.97 g., 61%), after crystallization from chloroform–ethanol, formed light yellow needles which melted at 176.5–177.5°.

Anal. Calcd. for $C_{10}H_{12}O_2NBr$: C, 46.51; H, 4.69. Found: C, 46.13; H. 4.90.

Bromonitroprehnitene was prepared as above from bromoprehnitene (3.81 g.). The product (1.51 g., 33%) after two crystallizations from chloroform–ethanol formed light yellow needles which melted at 180–181.5°.

Anal. Calcd. for $C_{10}H_{12}O_2NBr$: C, 46.51; H, 4.69. Found: C, 46.88; H, 4.83.

Aminodurene.—Bromonitrodurene (3.28 g.) in acetic acid (35 cc.) was refluxed for four hours with granular tin (7 g.) and hydrochloric acid (32 cc.). The reaction mixture was made strongly alkaline and steam distilled. From the distillate there was isolated 1.45 g. (75%) of aminodurene which, after vacuum sublimation, softened at 68.5° and melted at 71.5–74.5°.[13] A mixture of aminodurene and aminoprehnitene (m. p. 66–68°) was entirely liquid at 51°.

Bromoaminoisodurene.—Reduction of bromonitroisodurene (1 g.) as above gave 0.70 g. (79%) of bromoaminoisodurene which melted at 145.5–147° after crystallization from petroleum ether.

Anal. Calcd. for $C_{10}H_{14}NBr$: C, 52.62; H, 6.19. Found: C, 52.87; H, 6.29.

Aminoprehnitene.—Reduction of bromonitroprehnitene (1.27 g.) as above gave 0.55 g. (75%) of aminoprehnitene, which after vacuum sublimation melted at 66–68°.[14]

Summary

1. The action of fuming nitric acid upon bromopentamethylbenzene produced an inseparable mixture of two benzyl nitrates, 5-bromo-2,3,4,6-tetramethylbenzyl nitrate (V) and 6-bromo-2,3,4,5-tetramethylbenzyl nitrate (VI) in the approximate ratio of 3 to 2. These nitrates were converted into nitro compounds, bromonitroisodurene (VII) and bromonitroprehnitene (VIII), by sulfuric acid.

2. The action of a mixture of fuming nitric

(14) Limpach, *Ber.*, **21**, 644 (1888); Töhl, *ibid.*, **21**, 905 (1888).

and sulfuric acids upon bromopentamethylbenzene gave 4-bromo-5,6-dinitrohemimellithene, in which two methyl groups had been replaced by nitro groups.

3. The benzyl nitrates V and VI were intermediates in the replacement of methyl groups by nitro groups; this may possibly be the course of other aromatic nitrations in which alkyl groups are replaced by nitro groups.

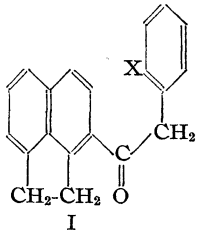
7-Cholanthroic Acid

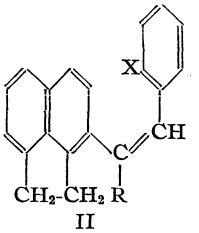
BY LOUIS F. FIESER AND GLEN W. KILMER[1]

The recently described preparation of 1-acetoacenaphthene by the acetylation of the hydrocarbon in the presence of liquid hydrogen fluoride[2,3] has rendered this ketone far more readily available as an intermediate for synthesis than any other 1-substituted acenaphthene, and the present research was undertaken to determine whether this or other 1-acyl derivative obtainable with the use of hydrogen fluoride could be employed as the starting point for the construction of the cholanthrene ring system.

The ready availability of the 1-aceto compound, which in large scale preparations has now been obtained in yields as high as 45% of the theory, is dependent upon the formation of a large proportion of the 1-isomer and also upon the fact that this is less soluble than the 3-ketone present in the mixture and is very easily separated. This favorable combination of factors has not been encountered in such other hydrogen fluoride acylations as have been investigated,[2a] for in the benzoylation, succinoylation and condensation of the hydrocarbon with crotonic acid by the hydrogen fluoride method, the amount of 1-substitution is small or negligible and no greater than in the Friedel and Crafts reaction. Although the prospects of obtaining other 1-acyl derivatives easily by direct hydrogen fluoride acylation are thus none too great, some trial was made of the condensation with phenylacetic acid derivatives with the thought that ketones of the type I might afford a short synthetic route to cholanthrenes. Thus a derived unsaturated compound (II) might be convertible to a cholanthrene by Pschorr ring closure (X = NO_2) or by the alkali fusion method employed by Hewett[4] (X = Br).



I



II

In a preliminary trial the hydrogen fluoride acylation of acenaphthene with phenylacetic acid itself was found to give a difficultly separable ketone mixture which on fractional crystallization afforded in 30% yield a pure compound identified as 3-phenylacetoacenaphthene by hypoiodite oxidation to the corresponding acid. The desired 1-isomer (I, X = H), which was similarly characterized as to structure, was isolated with difficulty and in only small amounts through the picrate. *o*-Bromophenylacetic acid, prepared from *o*-bromobenzoic acid by the Arndt–Eistert[5] reaction in 61% over-all yield, behaved similarly and gave a mixture from which two apparently pure compounds were isolated but only by tedious processing and in very small amounts. In view of these unfavorable indications, this approach was abandoned.

We then undertook to prepare intermediates of the type II starting with 1-acetoacenaphthene (III). Two routes were explored for the conversion of this ketone into 1-acenaphthylacetic acid (VII), the first being via the acid chloride and diazo ketone by the Arndt–Eistert procedure.[5] While the over-all yield of 50% is adequate, the process is time-consuming and not well adapted to the preparation of a quantity of the acetic acid derivative. Furthermore, the purified product probably was contaminated with a trace of the more sparingly soluble 1-acenaphthoic acid, for the melting point was not quite as high as that of

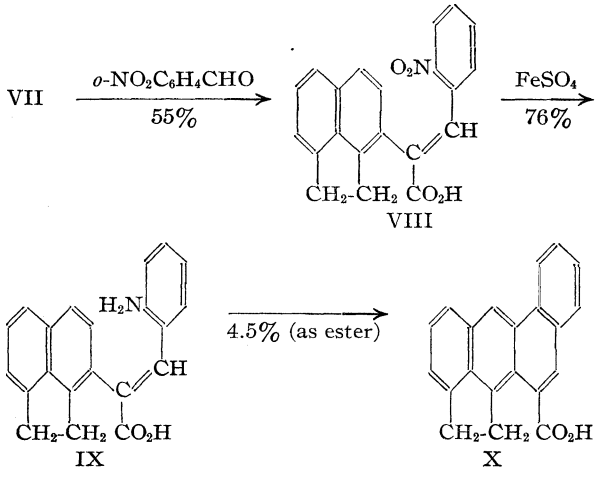
material prepared by the Willgerodt reaction,[6] which proved to be generally more satisfactory. This in the simplest case consists in heating a methyl ketone with yellow ammonium sulfide and results in the formation of an amide derivative, $ArCH_2CONH_2$, and in a certain amount of reduction. In a number of small scale experiments conducted in sealed tubes it was found that with 1-acetoacenaphthene the results are improved by the use of added dioxane and by conducting the reaction at a temperature (160°) considerably lower than recommended by Willgerodt. In the best case the yield of slightly colored but sharply melting acid (VII), isolated after hydrolysis of the crude amide, was 57%. This result could not be matched in large scale preparations conducted in an autoclave, for in the best case the yield of 1-acenaphthylacetic acid was 37% and considerable 1-ethylacenaphthene (47%) was produced. In one run in the autoclave the yield of the hydrocarbon was 67% of the theoretical. Cook, Haslewood and Robinson[7] prepared this hydrocarbon in a different way and reported the melting point of a purified sample as 30°. The redistilled material from the Willgerodt reaction had the m. p. 34.8–35.1° (constant) after a single crystallization from methanol.[8]

The Perkin condensation of 1-acenaphthylacetic acid with *o*-chlorobenzaldehyde proceeded satisfactorily (55%) to α-(*o*-chlorobenzal)-1-acenaphthylacetic acid (II, X = Cl, R = CO_2H), but fusion of this substance with potassium hydroxide or refluxing with potassium hydroxide in quinoline gave tars from which only traces of starting material could be isolated. Although these experiments were conducted with only rather small quantities of the chloro acid, the results discouraged further attempts to effect cyclization by this route. The case is comparable to an unsuccessful trial in the chrysene series.[9]

The Pschorr reaction then was tried, the intermediate α-(*o*-nitrobenzal)-1-acenaphthylacetic acid (VIII) being obtained by the Perkin condensation and reduced satisfactorily with ferrous sulfate and ammonia. Hydrogenation of the nitro compound in the presence of Adams catalyst



was less successful, for the yield of the amine IX was poorer (53%) and two unidentified neutral products were formed, one in 18% yield. The Pschorr ring closure proceeded poorly under all conditions tried, the procedure eventually adopted consisting in diazotization with isoamyl nitrite and treatment with Gattermann copper. The reaction gave a tarry acidic product which could not be purified as such, but by esterification with diazomethane and purification of the ester by

(8) Willgerodt and Merk (ref. 6) heated phenyl isobutyl ketone with yellow ammonium sulfide and isolated in 14–15% yield a substance melting at 118° and regarded as α-methyl-γ-phenylbutyramide. We prepared the ketone both by the Friedel and Crafts reaction (56%) [Claus, *J. prakt. Chem.*, **46**, 490 (1892)] and from benzamide and isobutyl bromide (59%) and tried the Willgerodt reaction under various conditions. The best yield of amide, isolated as glistening plates, m. p. 121–122° was 1.8%. Saponification and conversion to the anilide gave fine needles, m. p. 137–138°, with softening at 130°. Krollpfeiffer and Schäfer [*Ber.*, **56**, 620 (1923)] report the m. p. 140° for the anilide of α-methyl-γ-phenylbutyric acid, while the anilide of the β-methyl isomer is given as 101° [Anschütz and Motschmann, *Ann.*, **407**, 88 (1915)].

(9) Fieser, Joshel and Seligman, THIS JOURNAL, **61**, 2134 (1939).

chromatographic adsorption, distillation and crystallization, methyl 7-cholanthroate was isolated as a nicely crystalline product of sharp melting point in small yield (4.5%). Hydrolysis gave 7-cholanthroic acid (X), the alkali salts of which are moderately soluble in water, and the substance is being tested for carcinogenic activity. While the pure acid seemed rather resistant to decarboxylation by heating with basic copper carbonate (at least on a micro scale), the crude acidic product of the cyclization was converted by this catalyst into cholanthrene, identified by mixed melting point determination and by the preparation of the picrate. The yield of cholanthrene from the amino acid IX was 8.1%.

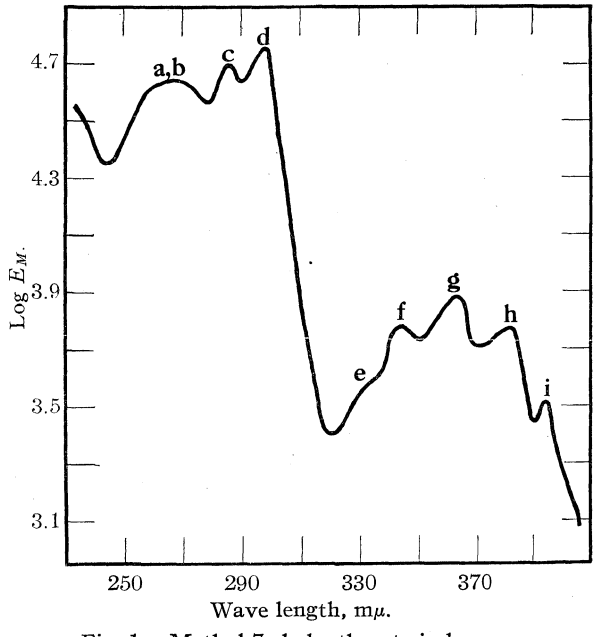

Fig. 1.—Methyl 7-cholanthroate in hexane.

The ultraviolet absorption spectrum of methyl 7-cholanthroate (Fig. 1), kindly determined by Dr. R. N. Jones, corresponds in general form and detail with that of cholanthrene,[10] although some resolution is lacking. A comparison of the wave lengths and intensities of the principal maxima with those of cholanthrene is given in Table I.

TABLE I

ULTRAVIOLET ABSORPTION MAXIMA

Experimental Part[11]

Acylation of Acenaphthene with Phenylacetic Acid.—A mixture of 10 g. of the hydrocarbon, 9.3 g. of phenylacetic acid, and 130 g. of anhydrous hydrogen fluoride was allowed to stand at room temperature in a platinum container for ten and one-half hours and poured onto ice. The greenish, amorphous precipitate was ground in a mortar with sodium carbonate solution to neutralize adhering acid, then washed and dried, giving 16.9 g. of gray-green powder, m. p. 65–95°. Repeated crystallization from benzene and from ethyl acetate–hexane gave **3-phenylacetoacenaphthene,** m. p. 111.5–113°, in 30% yield. The picrate, prepared in alcohol and crystallized from benzene–hexane, formed somewhat unstable, yellow-orange needles, m. p. 107.5–108.5°. The ketone recovered from the picrate with the use of an alumina adsorption tower crystallized from ethyl acetate–hexane in the form of colorless prisms, m. p. 113.5–114°.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.20; H, 5.92. Found: C, 87.96; H, 5.99.

By oxidation of 1 g. of this ketone in dioxane with sodium hypoiodite solution there was obtained 121 mg. of 3-acenaphthoic acid, m. p. 218–219°. The m. p. was not raised by recrystallization from alcohol and the acid showed no depression with an authentic sample.

The residual ketonic mixture on repeated crystallization afforded a small amount of substance melting at 73–90° which was converted into the picrate in benzene. After crystallization from ethyl acetate–hexane, this derivative was obtained as brilliant yellow needles which seemed to undergo a change in form at 130.5–131° and melted at 133–134°. **1-Phenylacetoacenaphthene** was recovered from the picrate with the use of benzene and ammonia solution and crystallized from benzene–hexane. It formed large, pale yellow prisms, m. p. 81–81.5°.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.20; H, 5.92. Found: C, 88.04; H, 5.99.

Oxidation of 200 mg. as above gave 59 mg. of crude acid, m. p. 240–250°. Crystallized from alcohol, the sample melted at 251–252.5° and did not depress the m. p. of authentic 1-acenaphthoic acid.

***o*-Bromophenylacetic Acid.**[12]—The diazomethane formed by dropping 55 cc. of nitrosomethylurethan in 55 cc. of ether into 60 cc. of a warm saturated solution of potassium hydroxide in absolute alcohol covered with ether (20 cc.) was distilled through a vertical coil condenser and absorbed in cold absolute ether. After dilution to 800 cc. with cold ether, 21.4 g. of *o*-bromobenzoyl chloride (b. p. 103–104° at 5 mm.) was added in ether with mechanical stirring at 0° during one hour. After five hours at room temperature a fluffy precipitate was removed by filtration and the ether evaporated in vacuum, leaving 22.8 g. of a brownish, oily, lachrymatory product, m. p. 36–41°. Crystallized by concentrating an ether–hexane solution of

(11) All final melting points are corrected.

(12) Following the procedure of Litvan and Robinson, *J. Chem. Soc.*, 1997 (1938).

the product in vacuum and cooling, this gave 14.6 g. (66.5%) of yellow and not appreciably oily **diazomethyl-*o*-bromophenyl ketone**, m. p. 42–43° (gas evolution). The mother liquor material was largely oily (6.2 g.). A solution of the crystallized diazo ketone (14.6 g.) in technical dioxane was added in one-half hour with stirring to a suspension of 16 g. of silver oxide in 800 cc. of water containing 24 g. of sodium thiosulfate at 60–65°. After one-half hour more the evolution of gas had practically ceased and the mixture was made alkaline with 25 cc. of 10% sodium hydroxide and filtered. The filtrate was washed with benzene, acidified with dilute nitric acid, and extracted with ether. On concentrating the extract and adding hexane the product separated as an oil. By slowly acidifying a solution of the acid in dilute alkali, 11.4 g. (81.7% from the diazo ketone) of *o*-bromophenylacetic acid[13] was obtained as an odorless, pale yellow, crystalline powder, m. p. 103–105°. Treatment with Norit in an aqueous solution containing a very slight excess of sodium carbonate gave pure white acid, m. p. 103.5–105.5°, and on two crystallizations from benzene–hexane it formed clusters of jagged prisms, m. p. 105–106°.

The impure diazo ketone (6.2 g.) gave 3 g. of yellow acid, m. p. 98–102°. Crystallization failed to effect much purification, but treatment with Norit in an aqueous solution containing little excess soda and precipitation gave 1.72 g. of pure white powder, m. p. 103.5–105.5°. The total yield of satisfactory acid was 13.1 g., a 62.5% over-all yield from the acid chloride (prepared from *o*-bromobenzoic acid in 98% yield with thionyl chloride).

Acenaphthene and *o*-Bromophenylacetic Acid.—The condensation of 1.43 g. of the hydrocarbon with 2 g. of the acid in hydrogen fluoride (85 g.), conducted at room temperature for one and one-half hours, gave 3.05 g. of neutral, light yellow powder, m. p. 85–102°. Little separation was effected by crystallization as such or through the oxime, but crystallization as the picrate and dissociation of alumina afforded small amounts of a white powder, m. p. 128–129.5°, and of tiny white needles, m. p. 122–123°, from the less and more soluble fractions, respectively. Another portion processed through the trinitrobenzene derivatives gave light yellow prisms, m. p. 128–129.5°, and light yellow needles, m. p. 110.5–112.5°. Since none of these substances was obtained in practical quantity they were not characterized further.

1-Acetoacenaphthene was prepared in the pressure vessel as described by Fieser and Hershberg.[2b] The crude product from two 80-g. batches of commercial "95%" acenaphthene was collected on a Büchner funnel (cold room) and then ground in a mortar three times with water, the material each time being collected on a funnel and pressed well to force out as much oil as possible. Two similar washings were made with sodium carbonate solution, and after a final washing with water the product was dried partially by exposure to air and then fully dried by adding benzene and distilling. Distillation gave 143.4 g. of ketone mixture boiling largely at 181–183° (3 mm.), m. p. 80–95°, and there was about 10 g. of tarry residue. Crystallization at room temperature from 400 cc. of methanol and then from 750 cc. of this solvent[3] yielded 87.1 g. of the 1-isomer, m. p. 103–105°, and 5 g. of equally good material was obtained by working the second mother liquor; total yield 45% (calculated for pure acenaphthene).

1-Acenaphthylacetic Acid (VII). (a) **Arndt–Eistert Reaction.**—1-Acenaphthoic acid and its chloride were prepared according to Fieser and Cason[3] with closely agreeing results. Nitrosomethylurethan (24.3 cc.) in absolute ether (198 cc.) was dropped into 42 cc. of a solution prepared from 3 g. of sodium and 50 g. of glycol at 50°[14] and the distillate collected in a flask cooled in ice. After flushing the apparatus with ether the solution was diluted to about 275 cc. with absolute ether and a solution of 7.59 g. of 1-acenaphthoyl chloride (m. p. 108–110.5°) in absolute ether (87 cc.) and purified dioxane (44 cc.) was added during 50 minutes while stirring and cooling in ice. After stirring for two and one-quarter hours longer at room temperature, the precipitated light yellow **diazo ketone** was collected (4.01 g., m. p. 141–142° dec.) and the filtrate was concentrated to about 4 cc. and cooled, giving 3.24 g. of orange–yellow material, m. p. 137–141° (crude yield 93%). The combined product was taken up in 70 cc. of technical dioxane and the solution, filtered from a slight residue (0.1 g.), was added dropwise in one hour to a stirred suspension at 60–70° of 8.2 g. of silver oxide in 435 cc. of water containing 21.4 g. of sodium thiosulfate. After stirring for one and one-half hours longer 0.5 g. of Norit was added and the mixture was cooled and filtered and the filtrate acidified with dilute acetic acid (hydrochloric or nitric acid caused darkening of the precipitate). The precipitated 1-acenaphthylacetic acid (5.96 g.) softened at 150° and melted at 157–165°. Crystallization from methanol (15 cc.) gave pale yellow needles, m. p. 155.5–160°; yield 4.74 g. (63.5% from the acid chloride). After crystallization of the potassium salt from absolute alcohol the recovered acid melted at 158–159.5°, and repeated crystallization from benzene–hexane gave fine white needles, m. p. 163.5–164.4°.

Anal. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70. Found: C, 78.87; H, 5.46.

(b) **Willgerodt Reaction.**—When 1-acetoacenaphthene was submitted to the reaction under the conditions specified by Willgerodt and Merk[6] (five to six hours at 200–220°) the material was badly decomposed and little amide could be isolated. After a number of variations had been tried the best results were obtained as follows. A solution of 1 g. of sulfur in 10 g. of a solution of ammonium sulfide prepared by saturating concentrated ammonia solution with hydrogen sulfide was sealed in a tube with 2 g. of 1-acetoacenaphthene and 8 cc. of purified dioxane and the mixture was heated at 160° for twelve hours. The dark solid product (m. p. 185–205°, a few yellow plates present melted at 205°) was collected and refluxed for four hours with 50 cc. of 15% sodium hydroxide. Water (50 cc.) and Norit (0.25 g.) were added and the solution was filtered hot and treated with dilute hydrochloric acid until just weakly alkaline, when a small amount of sludge separated and could be removed by filtration. Acidification of the filtrate gave 1.37 g. of 1-acenaphthylacetic acid, m. p. 159–162°. A further quantity was recovered from the ammonium sulfide filtrate. After acidifying and collecting the coagulated sulfur the filtrate was concentrated and a little gummy solid

(13) Jackson and White, *Am. Chem. J.*, **2**, 316 (1880).

(14) Meerwein and Burneleit, *Ber.*, **61**, 1845 (1928).

obtained. Extraction of the combined gum and sulfur with bicarbonate solution gave 80 mg. of crude acid. The combined material on crystallization from dilute alcohol afforded 1.24 g. (57%) of fine, light orange needles, m. p. 163–165°. On recrystallization with liberal use of Norit the substance formed pure white needles, m. p. 167.6–168.2° (slight softening at 163°).

Anal. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70. Found: C, 79.06; H, 5.77.

In larger runs conducted in an autoclave the reaction mixture was charged into a 500-cc. round-bottomed flask connected by means of a hemispherical ground-glass joint (which effectively prevented freezing) to a spiral made from about 60 cm. of 1-mm. capillary tubing.[15] Nitrogen (at 500–1000 lb. (33–67 atm.) pressure) was admitted, and allowed to escape, very slowly. From 19.2 g. of 1-acetoacenaphthene, 96 g. of ammonium sulfide solution, 9.6 g. of sulfur and 77 cc. of dioxane, heated for eighteen hours at 175–180°, there resulted 6.8 g. (33%) of reddish-brown, semicrystalline amide. The oily filtrate was extracted with benzene and the aqueous layer on acidification and extraction of the precipitate as above gave 426 mg. (2.1%) of yellow acid, m. p. 159–160°. The benzene solution was evaporated and the residual oil refluxed for four hours with 300 cc. of 15% sodium hydroxide, giving, on acidification of the separated aqueous phase, 358 mg. (1.7%). The combined yield of crude acid and amide was thus 36.8%. For the complete hydrolysis of as much as 20 g. of the crude amide a refluxing period of six hours was required.

The unsaponified oil after washing and drying distilled at 160–163° (6 mm.), yielding 8.3 g. (46.7%) of **1-ethylacenaphthene** as a pale yellow oil which crystallized on cooling. This was redistilled and crystallized from methanol, giving colorless needles, m. p. 34.8–35.1° (not changed by recrystallization).

Anal. Calcd. for $C_{14}H_{14}$: C, 92.26; H, 7.74. Found: C, 92.21; H, 7.89.

The **picrate**, purified to constant m. p. by crystallization from absolute alcohol–hexane, formed brilliant red needles, m. p. 104.7–105.1°. The hydrocarbon could be extracted from the picrate with hexane, and after passing the solution through an alumina tower, the recovered hydrocarbon crystallized from methanol as needles, m. p. 33.5–34.5°. For the hydrocarbon and its picrate Cook, Haslewood and Robinson[7] give the melting points 30° and 102–102.5°.

In a run conducted as above except that the temperature was kept at 170° for eighteen hours, the yield of crude amide was 22% and of ethylacenaphthene 65%. With the same reaction time but at 188–190° the corresponding yields were 29 and 43%. On increasing the amount of ammonium sulfide solution (139 g.) and dioxane (120 cc.) and heating for eighteen hours at 163–164° the yield of amide dropped to 7.5% and ethylacenaphthene was obtained in 67.5% yield.

α-(*o*-Chlorobenzal)-1-acenaphthylacetic Acid (II, R = CO_2H; X = Cl).—1-Acenaphthylacetic acid was titrated in methanol to a phenolphthalein end-point with 0.5 *N* potassium hydroxide in methanol; the solvent was evaporated completely and the residue dried at 100° in vacuum. This salt (250 mg.) was refluxed with 162 mg. of freshly distilled *o*-chlorobenzaldehyde, 1 cc. of acetic anhydride and one drop of pyridine at a bath temperature of 180° for twenty-four hours. Water (75 cc.) and excess sodium bicarbonate were added and on refluxing for about two hours only a small amount of tar remained undissolved. After extracting this with benzene, acidification gave 289 mg. of acid, m. p. 175–200°. Crystallization from dilute acetic acid (Norit) gave 145 mg. of bright yellow needles, m. p. 214–216°, and 45 mg. of slightly lower m. p. (total yield 55%). After further crystallizations from dilute alcohol, dilute acetic acid or chloroform–hexane the acid melted constantly at 221.5–223.5° with slight previous softening.

Anal. Calcd. for $C_{21}H_{15}O_2Cl$: C, 75.33; H, 4.52. Found: C, 75.20; H, 4.49.

Following Hewett's procedure,[4] cyclization was attempted by fusing the acid (0.4 g.) with 85% potassium hydroxide (3 g.) at a bath temperature of 254° (cor.) but only small amounts of starting material could be recovered. At slightly lower temperatures the reaction product gave a strong Beilstein test and at slightly higher temperatures the bulk of the product was insoluble in alkali.

α-(*o*-Nitrobenzal)-1-acenaphthylacetic Acid (VIII).—The potassium salt from 24.9 g. of 1-acenaphthylacetic acid was heated with 21.7 g. of *o*-nitrobenzaldehyde and 250 cc. of acetic anhydride for three hours at a bath temperature of 125–130° and the mixture was poured into 1200 cc. of water and allowed to stand overnight. The orange-yellow product was precipitated twice as the potassium salt from aqueous potassium carbonate, the somewhat oily salt being washed each time on the filter with half-saturated potassium carbonate solution. The liberated acid without being dried was dissolved in acetic acid, and after Norit treatment the solution was concentrated to 250 cc. and allowed to cool, when 23.8 g. (59%) of yellow, crystalline product separated, m. p. 239–241°. Recrystallized from alcohol and from acetic acid, the acid formed shiny, pale yellow needles, m. p. 244.5–244.9°, dec. (black melt).

Anal. Calcd. for $C_{21}H_{15}O_4N$: N, 4.06; neut. equiv., 345. Found: N[16] (Kjeldahl), 4.17; neut. equiv., 346.

α-(*o*-Aminobenzal)-1-acenaphthylacetic Acid (IX).—Following Cassaday and Bogert,[17] a solution of 15.8 g. of the nitro acid in 120 cc. of water and 15 cc. of ammonia solution was added during five minutes to a boiling mixture of 80 g. of ferrous sulfate crystals, 261 cc. of water and 20.4 cc. of ammonia solution. While boiling, and with the addition of a little octyl alcohol to suppress frothing, 158 cc. of ammonia solution was added during twenty minutes followed by 41 cc. in the next fifty-five minutes. After cooling, Celite was added and the cake obtained on filtration was extracted six times with boiling water containing ammonia. After treatment of the combined solutions with Norit and Celite the still dark filtrate on acidification with dilute acetic acid (avoiding an excess) deposited the acid as a gum which soon changed to a yellow solid. For crystallization the acid was dissolved in alcohol and

(15) Grosse, THIS JOURNAL, **60**, 212 (1938).

(16) Microanalysis by Lyon Southworth.

(17) Cassaday and Bogert, THIS JOURNAL, **61**, 2463 (1939).

water was gradually added at the boiling point until a considerable quantity of well formed crystals had separated. The substance was thus obtained as brownish-yellow prismatic plates, m. p. 227–229°; yield 11.0 g. (76%).

Reduction proceeded less satisfactorily when a suspension of 2 g. of the nitro acid and 25 mg. of Adams catalyst in 33 cc. of alcohol was shaken with hydrogen. After eight hours 94% of the theoretical amount of hydrogen had been absorbed. After dilution with water the product was extracted with benzene and the filtered solution extracted with bicarbonate. Acidification with dilute acetic acid gave 963 mg. (53%) of amino acid, m. p. 224–226°. Recrystallization from alcohol–water as above yielded pale yellow prisms, m. p. 229–230.5°, and further crystallizations seemed to cause slight deterioration.

Anal.[16] Calcd. for $C_{21}H_{17}O_2N$: N (Kjeldahl), 4.44. Found: N, 4.41.

Concentration of the extracted benzene solution yielded 304 mg. (18%) of a colorless, neutral substance. After repeated crystallization from dioxane and acetic acid fine white needles were obtained, m. p. 236.4–238.4° dec. (black liquid). The substance seemed resistant to hydrolysis with acid or alkali; it was characterized only by analysis[16]: C, 83.82; H, 5.54; N (Dumas), 4.85.

In another experiment a trace of another neutral by-product, m. p. 278–279.5°, was also obtained (see below).

Methyl 7-Cholanthroate.—A solution of 8 g. of the amino acid in 200 cc. of purified dioxane was treated with 1.9 cc. of sulfuric acid in 100 cc. of dioxane and the voluminous yellow solid which precipitated was brought into solution by the addition of dioxane (300 cc.) and alcohol (500 cc.) and warming gently. After cooling to room temperature 4.8 cc. of isoamyl nitrite in 10 cc. of dioxane was added with stirring in ten minutes.[17,18] No temperature rise was observed, but the solution took on a dark red color and a test sample gave an intense red coloration with alkaline β-naphthol. After stirring for one hour a solution of 26 g. of sodium hypophosphite in 26 cc. of water was added all at once, followed by the Gattermann copper paste[19] prepared from 31 g. of copper sulfate crystals and 75% of the theoretical amount of zinc. Gas was evolved at once. The mixture was stirred in a bath at 50° for one hour, the coupling test being negative after fifteen minutes. Potassium carbonate solution was added to the point of alkalinity and about 1 liter of solvent was removed under vacuum. The gum separating was brought into solution by the addition of water, and after filtration from the copper the solution was poured into 200 cc. of water and 25 cc. of concentrated hydrochloric acid. The precipitated acid was collected, dried, dissolved in 325 cc. of purified dioxane and a sediment was removed by filtration. The very dark filtrate was cooled and treated with an ethereal solution of diazomethane from 23 cc. of nitrosomethylurethane, the large excess of reagent apparently being all consumed. Evaporation of the solvent left a brown powder insoluble in alkali. This was dissolved in benzene and the solution was filtered from 1.62 g. of gelatinous material, concentrated, and passed through a tower of alumina–Celite (1:1). The first filtrate was very black and eventually was discarded. The adsorbed material was eluted with benzene containing about 10% of methanol until the filtrate no longer showed appreciable color, and after evaporation of the solvent distillation at 1 mm. yielded 1.57 g. of thick, dark oil, which was taken up in benzene. The solution, filtered from a pale yellow residue (A, 64 mg.) and concentrated to a small volume, deposited clusters of dark needles, and on recrystallization from benzene methyl 7-cholanthroate was obtained as pale yellow needles, m. p. 156–158° (293 mg.). The mother liquors afforded 67 mg. of similar material; total yield 360 mg. (4.5%). On two recrystallizations from alcohol the substance formed golden-yellow needles, m. p. 159.0–159.2°, exhibiting a dull blue-green fluorescence in benzene.

Anal. Calcd. for $C_{22}H_{16}O_2$: C, 84.59; H, 5.16. Found: C, 84.54; H, 5.30.

Material eluted from the column using higher concentrations of alcohol gave a black oil on distillation and this left a yellowish residue (B, 66 mg.) on treatment with benzene; concentration of the solution gave only tars.

The total benzene-insoluble product (A and B, m. p. 270–275°), after repeated crystallization from acetic acid–water (Norit) afforded a small amount of almost colorless needles, m. p. 280.3–281.2°, dec. (black melt), which gave no depression when mixed with the high melting by-product of the catalytic reduction of the nitro acid VIII. The substance can be dissolved in boiling alkali but after precipitation does not redissolve. The composition appears to be about the same as that of the other unidentified by-product of the hydrogenation (found[16]: C, 84.15; H, 5.01; N (Dumas), 4.75).

7-Cholanthroic Acid (X).—The pure ester (207 mg.) was refluxed for one and one-half hours with 65 cc. of 10% alcoholic potassium hydroxide solution. Most of the solvent was removed under vacuum, the residue was diluted with 200 cc. of water and the filtered solution poured into 200 cc. of water containing 15 cc. of concentrated hydrochloric acid. The precipitated acid, collected after coagulation by heating, was obtained as a pale yellow powder, m. p. about 253–256° (195 mg.). The material seemed to deteriorate slightly in acetic acid or alcohol but could be crystallized satisfactorily from a large volume of benzene. Acid so purified when heated in a sealed capillary showed a fairly constant decomposition point of 258.5–261°, after incipient sublimation at 255°.

Anal. Calcd. for $C_{21}H_{14}O_2$: C, 84.55; H, 4.73. Found: C, 84.36; H, 4.78.

When a small sample was ground with basic copper carbonate and melted in an evacuated tube, a white sublimate appeared on the upper walls and was found to melt above 200°, indicating that the pure acid is not readily decarboxylated by this method. On heating 17 mg. of slightly impure acid in high vacuum (10^{-3} mm.) at 200° for nineteen hours, 14 mg. of acid, m. p. 255–259°, sublimed leaving a dark residue.

Cholanthrene.—Following a simplified procedure, 1 g. of the amino acid was diazotized as above with isoamyl nitrite and after shaking for only about two minutes Gattermann copper was added and decomposition was conducted in a bath at 50° for twenty-five minutes. The crude acid precipitated from carbonate solution was

(18) Rüggli and Staub, *Helv. Chim. Acta*, **20**, 37 (1937).
(19) Gattermann, *Ber.*, **23**, 1219 (1890).

ground with 25 mg. of basic copper carbonate and heated under vacuum in a bath which was eventually brought to a temperature of 300°. The dark distillate (294 mg.) was extracted three times with cold absolute alcohol and the undissolved material taken up in benzene. After treatment with Norit and concentration, 65 mg. (8.1%) of light brown crystals separated. Purification by adsorption of impurities on alumina gave a yellow crystalline powder, m. p. 167.5–168.5°, which gave no depression when mixed with known cholanthrene, m. p. 166.5–168.5°. The picrate agreed in m. p. and appearance with the specimen described by Cook, Haslewood and Robinson.[7]

Summary

1-Acetoacenaphthene was converted to 1-acenaphthylacetic acid via 1-acenaphthoic acid by the Arndt–Eistert reaction and, more conveniently, by the Willgerodt process of heating the ketone with yellow ammonium sulfide. The acetic acid was condensed successfully with both *o*-chloro and *o*-nitrobenzaldehyde, but only the second of the products could be utilized for effecting a phenanthrene ring closure. Although the Pschorr reaction proceeded very poorly, the 7-carboxy derivative of cholanthrene was isolated through the ester in quantity sufficient for an investigation of its possible biological actions.

The hydrogen fluoride acylation of acenaphthene with phenylacetic acid and *o*-bromophenylacetic acid does not provide a practical route to intermediates suitable for the synthesis of cholanthrenes.

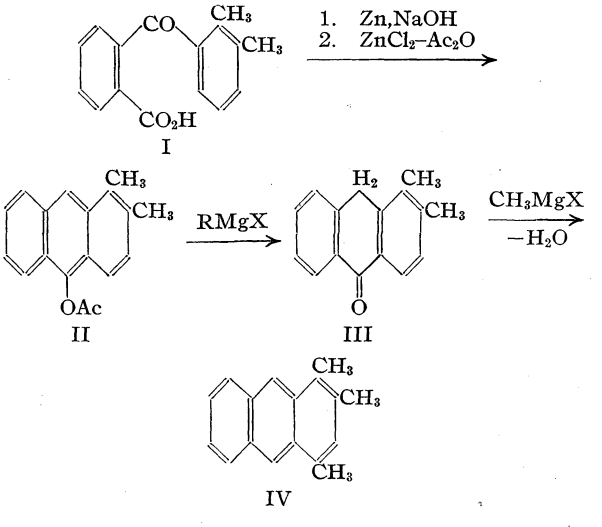
meso-Alkyl Anthracenes

BY LOUIS F. FIESER AND THOMAS G. WEBBER

In continuation of previous studies of model compounds structurally related to the more potently active carcinogens,[1] we sought to synthesize certain additional substituted 1,2-dialkyl anthracenes of types corresponding to known 1,2-benz derivatives of marked carcinogenic activity. The 1,2-dimethyl and 1,2-cyclopenteno derivatives of 5,10-aceanthrene were synthesized in earlier work[2] for comparison with cholanthrene, and the cyclopenteno compound was found by Shear (see ref. 1) to have definite if weak carcinogenic properties. It was hoped in the present work to obtain 1,2,10-trimethylanthracene and 1,2,9,10-tetramethylanthracene for comparison with 10-methyl-1,2-benzanthracene[3] and 9,10-dimethyl-1,2-benzanthracene,[4] respectively. The trimethyl compound was synthesized without difficulty, but the method tried for the preparation of the higher homolog proved unsatisfactory. Badger, Cook and Goulden[5] have recently reported an unsuccessful attempt to synthesize the same hydrocarbon by another method.

1,2,10-Trimethylanthracene was synthesized starting with the keto acid I[5] from *vic.*-bromo-*o*-xylene and phthalic acid. After reduction with zinc and alkali, cyclization with zinc chloride and acetic acid–anhydride[6] gave the anthranyl acetate (II), and on cleavage by the Grignard reagent the



anthranol isomerized readily to the anthrone. A methyl group was then easily introduced at the 10-position. As with anthracene and a number of its derivatives,[7] the yellow trimethyl compound IV forms a colorless dimer when exposed to sunlight in solution.

A projected synthesis of the desired tetramethyl

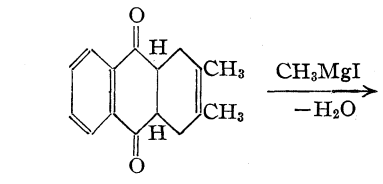
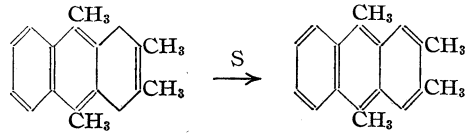
compound was tested first in a case requiring more readily available starting materials. 2,3-Dimethylbutadiene was added to α-naphthoquinone and the product (V)[8] treated with excess methylmagnesium iodide. The reaction proceeded well and a crystalline dihydroanthracene (VI) was obtained on dehydration of the crude diol. Dehydrogenation to VII was accomplished satisfactorily with the use of sulfur. The substance forms an amorphous dimer from which it can be regenerated in part by vacuum distillation.

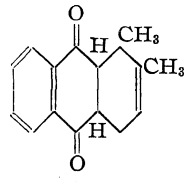


V



VI VII

3-Methylpentadiene-2,4 was then prepared according to Fisher and Chittenden[9] and found to add smoothly to α-naphthoquinone. The addition product VIII, however, behaved quite differently from the isomer in the Grignard reaction and no diol or hydrocarbon could be isolated after treatment with methylmagnesium chloride or iodide. Starting with 1,2-dimethylanthraquinone, Badger, Cook and Goulden[5] obtained a diol but found its dimethyl ether resistant to cleavage with sodium.



VIII

Experimental Part[10]

o-(2,3-Dimethylbenzoyl)-benzoic acid (I) was prepared from the Grignard reagent from 13 g. of *vic.*-bromo-*o*-xylene,[2] condensed with 30 g. of phthalic anhydride in ether–benzene. After hydrolysis and steam distillation the keto acid was precipitated from a steamed and filtered alkaline solution by pouring this into ice and hydrochloric acid. Crystallization from benzene–hexane gave 7 g. (32%) of colorless prisms, m. p. 129–131°, and after three further crystallizations the substance melted at 132–133° and remelted at 139.5–140.5°.

Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55. Found: C, 75.39; H, 5.71.

Badger, Cook and Goulden[5] used a smaller proportion of anhydride and obtained a much higher yield. They report the m. p. 126–127°.

o-(2,3-Dimethylbenzyl)-benzoic Acid.—The keto acid (3.5 g.) was refluxed in 50 cc. of 2 *N* sodium hydroxide with 3.5 g. of zinc dust for forty-seven hours, 45 cc. more alkali being added in three portions. The precipitated acid when crystallized from methanol afforded in two crops 3.1 g. (94%) of colorless prisms, m. p. 175–177°. Fully purified, the acid melted at 177.2–177.8°.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.91. Found: C, 79.80; H, 6.89.

The **lactone of o-(2,3-dimethyl-α-hydroxybenzyl)-benzoic acid** was isolated from the reaction mixtures resulting after shorter periods of heating by extraction of the acid with soda solution. The residual material crystallized from dilute alcohol as colorless prisms, m. p. 127–128°.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92. Found: C, 80.47; H, 6.07.

1,2-Dimethylanthranyl-10-acetate (II).—A solution of 7.3 g. of the above acid in 45 cc. of acetic acid and 30 cc. of acetic anhydride containing 0.5 g. of anhydrous zinc chloride was refluxed for one hour and water was then added cautiously to the point of saturation. On cooling, 6.5 g. (81%) of light yellow prisms of the acetate separated, m. p. 152–154°. After four recrystallizations from dilute acetic acid the substance melted at 158.1–158.7° and had a greenish yellow tinge.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10. Found: C, 81.46; H, 6.12.

1,2-Dimethyl-10-anthrone (III).—The solid anthranyl acetate (6.5 g.) was added to the Grignard reagent from 3.6 g. of magnesium and excess *n*-butyl bromide and after displacement of the ether with benzene refluxing was continued for one hour. After hydrolysis, two crystallizations from benzene afforded 3 g. (55%) of the anthrone, m. p. 169–170°. The further purified material formed colorless prisms, m. p. 170.3–171.3°. The properties of the substance and its behavior in the Grignard reaction indicate the ketonic structure; the tautomeric anthranol was not encountered.

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.45; H, 6.35. Found: C, 86.50; H, 6.48.

1,2,10-Trimethylanthracene.—A solution of 1.05 g. of the anthrone in 50 cc. of benzene was added to the reagent from 0.62 g. of magnesium and excess methyl bromide in ether and the mixture was refluxed for two hours before hydrolysis. The washed and dried organic layer was evaporated to dryness on the hot-plate to dehydrate the carbinol, and the residue was crystallized from hexane, giving 0.89 g. (77%) of the hydrocarbon as yellow needles, m. p. 88–90°. This was converted to the **picrate**, which crystallized from alcohol in minute dark brown needles, m. p. 138.5–139.5°. The regenerated hydrocarbon (alumina tower) was yellow and melted at 90.6–91.4°.

Anal. Calcd. for $C_{17}H_{16}$: C, 92.68; H, 7.32. Found: C, 92.60; H, 7.49.

(8) I. G. Farbenindustrie A.-G., British Patent 320,375 (1930).
(9) Fisher and Chittenden, *Ind. Eng. Chem.*, **22**, 869 (1930).
(10) All melting points are corrected.

The **trinitrobenzene derivative** formed scarlet needles, m. p. 169.6–170.2°, from alcohol.

On exposing an alcoholic solution of the hydrocarbon to the sunlight for three weeks prisms of the colorless **dimer** were deposited. Recrystallized from benzene–alcohol the substance melted at 222–226°.

Anal. Calcd. for $C_{34}H_{32}$: C, 92.68; H, 7.32. Found: C, 92.91; H, 7.28.

2,3-Dimethylbutadiene–α-Naphthoquinone (V).—A solution of 5 g. of α-naphthoquinone and 10 cc. of the diene in 20 cc. of alcohol was refluxed for three hours, and on cooling the addition product separated as fine, colorless needles. This material was collected, washed with alcohol, and dried in vacuum at 50°; m. p. 148.5–149.1°; yield, 7.25 g. (95%).

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71. Found: C, 79.88; H, 6.79.

2,3,9,10 - Tetramethyl - 1,4 - dihydroanthracene (VI).—A solution of 7.2 g. of V in 50 cc. of warm benzene was added to a stirred solution of the methylmagnesium iodide from 4.2 g. of magnesium in about 70 cc. of ether–benzene and stirring was continued at room temperature for three hours. After hydrolysis and removal of the solvent the oily diol was heated to 140° to effect dehydration. On adding a little alcohol to the dark residual oil the hydrocarbon crystallized, and when collected and washed with a small volume of cold alcohol was obtained in a nearly colorless condition suitable for dehydrogenation; m. p. 165–170°, yield 3.0 g. (42%). A sample was purified by passage in benzene solution through a tower of alumina and crystallization from benzene–hexane. It formed colorless needles, m. p. 175.3–176.3°; the solutions showed intense blue fluorescence in ultraviolet light.

Anal. Calcd. for $C_{19}H_{20}$: C, 91.47; H, 8.53. Found: C, 91.42; H, 8.70.

The hydrocarbon appears to undergo ready disproportionation or other change, for further crystallized samples had higher and broader melting ranges. The **picrate** crystallized in small, dark brown needles from benzene–hexane, m. p. 149.2–149.9°. The **trinitrobenzene derivative** was obtained from benzene as scarlet needles, m. p. 150.8–151.8°.

Anal.[11] Calcd. for $C_{18}H_{20}\cdot C_6H_3O_6N_3$: N, 9.35. Found: N, 9.25.

2,3,9,10-Tetramethylanthracene.—The dihydride VI (3 g.) was heated with 0.4 g. of sulfur to 325° in one-half hour, when the evolution of gas had ceased. After heating with a pinch of zinc dust for fifteen minutes the dark residue was extracted with benzene and the solution was put through a tower of alumina. The hydrocarbon crystallized from alcohol–benzene in brownish-yellow plates, m. p. 137–139°; yield 1.65 g. (55%). On using palladium charcoal for dehydrogenation the yield dropped to 25%. The further purified hydrocarbon formed dark yellow plates, m. p. 139.4–140.2°, from benzene–hexane.

Anal. Calcd. for $C_{18}H_{18}$: C, 92.26; H, 7.74. Found: C, 92.14; H, 7.71.

Exposure of solutions of the hydrocarbon to light resulted in the separation of an amorphous, brown **dimer** which melted at about 270°. On heating this at 2 mm. pressure in a bath at 210° the monomeric form distilled and was recovered in 63% yield.

The **picrate** formed dark brown needles from benzene–hexane, m. p. 177.3–178.3°. The **trinitrobenzene derivative** separated from benzene in scarlet needles, m. p. 188.8–189.3°.

Anal.[11] Calcd. for $C_{18}H_{18}.C_6H_3O_6N_3$: N, 9.39. Found: N, 9.69.

3-Methylpentadiene–α-Naphthoquinone (VIII).—The diene (b. p. 77–80°) was prepared by the method of Fisher and Chittenden[9] in over-all yield of 2.3%. The keto alcohol resulting from the condensation of acetaldehyde with methyl ethyl ketone could not be reduced satisfactorily to the 1,3-glycol either with Adams catalyst at a low pressure or with Raney nickel in the high pressure apparatus. With a combination of the two catalysts reduction was effected at 86° and 1500 lb. (100 atm.) pressure in 75% yield, based on starting material consumed.

A solution of 10 g. of α-naphthoquinone and 6.9 g. of the diene in 20 cc. of alcohol was refluxed for three hours, and after cooling to 0° 12.3 g. (81%) of the addition product separated as fine, colorless needles, m. p. 100.2–101.4°. Recrystallization from benzene–alcohol raised the m. p. to 101–101.7°.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71. Found: C, 79.91; H, 6.86.

The condensation of this substance with methylmagnesium iodide or chloride was tried under various conditions but in no case could a product having the properties of a diol be isolated. In the case of the iodide a reaction occurred and two ill-defined products of lower carbon content than the starting material were encountered. One of these, amounting to nearly half the weight of starting material, formed colorless needles melting in the range 140–154° (found: C, 78.35, 78.35; H, 7.87, 7.84). With methylmagnesium chloride the only product isolated was **1,2-dimethylanthraquinone,** which was readily obtained from the addition product by air oxidation in alcohol solution to which a trace of alkali had been added. Purified by chromatographic adsorption and crystallized from benzene–hexane, the quinone melted at 157.8–158.2° (Barnett and Carlisle,[12] m. p. 156°).

Summary

1,2,10-Trimethylanthracene, desired for comparison with the carcinogenically active 10-methyl-1,2-benzanthracene, was synthesized by known methods from *vic.*-bromo-*o*-xylene and phthalic anhydride. 2,3,9,10-Tetramethylanthracene was obtained readily from the addition product of α-naphthoquinone and 2,3-dimethylbutadiene by reaction with methyl Grignard reagent, dehydration of the resulting diol, and dehydrogenation. An attempted synthesis of the 1,2,9,10-isomer by this route failed at the stage of interaction with the Grignard reagent.

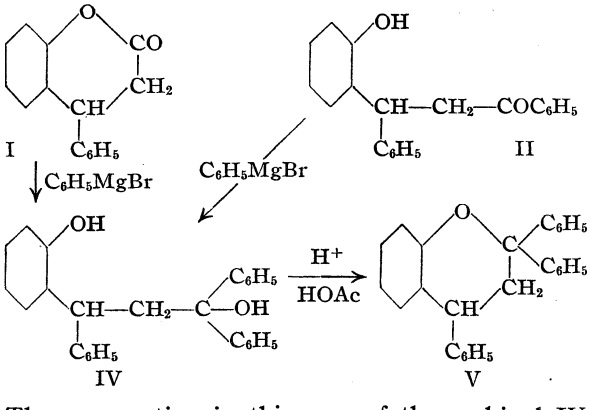
The Reaction of o-Hydroxybenzhydrylacetophenone and o-Hydroxybenzaldiacetophenone with Phenylmagnesium Bromide

BY T. A. GEISSMAN

The reactions of 4-phenyldihydrocoumarin (I) and ω-(o-hydroxybenzhydryl)-acetophenone (II) with phenylmagnesium bromide have been studied, originally in an attempt to correlate the results with the question of the mode of reaction of Grignard reagents with lactones of the dihydrocoumarin type.[1] The reaction between alkylmagnesium halides and a substance which may be either a chromanol or the corresponding hydroxyketone was first carried out by John and Schmeil.[1a] The choice of the hydroxyketone (II) used in the present study was based upon Löwenbein's[2] statement that the compound possesses neither phenolic nor ketonic properties and thus has the structure of the chromanol (III).

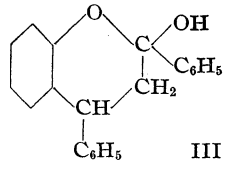
The present work has shown, however, that the properties of the compound are in agreement with its formulation as the hydroxyketone (II), a result which invalidated the original purpose of the study. The so-called chromanol is readily soluble in methanolic potassium hydroxide and forms a semicarbazone, thus showing both phenolic and ketonic characteristics.

The product of the reaction of both the dihydrocoumarin (I) and the hydroxyketone (II) was 1,1,3-triphenyl-3-(o-hydroxyphenyl)-propanol-1 (IV). The latter compound was readily dehydrated to 2,2,4-triphenylchromane (V).



The preparation in this way of the carbinol IV and chromane V constitutes, in the light of previous work[1] on the reaction between dihydrocoumarins and Grignard reagents, a proof of their structures. Consequently it became of interest to examine a report by Gomm and Hill[3] who claimed to have prepared these compounds by the reaction of phenylmagnesium bromide with o-hydroxybenzaldiacetophenone (VI). The products of this reaction have properties different from those of IV and V prepared as described above, and so the reaction of o-hydroxybenzaldiacetophenone with phenylmagnesium bromide has been reinvestigated in an attempt to elucidate the structures of the products obtained

When o-hydroxybenzaldiacetophenone is treated with phenylmagnesium bromide in boiling benzene and the reaction mixture decomposed with iced ammonium chloride, the product is an uncrystallizable oil, probably the glycol VII. This oil on treatment with a trace of sulfuric acid in acetic acid solution yields 2,2-diphenyl-4-benzhydrylidenemethylchromane (VIII). The structure of VIII was proved by its synthesis from methyl dihydrocoumarin-4-acetate (IX), the first product of the reaction between this ester and phenylmagnesium bromide being again an uncrystallizable oil, probably VII, which was converted smoothly to VIII by dehydration. Gomm and Hill obtained VIII (to which they assigned the structure of V) as the direct product of the reaction between VI and the Grignard reagent, a result which was undoubtedly due to the fact that they decomposed the reaction mixture with, and steam-distilled from, dilute acid dehydration of the glycol (VII) occurring during these operations.



When the reaction between o-hydroxybenzaldiacetophenone and phenylmagnesium bromide was carried out in cold ether solution the product was a crystalline compound to which has been assigned the structure (X) (it is this compound to which

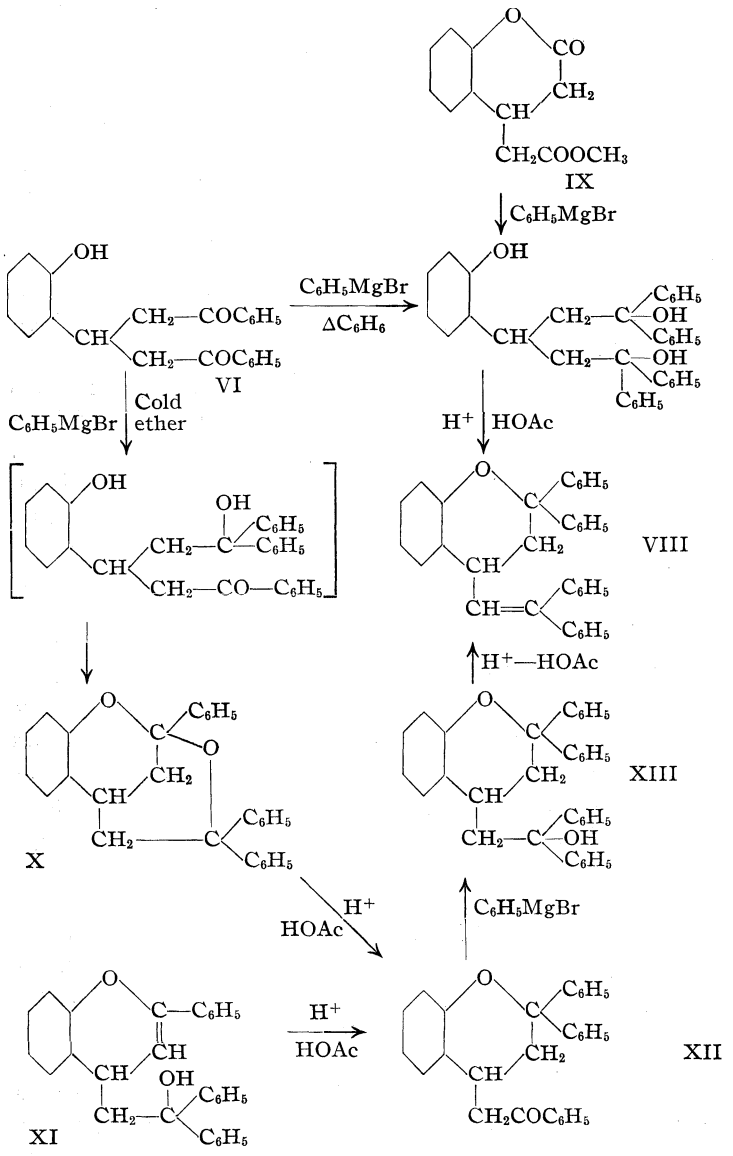
(2) Löwenbein, *Ber.*, **57**, 1517 (1924).

(3) Gomm and Hill, *J. Chem. Soc.*, 1118 (1935).

Gomm and Hill assigned the structure of IV), on the basis of the following evidence. The compound does not react with carbonyl reagents in neutral or basic solution and is recovered unchanged after treatment with phenylmagnesium bromide in ether. It is isomeric with 1,1-diphenyl-2-(4-flavenyl)-ethanol-1 (XI), prepared



by the addition of phenylmagnesium bromide to 4-phenacylflavene, and upon treatment with a trace of acid in acetic acid solution both X and XI are converted to the same (isomeric) compound (XII). Structures X and XI contain groupings which are known to be unstable in acid media, and it is probable that the course of the isomerization involves attack upon these centers leading by ring-opening and subsequent closure to XII, which contains a chromane ring system and would be stable under the conditions of the reaction. The structure of XII was established by the facts that it formed a 2,4-dinitrophenylhydrazone and upon treatment with phenylmagnesium bromide was converted into a crystalline carbinol (XIII). The carbinol XIII readily underwent dehydration to yield the chromane VIII, the structure of which has been proved by its preparation as described above. The dinitrophenylhydrazone of XII can be formed directly from X or XI by treatment of these compounds with 2,4-dinitrophenylhydrazine in boiling glacial acetic acid solution.

Tricyclic structures analogous to that proposed for X have been suggested for certain chromane derivatives by Boehme and Themlitz.[4] The reactions discussed above are shown on the accompanying chart. It is probable that compound X (as the tricyclic acetal) is not produced directly, since the product obtained after careful decomposition of the reaction mixture with iced ammonium chloride is an oil which crystallizes only slowly from such solvents as ligroin or alcohol, even when seeded with crystalline material, but which rapidly deposits the compound X from glacial acetic acid solution. The direct product of the reaction is thus probably a carbinol (shown in brackets) which under the mild dehydrating action of the acetic acid is cyclized to X.

The reaction of phenylmagnesium bromide with *o*-hydroxybenzaldiacetophenone is thus seen to involve the addition of either one or two moles of the reagent to the diketone, depending upon experimental conditions, and is not a cleavage reaction as reported by Gomm and Hill.

Experimental

ω-(*o*-Hydroxybenzhydryl)-acetophenone (II).—This was prepared from *o*-hydroxybenzalacetophenone and phenyl-

(4) Boehme and Themlitz, *Arch. Pharm.*, **272**, 406 (1934).

magnesium bromide according to the directions of Löwenbein.[2] The material melted at 167–167.5° (reported, 166°). The pyrilium ferrichloride derived from it[2] melted at 167° (reported, 168°).

Semicarbazone of II.—A solution of 0.5 g. of semicarbazide hydrochloride and 1.5 g. of sodium acetate in a little water was added to a solution of 0.5 g. of the hydroxyketone (II) in 10 cc. of alcohol. The solution was heated to boiling and allowed to stand overnight. The following day water was added to cloudiness at the boiling point and the solution digested at this temperature for fifteen minutes. On cooling white prisms separated. Recrystallized from dilute alcohol the product melted at 177–178°.

Anal. Calcd. for $C_{22}H_{21}O_2N_3$: N, 11.70. Found: N, 11.57.

4-Phenyldihydrocoumarin (I).—The procedure of Liebermann and Hartmann[5] was followed. The compound was recrystallized from dilute alcohol, stout needles, m. p. 82–84° (reported, 82°).

1,1,3-Triphenyl-3-(*o*-hydroxyphenyl)-propanol-1 (IV).—(a) **From (II).**—To the Grignard reagent prepared from 6.3 g. of bromobenzene and 0.97 g. of magnesium in 40 cc. of dry ether was added 3.0 g. of the (solid) hydroxy ketone (II). The resulting solution was refluxed for thirty minutes, decomposed with iced ammonium chloride solution and the solvents removed by steam-distillation. The oily residue was extracted with ether and upon removal of the ether was obtained as a viscous oil which could not be induced to crystallize.

In a second experiment using 5.0 g. of the chromanol and equivalent amounts of the other reagents, the oil crystallized on seeding with some of the material obtained as described in (b) and yielded 4.3 g. of crystalline product after recrystallization from ligroin (b. p. 75–135°); m. p. 109–110°. Recrystallized from benzene–petroleum ether the material appeared as transparent colorless prisms containing solvent and melting indefinitely at around 85° with loss of solvent. Dried at 80° (20 mm.) or recrystallized from ligroin the compound melted at 112–113°.

(b) **From (I).**—A solution of 2.25 g. of 4-phenyldihydrocoumarin in 10 cc. of dry benzene was added to a solution of phenylmagnesium bromide prepared from 6.50 g. of bromobenzene and 1.00 g. of magnesium in 50 cc. of dry ether. The solution was refluxed for thirty minutes, decomposed with iced ammonium chloride solution and steam-distilled. The oily residue was removed with ether and after removal of the solvent was obtained as a pale yellow oil. This material could not be induced to crystallize when first obtained and 1.0 g. of it was removed for dehydration to the chromane. The remainder crystallized upon standing in ether–petroleum ether and yielded 1.5 g. of white prisms, m. p. 106–108°. Recrystallized from ligroin (b. p. 75–135°), it melted at 111–112°, showed no depression when mixed with a sample of the material obtained in (a), and caused rapid crystallization of the oil obtained in (a) when used as seed.

The compound is difficultly soluble in dilute aqueous alkali, readily soluble in methanolic potassium hydroxide, gives no color with ferric chloride and a red-orange color with concentrated sulfuric acid.

(5) Liebermann and Hartmann, *Ber.*, **24**, 2586 (1891).

Anal. Calcd. for $C_{27}H_{24}O_2$: C, 85.22; H, 6.37. Found: C, 85.20, 85.40; H, 6.54, 6.53.

2,2,4-Triphenylchromane (V).—To a hot solution of 0.50 g. of the crystalline carbinol (IV) in 5 cc. of glacial acetic acid was added two drops of concentrated sulfuric acid. Upon cooling and scratching the walls of the flask the product crystallized. There was obtained 0.47 g. of white prisms, m. p. 162–163°.

The chromane was also obtained by a similar treatment of the oily product first obtained (above, part a) as the product of the reaction between the hydroxyketone (II) and phenylmagnesium bromide. From 1.0 g. of the oily carbinol was obtained 0.9 g. of V, m. p. 161–162°, a result which indicates that the reluctance of the oil to crystallize cannot be laid to the presence of significant amounts of impurities.

The chromane gives no immediate color with concentrated sulfuric acid, but on standing a yellow color develops which gradually turns reddish. It is insoluble in methanolic potassium hydroxide and does not absorb bromine in carbon tetrachloride solution.

Anal. Calcd. for $C_{27}H_{22}O$: C, 89.45; H, 6.13. Found: C, 89.27; H, 6.16.

The Reaction between *o*-Hydroxybenzaldiacetophenone and Phenylmagnesium Bromide.—(a) In Ether: Compound (X).—A solution of phenylmagnesium bromide prepared from 57.1 g. of bromobenzene and 7.2 g. of magnesium in 150 cc. of ether was added to a well-cooled (5–10°) suspension of 35.4 g. of *o*-hydroxybenzaldiacetophenone in 150 cc. of dry ether. The initial reaction resulted in the formation of a heavy white precipitate which upon the addition of more of the reagent became semi-solid and finally formed a viscous liquid phase insoluble in the ether solution. The mixture was stirred for six hours at 5°, allowed to stand overnight and decomposed with iced ammonium chloride. After the solvents and diphenyl were removed by steam distillation, the product was isolated by taking up the residue from the steam-distillation in ether, drying the solution and evaporating the solvent. The product, a viscous oil, was dissolved in an equal volume of alcohol and allowed to stand overnight. The 3.5 g. of material which crystallized was unchanged starting material. The alcohol was removed in a stream of dry air and a further amount (3.0 g.) of starting material separated. This was removed, after dilution of the residual oil with ligroin, by filtration. The ligroin solution deposited no crystalline material, even on seeding with a sample of the expected product (obtained in a previous run). The ligroin was removed and the oil dissolved in glacial acetic acid. Crystallization began immediately and on standing a total of 10.9 g. of crystalline material separated.

Recrystallized from *n*-butanol, the product formed hard, colorless prisms, m. p. 185–186°.

Anal. Calcd. for $C_{29}H_{24}O_2$: C, 86.10; H, 6.00. Found: C, 86.39; H, 6.22.

The compound is insoluble in 10% methanolic potassium hydroxide; it instantly decolorizes bromine in chloroform solution with hydrobromic acid evolution, and reacts with bromine in acetic acid in the cold. It did not react with semicarbazide in dilute propanol solution, nor with phenylmagnesium bromide in ether solution.

The acetic acid mother liquor from the crystallization of the 185° compound was heated to boiling and several drops of sulfuric acid added. Formation of a crystalline precipitate quickly began and on cooling there was obtained 12.0 g. of compound VIII, described below (part b).

(b) **In Ether–Benzene: Compound (VIII).**—To a solution of phenylmagnesium bromide prepared from 27.5 g. of bromobenzene and 4.1 g. of magnesium in 150 cc. of ether was added a solution of 10.0 g. of *o*-hydroxybenzaldiacetophenone in 100 cc. of dry benzene. The solution was refluxed for two and one-half hours, decomposed with iced ammonium chloride solution and, after steam distillation, the product was removed with ether. Removal of the ether left 15.5 g. of a sirupy oil which could not be crystallized.

The oily material was soluble in alcoholic alkali (its solution in alcohol remained clear upon the addition of dilute alkali, but became cloudy when water was added), absorbed bromine in carbon tetrachloride solution and gave a deep red color with sulfuric acid.

When to a solution of the oily product in hot glacial acetic acid was added a trace of concentrated sulfuric acid, a crystalline precipitate formed rapidly. The material so obtained (VIII) formed soft, white needles from acetic acid, m. p. 219–220°.[6]

Anal. Calcd. for $C_{35}H_{28}O$: C, 90.48; H, 6.09. Found: C, 90.43; H, 6.24.

The compound is insoluble in 10% methanolic potassium hydroxide and is unattacked by bromine in chloroform or acetic acid solution. In contrast to its extremely difficult solubility in acetic acid, ether, alcohols and even acetic anhydride, it is readily soluble in warm benzene.

4-Phenacylflavene.—This was prepared from *o*-hydroxybenzaldiacetophenone according to the directions of Hill.[7] It was found necessary to buffer the ordinary glacial acetic acid by the addition of a small amount of sodium acetate in order to prevent the formation of large amounts of 4-phenacylideneflavene,[8] a colored impurity difficult to remove. The product formed soft, white needles, m. p. 95–96° (reported,[7] 96°).

1,1-Diphenyl-2-(4-flavenyl)-ethanol-1 (XI).—This was prepared in good yield according to the directions of Gomm and Hill.[3] The compound forms soft, white needles from *n*-butanol, m. p. 193–193.5° (reported[3] 194°).

Anal. Calcd. for $C_{29}H_{24}O_2$: C, 86.10; H, 6.00. Found: C, 86.09; H, 6.20.

The compound is insoluble in 10% methanolic potassium hydroxide and was recovered unchanged when treated with 2,4-dinitrophenylhydrazine in propyl alcohol. It decolorizes bromine in chloroform or acetic acid solution with the evolution of hydrobromic acid. A mixture of the m. p. 193° compound and compound X, m. p. 185–186°, melted at 165–170°.

4-Phenacyl-2,2-diphenylchromane (XII).—(a) **From Compound (X).**—To a solution of 1.0 g. of X, m. p. 185–186°, in 15 cc. of glacial acetic acid was added two drops of concentrated sulfuric acid. The solution was boiled for a minute, diluted slightly and cooled. The product crystallized as colorless needles weighing 0.82 g., m. p. 115–116°. Crystallized from ligroin (b. p. 75–135°) it separated as crisp white needles, m. p. 115–116°.

Anal. Calcd. for $C_{29}H_{24}O_2$: C, 86.10; H, 6.00. Found: C, 85.73; H, 6.02.

(b) **From Compound XI.**—Treatment of compound XI in the manner described in (a) resulted in the formation of the same substance, m. p. 115–116° (mixed m. p. 115–116°), as that obtained from X.

Anal. Calcd. for $C_{29}H_{24}O_2$: C, 86.10; H, 6.00. Found: C, 85.90; H, 6.04.

The compound (XII, m. p. 115–116°) is insoluble in 10% methanolic potassium hydroxide and does not react in the cold with bromine in chloroform or acetic acid; on warming with bromine in either solvent reaction occurs with evolution of hydrobromic acid.

2,4-Dinitrophenylhydrazone from X, XI, and XII.—To a solution of 0.5 g. of 2,4-dinitrophenylhydrazine in 10 cc. of glacial acetic acid was added 0.5 g. of (XII). The deep red solution was refluxed gently for five minutes; crystallization began while the solution was still boiling. On cooling there was obtained 0.66 g. of orange-red crystals which on recrystallization from chloroform–petroleum ether formed bright red-orange leaflets, m. p. 243–244° dec.

The same compound was formed when X (m. p. 185–186°) or XI (m. p. 193°) was treated with 2,4-dinitrophenylhydrazine in boiling glacial acetic acid.

Anal. Calcd. for $C_{35}H_{28}O_5N_4$: C, 71.90; H, 4.83; N, 9.50. Found: C, 71.46; H, 4.73; N, 9.51.

1,1 - Diphenyl - 2 - (2,2 - diphenyl - 4 - chromanyl)-ethanol-1 (XIII).—A solution of 2.0 g. of XII in a mixture of ether and benzene was added to an excess of phenylmagnesium bromide in ether. After one hour of refluxing the solution was decomposed with iced ammonium chloride solution and steam-distilled. The product was a viscous oil which crystallized slowly from ether–petroleum ether to form colorless prisms, m. p. 148–149°. Recrystallized from benzene–petroleum ether the compound formed colorless prisms, m. p. 149–149.5°.

Anal. Calcd. for $C_{35}H_{30}O_2$: C, 87.07; H, 6.29. Found: C, 87.06; H, 6.35.

The substance is insoluble in 10% methanolic potassium hydroxide and does not decolorize bromine in acetic acid solution.

Dehydration of XIII.—To a solution of 0.20 g. of the carbinol (XIII) in 5 cc. of warm glacial acetic acid was added a trace of concentrated sulfuric acid. Crystallization began immediately. On cooling there was obtained 0.18 g. of soft white needles of compound VIII, m. p. 219–220°.

Methyl Dihydrocoumarin-4-acetate (XII).—Dihydrocoumarin-4-acetic acid was prepared by hydrolysis of the addition product of coumarin and cyanoacetamide, according to the directions of Seshadri.[9] The acid was esterified with methanol and sulfuric acid in the usual way. The ester is a colorless, viscous oil, b. p. 208–210° (20 mm.); $n^{22}D$ 1.5369.

(6) In their experiment in which the Grignard reaction was run as just described, Gomm and Hill[3] decomposed the reaction mixture with dilute acid and obtained as the direct product a crystalline compound, m. p. 216–217°.

(7) Hill, *J. Chem. Soc.*, 1255 (1934).

(8) Feuerstein and Kostanecki, *Ber.*, **31**, 710 (1898).

(9) Seshadri, *J. Chem. Soc.*, 166 (1928).

Anal.[10] Calcd. for $C_{12}H_{12}O_4$: C, 65.42; H, 5.50. Found: C, 64.87, 65.10; H, 5.82, 5.91.

Reaction of Phenylmagnesium Bromide with Methyl Dihydrocoumarin-4-acetate.—A solution of 2.1 g. of the redistilled ester in 20 cc. of dry ether was added to an excess of phenylmagnesium bromide in ether. A vigorous reaction occurred with the formation of a white precipitate which quickly dissolved. The solution was refluxed for thirty minutes and decomposed with ice–ammonium chloride solution. The product, after steam distillation and recovery with ether, was a viscous oil which could not be induced to crystallize.

The addition of a trace of sulfuric acid to a solution of the oil in acetic acid transformed it quickly into a white crystalline material. Recrystallized from acetic anhydride this product formed soft white needles, m. p. 216–218°. Mixed with a sample of VIII, m. p. 218–219°, the melting point was 216–218°.

(10) Analysis by Dr. J. Haagen-Smit, California Institute of Technology, Pasadena, Calif.

Summary

1. It has been shown that the compounds produced by the reaction of phenylmagnesium bromide with *o*-hydroxybenzaldiacetophenone do not have the structures proposed for them by Gomm and Hill.[3]

2. The structure of one of these compounds has been established by a different method of synthesis, and a structure for the other proposed on the basis of its properties and its relationship to compounds of known structure.

Chlorides and Hydrochlorides from 1-Hexyne[1]

BY G. F. HENNION AND CHARLES E. WELSH

Introduction

When 1-hexyne is chlorinated in various oxygen-containing media a complex mixture of products results, some of which contain oxygen as well as chlorine.[2] Various chlorine derivatives of 1-hexyne are thus obtained together and may be separated by fractional distillation. It was thought advisable to prepare these separately, by chlorination in inert solvents, in order to obtain pure substances for the determination of reliable physical data. It was desired also to prepare the mono and dihydrochlorides of 1-hexyne for comparison with the chlorides. During this investigation certain observations were made which may be of interest, and hence are recorded here.

Chlorination of 1-hexyne in either carbon tetrachloride or *n*-heptane containing a small amount of antimony pentachloride gave a mixture of *trans*-1,2-dichloro-1-hexene and 1,1,2,2-tetrachlorohexane only. When the antimony pentachloride was omitted the product was much less tractable and boiled over a wide range.

Direct addition of hydrogen chloride to 1-hexyne, with or without a solvent, was unsuccessful in the absence of a catalyst. Numerous metal chlorides were studied for catalytic activity. Of these bismuth chloride appeared to be best and with its use hydrogen chloride added readily to 1-hexyne to yield both 2-chloro-1-hexene and 2,2-dichlorohexane. By heating with potassium hydroxide in propyl alcohol the latter product could be reverted to the former.

Chlorination of 2-chloro-1-hexene in carbon tetrachloride containing antimony pentachloride was of particular interest because the reaction did not lead to 1,2,2-trichlorohexane, as anticipated. Instead a mixture of *cis*-1,2-dichloro-1-hexene and 1,1,2,2-tetrachlorohexane was obtained. Attempts to prepare 1,2,2-trichlorohexane by the addition of hydrogen chloride to both *cis*- and *trans*-1,2-dichloro-1-hexene likewise were unsuccessful. No reaction was observed in either case, even when bismuth chloride was present.

Physical data for the compounds prepared are given in Table I.

Experimental

Chlorination of 1-Hexyne.—A solution of 41 g. (0.5 mole) of 1-hexyne in 200 ml. of carbon tetrachloride was placed in a one liter, three-necked flask equipped with an efficient stirrer, a reflux condenser, and a chlorine inlet tube. To the solution was added slowly, with stirring, 50 ml. of carbon tetrachloride containing 1.5 ml. of antimony pentachloride. Chlorine was then passed over the solution in a fairly rapid stream, at a temperature of 45 ± 5°, until 35.5 g. (0.5 mole) was absorbed. The solution was washed with water, dilute sodium carbonate solution, again with water, dried over calcium chloride, and fractionally distilled: yield, 15 g. (19.6%) of *trans*-1,2-dichloro-1-hexene and 39.3 g. (30.6%) of 1,1,2,2-tetrachlorohexane.

Addition of Hydrogen Chloride to 1-Hexyne.—A solution of 82 g. (1.0 mole) of 1-hexyne in 350 ml. of benzene was placed in a one-liter, three-necked flask equipped with an efficient stirrer reflux condenser, and a hydrogen chloride inlet tube. To the solution was added 3 g. of bismuth chloride. Dry hydrogen chloride gas was then bubbled beneath the surface of the liquid, at a temperature of 80–85°, until no more was absorbed. The increase in weight during the addition of hydrogen chloride was 37 g. The solution was then washed twice with water, with dilute sodium carbonate solution, again with water, dried over calcium chloride, and fractionally distilled: yield, 24 g. (20%) of 2-chloro-1-hexene and 62 g. (40%) of 2,2-dichlorohexane.

Preparation of 2-Chloro-1-hexene by Desaturation.—A solution of 78 g. (0.5 mole) of 2,2-dichlorohexane in 200 ml. of *n*-propyl alcohol was placed in a 500-ml. three-necked flask equipped with an efficient stirrer, and a reflux condenser. The solution was heated to 95° and a slight excess of solid potassium hydroxide added. After heating for five hours the reflux condenser was replaced with a short Vigreux column and the contents of the flask distilled to dryness. The distillate was washed three times with water, the organic layer separated and dried over anhydrous magnesium sulfate: yield, 35 g. (60.5%) of 2-chloro-1-hexene.

Addition of Chlorine to 2-Chloro-1-hexene.—The same procedure was followed as in the chlorination of 1-hexyne, except that the temperature was maintained at 35–40°: yield, 20.3 g. (26.7%) of *cis*-1,2-dichloro-1-hexene and 28.5 g. (25.4%) of 1,1,2,2-tetrachlorohexane.

Summary

Chlorination of 1-hexyne in inert solvents in the presence of antimony pentachloride gives *trans*-1,2-dichloro-1-hexene and 1,1,2,2-tetrachlorohexane as the sole products.

Bismuth chloride is an effective catalyst for the addition of hydrogen chloride to 1-hexyne.

The reaction of chlorine with 2-chloro-1-hexene in the presence of antimony pentachloride leads to *cis*-1,2-dichloro-1-hexene and 1,1,2,2-tetrachlorohexane.

Hydrogen chloride could not be added to either *cis*- or *trans*-1,2-dichloro-1-hexene.

Chlorination of the Acetylenic Alcohols Derived from Acetone[1]

BY G. F. HENNION AND G. M. WOLF

Introduction

In general, chlorination of acetylenes in oxygen-containing solvents gives mixtures of chlorinated compounds.[2] Continuing these studies the action of chlorine on two acetylenic alcohols has been investigated. Dimethylethynylcarbinol (I) and 2,5-dimethyl-3-hexyne-2,5-diol (II) were selected for this work because they are easily obtainable in large quantity.[3] Carbon tetrachloride, methanol, and water were used separately as solvents. Methanol and water function also as reagents in the chlorination reactions, thus affording products not obtainable when carbon tetrachloride is used.

Chlorine added directly to (I) in carbon tetra-

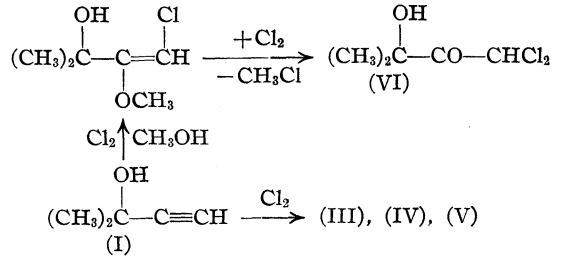
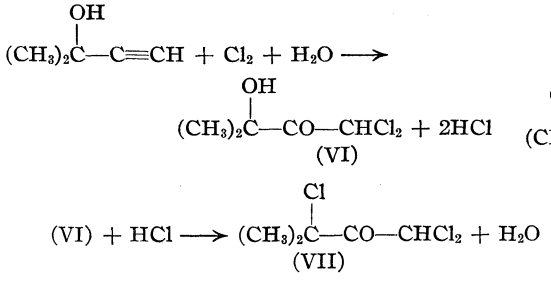
(IV)

chloride to yield only *trans*-1,2-dichloro-3-methyl-1-butene-3-ol (III) and 1,1,-2,2-tetrachloro-3-methyl-3-butanol (IV). A methanol solution of (I) reacted at 25–30° to give (III), (IV), *cis*-1,2-dichloro-3-methyl-1-butene-3-ol (V) and 1,1-dichloro-3-methyl-3-hydroxy-2-butanone (VI). These products may be explained according to the following mechanism, based on previous work.[2]

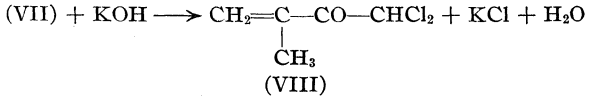


When the reaction in methanol was carried out at 60–65°, (V) was eliminated and the yield of (IV) was increased.

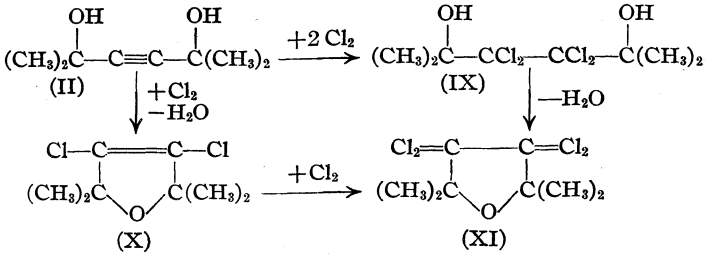
Chlorination of (I) in aqueous solution gave (V) and considerable quantities of 1,1,3-trichloro-3-methyl-2-butanone (VII). No doubt (VII) was formed by reaction of hydrogen chloride with the tertiary hydroxyl group of (VI).



Attempts to revert (VII) to (VI) by treatment with potassium hydroxide resulted in desaturation and gave 1,1-dichloro-3-methyl-3-butene-2-one (VIII).

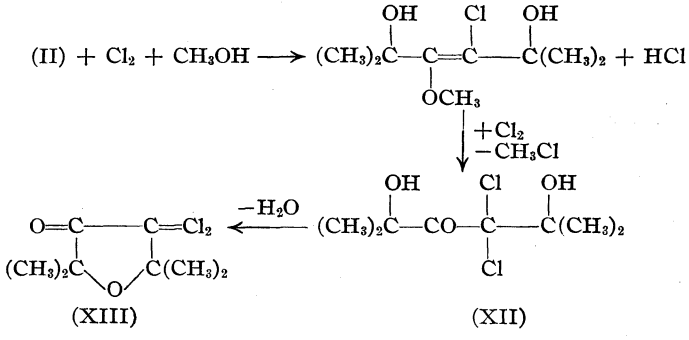


Chlorination of the acetylenic glycol (II) invariably was accompanied by considerable cyclodehydration and thus gave rise to furan derivatives as well as direct addition products. In carbon tetrachloride solution (II) gave (IX), (X) and (XI).



These results are in accord with those of Kruglov,[4] who obtained a 30% yield of 2,5-dimethyl-3,4-dibromo-3-hexenediol and nearly a 70% yield of 2,2,5,5-tetramethyl-3,4-dibromodihydrofuran by the action of bromine on a chloroform solution of (II).

Chlorination of (II) in methanol solution also gave (XI). In addition small amounts of 2,5-dimethyl-2,5-dihydroxy-3,3-dichloro-4-hexanone (XII) were obtained as well as considerable quantities of 2,2,5,5-tetramethyl-3,3-dichlorotetrahydro-4-furanone (XIII). There was evidence also for small amounts of a methoxyl-containing product, b. p. 47–49° at 6 mm., not identified for lack of sufficient material.



Aqueous solutions of (II) absorbed chlorine readily and gave preponderantly (XIII) and low yields of its precursor (XII).

Yield data for the various experiments are given in Tables I and II. Physical constants and analytical data are given in Table III. Parachor values were determined to establish structures for the products. Practically all of the compounds enumerated are unstable and darken upon standing. The dichloroketones are

the least stable and turn almost black after several weeks.

Experimental

Reagents.—Dimethylethynylcarbinol (I) and 2,5-dimethyl-3-hexyne-2,5-diol (II) were prepared as previously described.[2] Further quantities of (II) were obtained by the method of Macullum.[5]

Chlorination of (I) in Methanol.—Into a 1-liter 3-necked flask equipped with a mechanical stirrer, reflux condenser and a gas inlet tube were introduced 500 ml. of anhydrous methanol and 84 g. (1 mole) of (I). A moderately rapid stream of chlorine was introduced below the surface of the agitated solution. The temperature was held at 25–30°, by occasional cooling, for seven hours, after which time the solution acquired a greenish-yellow color. Methanol was removed by distillation through a helix-packed total-condensation, partial take-off column. The residue separated into two layers. The upper layer was an aqueous solution of hydrogen chloride. The lower layer (165 g.) was fractionally distilled, *in vacuo*, and successive small fractions collected in 15-ml. vials. Fractions were recombined on the basis of boiling range and refractive index and refractionated.

Chlorination of (I) in Water.—After chlorination as described above the reaction mixture separated into two layers. The organic material was removed, washed with water, twice with 10% sodium bicarbonate solution, again with water, and dried over calcium chloride. Fractional distillation at 6 mm. gave (V) and (VII).

Haloform Reaction with (VI).—Ten grams of (VI) and 20 g. of bleaching powder were mixed with 100 ml. of distilled water, refluxed for thirty minutes and steam distilled. The distillate contained 3 g. of chloroform, b. p. 59–60°; d^{20} 1.485; $n^{20}D$ 1.4443.

Desaturation of (VII) to (VIII).—To 14 g. of (VII) in 30 ml. of methanol was added 10 ml. of 50% potassium hydroxide solution. There was an immediate exothermic reaction. The potassium chloride was removed by filtration and methanol distilled from the filtrate. The residue was dried and fractionated to obtain (VIII). The yield was 60% of the theoretical.

Chlorination of (II) in Methanol.—Seventy-one grams (0.5 mole) of (II) was dissolved in 500 ml. of methanol and chlorinated as described above. Temperature was held at 60–65°. After the chlorination reaction, methanol was distilled directly from the product. The organic layer was removed from the residue and fractionally distilled at 6 mm. Fractions boiling between 85–95° (6 mm.) deposited fine white crystals on standing. These fractions were filtered and the solid crystallized from petroleum ether to yield (XII), m. p. 99°. In addition (XI) and (XIII) were obtained as shown in Table II.

Other Chlorinations.—The above procedures were followed for the six chlorination reactions studied. Since

(5) Macullum, U. S. Patent 2,162,676 (1939).

mixtures of products were obtained in all cases, it was necessary to fractionate repeatedly so as to obtain compounds sufficiently pure for analysis. All distillations were carried out at 6 mm., through suitable fractionating columns, and small fractions collected in 15-ml. vials. The yields of crude products were estimated from the first distillation. Ordinarily 10 to 20 fractions were collected. These were recombined for subsequent distillations on the basis of boiling range, refractive index, and chlorine content.

Summary

Dimethylethynylcarbinol and 2,5-dimethyl-3-hexyne-2,5-diol have been chlorinated, each in three solvents: carbon tetrachloride, methanol, and water. The products have been identified and characterized.

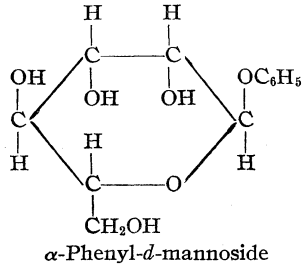
NOTRE DAME, INDIANA RECEIVED MARCH 2, 1940

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE UNIVERSITY, LEIPZIG, GERMANY]

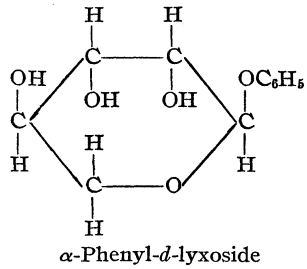
The Action of Almond Emulsin on α-Phenyl-d-lyxoside

BY WILLIAM WARD PIGMAN[1]

The occurrence in almond emulsin of enzymes which hydrolyze glycosides is well known. However, with very few exceptions, the previous work with these enzymes has been confined to glycosides of naturally occurring sugars. In an earlier paper,[2] the results of a study of the action of almond emulsin on a number of methyl glycosides of synthetic sugars were reported and in no instance was an hydrolysis observed which was larger than the experimental error. In general, the phenyl glycosides are much better materials for such studies since, when they are hydrolyzable, the rate of hydrolysis is much greater than that of the corresponding methyl glycosides. Also, a very sensitive method for the measurement of the degree of hydrolysis of the phenyl glycosides is available.[3] The negative results reported for α-methyl-d-lyxoside in the previous work[2] were somewhat surprising since α-phenyl-d-mannoside is known to be hydrolyzed by the enzymes in almond emulsin and as illustrated in the following formulas the pyranose rings of the phenyl-d-mannosides and lyxosides are identical except for the groups attached to the fifth carbon atom.



α-Phenyl-d-mannoside



α-Phenyl-d-lyxoside

In order to settle this question definitely α-phenyl-d-lyxoside was prepared according to the general method of Helferich and Schmitz-Hillebrecht.[4] The new substance which most probably has a pyranose structure and which has the expected rotation for the alpha isomer was found to be hydrolyzed by almond emulsin (the "Rohferment" of Helferich[5]). The rates of hydrolysis of β-phenyl-d-glucoside and α-phenyl-d-mannoside also were determined under the same conditions. The results are summarized in Table I.

TABLE I

Glycoside	$k \times 10^3$	Enzyme efficiency (Wertigkeit)
α-Phenyl-d-lyxoside	0.088[a]	9.4×10^{-4}
α-Phenyl-d-mannoside	3.5	0.15[b]
β-Phenyl-d-glucoside	7.3	.31[b]

[a] The enzyme concentration was four times as great for the lyxoside experiments as for the other experiments.

[b] The substrate concentrations were more dilute than those normally used but the values found are substantially the same as those reported by Helferich and Winkler.[6]

The value of 9.4×10^{-4} found for the α-phenyl-d-lyxoside is the smallest value reported for a hydrolyzable phenyl glycoside and compares with a value of 20×10^{-4} for β-phenyl-d-xyloside and a value of 3000×10^{-4} for β-phenyl-d-glucoside.

(1) This work was made possible by a grant from the Lalor Foundation of Wilmington, Del. The present address of the author is National Bureau of Standards, Washington, D. C.

(6) B. Helferich and S. Winkler, *ibid.*, **209**, 269 (1932).

Almond emulsin contains a number of enzymes and it was considered important to determine which of these is responsible for the hydrolysis of the α-phenyl-*d*-lyxoside. The similarity of the pyranose rings of mannose and lyxose made it seem probable that the enzyme in question was α-mannosidase. This was easily tested since α-mannosidase is more stable to heating than the other important enzymes found in almond emulsin.[7] Therefore, a solution of emulsin was heated and its action on α-phenyl-*d*-lyxoside, α-phenyl-*d*-mannoside, and β-phenyl-*d*-glucoside determined. The results are summarized in Table II. As seen

TABLE II

Glycoside	Enzyme	$k \times 10^3$	$\frac{k(\text{heated})}{k(\text{unheated})}$
α-Phenyl-*d*-lyxoside	Heated	0.071	0.81
α-Phenyl-*d*-lyxoside	Unheated	0.088	
α-Phenyl-*d*-mannoside	Heated	3.1	.89
α-Phenyl-*d*-mannoside	Unheated	3.5	
β-Phenyl-*d*-glucoside	Heated	3.9	.53
β-Phenyl-*d*-glucoside	Unheated	7.3	

from the table, the enzyme responsible for the hydrolysis of the α-phenyl-*d*-lyxoside is quite resistant to heat and is, therefore, most probably α-mannosidase.

The action of almond emulsin on the phenyl-*d*-xylosides and *l*-arabinosides has been studied previously.[8] The β-phenyl-*d*-glucoside, which except for a group substituted on the fifth carbon atom has the same pyranose ring as β-phenyl-*d*-xyloside, is hydrolyzed 126 to 165 times as fast as the xyloside. The enzyme responsible for the hydrolysis of the *d*-xylosides is most probably β-glucosidase or a special β-*d*-xylosidase. The presence of a special *d*-xylosidase, *i. e.*, an enzyme cleaving *only* *d*-xylosides, in a natural enzyme mixture would not be unexpected since the sugar *d*-xylose is a constituent of natural products. However, the *d*-lyxosides are derived from a sugar which is not found in naturally occurring materials and therefore the existence of a special *d*-lyxosidase seems improbable. The relative rates of hydrolysis of α-phenyl-*d*-mannoside and lyxoside (160:1) are approximately the same as those for β-phenyl-*d*-glucoside and xyloside (125–165:1). This approximate agreement of the relative rates when considered with the reasons given for ascribing the hydrolysis of α-phenyl-*d*-lyxoside to α-mannosidase, indicates that the postulation of a special *d*-xylosidase is not necessary and that the *d*-xylosides are hydrolyzed by β-glucosidase. On the other hand, β-phenyl-*d*-galactoside, which in the configuration of its pyranose ring closely resembles phenyl-*l*-arabinoside,[9] is hydrolyzed only 2.2 times more rapidly than the arabinoside. This small difference may be due to the presence of a special arabinosidase in the emulsin or to a closer configurational relationship between the galactosides and arabinosides than that between the glucosides and xylosides or the mannosides and lyxosides.

In the heptose series of sugars, there are found synthetic sugars with ring configurations similar to the naturally occuring hexose sugars. From the results reported in this paper, it is possible to indicate which of the glycosides of these sugars should be hydrolyzed by the enzymes of almond emulsin. It seems probable that the heptosides which have ring configurations similar to hydrolyzable hexosides also should be hydrolyzed. Thus, the β-*l*-β-galaheptosides (*d*-glucose ring) the α-*l*-α-galaheptosides (*d*-mannose ring) and the β-*d*-α-mannoheptosides (*d*-galactose ring) should be cleaved by β-glucosidase, α-mannosidase and β-galactosidase, respectively. In all of these cases, however, it is to be expected that the heptosides will be hydrolyzed at a slower rate than the corresponding hexosides since it is known that an increase in the size of the atom or group attached to the fifth carbon atom decreases the rate of hydrolysis.[10] Experiments to verify these predictions are now in progress in the laboratories of the National Bureau of Standards.

The prediction given above, as to the action to be expected of the enzymes of almond emulsin on the synthetic heptosides, may be extended to describe the specificity to be anticipated for the enzymes of this general type. In general it seems most probable in light of the existing information *that special enzymes are required to split each of sixteen fundamental hexose types,*[11] *(eight "d" and eight "l" isomeric aldohexopyranosides) as well as each of the alpha-beta isomers.* It is anticipated, however, that *naturally occurring enzymes are only such which will hydrolyze glycosides with pyranose rings identical (except for groups substituted on the*

fifth carbon atom) with those of naturally occurring glycosides. Enzymes hydrolyzing furanosides have been omitted from this classification since only one of this type, fructofuranosidase, is known. Disaccharides apparently fit into this scheme when considered as glycosides[12] although there is some objection to this.[13] According to this generalization, it may be expected that enzymes which split hexosides also will cause a cleavage of the pentosides, heptosides and higher homologs which have similar ring configurations. It seems probable that special pentosidases may exist which hydrolyze particular pentosides but the action of which on the hexosides is very weak. The generalizations here outlined are extensions of those proposed by Weidenhagen[12] and by Lettré.[14] Previous work, principally by Helferich and his coworkers,[15] also makes it possible to generalize as to the effect of structural changes of the substrate on the action of the enzyme. Thus it can be said that the substitution of the hydroxyls attached to carbons 2, 3, and 4 of "hydrolyzable" glycosides by other groups causes the substituted glycoside to be unhydrolyzable. Changes in the groups attached to carbons 1 and 5 cause only a change in the rate of hydrolysis. As shown above, configurational changes of the carbons forming the pyranose ring produce new hexose types each of which requires a special enzyme. It is possible that hexose types differing in configuration only at carbon 4 may be hydrolyzed by the same enzyme but as yet this problem is not settled since there is some doubt as to whether β-glucosidase and β-galactosidase are identical.

Experimental

A. Preparation of α-Phenyl-*d*-lyxoside.—A mixture of 7.4 g. of *d*-lyxose tetraacetate ($[\alpha]^{20}D$ +26.0, $CHCl_3$) and 9.5 g. of phenol was heated on a water-bath until melting occurred and after 2.5 g. of freshly fused zinc chloride had been added, the heating was continued for fifteen minutes. After the mixture had cooled, 50 cc. of benzene and 100 cc. of water were added and the sirupy phase was brought into solution. The layers were separated and the benzene solution was washed several times with water, then several times with *N* sodium hydroxide solution and again with water. The benzene was removed by vacuum distillation and the residue dried by dissolving it in absolute alcohol and then evaporating the solvent *in vacuo*. The residue was dissolved in 35 cc. of absolute methyl alcohol, 2 cc. of 0.1 *N* barium methylate was added and the solution was refluxed for ten minutes. When the solution had cooled, crystallization occurred, yield, 1.6 g. An additional 1.2 g. was obtained by evaporating the mother liquors. The material was recrystallized from a boiling mixture of equal amounts of alcohol and water. The new substance, after three crystallizations, melted at 178–181°. In aqueous solution, the phenyl lyxoside had a rotation of $[\alpha]^{20}D$ 123 (*c*, 0.6; 0.0307 g. substance; 5 cc. of solution; 2 dm.). The solubility in water at 20° is approximately 0.5 g. per 100 cc.

B. Action of Almond Emulsin on α-Phenyl-*d*-lyxoside

1. Preparation of Enzyme Solution.—Two and one-half grams of almond emulsin ("Rohferment" of Helferich[5]) was rubbed up in a mortar with 100 cc. of water, and after standing for two hours at 0° the solution was centrifuged until clear. Ten cc. of the solution when dried to constant weight in a vacuum desiccator over calcium chloride yielded a residue of 0.1886 g. The beta-glucoside-value (β-Gl.-V. or β-Gl.-W.[16]) of the solution was 0.85.

2. Method of Making Measurements.[3]—To 5 cc. of a solution of 0.0423 g. of α-phenyl-*d*-lyxoside in approx. 0.1 *N* acetate buffer[17] (*p*H 5.0 at 18°) was added 2.5 cc. of the enzyme solution. The reacting solution after several drops of toluene had been added was kept a measured time in a thermostat set at 30.0°. The reaction was then stopped by adding the solution to a mixture of 2.5% potassium carbonate solution and 50 cc. of 0.1 *N* iodine–potassium iodide solution. After fifteen minutes of standing the solution was acidified by the addition of 30 cc. of 2 *N* sulfuric acid solution and the excess iodine determined by titration with 0.1 *N* sodium thiosulfate solution.

Blank experiments also were made in a similar manner, in one experiment by replacing the substrate solution with water and in a second experiment by replacing the enzyme solution with water. These solutions were kept at 30° for 3780 minutes. The experimental results and calculations are given in Table III.

TABLE III

ACTION OF ALMOND EMULSIN ON α-PHENYL-*d*-LYXOSIDE

(17) The solutions were supersaturated but did not crystallize while the experiments were in progress. Since the solubility of the substrate is quite low, a lower concentration than usual was used.

C. Comparison of Rate of Splitting of the Phenyl Glycosides of Lyxose, Mannose and Glucose

1. Preparation of Enzyme Solutions.—Two solutions were used for this work. The one, called "unheated," was the same as that used in the above work. The second, called "heated," was prepared by heating the first solution in a soft glass bottle for thirty-six hours at 50° and then centrifuging. Some evaporation occurred during this process. The dry residue determined in the same manner as for the "unheated" solution was 0.1765 g. in 10 cc.

2. Preparation of Substrate Solutions.—Equivalent solutions were prepared by dissolving the following amounts in 25 cc. of 0.1 *N* acetate buffer (*p*H 5.0): 0.240 g. α-phenyl-*d*-mannoside, 0.273 g. β-phenyl-*d*-glucoside-$2H_2O$ and 0.212 g. α-phenyl-*d*-lyxoside.

3. Method of Making Measurements.—To 1 cc. of the enzyme solutions, diluted 1:4 for the mannoside and glucoside experiments, there was added 2 cc. of the substrate solution and after the reaction was allowed to take place at 30° for the required time, it was stopped by the addition of 20 mg. of potassium carbonate. The optical rotation (D line of sodium) was then measured in 2-dm. tubes at 20° and the degree of hydrolysis calculated from the observed value and the known specific rotations of the unhydrolyzed glycosides and the corresponding sugars. The results are given in Table IV. The measurements on the lyxoside were carried out as described for the hydrolysis experiments reported in Table III and are given in that table.

TABLE IV

Acknowledgment.—The writer wishes to express his appreciation of the coöperation, assistance and advice given by Professor B. F. Helferich during the progress of this investigation. The assistance given by the Lalor Foundation of Wilmington, Del., is also gratefully acknowledged.

Summary

The preparation of α-phenyl-*d*-lyxoside is reported. This substance is hydrolyzed by almond emulsin. The rate is the slowest reported for a hydrolyzable phenyl glycoside. The enzyme responsible for the hydrolysis is shown to be α-mannosidase. A prediction is made of the specificity to be expected of the enzymes found in almond emulsin and of other similar enzymes.

A Laccase from the Wild Mushroom, *Russula Foetens*

BY DONALD C. GREGG[1] AND WILBUR H. MILLER

Much of the early information regarding the enzyme, laccase, resulted from the researches of Bertrand and his students.[1a] Bertrand reported that laccase, the enzyme responsible for the blackening of lac tree juices, could be distinguished from tyrosinase by its ability to catalyze the oxidation of polyphenols such as hydroquinone, pyrogallol and guaiacol. In recent years, the enzymatic oxidation of these substrates, and in addition *p*-phenylenediamine, has become a criterion of laccase activity.[2–5] Most of this work has been concerned with an enzyme prepared from lac tree juices. In 1939, Graubard[5] reported limited studies on an enzyme that he obtained from the wild mushroom, *Russula foetens*. This enzyme was called laccase because of its ability to catalyze the aerobic oxidation of hydroquinone and *p*-phenylenediamine. In view of the present limited knowledge regarding the action of the plant oxidases, a more extensive study on the laccase from *Russula foetens* seemed desirable.

The enzyme preparations were obtained by the general method used in these laboratories for the preparation of oxidases from mushrooms. In a typical preparation, 100 g. of dried mushroom powder was suspended in 500 cc. of water in a refrigerator for seventy-two hours. To the resulting crude extract, solid ammonium sulfate was added to make the solution 0.5 saturated. The dark colored, gummy precipitate was triturated with a small quantity of disodium phosphate and dissolved in water. For each volume of solution, two volumes of acetone were added. At room temperature, the acetone not only precipitates the

laccase, but apparently inactivates the tyrosinase. Three or more adsorptions to alumina, each followed by elution and subsequent dialysis, removed much inert protein and all color. Such preparations had a dry weight of about 5 units (defined below) per mg. which corresponds to a Q_{O_2} of about 3000. Because of a very limited supply of this wild mushroom, it was not practical to further concentrate and purify the enzyme. For the same reason, no extensive attempt was made to correlate the copper content with enzyme activity. These laccase preparations were found to be unstable to heat treatment and were markedly inhibited in their action by cyanide.

The activity of the laccase preparations was determined by measuring the rate of oxygen uptake during the enzymatic oxidation of hydroquinone. This substrate was chosen since its oxidation by laccase is not measurably affected by the presence of other common plant oxidases. The measurements were made in Warburg respirometer flasks of 30 cc. capacity.[6] The rate of shaking was 120 complete oscillations per minute, and the temperature was maintained at 25°. The reaction mixture consisted of 1 cc. of an aqueous solution of hydroquinone (10 mg.) added from the side arm at zero time, 3 cc. of (0.2 *M*) citrate–(0.4 *M*) phosphate buffer (*p*H, 6.1), 1 cc. of an aqueous solution containing 5 mg. of gelatin, enzyme solution and sufficient water to make a total volume of 8 cc. The amount of enzyme causing an oxygen uptake of 10 cu. mm. per minute is defined as one "hydroquinone" unit. Under these conditions, the rate of oxygen uptake is directly proportional to the amount of laccase used provided the amount of enzyme in the flask is not much in excess of two "hydroquinone" units. Furthermore, the rate of oxygen uptake remains constant for periods of at least thirty minutes.

As previously mentioned, the rate of oxidation of hydroquinone by laccase is not significantly affected by the presence of other plant oxidases. This has been demonstrated by the introduction of varying quantities of other oxidases into the reaction mixture containing a fixed amount of laccase (0.90 "hydroquinone" units). The introduction of tyrosinase (*campestris*) preparations with catecholase activity varying from 10 to 60 units and cresolase activity ranging from 1 to 33 units[7] caused less than a 5% variation in the rate of oxidation of hydroquinone by the laccase. Ascorbic acid oxidase also was found to have very little effect, 142 units[5] causing a variation of less than 8%. These experiments were performed according to the procedure for measuring hydroquinone units of laccase except that the additional enzyme solutions replaced part of the water in the flask.

Since tyrosinase is without effect on the oxidation of hydroquinone by laccase, it cannot be detected by this procedure. However, with the catechol–hydroquinone mixture used for measuring catecholase activity,[7] the activity of these two enzymes appears to be additive. Thus, in a typical experiment, 0.68 "hydroquinone" units of laccase gave an oxygen uptake of 6.8 cu. mm. per minute with the catechol–hydroquinone mixture. 0.80 tyrosinase catecholase unit gave no measurable activity toward hydroquinone alone, but did cause an oxygen uptake of 8 cu. mm. per minute with the substrate mixture. Upon mixing the 0.68 laccase unit and 0.80 tyrosinase (*campestris*) catecholase unit, an oxygen uptake of 14.7 cu. mm. per minute was observed with the catechol–hydroquinone mixture. Therefore, if tyrosinase is present in the laccase preparations, the rate with the catechol–hydroquinone mixture should be greater than with hydroquinone alone. No such differences were observed with the laccase preparations used in this paper.

The marked stability of this enzyme to changes in *p*H over a wide range (*p*H, 2 to 9.5) is of considerable interest. In comparison with other oxidases of this type it appears to be more stable, the contrast in stability being especially marked in the lower *p*H regions. This is illustrated by the data in Table I in which tyrosinase has been used for comparison.

TABLE I[a]

SHOWING THE DIFFERENCE IN RESISTANCE OF LACCASE AND TYROSINASE PREPARATIONS TO *p*H INACTIVATION

Enzyme	Prep. no.	Units[a] cc. at start	*p*H	Exposed to indicated *p*H	Activity remaining, %
Laccase	Crude juice	0.18	2.20	20 days	70
Laccase	L-64	.40	1.95	13 days	65
Laccase	L-64	.20	1.50	13 days	17
Laccase	L-64	.20	1.10	30 min.	15
Tyrosinase	C-7-25-10	1.50	2.50	3 min.	2.2
Tyrosinase	C-7-25-10	2.25	2.20	1 min.	3.5
Tyrosinase	C-7-25-10	0.92	2.00	1 min.	0.0

[a] The tyrosinase units in the table are catecholase units.[7] All activities were measured at *p*H 6.10. Low *p*H values were obtained by using citric acid and acetic acid, the latter being used for all values below *p*H 2.0.

(6) M. Dixon, "Manometric Methods," Univ. Press, Cambridge, 1934.

(7) M. H. Adams and J. M. Nelson, THIS JOURNAL, **60**, 2479 (1938).

When laccase activities of equal quantities of the same enzyme preparation were determined at different *p*H values over a range of *p*H 2.6 to 8.1, a marked *p*H optimum was observed in the vicinity of *p*H 6.1 (Fig. 1, Curve I). With other substrates such as catechol the same *p*H optimum effect was observed (Curve II, Fig. 1). The apparent decrease in laccase activity observed on both sides of the *p*H optimum is a reversible effect. This was demonstrated by bringing the *p*H to 6.10 after a fifteen to twenty minute reaction period at the indicated *p*H. In all cases the optimum rate of oxidation was observed within experimental error. The reason for measuring laccase activity at a *p*H 6.10 is now apparent.

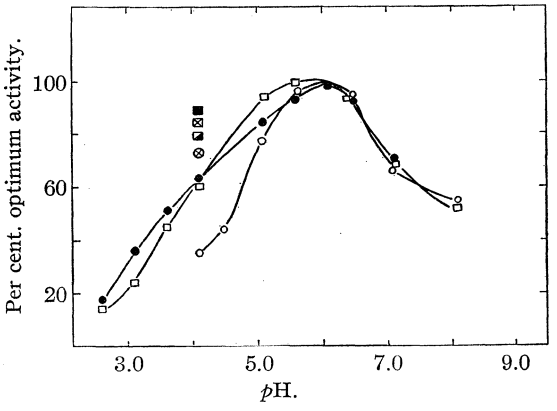

Fig. 1.—Showing the combined effect of *p*H and substrate concentration on the percentage optimum activity of laccase based on the maximum obtainable rate at *p*H 6.10. Oxygen uptake determined by means of Warburg respirometer (Barcroft differential manometers used for *p*H 7.1 and 8.1), temperature 25°. Citrate–phosphate buffers were used in all cases. ○, Curve I, reaction mixture: 3 cc. buffer, 1 cc. gelatin solution (5 mg.), 1 cc. hydroquinone solution (10 mg.) (added from side arm at zero time), 1 cc. laccase preparation containing 1 unit, and sufficient water to make final volume in reaction vessel 8.0 cc. ●, Curve II, reaction mixture same as for Curve I except 1 cc. catechol solution (25 mg.) in place of hydroquinone. □, Curve III, reaction mixture same as for Curve I, 1 cc. hydroquinone solution containing 25 mg. instead of 10 mg. The additional data noted at *p*H 4.10 were obtained using the same reaction mixture as for Curve I except for the following substrate concentrations: ■, IV, 75 mg. catechol; ⊗, V, 1.5 cc. hydroquinone solution (75 mg.); ◭, VI, 50 mg. catechol; ⊗, VII, 40 mg. hydroquinone.

The activity of laccase (*Russula foetens*) is dependent on substrate concentration as well as hydrogen-ion concentration. Thus, for each substrate, a concentration has been observed above which further increase in substrate caused no appreciable increase in the rate of oxidation. This value of concentration varies considerably with the choice of substrate (Fig. 2). After a consideration of the results shown in Fig. 2, 10 mg. of hydroquinone was chosen as a suitable concentration for the measurement of laccase units. For the measurement of maximum activity on catechol, 25 mg. has been used.

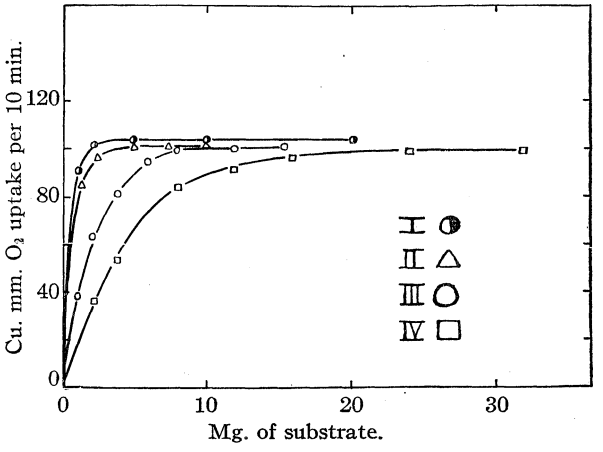

Fig. 2.—The effect of concentration of substrate on laccase activity, using four different substrates at *p*H 6.10. The rate of oxidation was determined by means of Warburg respirometers; temperature 25°. ◑, Curve I, reaction vessels contained: 1 cc. enzyme solution (1.0 unit), buffer, gelatin, aqueous *p*-phenylenediamine solutions to give indicated concentrations, and sufficient water to make the final volume 8.0 cc. △, Curve II, reaction mixtures same as for Curve I except dimethyl catechol was used as substrate. ○, Curve III, same as for Curve I, hydroquinone as substrate. □, Curve IV, same as for Curve I, catechol as substrate.

Curve III, Fig. 1, represents the results of a *p*H optimum study of laccase using 25 mg. of hydroquinone. It will be noted that this curve is similar to that obtained using 25 mg. of catechol (Curve II, Fig. 1). A comparison of Curve III with Curve I (dataf rom 10 mg. hydroquinone) demonstrates that the effect of substrate concentration is more pronounced at *p*H values below the optimum. Additional data obtained at *p*H 4.10 have been included in Fig. 1 to emphasize this point. The maximum rate obtainable at *p*H 4.10 is that obtained using 75 mg. of catechol or hydroquinone. It is interesting to note that this rate does not equal that obtained at the optimum *p*H (6.10), using much smaller concentrations of substrate (Fig. 2). In the case of catechol at *p*H 4.10, an increase in substrate from 25 mg. to 75 mg. caused about a 25% increase in rate, yet this rate was less than the optimum value at *p*H 6.10 by about 12%. A similar

increase in rate was observed with hydroquinone, the maximum rate being about 18% less than the optimum rate. Due to the fact that on the alkaline side of the *p*H optimum, both hydroquinone and catechol show an increasing tendency to undergo autoxidation, enzymatic studies become less reliable in this region. This is especially true with substrate concentrations larger than those used to obtain maximum activity at *p*H 6.10 (Fig. 2). For this reason, the alkaline side of the *p*H optimum has not been studied as extensively as in the acid regions. Regardless of this fact, the data in Fig. 1 clearly support the contention that laccase exhibits a *p*H optimum, and the nature of the *p*H effect is dependent on the substrate concentration used during the study.

Laccase preparations from *Russula foetens* are unusual in their ability to catalyze the aerobic oxidation of a wide variety of substrates. Because of this ability it is probable that these activities will be confused with those of other plant oxidases. This has been the case with laccase preparations reported from other sources. Before this confusion in classification can be eliminated, careful comparisons of these activities must be made. For future study of the relative abilities of these enzymes to react with various substrates, it is the writers' contention that unless the maximum activity of the enzyme toward the substrate at any given *p*H is obtained the results are of little comparative value. Comparable studies of the catalytic effect of these laccase preparations on the oxidation of certain common substrates follow.

Hydroquinone.—The aerobic oxidation of hydroquinone by laccase involves one atom of oxygen per molecule of substrate (Table II), the oxidation of the product *p*-quinone being immeasurably small. The effect of substrate concentration on the rate has been discussed. No appreciable inactivation was noted under normal conditions over periods of one to two hours. Chlorohydroquinone was similar in its behavior (Table II).

***p*-Phenylenediamine.**—This substrate has been used for the measurement of laccase activity by other investigators.[4] Since *p*-phenylenediamine is not as water soluble, is more easily autoxidized, and apparently has a more complex reaction mechanism than hydroquinone, it is felt that the latter substrate is a better choice for the measurement of laccase activity. While the rate with *p*-phenylenediamine approximates that of hydroquinone and remains constant over a concentration range of 2 to 20 mg. of substrate (Fig. 2), the total oxygen uptake is indefinite (Table II).

TABLE II

SHOWING THE TOTAL OXYGEN UPTAKE CORRESPONDING TO THE TOTAL OXIDATION OF 1 MG. OF SUBSTRATE BY TWO UNITS OF LACCASE FOR FIVE DIFFERENT SUBSTRATES AT *p*H 6.10

Substrate	Total uptake in cu. mm. corresponding to 1 atom oxygen per mg. substrate	Total observed oxygen uptake in cu. mm. using 1 mg. of substrate	No. of atoms of oxygen per molecule of substrate
Hydroquinone	102	106	1
Chlorohydroquinone	77	80	1
p-Phenylenediamine	104	145+	1.4+
Catechol	102	207	2
Dimethylcatechol	81	83	1

Catechol.—The enzymatic oxidation of catechol by laccase (*Russula foetens*) occurs at nearly the same rate as *p*-phenylenediamine and hydroquinone (Fig. 2). Some laccase preparations described in the literature,[4] however, are reported to oxidize *p*-phenylenediamine twice as rapidly as catechol. No substrate concentrations were given and so no conclusion concerning the similarity or dissimilarity of the laccase preparations may be made. The aerobic oxidation of catechol by our laccase preparations involves two atoms of oxygen per molecule of substrate (Table II). This behavior is similar to that of tyrosinase.[8] However, the apparent absence of inactivation of laccase in the oxidation of catechol in contrast to the marked inactivation experienced by tyrosinase (*campestris*) indicates the dissimilarity of the two oxidases. According to Ludwig and Nelson[9] one unit of purified *campestris* tyrosinase is completely inactivated after an oxygen uptake of approximately 100 cu. mm. According to their definition of a catecholase unit, this means that one unit of tyrosinase remains active with catechol for only about ten minutes. The writers have found that one unit of laccase with 24 mg. of catechol caused an oxygen uptake of 3100 cu. mm. during a period of eight hours. During this eight hour period the gradual drop in rate of oxidation was little more than that to be expected due to the constantly decreasing concentration of catechol. In other words, there appeared to be little inactivation of the laccase during this long period of oxidation.

Dimethylcatechol.—The behavior of dimethylcatechol with laccase contrasted to that of the

(8) H. Wagreich and J. Nelson, THIS JOURNAL, **60**, 1545 (1938).
(9) B. Ludwig and J. Nelson, *ibid.*, **61**, 2601 (1939).

closely related substrate catechol is of interest from two viewpoints. First, the mode of oxidation differs from that of catechol in that the reaction proceeds rapidly to an oxygen uptake of one atom per molecule (Table II). Further oxidation is very slow. Second, the same rate of oxidation was observed over a concentration range of 2 to 10 mg. of substrate (Curve II, Fig. 2).

Potassium Ferrocyanide.—Laccase preparations (*Russula foetens*) have been found to have the ability to catalyze the oxidation of potassium ferrocyanide. This enzymatic oxidation of an inorganic salt is rather unusual. In measuring the activity of the enzyme on this substrate, Barcroft differential manometers[6] were used to avoid any possible errors due to autoxidation of the salt. One "hydroquinone" unit of laccase with 5 mg. of potassium ferrocyanide resulted in an oxygen uptake of 10 cu. mm. per ten minutes. With this concentration of potassium ferrocyanide, the enzyme appeared to have very little catalytic effect. However, when the concentration of this substrate was increased to 100 mg., one "hydroquinone" unit of laccase caused an oxygen uptake of 70 cu. mm. per ten minutes. This rate of oxidation did not appear to be further increased by larger concentrations of substrate. From these results, potassium ferrocyanide seems to compare favorably with certain organic substrates.

Less detailed studies have been made on some other substrates. More work on these is being carried out along the lines of the above discussion.

Discussion

Measurement of Laccase Activity.—A practical method for the measurement of enzyme activity should be specific, reproducible, and convenient. The method that has been proposed herein for the measurement of laccase activity meets these requirements. The convenience of using the Warburg respirometer in following oxidase activity is well established. The high reproducibility of the method is a result of the fact that during the laccase-catalyzed oxidation of hydroquinone, the rate of oxygen uptake remains constant over periods of a half hour to an hour, thus allowing several observations on the rate to be made. The specificity of the method is demonstrated by the fact that relatively large concentrations of other plant oxidases have no appreciable effect on the measurement of laccase activity.

Effect of *p*H.—In defining the experimental conditions for the measurement of laccase activity, it was stated that the reaction mixture should be buffered to about *p*H 6. This is necessary since it was found experimentally that the same quantity of enzyme caused lower rates of oxygen uptake at higher and lower *p*H values than the one indicated. The fact that this *p*H optimum effect is reversible shows that the enzyme is not inactivated. This *p*H optimum effect is partially offset by increasing the substrate concentration. The marked stability of laccase over a wide *p*H range, and especially at the low *p*H values, is in contrast to the behavior of many plant oxidases, in particular tyrosinase with which it has been compared.

Substrate Concentration Effects.—The apparent activity of a fixed quantity of laccase varies with the substrate concentration up to a certain value above which further increase in substrate concentration causes no greater rate of oxygen uptake. It has been shown that this optimum substrate concentration varies with different substrates. Likewise, different enzymes which act on the same substrate show a difference in the amount of that substrate needed for optimum activity. Because of these facts, the substrate concentrations used have been fixed to ensure maximum activity at a definite *p*H. It is felt that this general procedure of fixing conditions of substrate concentrations and *p*H relative to a definite quantity of enzyme for maximum activity is necessary in all cases where a differentiation between the laccase preparations and other oxidase preparations is to be made.

Substrate and Enzyme Behavior.—The reproducibility of measuring laccase units has been found to result largely from the stability of the enzyme during the oxidation of hydroquinone. This stability has been observed with other substrates, especially catechol. In contrast to tyrosinase, which is completely inactivated by catechol after a short period of time, laccase does not appear to be inactivated to any appreciable extent even after a long reaction period. The oxidation of substrates considered here appears to proceed in a manner similar to that with other enzymes, except for the extent of enzyme inactivation.

Acknowledgment.—The authors wish to express their appreciation to Professor J. M. Nelson for his interest and friendly advice during this investigation. They are grateful to Dr. C. R.

Dawson for his help and constructive criticism in preparing the material for publication.

Summary

1. A method is described for the preparation of the enzyme, laccase, from the wild mushroom, *Russula foetens*. A typical preparation has a Q_{O_2} of 3000.

2. A measurement of units using hydroquinone as the substrate is outlined. Common plant oxidases do not appear to interfere in this procedure.

3. The unusual stability of the laccase preparations over a wide *p*H range is demonstrated.

4. The optimum *p*H for measurement of laccase activity is shown to be in the vicinity of *p*H 6.0.

5. The enzymatic oxidation of hydroquinone, *p*-phenylenediamine, catechol, dimethylcatechol, and potassium ferrocyanide has been described.

6. The behavior of the laccase preparations is contrasted when possible with tyrosinase (*campestris*).

7. The importance of substrate concentration in studying the behavior of the enzyme has been emphasized.

The Ionization Constant of Monoethanolammonium Hydroxide at 25° from Electrical Conductance Measurements

BY V. SIVERTZ, R. E. REITMEIER AND H. V. TARTAR

In this investigation use has been made of the work of several investigators[1-5] who have shown that accurate conductance measurements of solutions of weak electrolytes are adequate for the determination of limiting equivalent conductance and of thermodynamic ionization constants. The method finally developed is based upon the solution of three simultaneous equations. The first is

$$K = \frac{Cx^2f_{\pm}^2}{1-x} = K'f_{\pm}^2$$

where K and K' are the thermodynamic and stoichiometric ionization constants, respectively, x is the degree of dissociation, C is the concentration of base in equivalents per liter of solution and $f_{\pm}$ is the mean activity coefficient of the ions. The activity coefficient of the undissociated base is assumed to be unity. The second equation is

$$-\log f_{\pm} = a\sqrt{Cx}$$

where a is the Debye and Huckel coefficient. Lastly

$$x = \frac{\Lambda}{\Lambda_0}\left[1 + \frac{(\alpha\Lambda_0 + \beta)}{\Lambda_0}\sqrt{Cx}\right]$$

where α and β are the Onsager coefficients.

The authors have determined the electrical conductance at 25° of aqueous solutions of monoethanolammonium hydroxide. Since we were unable to obtain from the literature an accurate value for the equivalent conductance of the hydroxyl ion, the conductances of sodium and potassium hydroxide solutions have also been measured over a limited range of concentrations.

Experimental

Apparatus and Technique.—A Leeds and Northrup conductivity bridge[6,7] was used. The conductance cell, used with nitrogen, was similar in design to a cell described by Shedlovsky[8] and made of Pyrex glass. The electrode chamber met the specifications given by Jones and Bollinger.[9] Because of the magnified effects due to adsorption at very dilute concentrations, platinization was limited to the minimum value to prevent polarization. The electrodes were given a light gray coating, using the procedure suggested by Jones and Bollinger.[9] The cell constant at 25° was of the order of 0.26228 and was determined by comparison with a cell which had been calibrated with 0.01 demal potassium chloride, the specific conductance of which was taken from the recent work of Jones and Prendergast.[10] The cell was cleaned before each run with redistilled alcohol and ether and dried under nitrogen. This procedure produced no undesirable effects either on the character of the platinized electrodes or in the operation of the cell.

The current was supplied to the bridge by a Leeds and Northrup a. c. oscillator, the frequency of which could be varied in steps over a range of 500 to 2000 cycles. Several trials in each series of measurements showed that the conductance was essentially independent of the frequency. A Leeds and Northrup two-stage amplifier and telephone formed the detector circuit.

The temperature of the oil thermostat, controlled to ±0.001° by a Thyratron relay, was established by a thermometer certified by the Bureau of Standards.

All solutions were made up by weight. An analytical balance accurate to 0.1 mg. was used for the more accurate weighings, and a large balance which was read to 1 mg. was used for weighing the water and solutions. The weights were calibrated against a set standardized by the Bureau of Standards.

Materials.—The water used in the preparation and dilution of solutions had a specific conductance of 5.0 (10^{-7}) mho. Since the measurements were made on alkaline solutions, it was necessary to know the carbon dioxide content of the water used. The conductivity water was drawn into a weight pipet, paraffined with material which had been specially purified, and nitrogen, free from carbon dioxide, was passed through for sixty minutes. This procedure gave water with a constant specific conductance which was assumed to be due to the presence of residual carbon dioxide and the specific conductance of pure water. The water correction was made accordingly, using the method suggested by Kolthoff,[11] and by Jeffery and Vogel.[12]

The monoethanolamine was from two sources and, after fractional crystallization and distillation, had a boiling point of 171.1° at 760 mm. pressure and a melting point of 11.52°. The density was found to be 1.0117 at 25° and the refractive index measured with an Abbé refractometer was 1.4539 at 20°. As a check on its purity, the monoethanolamine was analyzed by potentiometric titration against hydrochloric acid and by weight titration using methyl orange indicator. Several titrations gave the purity as 99.97% by the potentiometric titration and 99.96% by the weight titration. The standard hydrochloric acid used was a carefully prepared constant boiling mixture using the data of Foulk and Hollingsworth.[13] As a check on its standardization, the chloride content was determined by precipitation as silver chloride.

Paraffin was purified by shaking the melted material with hot concentrated sodium hydroxide. It was then leached thoroughly with conductivity water until the conductance of the wash water reached that of the original.

The solutions of monoethanolammonium hydroxide were prepared from monoethanolamine that was freshly distilled under nitrogen, care being taken that it did not come in contact with carbon dioxide at any time.

The stock solutions of sodium hydroxide were prepared by two methods. One solution was prepared by permitting pure metallic sodium to react with carbon dioxide-free conductivity water in a paraffined flask. The metallic sodium was cut under benzene, transferred under an atmosphere of nitrogen to the paraffined flask and the reaction permitted to take place under nitrogen. A second stock solution was prepared from sodium amalgam prepared by the electrolysis of a solution of C. P. sodium chloride over pure mercury. The stock solution of potassium hydroxide was prepared in a similar manner from C. P. potassium chloride. All solutions were stored in Pyrex bottles lined with specially purified paraffin and were maintained carbon dioxide-free. These stock solutions were standardized by titrating potentiometrically against hydrochloric acid and by weight titration using methyl red indicator.

The monoethanolammonium chloride solutions were prepared by neutralizing standard hydrochloric acid (to *p*H of 7.5) with monoethanolammonium hydroxide. It was necessary to know the *p*H of these solutions in order to make the proper correction for the trace of excess monoethanolammonium hydroxide, a procedure adopted to control hydrolysis.[8] The measurement was made electrometrically using a Leeds and Northrup *p*H meter that had been checked against standard *p*H buffers over the range used.

Results

Table I gives the data for monoethanolammonium hydroxide. The columns are, respectively, the concentration in equivalents per liter,

$\Lambda_0 = 118.58$

The limiting conductance values of potassium and sodium hydroxides and monoethanolammonium chloride were determined by using Shedlovsky's method of extrapolation in which $1/\Lambda$ is plotted against $\sqrt{C}$. This gives $\Lambda_0 = 247.83$ for sodium hydroxide, $\Lambda_0 = 270.94$ for potassium hydroxide and $\Lambda_0 = 118.58$ for monoethanolammonium chloride. These values, combined with limiting conductance for the Na^+, K^+ and Cl^- as determined by MacInnes, Shedlovsky and Longsworth[14] (corrected to the Jones and Prendergast basis[11]), give the Λ_0 value for monoethanolammonium hydroxide which was used in Table I, as well as 197.71 and 197.41 for the limiting conductance of the hydroxyl ion, obtained from sodium hydroxide and potassium hydroxide, respectively.

The mean of the values of K in the concentration range below 0.0015 N gives 3.19×10^{-5}. Other weak electrolytes show a constant value of K below this concentration.[15,16] The values of K in this range show a variation to be expected with a weak base. It is improbable that this variation is due to the solution of glass, since we were able to confirm the findings of Jeffery and Vogel[12] and Wynne-Jones[17] that the change in conductance of the more concentrated solutions (0.005–0.01 N) was inappreciable over the period of time required for a series of measurements. It is more likely that this variation results from fluctuations in the carbon dioxide content of the water used in preparing solutions, *i. e.*, a failure to comply strictly with the assumption made earlier in this paper regarding constancy of carbon dioxide content of the water.

Table I also shows a tendency for the constant, K, to decrease as the concentration of the monoethanolammonium hydroxide increases. This decrease is expected due to the assumption made that the activity of the undissociated base is unity.

Summary

1. Conductances of sodium and potassium hydroxides, of monoethanolammonium chloride and of monoethanolammonium hydroxide have been measured over a limited range of concentrations at 25°.

2. A new value for the limiting conductance of hydroxyl ion is reported.

3. From these measurements the thermody-

Vapor Pressures of Nickel and of Nickel Oxide

BY H. L. JOHNSTON* AND A. L. MARSHALL

Vapor pressures of copper and of iron, determined by measuring the rates of evaporation from metal rings heated inductively in a vacuum, were recently published from this Laboratory.[1] We have completed a similar investigation with nickel between the temperatures of 1300 and 1600°K., and have also determined vapor pressures of nickel oxide, by measuring rates of nickel and of oxygen loss from nickel rings coated with a thin film of the oxide. From these data, and thermodynamic and quantum-statistical data on both the solid and gaseous forms of nickel and of nickel oxide, we have computed their heats of sublimation and have derived vapor pressure formulas.

Vapor pressures, p, are computed from the measured rates of evaporation, m, by use of the relationship[1,2]

$$\log p + \log \alpha = \log m - {}^1/_2 \log M + {}^1/_2 \log T - 1.647 \quad (1)$$

where p is in atmospheres; m is in grams per square centimeter per second; M is the molecular weight in the vapor phase; T the absolute temperature; and α, termed the *accommodation coefficient*, is a measure of the efficiency with which molecules that strike the equilibrium surface from the vapor phase are condensed. The accommodation coefficient is unity if condensation results at every collision.

As with copper and with iron, the results with nickel establish this coefficient as unity and support the general validity of the Langmuir method in its application to metals. Vapor pressures, and the accommodation coefficient, could not be determined for the oxide with the same accuracy as for the metal, but the accommodation coefficient appears to be unity within the limits of experimental error.

Nickel

Experimental.—Apparatus and procedure were described previously.[1] Except as noted below the same description applies here.

The nickel used, in all but one of the runs, was electrolytic in origin and had been vacuum melted in an alundum crucible. Spectrographic analysis indicated the absence of any impurity, in significant amount, other than cobalt. The latter was present to the extent of 0.64% in the original specimen and, within limits of a colorimetric method employed for the analysis, this percentage remained unchanged in the evaporated film.[3] The results obtained in a single (subsequent) run[4] with a ring turned from pure carbonyl nickel[5] were undistinguishable from those obtained with the electrolytic nickel.

Dimensions of the nickel ring turned from the vacuum ingot were: outer diameter, 2.23 cm.; inner diameter, 1.13 cm.; thickness, 0.63 cm.; total surface, 12.46 sq. cm. Correction for condensation of atoms which strike the inner surface of the ring reduces the effective surface area to 11.74 sq. cm.

Evaporation losses were determined by weighing the approximate 16 g. ring on a sensitive balance. Weighings were reproducible to within 0.02 milligram.

Temperatures were determined by setting the filament of the optical pyrometer on two holes, 1.2 mm. in diameter, drilled vertically into the face of the specimen to a depth of about four millimeters. Measurements on a specimen drilled with holes of 0.6 mm., 1.2 mm. and 1.8 mm. diameter proved that the emissivity from the 1.2 mm. hole was indistinguishable from that from the 0.6 mm. hole to the highest temperature to which measurements were carried, 1600°K., and was therefore the equivalent of black body radiation. On the other hand, the emissivity from the 1.8 mm. hole was definitely less than black body at 1100° and yielded brightness temperatures more than twenty degrees in error at 1600°.

Temperatures determined as described above were normally reproducible within limits of approximately three degrees (each determination the average of five to ten successive observations). This corresponds to limits of approximately 10% on individual vapor pressure determinations. Temperatures were taken continuously during

(2) Langmuir, *Phys. Rev.*, **2**, 329 (1913).

(3) The influence of this amount of cobalt on the measurements of the evaporation of nickel must lie well within the accuracy of the latter. The observation that the composition of the evaporated metal is identical with that of the original specimen within limits of the analytical error indicates that vapor pressures of cobalt and of nickel are nearly equal, which is in agreement with the data of Ruff and Bormann (*Z. anorg. Chem.*, **88**, 386, 397 (1914)) on liquid nickel and cobalt.

(4) Run *M* in the tables. This run was made by Dr. F. J. Norton and Dr. R. W. Dornte.

(5) The metal for this ring was furnished through the courtesy of the International Nickel Co. Its composition was stated to be: 99.89% nickel, 0.048% iron, 0.035% carbon, 0.014% copper and 0.008% sulfur.

short runs and at frequent intervals during longer runs. Corrections were applied for evaporation losses during a preliminary period of degassing the nickel and during the period that the sample was coming up to temperature. Corrections were also made for small temperature fluctuations that sometimes resulted from variations in operating conditions during the period of the run. It was found convenient to make these corrections graphically by plotting relative evaporation rates (obtained as a function of the temperature) against time and to apply them to yield an "effective" length of run at constant rate of evaporation. The magnitudes of these corrections may be judged by comparison of the third and fourth columns of Table I.

The pyrometer used in this work was the one previously employed by Marshall, Dornte and Norton,[1] and calibrated by them against a standard tungsten ribbon filament lamp (designated as Standard Lamp W 91) supplied and calibrated by Forsythe.[6] The pyrometer calibration has been rechecked by Dr. R. W. Dornte subsequent to the work reported in this paper, and found not to deviate from the earlier calibration.

Window corrections which normally amounted to about 12 degrees, were determined by calibrations *in situ*.

Data.—The experimental results are recorded in Table I. All of our runs are included although 7 and 11 are entitled to less weight than the others. Runs 1 to 7 inclusive were made with a preliminary 600–700° bakeout in vacuum. In runs 8 to 11 hydrogen was present during the bakeout. There was no significant difference in results.

Thermodynamic Treatment.—The reliability of vapor pressure data is best confirmed by establishing the constancy of ΔH_0° in the thermodynamic relationship

$$R \ln p \text{ (atmospheres)} = \left(\frac{F^\circ - H^\circ}{T}\right)_{\text{condensate}} - \left(\frac{F^\circ - H_0^\circ}{T}\right)_{\text{vapor}} - \frac{\Delta H_0^\circ}{T} \quad (2)$$

applied to the individual data. Here $F^\circ - H_0^\circ/T$ for a solid is calculable from its heat capacity by the equation

$$\left(\frac{F^\circ - H_0^\circ}{T}\right)_{\text{solid}} = \frac{1}{T}\int_0^T C_p dT - \int_0^T C_p d \ln T \quad (3)$$

and $(F^\circ - H_0^\circ/T)_{\text{vapor}}$ can be evaluated accurately by statistical methods which depend partly on information gained from the spectrum.[9] ΔH_0° has the significance of the heat of sublimation to ideal gas at the absolute zero.

Kelley[10] has reviewed the experimental data on solid nickel published prior to 1934, and has computed and tabulated the free energy function on the basis of these data. More recent work[11] indicates that the heat capacity curve in the high temperature region should run somewhat under the values adopted by Kelley. We have accordingly recalculated the thermodynamic functions for solid nickel to conform with the newer data. The results, which differ from Kelley's tables by amounts sufficient to make a difference of about 0.3 of a unit in the free energy function at 1500°, are entered in Table II, together with the free energy function for nickel vapor computed by Overstreet[12] and quoted by Kelley.[10] The last column is the change in the standard free energy function, in the evaporation of nickel.

(6) Forsythe, *J. Optical Soc. Am.*, **4**, 305 (1920).

(7) This figure is the smoothed average of the weight determination (0.00014 g.) and of a colorimetric determination of nickel in a nitric acid solution of the deposit formed on the walls of the cell (0.000104 g.). Colorimetric determinations on deposits from other runs differed from the more accurate weight determinations by amounts which were generally under 5% but doubled this percentage in one or two instances.

(8) There is an uncertainty of approximately eleven minutes in the duration of Run 11 due to the fact that the power went off unexpectedly during a period when the apparatus was not under continuous observation. This is equivalent to a 6% uncertainty in evaporation rate and in pressure.

1700	11739	6.91	19.84	−12.93	−47.901	−34.97

Our values are based principally on the data of Keesom and Clark[13] for temperatures below 10°K.; on those of Clusius and Goldmann[11] for the interval 10 to 26°; those of Eucken and Werth[14] and of Rodebush and Michalek[15] for the interval 25 to 200° and on the recent careful work of Moser[11] for the interval 300 to 1000°K. Above 1000°K. we have extrapolated the curve of Moser by continuing it parallel to that of Ewert.[11] There may be an uncertainty of 100 calories in the enthalpy at 1600° in this extrapolation, but this will be almost fully compensated in the entropy term. The work of Moser on pure carbonyl nickel, with a carefully controlled adiabatic calorimeter, appears to justify this weighting to the exclusion of earlier data. The enthalpy values secured from Moser's data are in good agreement with the total heats between room temperature and about 800°K., determined by Bronson, Hewson and Wilson who estimate their limits of error at 0.2 of 1%. The entropy of the magnetic transformation was obtained by dividing Moser's heat input for the interval 600 to 673° by 641°, the "center of gravity" of this input, determined from the C_p *vs.* log T plot.

TABLE III

ΔH_0° FOR THE EVAPORATION OF SOLID NICKEL

Run	T, °K.	$4.575 \log_{10} p$	$\Delta\left(\frac{F^\circ - H^\circ}{T}\right)_{\text{evap.}}$	ΔH_0°

3	1578	−29.02	35.05	101,102
M	1583	−28.98	35.05	101,359

Average ΔH_0° (Runs 7 and 11 not included), 101,141 ± 150 cal.

Table III gives the values of the sublimation heat at 0°K., obtained by combination of the data of Table II with the experimental vapor pressures recorded in Table I.

Substitution of the average ΔH_0° into equation (2), with a linear expansion of $\Delta(F^\circ - H_0/T)$ as a function of T (Table II), leads to the vapor pressure equation

$$\log p \text{ (atmospheres)} = -\frac{22{,}107}{T} - 1.31 \times 10^{-4} T + 7.869 \quad (4)$$

which we believe accurate to within 5% of the pressure. The fit with our experimental data is shown graphically in Fig. 1. The curve in this graph is constructed from equation (4), and the radii of the circles drawn to correspond to the uncertainty in the individual measurements (±3° in all runs except Nos. 7 and 11).

The Accommodation Coefficient.—The good agreement of ΔH_0° among runs, and the absence of any temperature trend, establish the accommodation coefficient as unity within sensible limits of error. This depends on the fact that, for α other than unity, the entries in the third column of Table III would be in error by the amount 4.575 log α, and those in the fifth column by the

(13) W. H. Keesom and C. W. Clark, *Physica*, **2**, 513 (1935).

(15) W. H. Rodebush and J. C. Michalek, THIS JOURNAL, **47**, 2117 (1925).

amounts 4.575 T log α. The values of the *supposed* ΔH_0° would thus vary with the temperature at a rate proportional to the magnitude of α (except in the fortuitous case that log α vary in exact inverse proportion to T). The absence of any sensible variation in the ΔH_0°'s computed from the nickel data thus makes it reasonably certain that the accommodation coefficient for nickel is unity. The data would not preclude an α intermediate between 0.75 and 1.00, however.[16]

This conclusion receives qualitative confirmation from: (1) the absence of condensation in the re-entrant portions of the quartz cell[17]; and (2) the observation that, within limits of error, the loss in weight per unit time is no different for a nickel cylinder perforated with many deep, narrow drill holes than for a non-perforated cylinder of equal external dimensions.[18]

Comparison with other Investigators.—Rates of evaporation from nickel surfaces have been reported previously by Jones, Langmuir and Mackay[19] and by Bryce.[20] These data are entered in Table IV and Fig. 1, and ΔH_0°'s likewise computed.

Both Langmuir and co-workers and Bryce measured evaporation losses from nickel filaments. The ring evaporation method possesses the advantage of being free from the following sources of error, which are difficult to avoid in filament evaporation: the considerable variation in evaporation rate in the course of each run due to decrease in the dimensions of the filament; the effect of superheating at thin spots in the filament; the difficulty of obtaining good pyrometer settings on a thin wire and of properly correcting for temperature gradients along the wire and the necessity of making corrections for surface emissivity.[21]

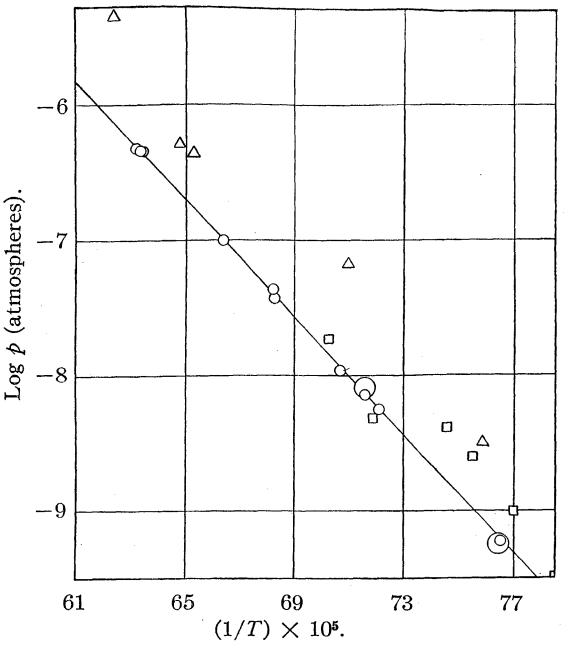

Fig. 1.—Vapor pressures of nickel: ○, this research; △, Jones, Langmuir and Mackay; □, Bryce. The dimensions of the circles, representing this research, are drawn in scale to represent error limits. The curve is constructed from equation (4).

Nickel Oxide

Experimental.—The rings used to determine evaporation rates of nickel oxide were of approximately the same

(16) If one out of every four atoms fails to condense on the *hot* surface at equilibrium (an accommodation coefficient of 0.75) there would result an apparent increase in ΔH_0° of 180 calories, between 1300° and 1600°. This is just under the precision of our measurements (±300 calories on individual points from an estimated limit of 3° in temperature). Actually, our deviations from the mean ΔH_0° lie within 150 calories with two exceptions.

(17) This relates directly to the accommodation coefficient on a *cold* surface while the calculation of vapor pressures from evaporation rates requires a knowledge of the accommodation coefficient on the *hot* equilibrium surface. We may ordinarily expect the accommodation coefficient to be unity on both hot and cold surfaces if unity on either but this is not a necessary consequence and is apparently not true in the case of graphite (which we expect to discuss in a subsequent communication).

(18) This is evidence that atoms evaporated from the walls of the drill holes are recondensed before they reach the surface. The data obtained with the nickel cylinders will be included in a subsequent paper on the evaporation of graphite.

(19) H. A. Jones, I. Langmuir, and G. M. J. Mackay, *Phys. Rev.*, **30**, 20 (1927).

(20) Bryce, *J. Chem. Soc.*, 1517 (1936). Dr. Bryce kindly communicated the numerical values of the data which he shows graphically in his paper, in correspondence with Dr. H. A. Liebhafsky of this Laboratory, and has consented to their use. The pressures attributed by us to Bryce, in our Table IV, and the corresponding values of ΔH_0°, were computed by us from Bryce's evaporation rates, with the aid of our equations (1) and (2).

(21) In conjunction with our own work we obtained a value of 0.41 for the emissivity of nickel at $\lambda = 0.665\ \mu$. This is slightly higher than the value employed by Jones, Langmuir and Mackay, but of the wrong sign and wrong magnitude to account for the approximately 50° discrepancy between their data and ours. Our own temperature scale in no wise depends on the value adopted for the emissivity of nickel since we obtained the equivalent of "black body" radiation.

dimensions as the one employed with nickel and were corrected in the same manner for condensation on the inner surface of the ring. Results obtained with rings turned from electrolytic nickel (0.64% cobalt) were indistinguishable from those obtained with a ring of carbonyl nickel.[5]

The rings were oxide coated prior to each run by oxidation in air for several minutes at about 900° and were partially degassed prior to evaporation by a preliminary bakeout in vacuum at about 400°. Uniform, adhering films of olive-green oxide were produced. Approximate calculations indicate that the film thicknesses varied from 10,000 to about 50,000 NiO layers. Lengths of runs were ordinarily chosen so that only 4 or 5% of the oxide coating was evaporated. One run (1566°K.) in which 35% of the oxide was evaporated yielded data in good agreement with the lesser removals of film.

The measurements were complicated by the fact that evaporation losses were made up in large part of pure nickel which escaped through the film. It was thus necessary to distinguish between total losses in weight and the weight loss of oxygen. The latter was obtained, by difference, through determination of the residual oxygen which remained on the ring. This determination was made by reducing the ring in an atmosphere of hydrogen at 800°. The reduction was repeated, for ten or twenty minute reduction periods, until the ring came to constant weight. This result was usually attained (within an accuracy of 0.01 or 0.02 mg.) with two reductions. The final weighing was corrected (a correction of 0.08 mg.)[22] for hydrogen dissolved in the nickel at 800°.

Temperatures were determined by pyrometer settings on 1.2-mm. holes drilled into the surface of the specimen.[23] Corrections for fluctuations in temperature and for preliminary heating periods were applied in the manner described for nickel.

No deposit was formed in the re-entrant portions of the cell. On the basis of this observation the accommodation coefficient was taken to be unity.

Data.—Data from a typical run are shown in Table V. Summaries from all of the runs are entered in Table VI.

Thermodynamic Treatment.—The integral $\int_{296}^{T} C_p dT$, for solid nickel oxide, has been measured by Kapustinsky and Novoseltsev[24] for various upper limits of the integral to 1396°K. They employed a high temperature calorimeter of new design.[25] Heat capacities between 68° and 298°K. have been measured with a vacuum calorimeter, by Seltz, DeWitt and McDonald,[26] who extrapolate their data to 0°K. by means of a combination of Debye and Einstein terms in accordance with the formula

$$C_p = D\left(\frac{404}{T}\right) + E\left(\frac{620}{T}\right) \qquad (5)^{27}$$

They further find that their own data at 298° and the integrals $\int_{298}^{T} C_p dT$ determined by Kapustinsky and Novoseltsev can be represented by the equation

$$C_p = 13.69 + 0.83 \times 10^{-3}T - 2.915 \times 10^{5}T^{-2} \quad (6)$$

up to the highest limits of Kapustinsky's measurements (1396°K.). This represents an improvement over the equation published by Kapustinsky and Novoseltsev,[24] which fails to reproduce the heat capacity at low temperatures. The fact that the data can be so represented excludes the possibility of a transition below 1400°.

From the values[27] for $(H^\circ_{298.1} - H^\circ_0)$ and for $S^\circ_{298.1}$ obtained from Seltz' data and from the integration of equation (6) between 298.1 and T we obtain, for the free energy function of solid nickel oxide, the relationship (*cf.* eq. 3)

TABLE V

DATA FROM RUN 4

Temperature, 1511°K. Effective time, 609 seconds

Initial wt. before oxidation, g.	15.46038
Wt. after oxidation, g.	15.46955
Wt. after evaporation, g.	15.46490
Wt. after H_2 reduction (corrected for dissolved hydrogen), g.	15.45613
By difference:	
Oxygen initially added, g.	0.00917
Evaporation loss (NiO + Ni), g.	.00465
Residual oxygen, g.	.00877
Oxygen evaporated (as NiO), g.	.00040
NiO evaporated, g.	.00187
Free nickel evaporated, g.	.00278
m (g./sq. cm./sec.) for NiO	2.62×10^{-7}
p (atm.)	2.66×10^{-8}

(22) This correction was determined experimentally by collecting, and measuring, the gas liberated from the ring of electrolytic nickel subsequent to one of the 800° reductions. To accomplish this the bare nickel ring was sealed into the quartz apparatus[2] and heated by means of high frequency to approximately 1000°. By means of a mercury diffusion pump the evolving hydrogen was pumped into a separate vessel of known volume and the final pressure was determined on a McLeod gage.

As the correction was not large, and care was taken always to reproduce the approximate 800° temperature and other experimental conditions under which reduction was brought about, it was considered justifiable to apply this same correction in all of the runs.

(23) The holes were clearly visible at temperatures above about 900°. We obtained an average value of 0.86 (for $\lambda = 0.665\ \mu$) for the emissivity of the oxide coated surface. This value is higher than that we have obtained for a specimen of graphite (0.53) and is a reasonable value. Consequently we may conclude that no significant temperature gradient exists between the oxide film and the metal.

(24) Kapustinsky and Novoseltsev, *J. Phys. Chem.* (U. S. S. R.), **11**, 61 (1938).

(25) Kapustinsky and Veselovsky, *ibid.*, **11**, 68 (1938).

(26) Seltz, DeWitt and McDonald, THIS JOURNAL, **62**, 88 (1940).

(27) The extrapolation below 68° contributes only 33 calories to $(H - H_0)$ and 0.65 E. U. to the entropy. We obtain $H^\circ_{298.1} - H^\circ_0 = 1630$ calories by graphical integration of Seltz's data, which was kindly furnished us in advance of its publication. Dr. Seltz (personal communication) informs us of an error in the published value of the entropy. The correct value is $S_{298.1^\circ} = 9.22$ E. U. We have used this corrected value in the subsequent calculations.

TABLE VI

2	1529	1340	.00921	.01139	.00837	.00392	2.72×10^{-8}
1	1566	759	.0044	.01893	.00289	.0070	8.51×10^{-8}

$$\left(\frac{F^\circ - H_0^\circ}{T}\right)_{\text{NiO solid}} = 84.360 - 0.415 \times 10^{-3}T - 31.523 \log T - (3465/T) + (1.46 \times 10^5/T^2) \quad (7)$$

For gaseous NiO we have used the equation

$$\left(\frac{F^\circ - H_0^\circ}{T}\right)_{\text{NiO gas}} = 3.5\,R - 3.5\,R \ln T - 1.5\,R \ln M - R \ln \mu - 2\,R \ln r_0 - 175.38 - R \ln q + R \ln (1 - e^{-ch\nu/kT}) \quad (8)^{28}$$

with ν set equal to 700 wave numbers,[29] r_0 set equal to 1.65×10^{-8} cm.,[30] and q set equal to 3.[31]

(28) The first term in this equation is the contribution to $(H^\circ - H_0^\circ/T)$ arising from translation and rotation; the succeeding five terms constitute the sum of translational and rotational entropies for a rigid rotator of molecular weight M, reduced mass μ and internuclear distance r_0 [Sackur, *Ann. Phys.*, **36**, 958 (1911); Tetrode, *ibid.*, **38**, 434 (1921); Ehrenfest and Trkal, *Proc. Acad. Sci. Amsterdam*, **23**, 162 (1920)] the seventh term is the electronic contribution to $(F^\circ - H_0^\circ)/T$ from the multiplicity of the ground state; and the final term is the contribution from an harmonic oscillator with the fundamental frequency ν (expressed in wave numbers). R, c, h and k have their usual meaning.

(29) Our estimate of 700 cm.$^{-1}$ for the fundamental frequency of NiO is an interpolation within the group of transition elements of which nickel is a member. In order of increasing atomic number the series runs: TiO, 1007; VO, 1011; CrO, 896; MnO, 840; FeO, —; CoO, —; NiO, (700 est.); CuO, 620 cm.$^{-1}$ [*cf.* Herzberg, "Molecular Spectra," I, Table 36, Prentice–Hall, New York, N. Y., 1939]. Among the monochlorides and the hydrides nickel fits regularly into position: (a) TiCl, 456; VCl, —; CrCl, —; MnCl, —; FeCl, 406; CoCl, 420; NiCl, 418; CuCl, 417; ZnCl, 390; (b) MnH, 1580; FeH, —; CoH, 1890; NiH, 1926; CuH, 1940. (In some instances—*e. g.*, FeCl—these frequencies may not represent the ground electronic state.)

(30) Our estimate of 1.65 Å. for the covalent bond in NiO vapor is based on values for the atomic radius of nickel in various of its covalent compounds. We further assume the bond to be double (*cf.* ref. 31).

Pauling ["The Nature of the Chemical Bond," The Cornell University Press, 1939, p. 232] makes an estimate of about 1.22 Å. for the covalent single bond radius of nickel. A recent reliable determination of r_0 in the vapor of NiH [Heimer, Dissertation, Stockholm, 1937; *cf.* Herzberg, *loc. cit.*] yields 1.487 Å. for the Ni-H bond. Taking the H covalent radius to be 0.30 ± 0.03 Å. (Pauling, *loc. cit.*, p. 158) this gives 1.19 ± 0.03 Å. for the nickel single bond radius, in good agreement with the X-ray measurements. Use of the factor 0.915 for the double bond–single bond ratio (Pauling, *loc. cit.*, p. 154) yields 1.09 Å. for the double bond radius of nickel, and 1.66 Å. for r_0 in NiO vapor. This lies within the limits imposed by the results of electron diffraction measurements on the vapor of $Ni(CO)_4$ [Brockway and Cross, *J. Chem. Phys.*, **3**, 828 (1935); *cf.* also Pauling, *loc. cit.*, p. 232, *et seq.*]. These yield 1.82 Å. for the Ni–C bond, which resonates between single bond and double bond character, and result in extremes of 1.53 Å. and 1.72 Å. for the Ni–O double bond, with the most probable value near the upper limit.

(31) Professor R. S. Mulliken (private communication) expresses the opinion that the ground state of NiO is probably $^3\Sigma^-$, resulting from either the configuration Ni $d\sigma d\pi^3 d\delta^4 s\sigma^2$; O $p\sigma\ p\pi^3$ or Ni $d\sigma^2 d\pi^3\ d\delta^4\ s\sigma$; O $p\sigma\ p\pi^3$, or a mixture, and that the Ni–O bond would be expected to exhibit properties similar to the double bond in molecular oxygen. The multiplicity (q) of the $^3\Sigma$ state would be 3. It is possible, though less likely that $^1\Sigma^+$ (with $q = 1$) would be more stable than $^3\Sigma^-$ (analogy to the possible situation in Se_2 and Te_2). Less probable multiplicities are 2, 5, 6 or 10.

The first two of these constants are necessarily estimates since no band spectra have been observed for nickel oxide. However, they are probably reliable to within 50 cm.$^{-1}$ in ν and to within 0.1 Å. in r_0. Combined errors of 50 cm.$^{-1}$ and 0.1 Å., respectively, would influence our calculations of ΔH_0° (Table VIII) by less than 600 calories in an absolute sense and would introduce a temperature trend into the supposed values of ΔH_0° of only 50 calories over the 130° experimental range. These are well within the limits of

error imposed by the measurements of sublimation rates of nickel oxide, and would not alter their interpretation.

Values of the free energy function, computed by equation (7) for solid nickel oxide and by equation (8) for the vapor, are given in Table VII, together with $\Delta(F^\circ - H_0^\circ)/T$ for the sublimation process. The latter is well represented, empirically, by the equation

$$\left(\frac{F^\circ - H_0^\circ}{T}\right)_{\text{NiO (gas)}} - \left(\frac{F^\circ - H_0^\circ}{T}\right)_{\text{NiO (solid)}} = -46.656 + 3.508 \times 10^{-3}T - 3.30 \times 10^{-7}T^2 \quad (9)$$

Values for the sublimation heat at the absolute zero, based on $^3\Sigma^-$ as the probable ground state of nickel oxide vapor, are given in the fourth column of Table VIII. These are computed by combination of equations (2) and (9) with the experimental pressures recorded in Table VI.

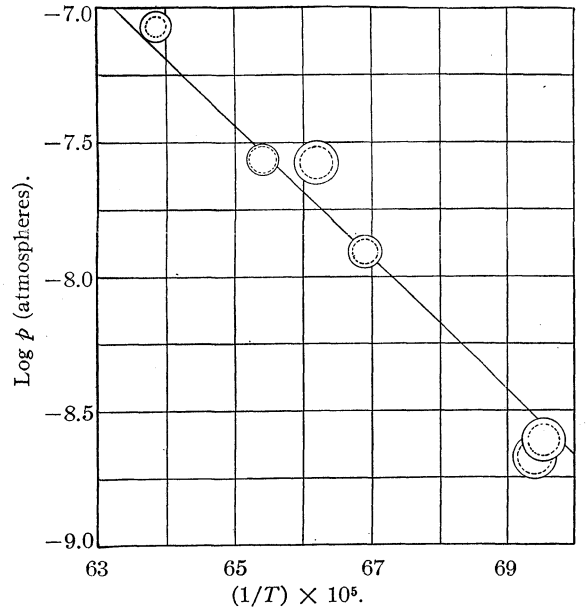

Fig. 2.—Vapor pressures of nickel oxide. The dimensions of the outer (solid line) circles are drawn to scale to represent approximate error limits. The inner (broken line) circles represent probable errors. The curve is constructed from equation (10).

Substitution of the average value for ΔH_0° (117,055) into equation (2), in combination with equation (9), leads to the vapor pressure equation

$$\log p \text{ (atmospheres)} = -\frac{25{,}586}{T} - 7.67 \times 10^{-4}T + 7.21 \times 10^{-8}T^2 + 10.198 \quad (10)$$

The fit with the individual experimental data is shown graphically in Fig. 2, in which the curve is constructed from equation (10). Approximate error *limits* of the individual data are represented by the dimensions of the outer (full line) circles and their *probable* errors by the inner (broken line) circles.[32]

Although 3 is the most likely value for q in equation (8) extreme limits of 1 and of 10 are not definitely excluded (*cf.* ref. 31). Accordingly, we include in Table VIII columns (italics) based on these extreme assignments. When allowance is made for the added small uncertainties from r_0 and from ν and from an experimental uncertainty of 1000 calories in the average of ΔH_0° for a single column, it is seen that the total uncertainty in ΔH_0° may attain 4 to 5 kilocalories as a limit. A "best" straight line drawn among the experimental points, as in graphic treatment by the Clausius-Clapeyron equation, yields about 127 kilocalories for ΔH_{1500°, which is equivalent to about 132 kilocalories for ΔH_0°. However, the slope of this line may be varied, within the limits of error of the data, by an amount that corresponds to nearly ±15 kilocalories in ΔH_0°. Hence, even with the possibility of a four kilocalorie error in the estimates of r_0, ν and of q the thermodynamic treatment represented in equations (2), (7) and (8) is markedly superior to treatment by the Clapeyron equation, for the purpose of smoothing up vapor pressure data, or of computing ΔH_0°.

Evidence against the Presence of Dissociation.—The preceding kinetic and thermodynamic treatment for nickel oxide is based on the supposition that sublimation as nickel oxide represents the only mechanism by which oxygen escapes from the oxide film during the process of evaporation. The good agreement of ΔH_0° among the several runs (Table VIII) substantiates this treatment. However, in view of the conflicting values reported in the literature for nickel oxide dissociation pressures[33] (some being higher, at 1500°,

(32) The error limits for NiO are considerably greater than for nickel (Fig. 1) due to the small evaporation losses of oxygen (on which the evaporation losses of NiO are based) and to the fact that these must be computed as differences between four weighings (each uncertain to ±0.02 mg. (*cf.* Table V). The error *limits* were arrived at by combining arithmetically the error from ±3° uncertainty in temperature with a 0.05 mg. probable error from accumulation of four weighing errors. The *probable* errors of the plotted points are computed from the usual probable error formula for addition or subtraction of chance errors, namely, P. E. = $\sqrt{\Sigma e^2}$, and make allowance for the chance that temperature and weighing errors may be of opposite sign.

than the residual gas pressure in our apparatus) we have given special consideration to the alternative mechanism of nickel oxide decomposition into nickel and free oxygen.

Direct evidence that dissociation was not taking place was provided by a micro-determination[34] of the gases pumped off continuously and collected, during one of the runs. No measurable trace of oxygen was present. Had decomposition into nickel and free oxygen been the evaporation mechanism the order of 0.5 cc. of oxygen (N. T. P.) would have been liberated. While some of this would unquestionably react with the fresh nickel film which formed on the walls of the cell (*cf. seq.*), it does not appear plausible that no trace would reach the pump, out of such a relatively large sample.

The conclusion to be drawn from this evidence is also confirmed by a calculation of dissociation pressures which can now be made from the thermodynamic data for nickel (Table II), for nickel oxide (Table VII), and that for oxygen[35] in conjunction with Roth's[36] thermochemical value of -58.9 kilocalories for the standard ΔH of formation of solid nickel oxide from its elements at 25°. These data yield the following oxygen pressures (Table IV) for dissociation at the respective temperatures of our runs.

Consideration of the ($O_2 = 2\,O$) equilibrium[35] at these temperatures and O_2 pressures yields the result that the partial pressures of monatomic oxygen are negligible in comparison.

The pressures in Table IX lie below the residual pressure of gas in our apparatus, with the possible exception of the 1566° run. Therefore, we can definitely eliminate dissociation for any of the runs in the lower range of temperature. Furthermore, if dissociation occurred at significant rate in either the 1566 or 1529° runs, these runs would have been attended with an abnormally high loss of oxygen and we would have computed correspondingly low values for ΔH_0°. Actually, no significant variation was observed among the values for ΔH_0° (*cf.* Table VIII). Thus we may conclude that dissociaton cannot have occurred with any of the runs by amounts that can be regarded as significant in the data.

Evaporation of Nickel.—It is interesting to observe that the evaporation of free nickel is almost as great as it would be in the absence of the oxide film and that there is little correlation between nickel evaporation and the film thickness. This is brought out in Table X. In general, it does appear that very thick films of oxide permit more rapid escape of nickel than do thin films. This may be the result of mechanical breakage of the film in the process of heating up the coated rings or in the escape of dissolved oxygen during evacuation.

TABLE X
EVAPORATION OF NICKEL THROUGH A FILM OF NiO

1	1566	21,000	.0265	.0119	45

Summary

Rates of evaporation of solid nickel have been measured between approximately 1300 and 1600°K., and the data employed to compute vapor pressures of the metal. The results obtained are in good agreement with thermodynamic requirements for the free energy of evaporation and yield 101,141 (±150) calories for the heat of sublimation at the absolute zero. The data yield the accurate vapor pressure equation, for solid nickel

$$\log p \text{ (atmospheres)} = -\frac{22{,}107}{T} - 1.31 \times 10^{-4} T + 7.869$$

Comparisons are made with earlier data by Jones, Langmuir and Mackay, and by Bryce, who measured evaporation rates from thin nickel filaments.

The accommodation coefficient for the condensation of nickel vapor on the equilibrium surface is unity within the experimental limits of accuracy and cannot lie below 0.75 as a lower limit.

Vapor pressures of nickel oxide (NiO) also have been determined, for the temperature interval 1440 to 1566°K., by measurement of the evapora-

(35) H. L. Johnston and M. K. Walker, *ibid.*, **55**, 172, 187 (1933); *ibid.*, **57**, 682 (1935).

(36) Roth, *Z. angew. Chem.*, **42**, 981 (1929).

tion losses from oxide films coated on nickel rings. While less accurate than the data for nickel, the results are in agreement with the thermodynamic requirements for evaporation of nickel oxide, and yield 117,055 (±1000) calories for the heat of sublimation at the absolute zero. Allowance for some uncertainty in the ground state multiplicity of NiO vapor, and in molecular constants, increases the possible error limit by three to four kilocalories. The data yield the vapor pressure equation

$$\log p \text{ (atmospheres)} = -\frac{25{,}506}{T} - 7.67 \times 10^{-4}T + 7.21 \times 10^{-8}T^2 + 10.198$$

Absence of oxygen in the gases pumped from the sample during evaporation, and a comparison of the residual gas pressures in our apparatus with the dissociation pressures of NiO within the temperature range of our measurements, exclude any significant influence from NiO dissociation.

Evaporation of free nickel was little retarded by the presence of the oxide coatings ranging from 20,000 to 90,000 Å. in thickness.

Recent data on the heat capacity of nickel have been reviewed and values for the heat content, entropy and free energy function have been computed and tabulated. Tables of the free energy functions of NiO (solid) and NiO (vapor) are also included.

The Vapor Pressures of Salt Solutions[1]

BY MAX F. BECHTOLD[2] AND ROY F. NEWTON

A convenient and accurate method for measuring the activities of water in salt solutions is very desirable in those cases in which it is difficult or impossible to obtain satisfactory measurements of the activities of the solute by electromotive force measurements. The method of Washburn and Heuse[3] modified by Gibson and Adams[4] and by Newton and Tippetts[5] appears to be quite promising, and has been further modified to increase both its accuracy and its convenience. Essentially the method consists of passing a gas successively through saturators containing pure water, an absorber, saturators containing the solution, and finally through a second absorber. Passing the same gas through both the pure water and the solution eliminates the need of measuring the gas. The vapor pressure of the solution can then be expressed simply in terms of the vapor pressure of pure water, the total pressure at each saturator, and the gain in weight of each absorber. In the older apparatus the pressure at the saturators varied, and it was necessary to read the pressures at frequent intervals during long runs in order to obtain reliable averages. The adaptation of relays for controlling the discharge pressure and the rate of passage of gas through the apparatus has made necessary only a single reading of each pressure. Slight condensation in the tubes connecting the saturators with the absorbers may produce serious uncertainties in the results, which has been obviated by enclosing the absorbers and connecting tubes in an air-bath just above the water-bath, maintained about five degrees higher than the latter, and at high humidity, thus preventing cooling due to evaporation at the point where the connecting tubes leave the water-bath. During preliminary adjustments the air-bath must be removed, and condensation may then occur in the connecting tubes. To avoid error due to collecting this condensate in the absorbers, a pair of "dummy" absorbers is connected in parallel with the weighed ones, and the gas is passed through them for about an hour after the air-bath has been adjusted. The establishment of steady flow conditions before the collection of water in the weighed absorbers also ensures that the same quantity of gas passes through both absorbers.

Apparatus and Materials

Measurements were made on solutions of barium chloride and of calcium chloride. The barium chloride solutions were prepared and analyzed as reported by Newton and Tippetts.[5] A sample of Mallinckrodt Analytical

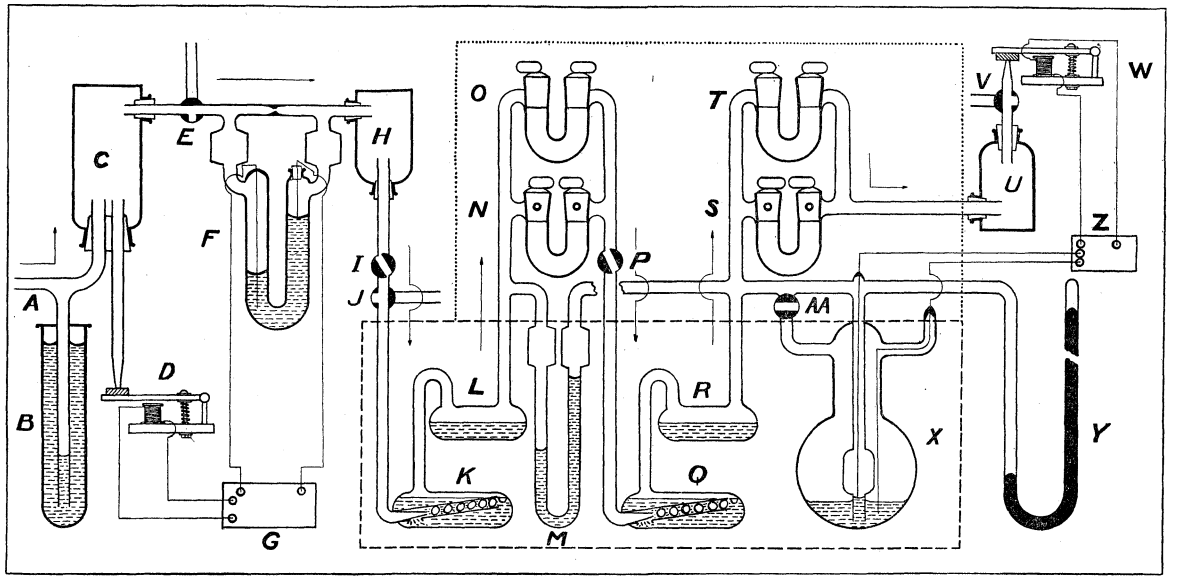

Fig. 1.

Reagent calcium chloride was found to contain only 0.12% of magnesium and alkali metal salts expressed as sulfates, and was judged sufficiently pure without recrystallization. The calcium chloride in the solutions was determined by adding a slight excess of sulfuric acid, evaporating, igniting, and weighing.

The final apparatus is shown diagrammatically in Fig. 1. The portion from A to J is a system for supplying the saturators with a stream of air at a uniform rate independent of atmospheric pressure and supply pressure. Air enters A at a rate in excess of that desired through the saturators. B acts as a safety valve which prevents the attainment of excessive pressures in case of accidental stoppage of the air stream. Flowmeter F maintains a constant rate through the saturators by controlling the action of magnetic valve D through the vacuum tube relay G. Dibutyl phthalate saturated with mercuric iodide is used as the manometer liquid in F because of its low density, negligible volatility and satisfactory electrical conductivity. Bottles C and H serve to smooth out pressure pulsations. The remainder of the apparatus is for the saturation of the air stream at a controlled temperature and pressure and for the absorption of water from it. The air stream passes into saturators K and L containing pure water, to absorber N or O, into saturators Q and R containing the solution being investigated, then through absorber S or T and out to the atmosphere. Throttling stopcocks I and P are necessary for satisfactory bubbling in the saturators. K and Q each represent a series of five similar saturators. It is necessary to place water in the first of the series Q because concentrated solutions crystallize in the jet of the bubbler and cause stoppage. The total pressures at L and R must be known in order to calculate the vapor pressure of the solution. The pressure at R is maintained constant within the accuracy of reading the barometer Y, by means of the regulator X which actuates the exhaust valve W through the relay Z. The conducting liquid used in X is the same as in F. The manometer M, which is filled with dibutyl phthalate, measures the difference in pressure between L and R. Previously it had been necessary to read M hourly because of change of porosity of the drying agent. This change is eliminated by using barium perchlorate in the left arm of each absorber and magnesium perchlorate in the right arm. The absorbers are completely refilled when the barium perchlorate is visibly wetted. The absence of clogging of the absorbers and the constant rate of gas flow make it unnecessary to read M more than once during a measurement. Only one reading of the barometer Y is required, whereas the hourly reading of a barometer and two manometers previously was necessary. The apparatus within the broken line is in a water-bath kept at 25, 35, or 45 ± 0.01°, while that within the dotted line is in an air-bath directly over the water surface. By the use of a small fan and a light bulb the air-bath was maintained about five degrees above the water-bath temperature and at about 85% humidity. These conditions prevent cooling the tubes which protrude from the water-bath. The stirring was such that no temperature difference between the bath around the upper saturators (K–L) and that around the lower ones (Q–R) could be detected by a Beckmann thermometer.

In places where flexibility is required, ends of glass tubing are joined by being butted together with neoprene tubing. Tests on these joints show no appreciable permeability to water vapor.

Procedure.—Assuming that the predetermined rate of flow has been set by adjusting the electrode in the right arm of F, air is started through A, and E is turned to connect C and F. The cocks of the "dummy" absorbers are opened, J is turned to connect H and K, and cock V is closed. When the pressure at R reaches a value not likely to be exceeded by the atmosphere, AA is closed and V is turned to connect U with the discharge tip controlled by W. After operating for some time, the air stream is diverted from the absorbers N and S to the

weighed absorbers O and T. The run is stopped by reversing all of the above operations.

Results

Measurements were made at 25, 35, and 45°, most of them on barium chloride, since comparison could be made with the activity calculated by the equations previously derived from electromotive force data.[5,6] The results are expressed in terms of the activity of water, assuming that

$$a_1 = p_1/p_0 \qquad (1)$$

and calculating p_1/p_0 by the equation

$$\frac{p_0 - p_1}{p_1} = \frac{m_0(B_0 - p_0) - m_1(B_1 - p_0)}{m_1 B_1} \qquad (2)$$

in which p_0 and p_1 are the vapor pressures of pure water and solution, m_0 and m_1 are the weights of water evaporated from pure water and from solution, and B_0 and B_1 are the total pressures at the ends of the saturators filled with pure water and with solution, respectively. Equations (1) and (2) will be strictly true only if the gaseous mixture is a perfect gas, but as previously pointed out[5] the activity calculated by (1) and (2) is much less sensitive to imperfection of the gas than is either (1) or (2) itself, and the a_1 so calculated is almost free of error due to imperfection of the gas.

As a check on the apparatus, $(p_0 - p_1)/p_1$ was determined with pure water in both sets of saturators. The average of ten runs, some performed at each temperature, is +0.00014, with a probable error of the mean of 0.00008.

The number of runs under each set of conditions was varied according to the agreement of the results. When they were very consistent, as few as four runs were made, but when the consistency was not so good, runs were continued until it was judged that the mean was reliable. The "probable error" of the mean is given merely as a crude measure of the consistency of the results, since for so few cases the usual formulas give only the order of magnitude of the probable error. On very dry days difficulty was experienced in getting reproducible weighings of the glass absorbers, and in spite of the precautions taken to obtain reproducible conditions on the glass surfaces, it is believed that a large part of the chance error is due to error in weighing. It may be noted in Table II that all the differences are positive, which seems to indicate a systematic difference of about 0.02% between the two sets of measurements. In the vapor pressure measurements, the gas always passed first through the pure water. Some slight imperfections in the apparatus may lead to a small systematic error which could undoubtedly be reduced by carrying out half of the measurements with the solution in the first set of saturators.

(6) A typographical error is present in each of equations (5) and (6) of reference (5). In equation (5) the term beginning 0.34444 should begin with 0.034444, and in equation (6) the term 0.1349 m should be 0.01349 m.

TABLE II

COMPARISON OF ACTIVITIES IN BARIUM CHLORIDE AT 25° BY INDEPENDENT METHODS

Molality	Activity from vapor pressure	Activity from e. m. f.	Difference

1.60010	.91483	.91466	.00017

Summary

An automatically controlled apparatus has been constructed for the precise measurement of vapor pressures of solutions by the dynamic method,

and measurements have been made on aqueous solutions of barium chloride and of calcium chloride at 25, 35, and 45°. The activity of water in the barium chloride solutions changes only very slightly with temperature. The activity of water by vapor pressure measurement is in very good agreement with that calculated from electromotive force data, the maximum difference being 0.035%.

The Hydrogenation of Ethylene at Surfaces of Certain Oxides. I. Zinc Oxide and Zinc Chromite

BY JOHN F. WOODMAN AND HUGH S. TAYLOR

The measurement of the activity of oxides as catalysts for the hydrogenation of ethylene was originally undertaken in the expectation of checking the results of Vaughen and Lazier[1] on zinc oxide. These authors had reported negligible amounts of ethane resulting from the passage of hydrogen and ethylene over zinc oxide and other oxides at 400°. It was hoped that this absence of activity would be confirmed by a few preliminary runs, after which it was planned to investigate possible activity of zinc oxide for deuterium substitution, with a view to developing a convenient method for the production of deutero-ethylenes free from overwhelming amounts of the ethanes.

Unfortunately for this program, the preliminary runs showed that the ability of zinc oxide to catalyze the hydrogenation of the double bond in ethylene is far from negligible, even at temperatures much below those used by Vaughen and Lazier. Since the latter authors had made their results the basis of a rather inclusive hypothesis regarding the specificity of oxide catalysts for the hydrogenation of organic compounds, it seemed worth while to investigate the discrepancy more closely, and, if possible, to determine the factors responsible for it.

Lazier and Vaughen[2] themselves soon discovered the high activity of chromium oxide for the hydrogenation of the alkene bond and stated that this property set chromium oxide apart from other oxides. Turkevich[3] showed that ethylene introduced to a mixed manganese–chromium oxide catalyst at temperatures of 184° and above, underwent activated adsorption accompanied by decomposition, the products pumped off at higher temperatures being largely saturated hydrocarbons. This indicated activity for hydrogenation at lower temperatures than had previously been reported for chromium oxide catalysts. As a consequence of his observations, Turkevich pointed out that the specificity of oxide catalysts must be regarded as a matter of degree.

The discovery of the activity of zinc oxide and its thorough study led to test of the activity of zinc chromite. In a later paper[4] we report work on compounds of molybdenum, chosen because of the well-known industrial applications of the oxides and sulfides of this element in hydrogenation and cracking of oils and tars.

Experimental Details

Apparatus.—The apparatus used consisted of the following units: (a) a catalyst tube, at controlled temperature, isolated from the system by a trap kept at −78° to keep out mercury vapor; (b) a mercury manometer; (c) a pump system for evacuation; (d) burets for gas mixing and measurement; (e) purification trains for the gases.

Catalysts.—Zinc oxide was prepared from the oxalate by the method of Taylor and Sickman,[5] zinc chromite according to the method of Taylor and Strother.[6]

Gases.—Electrolytic hydrogen and tank ethylene, carefully purified, were employed.

Procedure.—Originally the gaseous mixtures were circulated by means of a Toepler pump over the catalyst in a closed cycle. The later determinations were made in a static system of conventional design with the catalyst at the bottom of a Pyrex cylinder of 35 mm. diameter and 250 cc. capacity.

Experimental Results

Zinc Chromite.—A mixture of 357 mm. of hydrogen and 198 mm. ethylene was admitted to 5.5 g. of catalyst at 21° and slowly raised in temperature to 215°, with frequent gas circulation.

After thirty hours at 215° a decrease in pressure of 183 mm. was recorded. The final gas contained 53% C_2H_6, 44% H_2 and 2.2% olefins. A mixture of 222 mm. of H_2 and 403 mm. of C_2H_4 showed a slow pressure decrease at room temperature. After sixty hours at 250°, the gas contained 58% C_2H_6, 34.9% olefin and 7% H_2.

Zinc Oxide.—Qualitatively this catalyst behaved in the cyclic system at 200 and 300° like zinc chromite but was more active. With 333 mm. of H_2: 266 mm. of C_2H_4 at 200°, a pressure decrease of 256 mm. occurred in 2.5 hours, the product showing 77.2% C_2H_6, 20.4% H_2 and 2.2% olefin.

Static experiments showed that with evacuation at 450° of the air-ignited oxide the catalyst, weighing approximately 1 g., showed activity in the temperature range 0–80° with 56.5° (acetone vapor-bath) as a convenient working temperature. In successive experiments at 56.5°, with evacuation between experiments for intervals of two to twenty-one hours at the same temperature, a progressive decrease in velocity of reaction occurs, as shown by the following data for the period of half reaction, t_{50} = 19, 24, 35, 49, 68 minutes. In the succeeding experiment, after evacuation at 450° for twenty-nine hours, t_{50} fell once more to twenty minutes. Evacuation at 218° was not adequate to eliminate this progressive deterioration, as is shown by the following data for t_{50} at 56.6°, with intermediate evacuation at 218° for three hours: t_{50} = 74, 90, 100, 120, 140, 150 minutes.

Air activation of the surface by heating in a static system of air between each experiment to 450° for seventy-five minutes after evacuation of the catalyst for a few minutes at 56.5°, followed by a final three-hour evacuation at 450° immediately decreased the half-period of reaction of such deteriorated catalysts, as the following data with an initially inactive surface reveal: t_{50} = 170, 25, 23, 16, 19, 33, 44, 35, 29, 44, 44.

The decrease in reaction rate indicated by the final figures in the data just cited led to investigation of this secondary loss of activity. Since it would not appear to be due to inefficiency of removal of the primary agent of deterioration or its oxidation products, a test was made to ascertain whether the decrease might be due to strong adsorption of one of the components of the activating gas, most probably oxygen. This effect was tested thus: in a series of runs, activation with air for brief intervals at successively lower temperatures was tried, the conditions of evacuation, three hours at 450°, being maintained unchanged. The following data show that greater activity is obtained by using a shorter activation time. Further, lowering the activation temperature as far as 150° does not decrease the effectiveness of the activation. Activation with air at 56° is less effective.

TABLE I

INFLUENCE OF ACTIVATION CONDITIONS AT REACTION TEMPERATURE 56.5°

Activ. temp., °C.	450	450	400	345	305	250	200	150	56
Activ. time, min.	75	18	20	18	18	18	18	18	18
t_{50} min.	44	21	26	21	23	24	20	25	31

The increase in activity on decreasing the time and temperature of activation signifies that, with long activation, the primary effect of cleaning the surface, by removal of a deposit formed during reaction, is being partially nullified by a second effect, presumably oxygen adsorption, the resulting adsorbed layer not being completely removed by the evacuation procedure. To test this view, it was shown that admission of air, at 450°, for forty-five minutes to a surface of standard activity (t_{50} = 14–17 min.) followed by the standard evacuation at 450° for three hours gave a surface of lower activity, t_{50} = 29 minutes. The secondary film produced by air treatment is more tenaciously held than the primary poison, since evacuation at 250° of surfaces activated for eighteen minutes in air at 250° gave very slow reaction, t_{50} = 85 minutes. Evacuation, even at 450°, for less than twelve hours, does not clean an air activated surface completely. The highest and most reproducible activity was obtained by treating the catalyst with air at 250° for five to twenty minutes, then evacuating at 450° for twelve hours or longer.

Evacuation at 450° without activation with air was found to be undesirable practice since reduction of the catalyst by reactants may occur during the temperature rise after an experiment. Experiments at 218°, followed by evacuation at 450°, caused reduction of the surface and sublimation of metallic zinc. This does not occur after reaction at 56.5° if the system is thoroughly evacuated at 56° prior to raising the temperature to 450°.

The kinetics of the reaction on such surfaces, where the variability is great and not easily controlled, is difficult to study. A variation in the

H_2:C_2H_4 ratio from 5:1 to 3:1 ($p_{C_2H_4}$ = 50 mm.) gave no change in t_{50}. For H_2:C_2H_4 varying from 3:1 to 1:1 (for p_{H_2} = 160 mm.) the half-life varied from twenty-two to seventy-one minutes, and calculation from the initial slopes of the rate curves results in a dependence on the 0.1 power of the ethylene pressure. For equimolar mixtures with total pressures of 320 and 120 mm. the half-lives were seventy-one and forty minutes. Addition of 26 mm. of ethane to a 3:1 H_2:C_2H_4 mixture, $P_{C_2H_4}$ = 52 mm., did not change the half-life. Within these limits the reaction velocity appears to be independent of the reactant pressures.[7] The order of magnitude of the apparent activation energy of the reaction was determined, from two pairs of runs at 39 and 56°, as ~ 18 kcal.

To study the influence of water vapor, experiments were carried out at 56 and at 400°, the latter being the temperature used by Vaughen and Lazier. Water vapor is known to be a strong reversible poison for zinc oxide catalysts[5,8] and its effect on the hydrogenation of ethylene is of interest because the experiments of Vaughen and Lazier, which failed to detect any activity in this reaction, were carried out with moist gases stored over salt solution. At 56° a hydrogen–ethylene mixture containing 3% water vapor or 7×10^{-5} moles per gram of catalyst, required a half period of reaction equal to seventy-five minutes, or threefold the rate for dry gases. When the catalyst at 56° was equilibrated with water vapor from ice at 0° for two hours, the standard 3 hydrogen:1 ethylene mixture showed only a change of 1 mm. pressure in fifteen minutes. The catalyst was completely inactive.

At 400°, after the standard air activation and evacuation, the % reaction in fifteen minutes of a $3H_2$:$1C_2H_4$ mixture was negligible with 3.7 and 2% of water vapor in the gas, whereas the dry gas showed 72% reaction in the same interval. The 2% of water vapor present in the experiment corresponds to about 1.9 cc. at N. T. P. on the gram of catalyst used. Vaughen and Lazier used twenty grams of catalyst over which they several times passed samples of six to seven liters of gas stored over saturated salt solution. Thus, after the passage of 2.5 liters of gas, their catalyst would have been in contact with water vapor sufficient to stop reaction on our catalyst even if their technique had eliminated water vapor from the catalyst surface initially. Their failure to detect significant activity is thus completely explained. The greater effect of adsorbed water vapor at 400° compared to that at 56° is consistent with the known high temperature activated adsorption of water vapor on zinc oxide.[5]

Hydrogenation at 218° produced much more rapid decreases in velocity in successive runs; after three runs the velocity became almost negligible. Subsequent evacuation at 450° brought a tremendous increase in activity, to such an extent that diffusion became the rate-determining step, with t_{50} at 218° of the order of three minutes.

The evacuation process following reaction at 218° caused a grayish film of metal to appear on the cold walls of the reaction vessel, the deposit increasing with successive evacuations following later runs at 218°. The deposit could be sublimed. When the tube was heated after admission of air the color of the film changed to white. The film was evidently metallic zinc formed by reduction of the oxide surface by the reaction mixture at 218° or during the evacuation. Evacuation at 450° before access of the hydrogen–ethylene mixture produced no such deposit. The zinc was therefore not formed by thermal dissociation.

Pretreatment with 25 mm. of hydrogen for thirty minutes at 56° caused the adsorption of about 0.1 cc. at S. T. P. A mixture of hydrogen and ethylene added to make the total ratio a $3H_2$:$1C_2H_4$ mixture reacted slightly more slowly than normal. Exposure to hydrogen at 80° and 1 atm. pressure for five hours, with evacuation at 56° for fifteen minutes before the experiment, gave a retardation of the same order. Treatment with hydrogen at 218° turned the catalyst gray and the succeeding run at 56° after evacuation for fifteen minutes at 56° was very much slower. The change in color is a definite indication of reduction.

An atmosphere of hydrogen in contact with the catalyst at 218° for five hours changed the color to gray. After fifteen minutes of evacuation at 56° a run at this latter temperature showed very great retardation. Reduction of bulk zinc oxide by hydrogen has been shown not to occur below about 310°.[9] Reduction of active zinc oxide catalysts by hydrogen at lower temperatures has frequently been observed in this Laboratory[5,8,10]

and the effect seems to be enhanced by hydrocarbons.[11]

Ethylene at a pressure of 320 mm. in contact with 5 g. of catalyst at 218° gave a pressure decrease of 53 mm. in one hundred hours. The gaseous product was completely condensable in liquid air, indicating that polymerization had taken place with no significant formation of hydrogen or methane. At 445°, 600 mm. of ethylene on the same catalyst gave first a rapid absorption of gas to 474 mm. in two hours followed by a slow pressure increase to 504 mm. in ninety hours. From 77 cc. of ethylene initially present, 11 cc. of hydrogen and 11 cc. of methane were recovered. Polymeric products also were formed. The ability of zinc oxide slowly to attack both C–H and C–C bonds at 445° is thus demonstrated.

General Discussion

Lazier and Vaughen[2] assumed a specific capacity in chromium oxide for the activation of alkenes leading to their hydrogenation, and the absence of such capacity in other difficultly reducible oxides. The accumulated chain of evidence, of which this article furnishes the latest link, shows definitely that this assumption is not in agreement with the facts now available.

Howard[12] observed that on chromium oxide at 218°, adsorbed hydrogen reacted readily with ethylene. Turkevich[3] found ethylene activated by adsorption on manganese–chromium oxides at 184°, and recoverable largely as ethane. The present work shows that, already at 56°, zinc oxide is activating ethylene for hydrogenation, and moreover suggests that, even at this temperature, there is activation of specific bonds leading to the formation of a hydrocarbon deposit which poisons the active centers. That this deposit is actually of hydrocarbon origin, and is not merely adsorbed hydrogen, is attested by its accumulation in successive runs, contrary to what one would expect from the known behavior of hydrogen, and by the failure to detect an inhibitory effect of hydrogen present in the reaction mixture.

With rising temperature, the parallelism in the cases of chromium oxide, manganese–chromium oxides, and zinc oxide is complete. On the last catalyst, hydrogenation is rapid at 218°, and activation of specific bonds is clearly established by the disappearance of ethylene alone in contact with the catalyst, forming probably $(C_2H_4)_n$, but no permanent gases. At higher temperatures, both C–C and C–H bonds are broken, with formation of methane and hydrogen, and deposition of carbon. These results for zinc oxide over the range from room temperature to 444° are entirely analogous, at the higher temperatures, to the behavior of chromium oxide,[12] and manganese–chromium oxides,[3] no attempt having been made, on these catalysts, to test the possibility of hydrogenation at lower temperatures. It is even more interesting that the behavior of zinc oxide parallels that shown by Morikawa, Trenner and Taylor[13] to be characteristic of nickel in the temperature range from −78° to about +130°.

Summary

1. Zinc oxide and zinc chromite have been shown to act as catalysts for the hydrogenation of ethylene with measurable velocity at and above room temperature. At 56° the reaction velocity on zinc oxide has been shown to be independent of hydrogen, ethylene and ethane partial pressures within a range of variation of these quantities.

2. On zinc oxide at 56° the number of active centers decreases because of the deposition of some substance probably arising from very slow polymerization or decomposition of ethylene at the surface. This poison can be oxidized by air at 150° and above, and the products removed by long pumping at 450°.

3. There is some evidence that oxygen is strongly adsorbed on the active centers of zinc oxide at 150° and above.

4. Reduction of zinc oxide to metallic zinc by the reaction mixture does not take place at 56°, but does so at 218° and above. The reducing effect of hydrogen alone at 218° has been confirmed.

5. Ethylene has been shown to polymerize slowly on zinc oxide at 218°, without appreciable formation of permanent gases. At 445°, polymerization is rapid, but accompanied by the formation of considerable amounts of hydrogen and methane.

6. Small amounts of water vapor have been shown to poison the surface of zinc oxide completely at 56° and even at 400°. This effect is responsible for the failure of Vaughen and Lazier[1] to observe the activity of this catalyst with their experimental procedure.

The Hydrogenation of Ethylene at Surfaces of Certain Oxides. II. Molybdenum Oxide Compounds

BY JOHN F. WOODMAN, HUGH S. TAYLOR AND JOHN TURKEVICH

Following the study of the activity of zinc oxide and zinc chromite surfaces described in the preceding paper,[1] a series of experiments was carried out to test the activity of some molybdenum compounds, in view of the well-known industrial applications of the oxides and sulfides of this element in hydrogenation and cracking of oils and tars. Catalytic masses were prepared by decomposition and reduction of ammonium phosphomolybdate, ammonium paramolybdate, and ammonium nickel molybdate. Suspicion of the presence of metallic nickel in extremely active catalysts produced by reduction of the nickel compounds suggested tests of the efficiency of hydrogen sulfide as a poison for these surfaces and measurements of the magnetic susceptibilities of the materials.

Experimental Details

Apparatus and Procedure.—The catalytic system was the same as that used in the static experiments on zinc oxide.[1]

The magnetic susceptibilities were determined by the method of Gouy.[2] Measurements were carried out with magnetic fields up to about 4800 gausses, the magnet current being increased from zero to 12 amp. in steps of about 2 amp., then reduced again to zero in the same manner, with the change in weight of the sample determined at each step. For purposes of calculation, the results were plotted against current and values taken from the smooth curve at intervals of 2 amp. The relationship between current and field strength was established by calibration with Mohr salt, for which χ, the specific susceptibility, was taken as 32.1×10^{-6} cgsm. unit at 22°.[3]

The finely divided samples were contained in uniform 5 mm. Pyrex tubes, each filled to a depth of 12.2 cm. Reduced samples were filled into the tubes under vacuum and sealed off without access to air. Measurements were corrected for the small diamagnetic effect of the tubes.

During measurements the sample tube hung freely in a Pyrex jacket through which dry nitrogen gas had been passed for one-half to one hour.

Only the measurements at room temperature are reported; others at 0, −80 and −190° gave similar results.

Materials.—Ammonium phosphomolybdate, $3(NH_4)_2O \cdot P_2O_5 \cdot 24MoO_3 \cdot 6H_2O$, was prepared following the analytical procedure.[4] The yellow product was dried at 120°.

Molybdenum oxide was prepared by heating ammonium paramolybdate to 300° in a current of air until the off-gas gave no test for ammonia.

Ammonium nickel molybdate was prepared by dissolving 145 g. of ammonium paramolybdate in one liter of water, and adding the filtered solution to a solution of 27 g. of nickel nitrate hexahydrate in 100 cc. of water. The whole was heated to boiling, with mechanical stirring, while precipitation took place. Next, the solution was diluted with water to three liters, cooled, and allowed to settle. The slightly greenish supernatant liquid was decanted, and the precipitate stirred once with three liters of water containing 25 g. of ammonium nitrate. It was then filtered with suction, and washed with 100 cc. of water. The bluish, finely crystalline product was dried overnight at 125°. From this product all the catalysts containing nickel were prepared as subsequently noted. The most probable formula for the preparation, according to Barbieri,[5] is $(NH_4)_4H_6[Ni(MoO_4)_6] \cdot 5H_2O$.

Hydrogen sulfide was synthesized from hydrogen and molten sulfur at 350°.

Results and Discussion

Phosphomolybdate and Molybdenum Oxide Catalysts.—A catalyst from 1.5 g. of ammonium phosphomolybdate (B), heated for eight hours in a current of dry air, evacuated for thirty-six hours (BI) and then treated with hydrogen for nineteen hours, followed by a further evacuation, all at 300°, changed progressively from mustard yellow, through light green to black, after reduction. The preparation (BII) failed to show significant activity in catalyzing the reaction of a 3:1 mixture of hydrogen and ethylene below 256°.

A preparation ignited in an air stream at 475° for six hours, then reduced with hydrogen at 450–475° for eight hours, was similarly inactive at 256°, the half-life value, t_{50}, being about two and a half hours. A preparation of this nature has been shown by Kingman[6] to be an excellent catalyst for the reduction of phenol at 280–350°.

Ammonium paramolybdate decomposed at 300°, evacuated at 450° and reduced for eight hours at 300° gave on evacuation a black catalyst mass. It showed no activity for ethylene hydrogenation at 256° nor was its activity increased by further reduction at 450°.

Nickel Molybdate Catalysts.—A 1.5-g. sample of ammonium nickel molybdate (A) was heated

slowly in a dry air stream to 300° and kept there for nine hours while ammonia was evolved. The tube was then cooled, evacuated, and the air stream replaced by pure hydrogen for four hours. During the succeeding twenty hours a stationary hydrogen atmosphere caused further reduction. The catalyst was then evacuated for six and a half hours at 350°, further reduced at 305° for fifteen hours, and then thoroughly evacuated at 350°. The product (AII) was black. Its activity was very high, a half-life of three minutes being recorded at −80° for a $3H_2$:$1C_2H_4$ mixture. The rate was not increased by raising the temperature; the observed rate of change of pressure was determined by diffusion processes.

Catalyst masses (AI) prepared as above but without the hydrogen reduction were olive-green to gray in color. Evacuation at 350° for thirteen hours caused a color change to blue, evidently with formation of a lower oxide of molybdenum. This material showed no hydrogenation activity at 0, 100, 156 and 218°, even though before each run the surface was left in contact with hydrogen for eight hours at a temperature five to ten degrees higher than the operating temperature. Treatment with hydrogen at 270° for six hours caused water formation and the catalyst became black. Its activity was then similar to that of the reduced catalyst already discussed. The reduction of a component of the catalyst, occurring at 270–300°, is thus essential to its activity in ethylene hydrogenation.

That the high activity of the reduced nickel–molybdenum oxide catalysts was due to the presence of metallic nickel highly dispersed through the molybdenum oxide was indicated by three different lines of approach. Measurements of the magnetic susceptibility, discussed in the next section, gave an estimate of the amount of nickel present. This estimate was in agreement with measurements of the hydrogen sulfide required to poison the catalysts completely for hydrogenation. The inactivity of the other molybdenum oxide preparations not containing reducible metals discussed above, afforded indirectly a third corroboration.

Magnetic Measurements.—Values of χ, the specific susceptibility, calculated for samples of the nickel–molybdenum oxide compounds (A) which had undergone the various treatments described, are contained in Table I. For comparison, values for some preparations from ammonium phosphomolybdate (B) are included.

The striking feature of this table is the decrease in susceptibility with increasing field strength which occurs in the case of the reduced samples prepared from ammonium nickel molybdate. This behavior is characteristic of ferromagnetic substances. Its occurrence in the present instance can only indicate that under the conditions of preparation of these samples, some of the nickel present became reduced to the metal.

If we make the plausible assumption that the susceptibilities of the various phases present are additive, it is possible to calculate approximately the percentage of the total nickel present as metal after the various treatments. The additive relationship is

$$(m_1 + m_2)\,\chi = m_1\chi_1 + m_2\chi_2 \qquad (1)$$

where m_1 is the mass of the ferromagnetic material, χ_1 its specific susceptibility, m_2 and χ_2 are the corresponding quantities for the remaining, non-ferromagnetic material, and χ is the observed susceptibility of the sample. For χ_1, we may take the values for pure metallic nickel at room temperature,[7] and we know $(m_1 + m_2)$ and χ from the measurement at the same temperature. It is then possible to set up an equation of the form of (1) for each field strength. Solution of these equations simultaneously gives the approximate weight of nickel present in each sample.

Assuming the composition of the decomposed and reduced samples to be closely represented by the formula $2NiO{\cdot}6Mo_2O_3$, the calculated percentage of the total nickel present which has been reduced to the metal is shown in the last column of Table I. These values are of course to be considered as indicative only of order of magnitude, and as such are not significantly changed by selection of other formulas.

Poisoning with Hydrogen Sulfide.—Two catalysts corresponding to AII of Table I were tested for resistance to hydrogen sulfide by adding increasing amounts of this gas to the reaction mixtures in successive runs. In each case a reproducible minimum of hydrogen sulfide was found to be required in any single run to cause complete cessation of reaction at −80°. The poison was apparently completely removed by evacuation at 350° between runs, and the series of runs with increasing amounts of the sulfur compound could be repeated, with no observable retardation until the critical amount was present. We attribute this unusual behavior on poisoning to the fact that

Moles Ni metal, from χ	11×10^{-5}	5×10^{-5}
Moles H_2S to poison	12×10^{-5}	4×10^{-5}

Ogden[8] has measured the adsorption of hydrogen by material prepared in essentially the same way as that described in this section and found it to differ entirely from the adsorption characteristic of metallic nickel. The preparation showed no observable hydrogen adsorption from −78 to +110°, whereas nickel shows its maximum adsorptive capacity at 0°. His failure to detect adsorption characteristic of nickel is doubtless due to the very small amount of the metal present.

It is apparent from the results noted above that the activity of these nickel–molybdenum oxide structures is a function of their content of metallic nickel; and that, lacking reduction sufficient to produce the metal, such materials resemble other molybdenum oxide structures not containing nickel or any reducible metal, in being ineffective as catalysts for ethylene hydrogenation below 250°. It is striking that these molybdenum compounds fail to show activity comparable to that of zinc oxide, which hitherto had not been classed among the surfaces on which hydrocarbon reactions might be secured.

Summary

1. A catalyst prepared by decomposition and reduction of ammonium nickel molybdate at 300° is active at −80° in the hydrogenation of ethylene. Magnetic susceptibility measurements, together with poisoning experiments using hydrogen sulfide, have suggested that this activity is due to metallic nickel, very highly dispersed.

2. Catalysts prepared from ammonium phosphomolybdate and ammonium paramolybdate have shown negligible activity for ethylene hydrogenation below 256°.

Chemical Constitution and Reactivity. I. Phenyldiazonium Chloride and its Mono Substituted Derivatives

BY M. L. CROSSLEY, R. H. KIENLE AND C. H. BENBROOK

In this investigation an attempt has been made to throw some light on the relationship between chemical constitution and reactivity by making an exhaustive study of the reactions which occur when aromatic diazo compounds decompose in aqueous solutions. As a first step an accurate, simple and automatic apparatus was designed for measuring and recording evolved nitrogen.[1] By use of this apparatus, aqueous solutions of phenyldiazonium chloride,[2] and twenty-four of its mono substituted derivatives have been investigated.

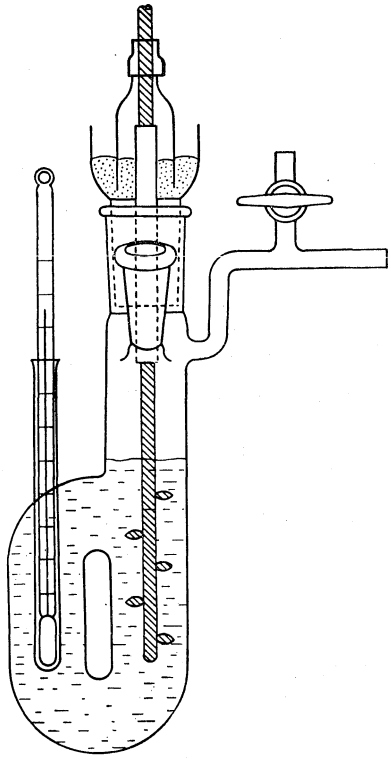

Fig. 1.—Reaction cell.

The experiments were carried out at constant temperature, within ±0.05°, in the dark in an 80-cc. glass cell of special construction, Fig. 1, equipped with an efficient stirrer to prevent supersaturation of the solution with nitrogen. The volume of the gas evolved from the reaction cell was continuously measured and recorded by means of the previously described apparatus.[1]

Effect of Temperature.—Freshly distilled aniline was diazotized at 0° in aqueous solution, using 2.2 molar equivalents of hydrochloric acid and 1.0 molar equivalent of sodium nitrite. The solution was diluted to 0.1 molar concentration with ice water, immediately added to the reaction cell and brought to the experimental temperature. The rate of decomposition was determined over a wide temperature range. The values of the reaction velocity constants are given in Table I. The accuracy of the method of measurement has been described previously.[1]

The data in Table I are linear when plotted as ln k *vs.* $1/T$, thus satisfying the Arrhenius equation

$$\ln k = \ln Z - (E/RT) \qquad (1)$$

The heat of activation for the reaction has been calculated from these data and found to be 27,200 cal./g. mole.

Effect of Concentration.—The effect of concentration on the reaction velocity was studied over a very wide range. In this series the solutions were prepared from crystalline phenyldiazonium chloride, synthesized as follows.

Aniline hydrochloride, 6.475 g., was suspended in 25 cc. of glacial acetic acid and cooled in an ice-bath to 10°; 10 cc. of octyl nitrite was added rapidly and the solution simultaneously cooled externally to about 5°. The solution was carefully examined for any undissolved and unreacted particles of aniline hydrochloride and these were broken up carefully. The solution was spotted against 5% sodium carbonate solution, and octyl nitrite was added dropwise as long as the spot test was red. As much as 15 cc. of octyl nitrite was necessary in some preparations. When the diazotization was complete, 125 cc. of ether was added in a steady stream, whereupon the product precipitated out as an oil. This was allowed to settle for two minutes and the excess ether decanted until there remained a volume of ether approximately equal to that of the oily precipitate. Then, 200 cc. of acetone was added as rapidly as possible and the solution stirred vigorously, whereupon the product came out as a thick slurry of

(1) Crossley, Kienle and Benbrook, *Ind. Eng. Chem., Anal. Ed.*, **12**, 216 (1940).

(2) In this paper, the term "phenyldiazonium chloride" will be used rather than phenyldiazochloride, although it is recognized that the nitrogens may be tri-valent under some of the conditions imposed.

coarse crystals. The product was filtered, washed by resuspension twice in acetone and twice in ether. It was dried in air until free of ether and then in a desiccator until free of moisture. The yield was 3.5 g. All reasonable safety precautions were taken because of the highly explosive nature of the product.

The product was stored in a desiccator. In the dry state, no measurable decomposition occurred. The evolved nitrogen per gram remained constant. Each aliquot was weighed out and dissolved immediately prior to use.

In order to justify the comparison of data obtained by use of crystalline diazonium chloride with those obtained by use of diazonium chloride solutions prepared by direct diazotization, two decomposition experiments, identical except as regards the method of preparation, were run. No difference in the rate data was found.

Separate experiments were carried out at concentrations ranging from a water–diazo ratio of 1280:1 (moles) to an extremely concentrated solution wherein the ratio was 2.36:1 (moles). It was observed that for all concentration ratios the reaction followed the first order law. Data showing both the mono- and bimolecular treatments of the most concentrated solution investigated illustrate this point (Fig. 2). The reaction, therefore, appears to be truly monomolecular.

The principal reaction products in the decomposition of phenyldiazonium chloride in water are usually considered to be phenol, nitrogen and hydrochloric acid. By analysis of the residues in the concentration series of experiments, it was found however, that the percentage yield of phenol is a function of the dilution. In the most concentrated experiments carried out, where the water–diazo ratio was 2.36:1 (moles), the percentage yield of phenol was 24.3%. On the other hand, in the most dilute experiment, the corresponding yield of phenol was 95.2%.

The reaction velocity constants and phenol yield obtained for the various concentrations studied are given in Table II.

An attempt was made to determine qualitatively what products other than phenol are present after decomposition has occurred. In the concentrated solutions monochlorobenzene, benzene, and biphenyl were identified, monochlorobenzene appearing in greatest quantity. The formation of monochlorobenzene has been observed by Hantzsch.[3]

TABLE II

EFFECT OF CONCENTRATION ON THE REACTION VELOCITY CONSTANT AND YIELD OF PHENOL IN DECOMPOSITION OF PHENYLDIAZONIUM CHLORIDE SOLUTIONS, TEMP. 35°

Moles H_2O/moles diazo	k (sec.$^{-1}$) $\times 10^5$	% yield of phenol
2.36	26.2	24.3
3.11	26.8	30.0
3.54	25.6	27.1
3.94	26.7	31.4
7.93	..	37.0

1268.00	19.2	95.2

Deuterium Oxide as Solvent.—Two runs were made under identical conditions except that in the first run the diazonium chloride was dissolved in water, whereas in the second run the solvent was deuterium oxide. The reaction velocity constants were essentially the same, *i. e.*, 0.00025 sec.$^{-1}$ and 0.00024 sec.$^{-1}$, respectively.

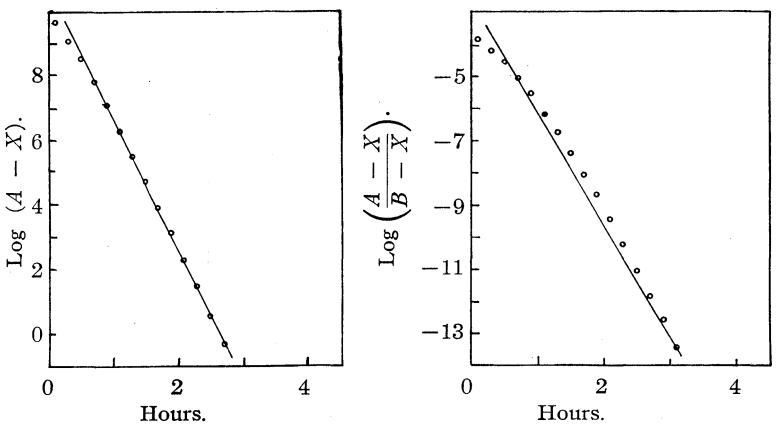

Fig. 2.—Comparison of unimolecular and bimolecular plots. Ratio of diazo to water 1:2.36 moles.

Effect of *p*H on the Reaction.—A series of experiments was run in which phenyldiazonium chloride was dissolved in different strengths of concentrated hydrochloric acid. In changing the normality of the hydrochloric acid from 0.1 to 12 *N*, only a slight change in the value of the reaction velocity constant is noticed (see Table III). It is interesting to note that the change in

(3) Hantzsch, *Ber.*, **33**, 2534 (1900).

reaction velocity is small even though Hantzsch[3] has found that in concentrated hydrochloric acid solution the yield of monochlorobenzene increases to 60%.

TABLE III

EFFECT OF ACID CONCENTRATION ON THE REACTION VELOCITY CONSTANT IN DECOMPOSITION OF PHENYLDIAZONIUM CHLORIDE SOLUTION, 0.1 MOLAR, TEMP. 35°

HCl concn., N	k (sec.$^{-1}$) $\times 10^5$
0.1	20.0
5.0	23.5
10.0	24.1
12.0	22.6

Several solutions of phenyldiazonium chloride were brought to different pH values by the addition of sodium hydroxide solution. Each sample was held at a temperature of 35°. When the pH was brought to a value of 11.2 (Fig. 3), it dropped within a period of forty minutes to a pH of 2.

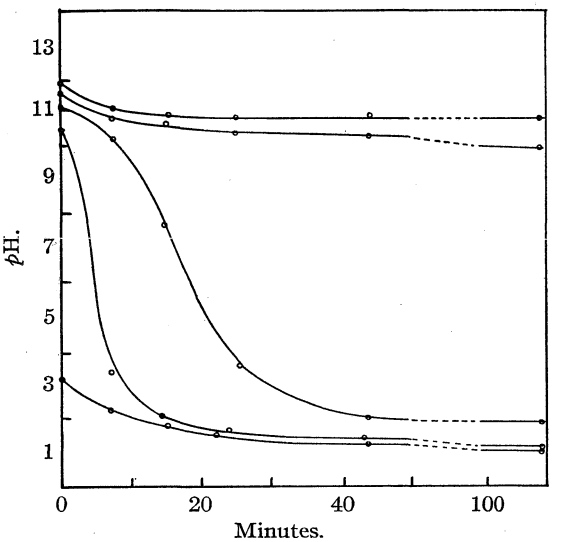

Fig. 3.—pH *vs.* time plot, phenyl diazo chloride solution, T = 35°, concn. = 0.1 molar.

However, when the original pH was 11.6 or more, the pH value remained above 10. This series was followed by another in which buffered samples were studied at various pH's to cover the range 3 to 11.8. The data obtained showing the percentage nitrogen evolved, together with the pH changes which occur in spite of the buffering, are given in Fig. 4.

Mono-substituted Derivatives of Phenyldiazonium Chloride.—A temperature study was made on the ortho, meta, and para methyl, methoxy, phenyl, hydroxy, chloro, carboxy, sulfo, and nitro phenyldiazonium chlorides. The amines from which the diazonium salts were prepared were Eastman Kodak Co. C. P. chemicals, except for *m*-aminobiphenyl, which was synthesized by the method of Fichter and Sulzberger.[4] The Eastman samples were further purified in our laboratory.

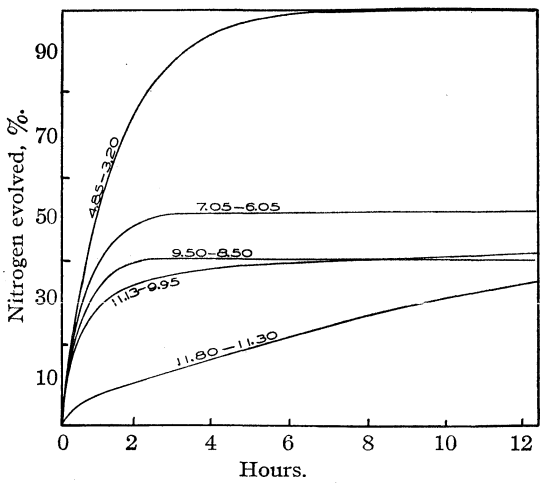

Fig. 4.—Per cent. nitrogen evolved *versus* time at pH values indicated, T = 35°, 0.1 M solution.

The amines were dissolved in water by the use of 2.20 molar equivalents of hydrochloric acid, iced to zero and diazotized by use of a normal solution of sodium nitrite and then diluted to 0.1 molar concentration of diazonium chloride and 0.02 molar concentration of hydrochloric acid. In general, the completely diazotized solutions were perfectly clear, but whenever a cloudiness occurred as a result of the formation of diazoamino compound, the cold solution was filtered before use. Prior to the decomposition experiments, the pH of each solution was checked with the glass electrode and used if between 1.60 and 1.80.

Rate of Decomposition.—On the basis of preliminary experiments, two or more temperatures were selected at which virtually 100% decomposition could be reached for each diazo within a reasonable time (three to thirty-six hours). Each experiment was then carried to completion and the unimolecular reaction velocity constants calculated, careful correction having been made for all such factors as slight changes in room temperature and/or barometric pressure. A linear relationship between log concentration and time was found over 95–96% of the entire reaction for every diazo in the present series, except for the diazo derived from *o*-anisidine. The latter com-

(4) Fichter and Sulzberger, *Ber.*, **37**, 878 (1904).

pound does not decompose according to the simple unimolecular law but rather with an autocatalytic trend with the production of an "S" curve. This has been found to be characteristic of several other less common mono-substituted derivatives of phenyldiazonium chloride as well as a large number of poly-substituted derivatives. These exceptions will be treated in a subsequent communication.

TABLE IV

VALUES OF k IN DUPLICATE EXPERIMENTS, SUBSTITUTED PHENYLDIAZONIUM CHLORIDE, CONCN. 0.1 M, pH 1.6–1.8

Diazo from	Temp., °C.	k (sec.$^{-1}$) × 10^5
o-Aminophenol	69.7	20.6
	69.7	20.7
o-Toluidine	35.0	96.0
	35.4	95.6
p-Nitroaniline	60.0	3.29
	60.0	3.30
p-Chloroaniline	59.3	1.72
	59.7	1.79

Duplicate experiments check closely as shown in Table IV.

A further test of the accuracy of the present investigation was obtained when experiments on the same diazo were run at more than two temperatures. From the values of ln k at two temperatures, E and ln Z were calculated by equation (1), after which ln k values at other temperatures were calculated. The calculated values of ln k were compared with the experimental values and agreements of the order of magnitude shown in Table V obtained.

All of the individually determined values of k, for simplicity, are given graphically in Fig. 5. The values of E and ln Z calculated by use of equation (1) are shown in Table VI.

It will be observed that the stabilities as measured by k vary greatly, although the values of E are surprisingly of the same order. Insofar as the latter are not equal, however, crossing of lines occurs when the data for each compound are plotted as ln k *vs.* $1/T$. Consequently, when the diazos are listed according to increasing or decreasing stability, one order is obtained at one temperature and a slightly different order may be obtained at another temperature.

TABLE V

Aniline	—H	27,200			35.8		

Summary

1. Rate measurements over 96% of the reaction indicate that the decomposition of phenyldiazonium chloride in dilute hydrochloric acid, pH 1.75, is a first order reaction. This is true over the entire range of concentrations studied, *i. e.*, 1280 moles of water:1 mole of diazo to 2.36 moles of water:1 mole of diazo.

2. The heat of activation of the reaction was found to be 27,200 cal./g. mole.

3. The nature of the decomposition products and the reaction velocity are functions of the concentration of the diazonium chloride solution. In very concentrated solution, the phenol yield falls to 24%. Other products formed under these conditions are monochlorobenzene, benzene and biphenyl.

4. The reaction velocity appears to increase very slightly as the concentration of hydrochloric acid is increased, but decreases again above 10 N hydrochloric acid.

5. In deuterium oxide solution the reaction velocity is substantially the same as in water.

6. At initial pH's below 11.2 the pH of the decomposing solution drops slowly to about 2. At initial pH's above 11.6 the pH drops only to about 10.

7. In buffered solutions the percentage of the total nitrogen which is evolved as a gas varies with the pH.

8. Rate measurements of the decomposition of 24 monosubstituted derivatives of phenyldiazonium chloride indicate that with the exception of the *o*-methoxy derivative, the reactions are of the first order. The diazos studied are the ortho, meta and para methyl, methoxy, phenyl, hydroxy, chloro, carboxy, sulfo and nitro phenyldiazonium chloride.

9. The stability of the parent compound, phenyldiazonium chloride, was decreased by *m*-hydroxy, *o*- or *m*-methyl, *m*-methoxy or *o*- or *m*-phenyl substitution. In all other cases studied, the stability was increased.

10. The values of E vary from 22,800 cal./g. mole for *m*-aminobiphenyl diazo to 33,200 for *m*-nitroaniline. The values of ln Z vary from 26.5 for *p*-aminophenol diazo to 38.9 for orthanilic acid diazo.

The Viscosity–Fluidity Relations of Proteins[1]

BY HENRY P. TREFFERS

In the course of an investigation on the properties of antibody solutions, comparison has been made with the viscosities of related constituents in normal animal sera. Numerous empirical equations have been proposed[2] to account for the variation of the viscosity with protein concentration but singularly enough, in spite of its wide application elsewhere,[3] little or no serious use of the fluidity function has been made in protein chemistry. As this relation, in addition to its advantages of simplicity and ease of application, fits the available data quite well, it would seem to deserve further mention.

If the relative viscosity of a solution be expressed by η/η_0, where η is the viscosity of the solution and η_0 the viscosity of the solvent, the relative fluidity $\varphi_{rel.}$ is defined by the reciprocal

$$\varphi_{rel.} = \eta_0/\eta \qquad (1)$$

The fluidity is thus obtained directly from the experimental measurements with no more calculation than is required for the relative viscosity.

In Fig. 1 data on two proteins of rather widely different viscosity–concentration relations, egg albumin,[4] and a horse serum globulin, PII,[2c] have been plotted according to three representative equations. Curves 1 and 2 represent the fluidities, as in equation (1), curves 3 and 6 the logarithms of η/η_0 (Arrhenius relation[2a]), as plotted against the protein concentration. Curves 4 and 5 are a modification of the Einstein equation in which $\eta/\eta_0 - 1$ has been plotted against the quantity KVC, in which K is a constant, V the partial volume, and C the concentration.[2c,5] The abscissas have all been set equal, which necessitates, however, that curve 5 be shorter than curve 4.[6]

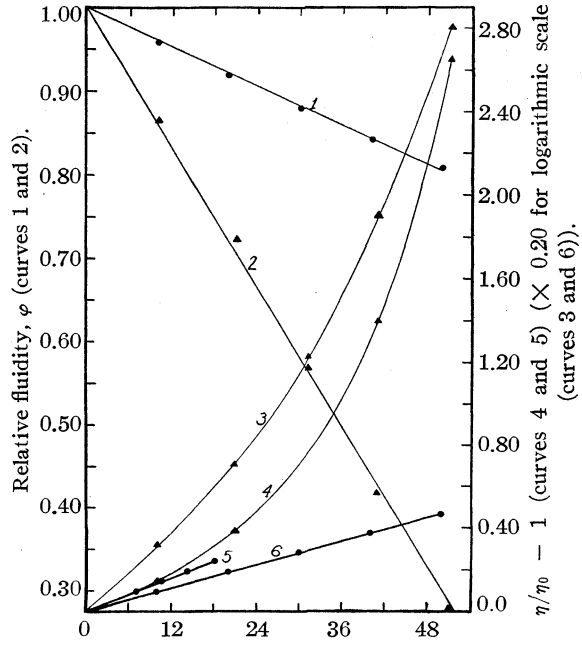

Fig. 1.—Viscosity and fluidity of egg albumin and horse serum globulin using three different equations: Curve (1) fluidity of egg albumin; (2) fluidity of serum globulin; (3) log η/η_0, globulin; (4) $\eta/\eta_0 - 1$, globulin; (5) $\eta/\eta_0 - 1$, egg albumin; (6) log η/η_0, egg albumin.

The utility of the fluidity function is seen from the fact that practically all protein solutions for which data are available in the literature yield a satisfactory linear plot for the relative fluidity φ against the protein concentration expressed in grams per liter of solution. The examples presented in Fig. 2 were selected for their representative slopes rather than for their agreement with the relation presented; nevertheless, the average deviation of all points from their respective "least square" lines is only 0.54%. In this calculation a deviation of the experimental fluidity 0.805 from the calculated 0.809 is taken as 0.5%.

Unfortunately only a few measurements are available at relatively high protein concentrations. Several of these, over their linear range, are given in Fig. 3. At sufficiently high concentrations of some proteins the measured fluidities lie above the line drawn through the lower points, but a comparison of the figures shows that the linearity

covers a useful working range which compares favorably with that provided by other relations. Deviations at very high concentrations may represent a failure of the relation, or perhaps a departure of the behavior of the solution itself from that of true viscous flow. For some reason which is not clear, the data on casein solutions do not pass through the origin. Tobacco mosaic virus protein solutions give a linear relation for six out of the seven points given by Lauffer,[7] *i. e.*, up to 1.0 mg. of protein per cc.[8]

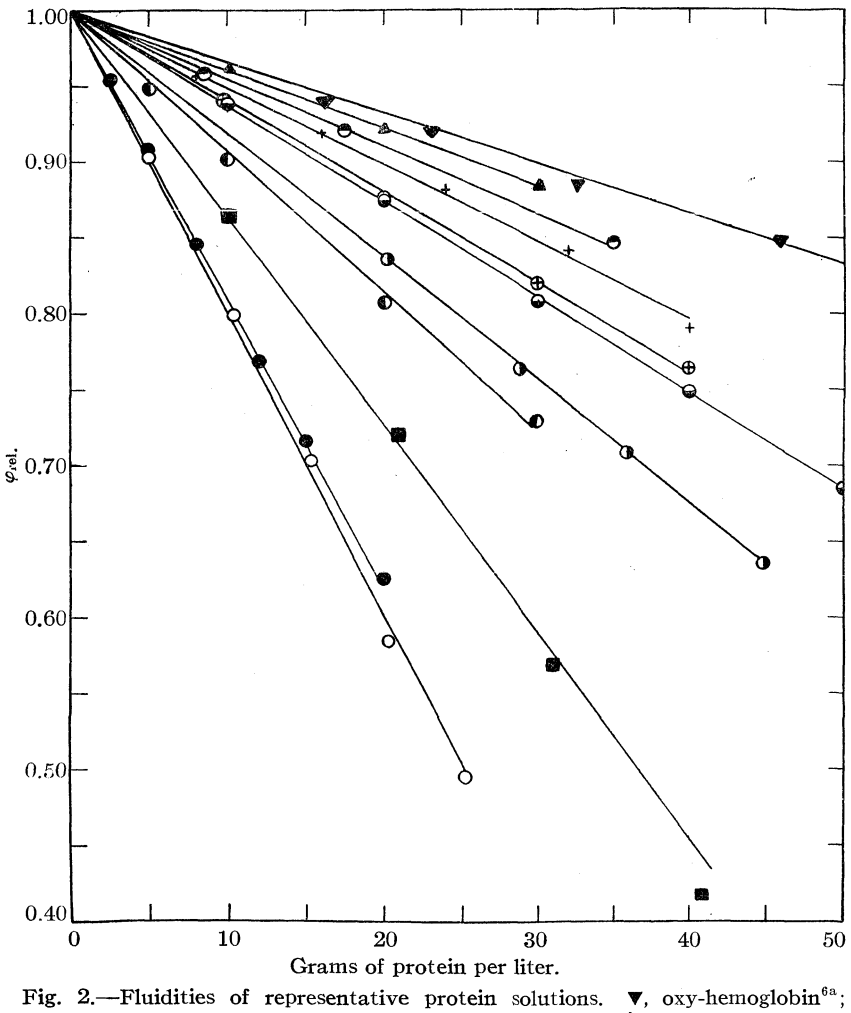

Fig. 2.—Fluidities of representative protein solutions. ▼, oxy-hemoglobin[6a]; ▲, CO-hemoglobin[4]; ◓, homarus hemocyanin[4]; +, trypsin[6b]; ⊕, octopus hemocyanin[4]; ◒, thyroglobulin[4]; ◑, horse pseudoglobulin, ■, PII, ○, PIII (horse globulin fractions)[2c]; ◐, gliadin[4]; ●, beef globulin.[6c]

The concentration of protein has been expressed in all cases in grams per liter rather than as the volume fraction, since the necessary density data were not always available. The volume fraction is probably the more general function on both theoretical and experimental grounds,[3] but since the concentration in grams per liter is proportional to it, it may be used in practice, provided that the partial specific volume of the protein remains constant. This constancy may be verified by plotting the specific volume against the weight fraction, which should yield a linear plot.[9]

Since the origin is always unity, each line may be determined in principle by a single accurate measurement, permitting the fluidity or, if desired, its reciprocal the viscosity, to be determined easily for any other concentration. However, two or more additional points are desirable to ensure greater accuracy and to establish the validity of the linear relation over the range in question.

That the linear relation holds for denatured as well as for native proteins, in spite of the change in absolute values, is seen when the viscosity data of Neurath and Saum[10] are converted to the corresponding fluidities. The resulting family of lines represents the behavior of horse serum albumin dissolved in urea solutions, a denaturing solvent (Fig. 4).

The relation holds as well for a protein which has been modified by the introduction of new chemical groupings, in this case a phosphorylated egg albumin[11] (Fig. 5).

In addition to providing a convenient interpolation formula, the fluidity method appears to offer a convenient tool in studying protein mixtures.

Experimental

Globulin prepared by half-saturation of diluted normal rabbit serum with ammonium sulfate was dialyzed for several days against frequent changes of distilled water.

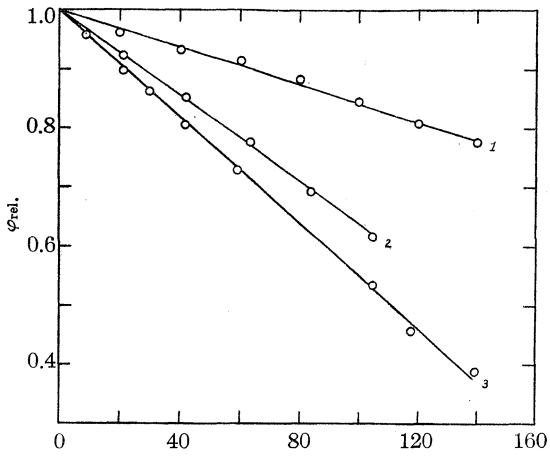

Fig. 3.—Fluidities at higher protein concentrations: Curve 1, egg albumin[8]; curve 2, CO-hemoglobin[6b]; curve 3, serum albumin.[20]

The portion which precipitated is designated euglobulin, the soluble material as pseudoglobulin. In order to avoid effects due to variation in the *p*H and salt concentration, both fractions were arbitrarily made up in solutions at *p*H 5.70 and 0.15 *M* potassium chloride. Several mixtures of the two solutions were made and the observed fluidities, compared with the calculated values from the fluidities of the separate components, are given in Table I.

As an albumin–globulin system was desired, a rather weak immune horse serum was centrifuged clear of lipid at 0° and an equal volume of half-saturated ammonium

43 : 57	.842	.838
0 : 100	.807	...

sulfate solution added. The supernatant albumin solution and the redissolved total globulin precipitate were dialyzed separately against 0.15 *M* potassium chloride until free of sulfate, and then adjusted to *p*H 5.70. Two series of mixtures were made, one from a concentrated albumin solution A and the globulin solution C, and the other from a more dilute albumin solution B with the same globulin solution C (Fig. 6). As Bingham has pointed out,[3] the fluidities of an ideal mixture do not in general lie exactly along a line joining the fluidities of the two separate components because of the difference between weight and volume concentrations. When the densities of the two component solutions are very close, however, the correction may be quite negligible, as is the case here.

Discussion

From the linear relation presented, the fluidity

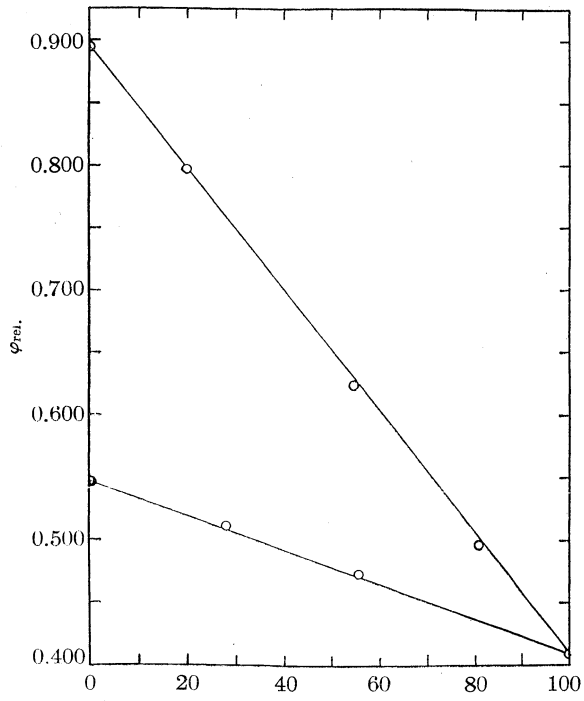

Fig. 6.—Fluidities of mixtures of a horse globulin solution with a horse albumin solution of two different concentrations.

of solutions of the water soluble globulin of concentration C_1 may be expressed as

$$\varphi_1 = 1 - k_1C_1 \qquad (2)$$

and that of the water insoluble euglobulin as

$$\varphi_2 = 1 - k_2C_2 \qquad (3)$$

where the k's are the respective slopes.

In the absence of any specific interaction between the two proteins the fluidity of a mixture of the two is therefore given by

$$\varphi_{mix.} = 1 - k_1C_1 - k_2C_2 \qquad (4)$$

Alternatively, for mixtures of protein solutions which do not differ greatly in density, the fluidities may be represented directly by a graphical method, as in Fig. 6.

Nugent and Towle[12] have outlined a method for the determination of albumin/globulin ratios—a quantity of some clinical importance—by the comparison of the viscosity at known total protein concentrations with that of standard curves for known mixtures. The modification employing fluidities, as shown here, should be somewhat more direct in application since an implicit value for the ratio is given by solving eq. (4) for the ratio C_1/C_2, which gives

$$\frac{C_1}{C_2} = r = \frac{A}{1 - A} \qquad (5)$$

where

$$A = \frac{\dfrac{1 - \varphi_{mix.}}{C_{total}} - k_2}{k_1 - k_2}$$

The ratio is thus given directly from the fluidity of the mixture, and the total protein concentration when the slopes of the fluidity lines of the separate components are known. For simplicity only two components have been assumed but there is nothing in the treatment to limit extension to systems of three or even more components.

Although no completely satisfactory theoretical justification is available at present for the use of the fluidity rather than the viscosity, comparison of the figures indicates the marked regularities which obtain with the fluidity. The graphical expression of experimental data is thus much easier, especially if it is desired to calculate a least square fit.[13]

It is not without interest that this single, simple relation should hold for such a diversity of protein solutions, and up to concentrations as high as 14% in some cases. The examples presented in Figs. 2 and 3 cover an important range of molecular weights, from that of gliadin 27,400, to that of octopus hemocyanin 2,785,000. The molecular shape factor, as given by the axial ratio, likewise varies from a value of 3.84 for egg albumin to 10.64 for gliadin.[4] Some of the solvents represented are half-saturated magnesium sulfate (trypsin), 0.85 M sodium chloride (beef globulin), and 61 vol. % alcohol (gliadin). Other examples, not given here, show that the same protein solution may give linear fluidity curves at several temperatures and, as indicated in Fig. 5, at various hydrogen-ion concentrations.

The ultimate dependence of the viscosity on the volume occupied by the protein molecules has been pointed out by numerous authors.[3,4] Furthermore, Kuhn, Polson and others have demonstrated that there is a close connection between the axial ratio and the viscosity.[14] It might be expected therefore that if a compound were to be

(12) Nugent and Towle, *Proc. Soc. Expll. Biol. Med.*, **33**, 374 (1935).

(13) For this special case, in which the line passes through the origin, the least square slope is given by the expression

$$\text{slope} = [\Sigma(C\varphi) - \Sigma(C)]/\Sigma(C^2)$$

in which each term denotes the summation of the corresponding column of data.

(14) A preliminary study indicates that, like the Polson relation for a viscosity function, the relation between the *slope* of the fluidity line and the square of the axial ratio may be a linear one for most proteins.

formed between two proteins, or a change in the state of aggregation were to occur, the volume fraction, or more especially the effective shape of the protein components, would be changed with a consequent deviation of the fluidity from that predicted on an additive basis (*cf.* Chap. V, ref. 3). The data in Table I and in Fig. 6 do not indicate such deviation, within the experimental error (*cf.* also ref. 2a). Nor do density determinations on beef albumin–globulin mixtures show any variation from strict additivity.[15] Even such a complicated mixture as serum yields a constant average partial specific volume, over the entire range, if one plots the density data of Chick and Lubrzynska.[16] A fair linear fluidity curve up to and including physiological concentrations of protein may also be obtained for this system.

Further discussion of this question, especially as to its bearing on the interesting effects observed in the ultracentrifuge by McFarlane[17] and by Pedersen[18] must await more accurate fluidity data, particularly on protein containing systems in which known compound formation and dissociation occur.

The author wishes to express his appreciation to Dr. Michael Heidelberger for his aid in the preparation of this paper.

Summary

1. It has been found that the fluidity, or reciprocal of the relative viscosity, is linear with the protein concentration over a wide range of proteins and concentrations.

2. The fluidity provides a convenient interpolation formula for converting the fluidity or viscosity obtained at one concentration to that at any other.

3. It is shown that the fluidity is additive for mixtures of rabbit eu- and pseudoglobulin, and for horse albumin and globulin fractions.

4. The relation of additive fluidities to the presence of compounds in mixtures of proteins is discussed.

Ascorbic Acid Oxidase from Summer Crook-neck Squash (C. pepo condensa)

BY P. L. LOVETT-JANISON AND J. M. NELSON

In 1928 Szent Györgyi[1] observed that certain plant tissues catalyzed the aerobic oxidation of ascorbic acid, and in 1930[2] he postulated the existence of a specific enzyme in cabbage leaves. Since then, other investigators[3,4,5,6,7] have reached the same conclusion working with different plant sources, such as apples, Hubbard squash, Drumstick, cauliflower, bananas, cabbage, carrots, cucumbers, potatoes and string beans.

Barron, DeMeio and Klemperer[8] were among the first to show that the aerobic oxidation of ascorbic acid was catalyzed by ionic copper, and in a later paper[9] they questioned the enzymic nature of ascorbic acid oxidase. Stotz, Harrer and King,[10] working upon this problem, were inclined to attribute the catalytic activity of squash juice to copper in combination with protein material, rather than to a specific oxidase. On the other hand, Spruyt and Vogelsang[11] working with fruit juices concluded that, "ascorbic acid oxidation and copper do not go hand in hand and that this oxidation is certainly not exclusively to be ascribed to the presence of copper."

From the above, it is obvious therefore that some confusion arises. It is the object of this paper to show that ascorbic acid oxidase is indeed a true enzyme, consisting of a copper-protein, similar in type to tyrosinase (polyphenol oxidase), which has been recognized as a true enzyme.

Purification of Enzyme from Summer Squash.—After experimenting with cucumber, cauliflower, summer squash, apples, parsnips, carrots, spinach, string beans, cabbage,

oranges and green peppers, we have found the best source of ascorbic acid oxidase to be that from summer crook-neck squash (*C. pepo condensa*).

Ebihara[12] has shown, in the cases of certain plants, that the enzyme is most abundant in the external layers. We have confirmed this in the case of summer crook-neck squash. Consequently, the rinds of squash were minced to a fine pulp, then subjected to hydraulic pressure in order to remove all juice. Determinations upon various crude juice preparations gave values ranging from 0.52 to 0.73 unit per mg. dry weight (for definition of unit see next section). This was followed by treatment with *M* barium acetate (20 cc. to 1 liter of juice), which removed a considerable amount of color and extraneous protein without appreciable loss of activity. After filtering, the juice was brownish-yellow in color. Excess barium ion was now removed as barium sulfate by the addition of 0.05 saturated ammonium sulfate solution and filtering. By the addition of ammonium sulfate to 0.6 saturated, the enzyme was precipitated. After filtering, the precipitate was washed with saturated ammonium sulfate solution until the filtrate was colorless. Addition of *M*/15 secondary sodium phosphate dissolved the precipitate which, after filtering, now contained about 85% of the original enzyme. The solution of the enzyme was then made 0.9 saturated with magnesium sulfate, which precipitated about two-thirds of the enzyme (Part I). After filtering the filtrate was now saturated with magnesium sulfate and the remaining third precipitated (Part II). After dialysis, these two parts, I and II, contained 70 and 144 units per mg. dry weight, respectively. Since on further treatment Part I failed to give preparations of low dry weight comparable with those obtained later from Part II, it was eventually discarded. The remaining steps in the purification apply, therefore, to Part II only.

Part II of the enzyme was now adsorbed to 10% alumina[12a] at *p*H 6.5, eluted with secondary phosphate and dialyzed in distilled water at *p*H 8.0. It was then fractionated with 0.1 saturated lead acetate and acetone (cooled with dry-ice) in the following manner. To the whole, lead acetate (14 drops per 100 cc. enzyme solution) was added, followed by the addition of 10% of the total volume of acetone and the precipitate centrifuged. The supernatant liquid was again treated with the same reagents (10 drops of lead acetate per 100 cc. of enzyme solution, followed by acetone up to 25% of the total volume), and the resulting precipitate again centrifuged. This procedure was repeated twice. The precipitates obtained were taken up in secondary phosphate, filtered and dialyzed in redistilled water at *p*H 8.0. Adsorption to 20% alumina followed by elution and dialysis yielded a fraction of 557 units per mg. dry weight. Further fractionations of this fraction with lead acetate and acetone, followed by treatments with alumina, yielded fractions of 600 to 631 units per mg. dry weight. Further treatments have, so far, failed to improve upon these values.

These purifications removed all the brownish-yellow pigment and it is interesting to note that while at dilutions of about 500 units per cc. the enzyme solution was colorless, at high concentrations of about 4000 units per cc. the solution was green and at intermediate dilutions the color was pale blue or greenish-blue.

Definition of Unit and Determination of Activity of Enzyme Preparations.—In these Laboratories one unit of ascorbic acid oxidase is that quantity which in the presence of its substrate, ascorbic acid, catalyzes a reaction involving an oxygen uptake of 10 c. mm. per minute.

The determinations were carried out in the Warburg respirometer at 25°. In the vessels were 2 cc. of 0.2 *M* phosphate–citrate buffer of *p*H 5.6, 1 cc. of gelatin (5 mg. per cc.), 1 cc. of *l*-ascorbic acid (2.5 mg. per cc.), the diluted enzyme solution and distilled water to make the total volume 8 cc. At all times one of the flasks contained no enzyme, being used as a control. Readings were usually taken every two minutes.

Adams and Nelson[13] have shown in the case of tyrosinase preparations that the addition of gelatin furnishes protection to the enzyme against inactivation. Similarly with ascorbic acid oxidase we have found that the addition of 3.0 mg. of gelatin helps by stabilization of the enzyme when in a highly purified state.

Determination of Copper.—The method used for the determination was that devised by Warburg[14] and is based upon the oxidation of cysteine by copper in the presence of sodium pyrophosphate, which inhibits the action of any iron or manganese which may be present.

The operation was carried out in a Warburg respirometer at *p*H 7.6. A typical run is shown in Table I.

TABLE I

Flask	1	2	3	4	5	6
0.2 *M* pyrophosphate, *p*H 7.75, cc.	2	2	2	2	2	2
(1) Copper soln. 0.1 γ/0.1 cc., cc.	0.1	0.2	...	...	...	...
(2) 0.2 *M* hydrochloric acid, cc.	.1	.1	0.1	0.1	0.1	0.1
(3) Enzyme solution, cc.	.1	.1	...	.1	.2	.3
(4) Cysteine hydrochloride 6 mg./ 0.2 cc., cc.	.2	.2	.2	.2	.2	.2
Water, cc.	.1	...	.3	.2	.1	...

The reagents (1), (2), (3), (4) were placed in the side arm and added to the buffer solution and water, contained in the reaction flask, when the temperature was constant at 25°. Flask 3 contained no enzyme, and served as a control, by being a blank on all the reagents used. The total volume in each flask was 2.6 cc., and the *p*H after mixing was 7.6. Readings were taken at five-minute intervals. It is obvious that when the manometer readings were converted to c. mm. of oxygen, then subtraction of the value for flask 4 from those of flasks 1 and 2 gave the values of the uptakes due to 0.1 γ and 0.2 γ of copper, while subtraction of the value for flask 4 from flasks 5 and 6 gave the values of the uptakes due to 0.1 cc. and 0.2 cc. of enzyme solution. In such a way two determinations of copper and enzyme uptakes were obtained in each run. In all cases at least two runs were performed. Dividing the uptake due to 0.1 cc. of enzyme solution by that due to 0.1 cc. of copper solution gave the concentration of copper in the enzyme solution. Knowing also the activity of enzyme in units per cc. enabled one to obtain the activity of enzyme in units of enzyme per γ of copper. The results of copper estimations carried out on different enzyme prepa-

rations have been found to give a constant value of 432 ± 30 units per γ of copper.

Table II shows that the percentage of copper increased with rise of enzyme activity until it reached the value of 0.15%. In spite of further attempts at purification, this was the highest purity reached to date. The figures given are those obtained only after a more or less constant value for the activity of the enzyme (in units per γ Cu) had been reached. This proportionality between the copper contents and enzyme activities (column 2) is, we think, strong evidence for the conclusion that the active group of ascorbic acid oxidase contains copper.

TABLE II

Prepn.	Concn. enzyme in sample (units/cc.)	Activity, units/γ Cu	% Cu	Activity, units/mg.
1	1412	488	0.029	142
2	161	400	.040	144
3	1287	390	.047	183
4	2248	480	.060	286
5	496	400	.10	379
6	730	415	.12	480
7	3480	431	.12	512
8	530	452	.12	525

10	5640	429	.15	600
11	531	406	.15	612
12	516	490	.15	631
		432 ± 30		

Further purification failed to alter this value for copper, which represented about 5% of the total copper present in the original squash juice. It was only by successive stages of purification that the copper which did not belong to the ascorbic acid oxidase was gradually eliminated, together with other impurities.

On comparing the activity of copper in units per γ with those of Stotz, Harrer and King,[10] who used solutions of copper only, copper–gelatin, and copper–albumin mixtures, and the juices of cauliflower and squash (somewhat purified), we find that our purified enzyme is 1100 times more active than copper alone, 13,000 times more active than the copper–albumin mixture, 4100 times more active than the copper–gelatin mixture, and 3800 and 1700 times, respectively, more active than the juices taken from cauliflower and squash and used by these investigators. This very great activity or increased specificity shown by our purified enzyme constitutes, we consider, a strong argument in favor of our purified squash juice containing a true enzyme. This is in line with the copper content of other enzymes such as tyrosinase (polyphenol oxidase).

Dry Weight Determinations.—For details of the method by which these determinations were performed, refer to the work of Lutz and Nelson[15] in 1934.

Determination of Manganese.—Theorell,[16] working upon dihydroxymaleic acid oxidase, has offered evidence to show that manganese is the activator for this enzyme. Since the configurations of dihydroxymaleic and ascorbic acids show similarity, it was thought at one time in this Laboratory that manganese might play some part as activator for ascorbic acid oxidase. With this end in view, the direct microdetermination of manganese, as outlined by Wiese and Johnson,[17] was carried out upon samples of ascorbic acid oxidase from squash, in which the samples varied from crude juice to purified preparations. It was found that the quantity of manganese in the samples was very small and bore no relation to enzyme activity. With each stage of purification, the value for manganese slowly diminished, even when the enzyme concentration was increased. From this work we must conclude that manganese seems to play no part in the catalytic function of ascorbic acid oxidase. This seems to be in agreement with the work of Barron, DeMeio and Klemperer,[8] who found that of the metals, manganese, iron, copper, nickel, cobalt and calcium, copper was the only metal to catalyze the oxidation of ascorbic acid.

Determination of Peroxidase.—Several investigators[5,18,19] have shown that ascorbic acid oxidase preparations contain peroxidase. We also have found this to be the case in crude or partially purified samples.

The method used by us for the determination of peroxidase was that of Balls and Hale,[20] a method which we used on samples of ascorbic acid oxidase varying from crude juice to our purest preparations. Determinations conducted through the various stages of purification indicated that considerable amounts of peroxidase were being removed as the purification proceeded. In the filtered crude squash juice the concentration of peroxidase was found to be 0.0022 unit of peroxidase per unit of ascorbic acid oxidase, while in the purest preparation (Prepn. 10 (see table) containing 600 units of ascorbic acid oxidase per mg. dry weight) this ratio was 0.0000078. This indicated that 99.65% of the peroxidase had been removed during purification, and for all practical purposes it may be considered as a peroxidase-free preparation. This should be of interest to other workers in this field, because of the importance that has been attributed to peroxidase in the respiration of plants by investigators such as Szent Györgyi,[21] St. Huszák,[18] and Robězieks.[22]

Behavior of Ascorbic Acid Oxidase toward Catechol, *p*-Cresol and Hydroquinone.—Since

we have shown that ascorbic acid oxidase is a copper–protein enzyme similar to tyrosinase (polyphenol oxidase), we thought it of interest to try its effect upon the above substrates, although some investigators[4,5] already have shown that the enzyme does not catalyze the oxidation of phenols. Using one of our preparations of highest purity (600 units per mg.) we found that it was about 520 times more active toward ascorbic acid than toward catechol and about 335 times more active toward its own substrate than toward hydroquinone. No activity toward *p*-cresol was obtained when an amount of ascorbic acid oxidase as high as 846 units was used. These activities are extremely small and to all intents and purposes it may be concluded that the enzyme does not catalyze the oxidation of these substances except at high concentrations.

Summary

1. A method has been described for the preparation of a highly purified ascorbic acid oxidase having an activity of 600 to 630 units per mg. dry weight.

2. At high concentrations the enzyme was green, at lower concentrations blue or bluish-green.

3. The ascorbic acid oxidase was found to be a copper-protein compound, containing 0.15% of copper.

4. The purest enzyme preparations obtained had an activity of 432 units per γ of copper.

5. Manganese seems to play no part as activator for this enzyme.

6. The purest enzyme preparation was found to have lost 99.65% of the peroxidase accompanying the enzyme in the crude juice and may be considered practically free of this enzyme.

7. Ascorbic acid oxidase has no action toward *p*-cresol and only shows a slight action toward catechol and hydroquinone at comparatively high concentrations.

Studies on Lignin and Related Compounds. XLVII. The Synthesis of Xylosides Related to Lignin Plant Constituents

BY J. H. FISHER, W. LINCOLN HAWKINS AND HAROLD HIBBERT

The question of whether lignin is in chemical combination with a carbohydrate constituent in the plant has been a matter of speculation for many years. Some workers[1] believe that lignin is present as an incrustant in the cell wall and is not in chemical union with any other product. Evidence[1] from a study of X-ray patterns of pure cotton cellulose and cellulose from wood appears to indicate the absence of a chemical union. However, the possibility of the existence of a lignin-hemicellulose complex as suggested by Harris, Sherrard and Mitchell[2] and later supported by Norman and Shrikhande[3] is not excluded.

Recent studies on the enzymatic degradation of wood by Ploetz[4] provide further evidence for the presence of a lignin carbohydrate complex. Bailey[5] in work dealing with lignin extracted by the use of butyl alcohol obtains evidence indicating a chemical combination of part of the lignin with cellulose in certain woods. Norman[6] and also Hägglund[7] have presented comprehensive reviews concerning the relationship between lignin and cellulose in the cell wall.

Possible Mode of Combination.—The two principal carbohydrate constituents of the cell wall, cellulose and xylan, may be combined with the lignin through ether, ester or glycosidic bonds, that of the last-named occurring most frequently in natural products. To obtain further information on the nature of the lignin union in wood, a number of glycosides have been synthesized from products presumably closely related to lignin.

Although the structure of "protolignin" is unknown, recent studies on the ethanolysis of wood[8] and the hydrogenation of certain isolated lignins[9]

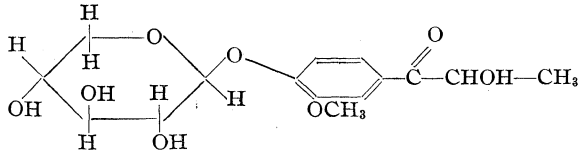
have indicated the fundamental building units are C_6-C_3 derivatives. Ethanolysis experiments have been highly informative in that, contrary to those carried out on high pressure hydrogenation, the functional groups of the aromatic nuclei as well as those of the aliphatic side chains remain intact. Thus it has been possible to isolate such C_6-C_3 lignin building units as α-ethoxypropiovanillone and α-ethoxypropiosyringone. These compounds are considered to be derived from etherification of the corresponding α-hydroxy compounds, their dismutation isomers or their ene-diol forms[10] during ethanolysis. Recently Brickman, Hawkins and Hibbert[11] have isolated the corresponding diketones, vanilloyl and syringoyl methyl ketones, from the ethanolysis products of wood.

The manner in which the building units may be combined in protolignin has been dealt with in a previous communication,[10] in which it has been shown that, in such polymers, there may be primary, secondary or tertiary aliphatic and phenolic hydroxyl groups present so that the carbohydrate material of the cell wall may be combined through any or all of these hydroxyls.

Degradation of lignin sulfonic acids has yielded other aromatic compounds containing the guaiacyl and syringyl nuclei, such as guaiacol,[12] acetovanillone,[13] acetosyringone,[14] and pyrogallol 1,3-dimethyl ether.[15]

In view of the isolation of these derivatives as part of the lignin complex, the synthesis of the following xylosides was undertaken as the first stage in a study of possible glycosidic linkages in protolignin: (1) α-hydroxypropiovanillone β-*d*-xyloside:



(2) α-hydroxypropiosyringone β-*d*-xyloside, (3) guaiacol β-*d*-xyloside, and (4) acetovanillone β-*d*-xyloside.

An extensive investigation of the properties of these xylosides, including a quantitative determination of their stability under a variety of conditions, is in progress. The acidity of the phenolic hydroxyl groups of the phenols in question is to be determined and the stability of the xylosides correlated with these values. The results of this investigation, and the conclusions which may be drawn therefrom regarding the plausibility of a phenolic glycosidic link between lignin and carbohydrate will be presented in a subsequent communication. Such results may possibly have a marked bearing on the mechanism of sulfite pulp manufacture.

Syntheses of Acetylated Xylosides.—The acetylated forms of the above xylosides were synthesized by condensation of acetobromoxylose with the phenol by a modification of Helferich's process.[16] Attempted synthesis of the acetylated xylosides of α-acetoxypropiovanillone and α-acetoxypropiosyringone by his method resulted in very low yields (13%), even when a large excess of acetobromoxylose was used. By (1) substitution of the potassium for the sodium salt of the phenol, (2) operating at 0° throughout the reaction, and (3) carefully controlling the *p*H of the reaction medium during addition of the reagents, it was possible to double the yield, an important point in view of the difficulties involved in the preparation of the phenolic products.

In the Helferich reaction the salt of the phenol used and the water present in the reaction mixture, both react with acetobromoxylose. Since the phenol reacts only in the form of its salt, the yield of the xyloside depends on the proportion of this salt present throughout the reaction. In Helferich's method the aqueous solution of the sodium salt of the phenol is mixed with an acetone solution of the acetobromoxylose and allowed to stand at room temperature. Part of the acetobromoxylose reacts with the water present producing hydrogen bromide which in turn liberates the phenol from its salt, resulting in an increasing amount of the free phenol. By adding alkali throughout the reaction this is prevented and a maximum amount of phenol available for condensation is obtained, thus ensuring maximum utilization of the acetobromoxylose. Excess of alkali is to be avoided in order to prevent decomposition of the acetobromoxylose and deacetylation of the xyloside as well as fission of the newly formed xylosidic union. Sufficient alkali is added to keep 90% of the phenol in the form of its potassium salt. The exact proportion of phenol as

potassium salt required to give a maximum yield will depend on the acidity of the phenolic group and the stability of the resulting xylosidic bond.

α-Acetoxypropiovanillone and α-acetoxypropiosyringone contain asymmetric carbon centers. Condensation of these racemic compounds with optically active acetobromo-*d*-xylose should give rise to isomers of slightly different properties. The difficulties encountered in the purification of the acetylated xylosides of the above two phenols, especially the latter, would indicate that this is the case.

Deacetyla ion of Acetylated Xylosides.—The Zemplén method[17] proved to be the most satisfactory process for deacetylation. Guaiacol triacetyl β-*d*-xyloside and acetovanillone triacetyl β-*d*-xyloside were successfully deacetylated by Mauthner's aqueous ammonia method[18] with yields of 85–90%. The former xyloside also was deacetylated by the anhydrous methanolic ammonia method.[19] However, the triacetyl xylosides of α-acetoxypropiovanillone and of α-acetoxypropiosyringone are unstable under both these conditions. The β-*d*-xyloside of α-hydroxypropiosyringone proved to be remarkably unstable. Mere solution in pure hydroxylic solvents, such as ethanol, acetone, dioxane or water, at 45° resulted in decomposition as indicated by a marked decrease in the melting point.

Experimental

α-Acetoxypropiovanillone.—α-Bromopropiovanillone[20] (24 g.), glacial acetic acid (144 cc.) and anhydrous potassium acetate (62 g.) were heated together on the steam-bath at 100° for six hours. The solution was poured into cold water (1152 cc.) with stirring, and the product allowed to crystallize at 0° for thirty-six hours. It was recrystallized from carbon tetrachloride in the form of fine needles; yield, 13.3 g. (60%); m. p. 105–106°. *Anal.* Calcd. for $C_{12}H_{14}O_5$: C, 60.48; H, 5.93; OCH_3, 13.0. Found: C, 60.45; H, 6.02; OCH_3, 13.0.

Triacetyl β-*d*-Xyloside of α-Acetoxypropiovanillone.—This was obtained by a *p*H controlled modification of the Helferich method.[16] The *p*H of an aqueous acetone solution of α-acetoxypropiovanillone containing 90% of an equivalent amount of potassium hydroxide was found to be approximately 9.0. The reaction was carried out under nitrogen at 0°.

A trace of phenolphthalein and 2.38 g. of α-acetoxypropiovanillone (0.01 mole) were dissolved at room temperature in a mixture of 8 cc. of acetone and 13.85 cc. of 0.724 *N* aqueous potassium hydroxide (0.01 mole). Acetobromoxylose (6.80 g., 0.02 mole) in 32 cc. of anhydrous acetone was then added to the above solution, and the flask shaken to ensure rapid admixture of the two solutions. In a few moments the *p*H of the resulting solution dropped below 9.0, as indicated by the color change. The dropwise addition of potassium hydroxide was begun at a rate sufficient to maintain the *p*H at 9.0. When 13.85 cc. of potassium hydroxide (0.724 *N*) had been added (twenty minutes) the reaction mixture was set aside for three hours, when the *p*H was approximately 7.0. The mixture was extracted thoroughly with benzene (150 cc.), the benzene extract shaken quickly with two 200-cc. portions of sodium carbonate (2%) at 5°, washed with water and dried for a few minutes with calcium chloride. The solution was evaporated at 40° under reduced pressure. Recrystallization of the residue twice from 50% aqueous ethanol (127 cc.) yielded 1.08 g. (25%) of fine needle-shaped crystals: m. p. 149.4–149.7°. *Anal.* Calcd. for $C_{23}H_{28}O_{12}$: C, 55.62; H, 5.69; OCH_3, 6.26; $COCH_3$, 34.7. Found: C, 55.50; H, 5.76; OCH_3, 6.20; $COCH_3$, 35.5.[21]

In the above reaction only 0.48 g. of α-acetoxypropiovanillone could be recovered unchanged.

α-Acetoxypropiosyringone.—This was synthesized by the method of Hunter, Cramer and Hibbert.[8] One of the steps in this synthesis involves the dehydration of 3,4,5-trimethoxyphenyldiethylcarbinol to the corresponding pentene. It was found convenient to effect this dehydration by heating with a trace of iodine at 100° for one hour.[22] This method gives a purer pentene derivative and an increase in yield to 60% of 3,4,5-trimethoxypropiophenone on ozonization.

Triacetyl β-*d*-Xyloside of α-Acetoxypropiosyringone.—This was synthesized by the same procedure as used with α-acetoxypropiovanillone. The crude product (m. p. 100°) was very difficult to purify, and this was effected by recrystallization from 33% aqueous ethanol. Six recrystallizations were necessary before a product in the form of small flaky crystals and of constant melting point (128.6–128.8°) was obtained, yield 25%. *Anal.* Calcd. for $C_{24}H_{30}O_{13}$: C, 54.73; H, 5.74; OCH_3, 11.78; $COCH_3$, 32.7. Found: C, 54.70; H, 5.75; OCH_3, 11.8; $COCH_3$, 34.1.[21]

Guaiacol Triacetyl β-*d*-Xyloside.—This was prepared, as above, by using equimolecular quantities of acetobromoxylose and potassium guaiacolate and omitting *p*H control of the reaction mixture. The xyloside crystallized from 50% aqueous ethanol in large rhombic crystals; yield 43%; m. p. 139.8–140.0°. *Anal.* Calcd. for $C_{18}H_{22}O_9$: C, 56.51; H, 5.81; OCH_3, 8.1; $COCH_3$, 33.8. Found: C, 56.50; H, 5.82; OCH_3, 8.0; $COCH_3$, 33.9.

Acetovanillone Triacetyl β-*d*-Xyloside.—A similar procedure was employed using a 50% excess of acetovanillone; yield 58%. It crystallized from aqueous acetone in large monoclinic crystals; m. p. 133.3–133.6°. *Anal.* Calcd. for $C_{20}H_{24}O_{10}$: C, 56.58; H, 5.71; OCH_3, 7.31; $COCH_3$, 30.4. Found: C, 56.50; H, 5.83; OCH_3, 7.29; $COCH_3$, 31.5.[21]

β-*d*-Xyloside of α-Hydroxypropiovanillone.—The deacetylation of the acetylated xyloside was carried out by the Zemplén method.[17] The reaction was allowed to pro-

ceed for four hours at 20°, the sodium methylate neutralized by addition of an equivalent amount of acetic acid, and the solvent evaporated at 20° under reduced pressure. The residue crystallized from a mixture of anhydrous methanol and ether (1:1) as dense rhombic crystals; yield 76%; m. p. 193–194.5°, with slight decomposition. *Anal.* Calcd. for $C_{15}H_{20}O_8$: C, 54.85; H, 6.14; OCH_3, 9.45. Found: C, 54.90; H, 6.30; OCH_3, 9.40.

β-d-Xyloside of α-Hydroxypropiosyringone.—Deacetylation was effected as described for the β-d-xyloside of α-hydroxypropiovanillone. The residue obtained after evaporation of the methanol from the reaction mixture had to be purified with utmost care, otherwise decomposition resulted. This was effected by dissolving in a minimum amount of anhydrous methanol at 20° and cooling to −10° when the xyloside crystallized in the form of fine needles; yield 73%; m. p. 149.4–150.0°. *Anal.* Calcd. for $C_{16}H_{22}O_9$: C, 53.60; H, 6.18; OCH_3, 17.32. Found: C, 53.51; H, 6.35; OCH_3, 17.28.

Guaiacol β-d-Xyloside.—This was prepared by deacetylation of the acetylated xyloside by the Zemplén method.[17] The xyloside crystallized from ethyl acetate in rod-shaped crystals, yield 85%, m. p. 175.3–176.0°. *Anal.* Calcd. for $C_{12}H_{16}O_6$: C, 56.23; H, 6.29; OCH_3, 12.10. Found: C, 56.20; H, 6.43; OCH_3, 12.05.

Acetovanillone β-d-Xyloside.—The conditions of deacetylation were as described by Zemplén.[17] The xyloside was recrystallized, first from ethyl acetate, and then from 50% anhydrous methanol–ether, and obtained in the form of very fine hair-like crystals; yield 85%; m. p. 145.2–145.7°. *Anal.* Calcd. for $C_{14}H_{18}O_7$: C, 56.25; H, 6.08; OCH_3, 10.40. Found: C, 56.20; H, 6.41; OCH_3, 10.30.

Acknowledgment.—The authors wish to thank the National Research Council of Canada for the financial assistance given to one of them (J. H. F.).

Summary

Methods are given for the synthesis of the β-d-xylosides of α-hydroxypropiovanillone, α-hydroxypropiosyringone, guaiacol and acetovanillone, and their corresponding fully acetylated derivatives.

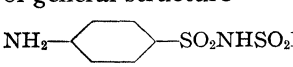
Sulfanilamide Derivatives. VII. N¹-Alkanesulfonylsulfanilamides and Related Compounds[1]

BY M. L. CROSSLEY, E. H. NORTHEY AND MARTIN E. HULTQUIST

We were led to further investigation of sulfanilamide derivatives containing a disulfonamide linkage, $-SO_2NHSO_2-$, by the preliminary pharmacological results on disulfanilamide.[2] Long chain N¹-alkanesulfonylsulfanilamides analogous to the N¹-acylsulfanilamides[3] were of most interest, but a series of compounds was synthesized of general structure



$NH_2-C_6H_4-SO_2NHSO_2R$, where R was alkane (from 2 to 12 carbons), cycloalkane, and aralkane.

The synthesis of the intermediate sulfonyl chlorides followed the procedure of Treat B. Johnson.[4]

These were treated with N⁴-acetylsulfanilamide in aqueous solution and the resulting N⁴-acetyl-N¹-alkanesulfonylsulfanilamides were hydrolyzed by boiling with sodium hydroxide to remove the N⁴-acetyl group. The resulting N¹-alkanesulfonylsulfanilamides were highly water soluble for the lower members of the series, but became increasingly water insoluble in the higher members. All were strongly acidic and formed neutral sodium salts.

Chemotherapeutic Properties.[5]—Preliminary results in mice against beta-haemolytic streptococci indicate that these compounds as a class are of low chemotherapeutic activity. A complete evaluation of them awaits the final results of the chemotherapeutic study.

Experimental Part

N¹-Butanesulfonylsulfanilamide.—78.3 grams (0.5 mole) of 1-butanesulfonylchloride was added to a slurry of 214 g. (1 mole) of N⁴-acetylsulfanilamide and 400 cc. of water; 50% sodium hydroxide solution was added gradually to maintain a pink spot test on benzoazurine paper (*p*H 11–12) while holding the temperature at 35–40° by addition of ice. The time of adding sodium hydroxide was thirty minutes. When no more sodium hydroxide was consumed after stirring for thirty minutes, the reaction was considered

TABLE I

N^1-ALKANESULFONYLSULFANILAMIDES

Alkanesulfonyl group	Appearance	Melting range, °C.	Assay by $NaNO_2$	Assay by NaOH
Ethanesulfonyl-	Short prisms	206.5–207.5	101.0	101.0
1-Butanesulfonyl-	Plates	209.0–210.5	100.1	100.8
1-Pentanesulfonyl-	Plates	183.0–184.5	99.6	98.5
2-Ethyl-1-hexanesulfonyl-	Plates	189.0–191.0	100.5	100.0
1-Dodecanesulfonyl-	Plates	188.8–189.9	...	99.4
Cyclohexanesulfonyl-	Leaflets	230 dec.	100.0	100.3
10-*dl*-Camphorsulfonyl-	Leaflets	213.0–214.5	100.8	100.2
Phenylmethanesulfonyl-	Plates	242.0–243.5	99.8	99.4

to be complete. Dilute hydrochloric acid was added to bring the *p*H to 8–9 and the mixture was cooled to 15°. The excess N^4-acetylsulfanilamide was filtered and washed well with cold water. The mother liquor was acidified to *p*H 1 with hydrochloric acid. A sticky precipitate formed which soon crystallized to white, sandy crystals of N^4-acetyl-N^1-(1-butanesulfonyl)-sulfanilamide. A portion of the crude product was saved and purified by solution as the sodium salt, treatment with activated charcoal and reprecipitation. On attempting to recrystallize from water, partial hydrolysis of the N^4-acetyl group resulted.

The balance of the crude product was hydrolyzed with sodium hydroxide by the same procedure used for N^1-acylsulfanilamides.[3] The hydrolyzate on cooling and standing deposited coarse crystals of sodium N^1-(1-butanesulfonyl)-sulfanilamide which were salted out of solution by the excess sodium hydroxide present. The salt was twice recrystallized from concentrated aqueous solutions. Recoveries from the sodium salt mother liquors were made by acidifying to *p*H 4.0–4.5 and filtering off the free compound. This was recrystallized from water.

The other compounds listed in Table I were similarly prepared. All were assayed by the same procedures used for the N^1-acylsulfanilamides.[3] N^1-1-Dodecanesulfonylsulfanilamide was too insoluble in mineral acids to be analyzed by diazotization.

Summary

1. Sulfanilamide derivatives of the general formula, $NH_2(4)C_6H_4SO_2NHSO_2R$, were synthesized where R was alkane (2 to 12 carbons), cycloalkane and aralkane.

2. Preliminary studies in mice indicated low effectiveness of these compounds against beta-haemolytic streptococci.

Differences Observed in the Behavior of Unsaturated Hydantoins under the Action of Bromine

BY MARGARET J. MCLEAN AND DORIS R. SEEGER[1]

Reactions involving the addition of bromine to hydantoins possessing unsaturated side chains in the C-5-position have been reported as leading to the formation of quite different classes of compounds, the character of which seems to depend upon the conditions of the experiment. For example, unsaturated hydantoins in which a bromine atom was found to have replaced a hydrogen atom in the side chain invariably were formed when benzalhydantoin, anisalhydantoin and many similar compounds,[2] dissolved in glacial acetic acid, were treated with molecular quantities of bromine

(a) $HNCONHCOC{=}CHC_6H_5 \xrightarrow{+\ Br_2} NHCONHCOC{=}CBrC_6H_5 + HBr$

In other cases[3] where reactions were carried out in chloroform or carbon tetrachloride and these solvents subsequently displaced by alcohol, saturated ethoxy-monobromo derivatives of the hydantoins were formed.

(b) $CH_3NCON(CH_3)COC{=}CHC_6H_5 \xrightarrow[+\ C_2H_5OH]{+\ Br_2} CH_3NCON(CH_3)COC(OC_2H_5)CHBrC_6H_5 + HBr$

The question naturally arises as to whether these differences are due to the nature of the unsaturated hydantoins involved, or solely to experimental conditions. In the latter case *all*

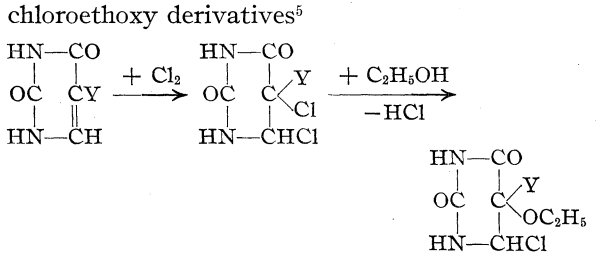
classes of unsaturated hydantoins,[4] as represented for example by benzalhydantoin, its N-3-methyl and its N-1-N-3-dimethyl derivatives, might be assumed to be capable respectively of undergoing both types of transformation (a and b). This has now been shown to be the case.

That in each instance the final product results from a secondary reaction appears obvious because of the fact that the bromine is decolorized as rapidly as added and the reaction, which is usually complete within five minutes, is not accompanied by any apparent evolution of hydrobromic acid. Recently reactions similar to those indicated as (b) have been reported as taking place when the 2,4-diketotetrahydropyrimidines were treated first with chlorine in chloroform solution and subsequently with alcohol. In the case of unsaturated compounds of this type it was possible, moreover, to isolate primary dichloro addition products and then later under the direct action of alcohol to transform them into secondary chloroethoxy derivatives[5]



In the case of the unsaturated hydantoins under investigation the problem of isolating similar primary dibromo addition products presented serious technical difficulties because of the fact that they were extremely unstable. Nevertheless a single compound belonging to this class, namely, N - 3 - methyl - C - 5,5 - bromo - bromobenzyl-hydantoin, finally was obtained in the form of fine white needles which possessed a well-defined melting point and which was sufficiently stable to allow of a fairly satisfactory analysis. That the latter was not completely satisfactory was due to the fact that the substance is so unstable that even in solid condition it loses hydrobromic acid slowly at ordinary temperatures and on long standing passes quantitatively into the corresponding *unsaturated* mono-bromo derivative. It is insoluble in cold alcohol but, when warmed slightly, passes instantly into the corresponding *saturated* ethoxybromo derivative with the evolution of heat and hydrobromic acid. The corresponding dibromo addition product of benzalhydantoin was also separated in solid crystalline form but never in a sufficiently pure condition to justify an analysis. In the case of dimethylbenzalhydantoin all of the compounds involved in the bromination were so extremely soluble as to preclude any possibility of separating them.

That the final products formed in the transformations (a) and (b) belong to unsaturated and saturated classes of hydantoins, respectively, was confirmed by a spectrographic study, the results of which are presented in Fig. 1.[6] The pronounced differences between these two classes of hydantoin derivatives both as to intensity and region of absorption already have been established[7] and the present results agree closely with earlier reports.

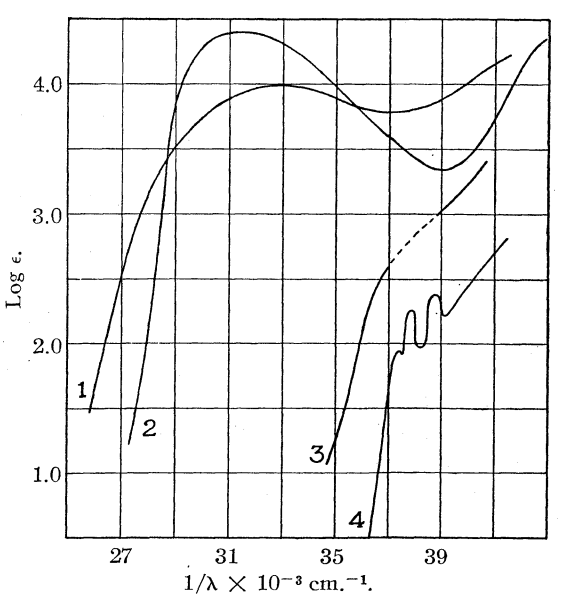


Fig. 1.—(1) Bromobenzalhydantoin; (2) benzalhydantoin; (3) C-5,5-ethoxy-bromobenzyl-hydantoin; (4) benzylhydantoin.

It may be noted in passing that the bromo-ethoxy addition products are compounds of phar-

(4) Compare Seikel, THIS JOURNAL, **59**, 436 (1937).

(5) Johnson and Sprague, *ibid.*, **59**, 2436–2439 (1937). It is interesting to note that ethylene linkages in both pyrimidines and hydantoins react under analogous conditions to form similar types of halogen-alkoxy addition products. This is perhaps remarkable in view of the fact that the double bond is incorporated in the ring structure in one case and in the side chain in the other. It should be added however that the kinetics of reactions of this kind have not as yet been completely elucidated [Bartlett and Tarbell, *ibid.*, **58**, 466 (1936)].

(6) Grateful acknowledgment is due Dr. Hildegard Stücklen for directing this work. The curves were plotted by Doris R. Seeger in partial fulfilment of the requirements for a B.A. degree with honors, June, 1939. In the case of 3 it may be added that a dotted line is used to indicate narrow bands due to the presence of the phenyl group although the exact positions could not be measured because of the diffuseness of the bands.

(7) Hahn and Evans, THIS JOURNAL, **50**, 809 (1928); Hahn and Dyer, *ibid.*, **52**, 2505 (1930); Hahn, McLean and Murphy, *ibid.*, **60**, 1928 (1938).

macological interest because of their relation as 5,5-disubstituted hydantoins to sodium diphenylhydantoin[8] and C-5,5-phenyl-ethylhydantoin.[9] The latter, due to their anticonvulsant and other therapeutic effects, are, as is well known, finding application in medicine in the treatment of epilepsy and related disorders. In this connection attention may be called to the marked decrease in toxicity that results from the substitution of methyl for hydrogen in the N-3- and N-1-N-3 positions in the hydantoin ring, as shown in the table,[10] where the figures represent the minimum lethal dose administered orally to mice:

$HN\overline{CONHCOC}(OC_2H_5)CHBrC_6H_5$	3.0 mg./M.
$HN\overline{CON(CH_3)COC}(OC_2H_5)CHBrC_6H_5$	80.0 mg./M.
$CH_3N\overline{CON(CH_3)COC}(OC_2H_5)CHBrC_6H_5$	120.0 mg./M.

These figures are especially significant in view of the fact that 12.0 mg./M. represents the minimum lethal dose of sodium diphenylhydantoin. None of the other possible physiological effects of the above bromoethoxyhydantoins have as yet been investigated.

Experimental

The N-3-methyl-C-5-benzalhydantoin[11] and N-1,N-3-dimethyl-C-5 benzalhydantoin[12] used in all of the following experiments were obtained by methods previously developed in this Laboratory. In preparing the corresponding unsaturated bromo derivatives the method used in the case of benzalhydantoin as reported by Wheeler, Hoffman and Johnson,[2] was followed.

N-3-Methyl-C-5-bromobenzalhydantoin, m. p. 173–173.5°, was obtained by adding bromine (4.5 g.) slowly to a suspension of N-3-methyl-benzalhydantoin (5.0 g.) in glacial acetic acid (25 cc.). The bromine was decolorized as rapidly as added and, on heating, copious fumes of hydrobromic acid were evolved. The clear solution, when evaporated to 15 cc. over a steam-bath and then set aside to crystallize, deposited 4.28 g. of a product, m. p. 160–166°, which was purified by recrystallization from alcohol.

Anal. Calcd. for $C_{11}H_9O_2N_2Br$: C, 46.99; H, 3.23; N, 9.97; Br, 28.43. Found: C, 46.79; H, 3.29; N, 10.00; Br, 28.50.

The substance is only slightly soluble in cold (1.0 g. in 100 cc.) but more soluble in boiling alcohol (10.0 g. in 100 cc.). Treated with hydrogen iodide and red phosphorus, it passed quantitatively into N-3-methylbenzylhydantoin which was identified by comparision with an analyzed specimen, m. p. 140–141°.[13]

N-1,N-3-dimethyl-C-5-bromobenzalhydantoin, m. p. 122–123°, was obtained and purified in a manner analogous to that described above.[14]

Anal. Calcd. for $C_{12}H_{11}O_2N_2Br$: C, 48.81; H, 3.76; N, 9.50; Br, 27.08. Found: C, 48.82; H, 3.94; N, 9.57; Br, 27.45.

The compound is very soluble in acetic acid and alcohol. Treated with hydrogen iodide and red phosphorus, it was transformed into N-1,N-3-dimethylbenzylhydantoin which was identified by comparison with an analyzed specimen, m. p. 86.5–87°.[11]

The method previously reported by Hahn, McLean and Murphy[3] was again applied in the preparation of C-5,5-ethoxy-bromobenzylhydantoin and of the corresponding N-3-methyl derivative although, due to the relative insolubility in carbon tetrachloride of the compounds taking part in both of these reactions, certain experimental difficulties were encountered. However, when care was taken to avoid the formation of any least trace of hydrobromic acid prior to the introduction into the reaction mixture of a relatively large volume of absolute alcohol, yields of more than 90% of each of the above products were obtained.

$N\overline{HCONHCOC}(OC_2H_5)CHBrC_6H_5$, **C-5,5-Ethoxy-bromobenzyl-hydantoin,** m. p. 202.5–203°, was prepared by adding a molecular quantity of bromine (17.2 g. diluted to 25 cc.) at 0° and under constant stirring, to benzalhydantoin, m. p. 218–219°, suspended in carbon tetrachloride (20.0 g. in 300 cc.). The reaction, which was complete in a few minutes, was accompanied by the transformation of the yellow crystals of benzalhydantoin into a precipitate of fine white crystals, the bromine being decolorized rapidly with no perceptible formation of hydrobromic acid. When, however, 300 cc. of absolute alcohol was added to the mixture and heat applied, hydrobromic acid was evolved in large quantities and a perfectly clear colorless solution was formed.[15] The latter was then alternately concentrated and treated with additional quantities of absolute alcohol until the carbon tetrachloride and last traces of hydrobromic acid had been largely eliminated, when upon cooling a white crystalline compound was deposited. Successive precipitates obtained from filtrates, all melting between 199 and 202°, were combined (31.9 g.) and purified by recrystallization from boiling absolute alcohol.[16]

(8) Merritt and Putnam, *Arch. Neurol. Psychiatry,* **42,** 1053 (1939).

(9) Pilcher and Gerstenberger, *Am. J. Diseases Children,* **40,** 1239 (1930).

(10) The biochemical investigation of ten gram specimens of these compounds, which were prepared in this Laboratory, was very kindly undertaken by Dr. Oliver Kamm, of the Research and Biological Laboratories of Parke, Davis and Company.

(11) Litzinger, THIS JOURNAL, **56,** 673 (1934).

(12) Hahn and Evans. *ibid.*, **50,** 817 (1928).

(13) For the electrolytic dissociation constant of this compound, compare Pickett and McLean, *ibid.*, **61,** 424 (1939).

(14) It is significant that the unsaturated monobromo derivatives can be recrystallized unchanged from alcohol and even from alcoholic solutions of hydrogen bromide. Great care must nevertheless be exercised in their preparation to avoid the presence of any trace of alcohol since otherwise mixtures are obtained which are very difficult to separate.

(15) In cases where hydrobromic acid was given off *before* the alcohol had been added, the product was found to be contaminated by the presence of a considerable quantity of bromobenzalhydantoin. Since the latter can be separated only with the greatest difficulty, care must be taken to avoid its formation which is always attended by the evolution of hydrogen bromide.

(16) The solubilities of the ethoxybromo derivatives of (a) benzal- and (b) methylbenzal-hydantoins in 100 cc. of absolute alcohol are respectively (a) 2.84 g. at 20° and 13.64 g. at the temperature of the boiling solvent; (b) 0.64 g. and 5.73 g. under the same conditions.

Anal. Calcd. for $C_{12}H_{13}O_3N_2Br$: C, 46.02; H, 4.18; Br, 25.52. Found: C, 46.09; H, 4.28; Br, 26.31.

$\overline{NHCON(CH_3)COC(OC_2H_5)CHBrC_6H_5}$, **N-3-Methyl-C-5,5-ethoxy-bromobenzyl-hydantoin,** m. p. 179–180°, was prepared under exactly the same conditions as those described above and obtained in approximately the same percentage yields. It was, however, also prepared by treating N-3-methyl-C-5,5-bromo-bromobenzyl-hydantoin directly with absolute alcohol, a reaction which will be described in more detail later. In both cases the product was purified by recrystallization from boiling absolute alcohol.[16]

Anal. Calcd. for $C_{13}H_{15}O_3N_2Br$: C, 47.71; H, 4.62; N, 8.57; Br, 24.42. Found: C, 47.71, 47.80; H, 4.62, 4.55; N, 8.59; Br, 24.37.

It will have been noted that the addition of bromine to both benzalhydantoin and N-3-methylbenzalhydantoin was accompanied by the formation of a voluminous white crystalline precipitate. This was thought to represent a primary dibromo addition product, but the fact that in each case it was practically as insoluble in carbon tetrachloride as the unsaturated hydantoin from which it was formed, made its separation from small unacted-upon quantities of the latter extremely difficult. In the case of benzalhydantoin this addition product was never obtained in a sufficiently pure condition to justify its analysis although a white crystalline compound was finally separated mechanically. The latter melted at 178–182° with an evolution of gas, formed a colorless solid on cooling and melted again at about 235°. This is interesting in view of the fact that bromobenzalhydantoin was reported by Wheeler, Hoffman and Johnson[2] as melting at 239–240°.

$\overline{NHCON(CH_3)COCBrCHBrC_6H_5}$, **N-3-Methyl-C-5,5-bromo-bromobenzyl-hydantoin,** m. p. 153–154° to a clear liquid prior to the evolution of gas, was prepared by treating 20 g. of N-3-methylbenzalhydantoin suspended in 300 cc. of boiling carbon tetrachloride with one equivalent of bromine. Within a few minutes the color had become pale orange and there was a heavy precipitate of very fine white needles which was filtered and washed free from bromine (27.0 g.). The precipitate was then suspended in cold carbon tetrachloride, and unchanged methylbenzalhydantoin which floated on the surface was removed by repeated decantations.

Anal. Calcd. for $C_{11}H_{10}O_2N_2Br_2$: C, 36.50; H, 2.78; Br, 44.15. Found: C, 36.82; H, 2.82; Br, 41.75. The same specimen analyzed two months later was found to have sustained a further loss of hydrobromic acid that made the amount practically quantitative.

Anal. Calcd. for $C_{11}H_9O_2N_2Br$: Br, 28.43. Found: Br, 28.67.

The compound is in fact so unstable that it loses hydrobromic acid slowly at room temperature, and when heated in an oven at 105° it passes quantitatively into N-3-methyl-C-5-bromobenzalhydantoin, m. p. 173–173.5°. It is almost insoluble in cold absolute alcohol but dissolves on warming to form a pale yellow solution. The latter suffers an almost immediate discharge of color accompanied by the evolution of hydrobromic acid and the separation of N-3-methyl-C-5,5-ethoxy-bromobenzyl-hydantoin, m. p. 179–180°.

Spectrographic measurements were made by the method developed by Stücklen[17] for use with a hydrogen lamp as the light source. Each compound was dissolved in absolute alcohol which had been especially purified for spectrographic use. A Hilger quartz spectrograph (E 36) was employed, and photographs were made on Eastman no. 40 plates. Although curves were plotted for the corresponding derivatives of both benzal- and methylbenzal-hydantoins, the latter corresponded so closely with the former that it has not been thought necessary to reproduce them.

Summary

The preparation under the action of bromine of C-5,5-bromoethoxy derivatives of both benzal- and N-3-methylbenzalhydantoins has been described and certain of their biochemical properties noted. In the case of N-3-methylbenzalhydantoin interest centers in the fact that a primary dibromo addition product was isolated which when warmed with absolute alcohol decomposed to give the corresponding bromo-ethoxy derivative but which when heated alone, passed quantitatively into N-3-methyl-C-5-bromobenzalhydantoin.

The Chemistry of Allergens. II. Isolation and Properties of an Active Protein Component of Cottonseed[1]

BY JOSEPH R. SPIES, E. J. COULSON, HARRY S. BERNTON AND HENRY STEVENS

The human allergic response provides the only available criterion for recognizing allergens, the substances in the diet or environment that act as specific incitants of a distinct group of human disease reactions called allergies. For the most part, allergens are considered to be either complete or partial antigens and, by virtue of this classification, closely related to the native proteins. To isolate and characterize as chemical entities the allergens of cottonseed is the objective of this investigation.

The isolation of a potent allergenic fraction CS-1[1a] from cottonseed recently has been described.[2] The previously characterized proteins of cottonseed were also shown to possess no important degree of inherent allergenic activity.[3]

The chemical procedures used in isolating CS-1 included alcohol precipitations, boiling in aqueous solution, precipitation of impurities with basic lead acetate, and removal of lead with hydrogen sulfide. These procedures are more drastic than are usually employed in the isolation of a biologically active substance. However, each step leading to the separation of CS-1 resulted in demonstrable increase in specific activity.

The literature concerning the immunological specificity of native plant proteins and protein split products is extensive.[4] As recently as 1936 Landsteiner stated, "The most important studies on the specificity of plant proteins were made by Wells and Osborne." The active protein constituent of CS-1 corresponds essentially in chemical and physiological properties with the "so-called proteoses" separated from seeds by Wells and Osborne.[5] Their proteoses were apparently chemically distinct from the other reserve proteins of seeds, possessed strong anaphylactogenic activity and were stable to heating at 100°. Earlier, Schloss[6] had demonstrated that the proteoses from almonds and oatmeal were more active than the other proteins in producing local skin reactions on a boy hypersensitive to these foods.

Clinically important allergenic constituents of cottonseed have been concentrated in CS-1. This paper describes the isolation from CS-1 of a protein-like substance possessing an unusual combination of chemical and physiological properties.

CS-1 formed a picrate having allergenic activity equal to that of CS-1. Retention of activity by the yellow picrate (CS-3) suggested chromatographic adsorption for further purification, characterization, and evaluation of homogeneity. The active constituents of CS-3 were quantitatively adsorbed by activated aluminum oxide in a sharply defined yellow layer which was resolvable into two layers by development with the solvent.

Diagram I shows the results of a typical chromatographic analysis of the picrate.

The major allergenic fraction, CS-5, appeared to be chromatographically homogeneous or composed of chemical entities too closely related to allow fractionation by this technique. Fractions CS-5 and CS-6 exhibited no appreciable differences in clinical activity. Both gave specific cutaneous reactions on cottonseed-sensitive patients in threshold dilutions ranging from $1:10^5$ to $1:10^6$ and could not be differentiated by im-

(3) Jones and Csonka, *J. Biol. Chem.*, **64**, 673 (1925), in their study of the proteins of cottonseed observed that a significant portion of the total nitrogen in sodium chloride extracts of cottonseed was lost during dialysis of the heat uncoagulable fraction. This fraction was precipitable by tungstic acid but was not isolated or further characterized. This non-coagulable, diffusible fraction is apparently contained in CS-1.

(4) For comprehensive reviews on these subjects see: H. Gideon Wells, "The Chemical Aspects of Immunity," The Chemical Catalog Co., N. Y., 1929; K. Landsteiner, "The Specificity of Serological Reactions," Charles C. Thomas, Baltimore, 1936; H. Zinsser, J. F. Enders and L. D. Fothergill, "Immunity—Principles and Applications in Medicine and Public Health," The Macmillan Co., New York, N. Y., 1939.

(5) Wells and Osborne, *J. Infectious Diseases*, **17**, 259 (1915), stated, "In their anaphylactic power these 'natural proteoses' differ sharply from proteoses obtained from animal proteins by digestion with enzymes or by chemical hydrolysis, such artificial products being almost if not entirely non-anaphylactogenic. Furthermore, those products of hydrolysis which result from heating vegetable proteins with acids, with water under pressure, or by peptic digestion, have, so far as we have tested them, no anaphylactogenic properties. From these facts it would seem that the vegetable 'proteoses' belong to a group of proteins which are chemically different from any heretofore recognized. They resemble highly soluble native proteins in their anaphylactogenic capacity and are probably quite as complex in their chemical constitution. Their designation as 'proteoses' is consequently improper." *Cf.* Fink, *J. Infectious Diseases*, **25**, 97 (1919).

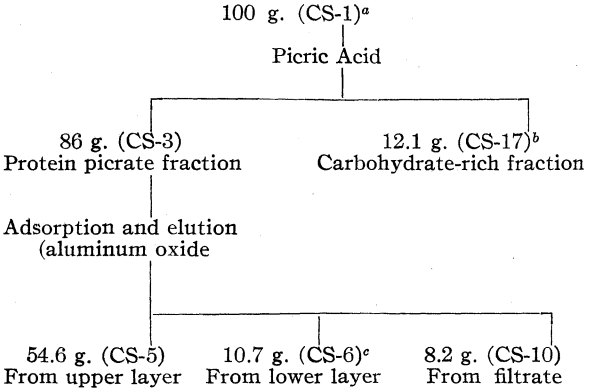
DIAGRAM I

CHROMATOGRAPHIC ANALYSIS OF ALLERGENIC PROTEIN PICRATE FROM COTTONSEED



[a] Contained 5.1% water. [b] CS-17 was obtained from the filtrate, after removal of the picrate, by precipitation with 75% alcohol. Purification involving further precipitations with alcohol yielded a colorless substance containing 8.7% nitrogen. CS-17 does not reduce Benedict's reagent, but after acid hydrolysis has strong reducing properties, indicating its polysaccharidic nature. CS-17 possessed lower allergenic activity than CS-5, but evidence obtained in preliminary hydrolysis studies which are in progress indicates that this activity is inherent and not due to incomplete separation from the active portion of CS-5. [c] A chromatographic analysis of CS-6 with prolonged development failed to cause sufficient partitioning to indicate separation of chemically different components.

munological tests.[7] CS-10 obtained from the filtrate of the adsorption showed no allergenic activity and no antigenic properties.

CS-5 was demonstrated to be immunologically identical with antigen present in the unheated aqueous extract of cottonseed embryo. Intramuscular injection of 0.5 mg. of CS-5 in one arm produced wheals (15–40 mm. in diameter) in sites on the opposite arm passively sensitized with 0.05 ml. of serum from cottonseed-sensitive patients.[8]

A picric acid-free, nitrogenous compound (CS-13) was recovered from CS-5. CS-13 exhibited allergenic activity greater than CS-5 and was also immunologically identified with antigen present in the unheated aqueous extract of cottonseed embryo.

The method originally developed for the isolation of CS-1 has been modified and adapted to a larger scale process. The use of hydrogen sulfide in removing excess lead was eliminated to avoid possible introduction of sulfur into the product, CS-1A. CS-1A yielded an active picrate from which the picric acid-free compound CS-13A could be obtained analogously to CS-13. CS-13 and CS-13A gave the usual protein color and precipitation tests. The Molisch test was positive but the amount of carbohydrate present in these fractions was insufficient to reduce Benedict reagent even after acid hydrolysis. CS-13A contained 2.06% sulfur. Intramuscular injection of 0.01 mg. of CS-13A in one arm produced wheals (15–25 mm.) in sites on the opposite arm passively sensitized with 0.05 ml. of serum from cottonseed-sensitive patients.[9]

Available evidence indicates that the allergenic fractions CS-13 and CS-13A are protein in nature and native to the cottonseed.[10] The possibility is recognized, however, that these fractions may represent the allergenic group of some larger protein molecule, native to cottonseed. Further study would be required to reach a definite conclusion as to which hypothesis is correct. Designation of this type of substance as native protein is not provided for in existing protein classification systems. It is suggested, therefore, that the term natural proteose be adopted to describe them.

(7) The anaphylactic reaction of the guinea pig was used to demonstrate antigenicity. A detailed account describing the immunological reactions of allergenic constituents of cottonseed will be reported elsewhere.

(8) Thereafter, all sensitized sites failed to respond to a second similar injection of CS-5. However, a subsequent injection of 0.5 ml. of an unfractionated water extract of cottonseed (1:11) produced moderate wheals of less than one-half the size induced by the initial injection of CS-5. These results showed that CS-5 contained the principal allergenic constituent of cottonseed. Also demonstrated was the fact that the unfractionated extract contained more than one allergen capable of inducing positive reactions in sites passively sensitized with serum from cottonseed-sensitive subjects. Clinical observations have previously prompted the hypothesis that foods or pollens contain multiple allergens. For the first time the validity of this hypothesis has been experimentally demonstrated by actual isolation of one of the allergenic components. Clinical significance of these observations will be presented elsewhere. *Cf.* Lippard and Schmidt, *Am. J. Diseases Children*, **54**, 288 (1937).

(9) This was the threshold dilution, as 0.001 mg. of CS-13A produced slight reaction only in some cases.

(10) In chemical properties CS-13 corresponds to the proteoses except, however, that it does not give a precipitate with nitric acid and is more diffusible. The best evidence available, however, for regarding CS-13 as a complete or native protein is based on immunological data. While the subject is somewhat controversial, weight of opinion supports the view that complete proteins are required for antigenicity. P. Hartley, "A System of Bacteriology," vol. 6, His Majesty's Stationery Office, London, 1931, page 231, states, "The results which have been obtained in carefully conducted experiments in which due regard has been paid to chemical changes produced by hydrolysis and to the properties of the materials used led to the conclusion that antigenic function, so characteristic a property of native proteins, is lost when the large protein molecule is broken down into smaller fragments. At what stage in the breakdown of the proteins the property is lost is unknown but all available evidence supports the view that this occurs very early and before substances known as proteoses have been formed." Zinsser and Bayne-Jones, "Textbook of Bacteriology," 8th edition, 1939, p. 166, state, "The antigenic substance of proteins is easily destroyed by cleavage. Even the higher cleavage products, polypeptides and proteoses, no longer show antigenic properties."

Experimental[11]

Isolation of Active Fraction (CS-1A).—The fat was removed from choice quality, ground cottonseed embryo by extraction with benzene at temperatures not exceeding 25°.[12]

Three kilograms of benzene-extracted cottonseed was mechanically stirred for at least two hours with 18 liters of distilled water. The cake was separated by centrifuging and discarded. The extract was filtered through cheesecloth and heated to 100° in 12-liter flasks in an autoclave. After cooling, the coagulum was filtered off on cheesecloth. The filtrate was concentrated under reduced pressure (water pump) so that the volume of the combined extracts from 6 kg. of cottonseed was reduced to 5 liters. During this concentration the extract was allowed to flow into a 12-liter, three-necked distilling flask heated at 92–95° on a water-bath at a rate slow enough to prevent excessive foaming. It was also necessary to occasionally remove the concentrate from the distilling flask to facilitate evaporation.

Ethanol[13] was added slowly to the concentrated extract (5 l.) with stirring to 75%. The sticky brown coagulum which formed was collected and the brown solution was decanted and discarded. The coagulum was dissolved in 5 liters of distilled water by mechanical stirring and warming with a glass steam coil. When solution and uniform suspension was complete, ethanol was added to 25%. To this suspension was added 2.5 liters of 10% basic lead acetate (of the type used for sugar analysis) dissolved in 25% ethanol solution. The precipitated lead salts were separated by centrifuging and discarded. Colloidal lead salts suspended in the solution were further removed by passing through a Sharples super-centrifuge at 50,000 r. p. m. To the slightly turbid solution ethanol was again added with stirring to 70% concentration. The resulting suspension was allowed to settle at −7° overnight. The clear supernatant liquid was decanted and discarded. The solid was freed from most of the ethanol by suction on a Büchner funnel. When dried in a vacuum desiccator over phosphorus pentoxide and ground, 100 to 130 g. of a brown powder was obtained. The next step can be carried out directly, however, without drying the solid. The brown solid obtained from 6 kg. of cottonseed was dissolved and suspended in 1200 ml. of distilled water by vigorous mechanical stirring for two hours. The suspension was centrifuged in 250-ml. lots in the batch bowl of the Sharples super-centrifuge for twenty minutes at 45,000 r. p. m. A viscous, brownish, slightly turbid solution was obtained. To the centrifuged solution 60 ml. of 10% sodium carbonate solution was added. The suspended lead carbonate was removed by centrifuging in the batch bowl of the Sharples super-centrifuge at 45,000 r. p. m. for thirty minutes. The slightly turbid solution was then filtered with pressure through a no. 7 Seitz clarifying pad. The average *p*H of the solutions thus obtained was 9.5.[14] The *p*H was adjusted to 6.1–6.3 with 50% acetic acid solution. This solution was poured slowly with stirring into five volumes of cold ethanol. The suspension was adjusted to *p*H 6.1–6.3 with 20% sodium hydroxide and cooled overnight at −7°. The supernatant solution, which should be clear, was siphoned off and the solid was obtained by centrifuging. The solid (CS-1A) was dried in a vacuum over phosphorus pentoxide and powdered. The average yield from twelve 6-kg. lots of cottonseed was 68.4 g. A dried sample of CS-1A equilibrated with air contained 10.7% total nitrogen and 3.6% water. Clinical comparison of CS-1 and CS-1A showed that they possessed equal activity. CS-1A did not reduce Benedict reagent but gave strong reduction after acid hydrolysis. Preparations of CS-1 contained 14.7 to 15.8% nitrogen and undoubtedly the lower nitrogen content of CS-1A was due to a greater proportion of polysaccharide.

Preparation of Allergenic Protein Picrate (CS-3).—To the solution of 50 g. of CS-1 in 800 ml. of water there was added with stirring 1 liter of a saturated aqueous solution of picric acid (25°). The picrate suspension was cooled overnight at 5° and the yellow precipitate was separated by centrifuging. The picrate precipitate was washed by stirring with 500 ml. of water and recentrifuged. The resulting solid (CS-3) was dried in a vacuum over phosphorus pentoxide; yield, 42.5 g.

Chromatographic Adsorption of Allergenic Picrate.—Approximately 20-g. lots of finely ground CS-3 were dissolved in 5 liters of 50% ethanol by warming (50–60°) and stirring. The clear filtered solution was allowed to flow slowly through a 44 × 188 mm. column of activated aluminum oxide[15] (Brockmann).

A sharply defined yellow layer formed at the top of the column. Development with 500 to 1500 ml. of 50% ethanol resolved the original layer with formation of two layers.

Elution of Picrate.—Ninety-one grams of the aluminum oxide–picrate adsorption compound from the upper layer (from 20 g. of CS-3) was stirred for ten minutes with 500 ml. of 0.05 *N* sodium hydroxide. The solid was separated by centrifuging and eluted with three more 400-ml. portions of 0.05 *N* alkali. To the combined alkaline extracts there was added with stirring an equal volume of a saturated aqueous solution of picric acid (excess). The precipitated picrate was separated by centrifuging and washed by stirring with 500 ml. of water. The picrate (CS-5) was dried in a vacuum over phosphorus pentoxide. The average yield of eluted picrate from this layer was 64%. CS-5 contained 18% total nitrogen, was insoluble in water and organic solvents, moderately soluble in 50% aqueous ethanol, and very soluble in 50% dioxane.

Recovery of Active Protein from the Picrate.—To a solution containing 15 g. of eluted picrate dissolved in 1150 ml. of 0.05 *N* sodium hydroxide an equal volume of ethanol was added with vigorous mechanical stirring.

(11) Microanalyses were carried out by Thomas H. Harris and Ernest J. Umberger. Dorris C. Chambers assisted in the clinical studies.

(12) A modification of the extractor described by Drake and Spies, *Ind. Eng. Chem., Anal. Ed.*, **5**, 284 (1933), was used which permitted extraction of 25-pound (11-kg.) lots with solvent cooled to room temperature.

(13) Throughout this work commercial absolute ethanol was used and concentrations are expressed as volume per cent.

(14) The *p*H of aqueous solutions was usually determined with a Beckman *p*H meter. The *p*H of alcoholic suspensions, later referred to, was determined colorimetrically on a spot plate using brom cresol purple indicator.

(15) Obtained from Merck & Company, Rahway, N. J. Celite (Johns Manville Co.) adsorbs CS-5 weakly. Commercial silica gel does not adsorb it at all from 50% ethanol solution.

The *p*H of the clear solution was adjusted to 6.3 with 50% acetic acid. A second 1150 ml. volume of ethanol was then added and the suspension was allowed to stand at 5° overnight. The separated solid was centrifuged off and extracted with 400 ml. of water. The insoluble portion was separated and discarded. The solution was brought to *p*H 6.3 and, after stirring with decolorizing carbon, was filtered through a Seitz sterilizing pad. The clear solution was poured into 3 volumes of cold ethanol. The *p*H was adjusted to the coagulation point and the solution was allowed to stand at 5°. The coagulation point in 75% ethanol lies between *p*H 6.1 and 6.3 and is very sharp. The solid was separated and redissolved in 500 ml. of water. The solution was boiled with activated carbon, filtered, and reprecipitated with ethanol as before. The solid, CS-13, was centrifuged off and dried in a vacuum over phosphorus pentoxide; yield, 2.9 g. *Anal.* Found: N, 17.9.

CS-13 was soluble in water but insoluble in organic solvents. Results of color tests were: pinkish biuret, deep blue ninhydrin, positive Millon, negative Hopkins–Cole, faintly positive Molisch, no reduction of Benedict reagent after acid hydrolysis. Results of precipitation tests were: precipitates with phosphotungstic acid, picric acid and 2.5% trichloroacetic acid after boiling and cooling. No precipitates with basic lead acetate nor mercuric acetate. All tests were conducted on a 1% aqueous solution of CS-13. CS-13 diluted $1:10^6$ gave strong cutaneous reactions on cottonseed-sensitive patients.

CS-13A.—In an electrophoretic system the picric acid precipitable fraction of CS-1 and CS-1A migrated toward the negative electrode. In an electrophoretic fractionation of CS-1A (which will be described separately) the active substance in the cell containing the negative electrode was precipitated as the picrate. From this fraction the picric acid-free protein was isolated as follows: 2.9 grams of picrate was dissolved in 230 ml. of 0.05 *N* sodium hydroxide and 230 ml. of ethanol was added. The *p*H of the clear solution was adjusted to 6.3 with 10% acetic acid. To the suspension was added 460 ml. of cold ethanol and the *p*H again carefully adjusted to the coagulation point (6.1–6.3). The suspension was cooled overnight at −5°. The precipitated solid was centrifuged off. The gummy solid was dissolved in 75 ml. of warm water and the solution was boiled with carbon, cooled, centrifuged, and filtered through a Seitz sterilizing pad. The filtrate was poured into 300 ml. of cold ethanol. If coagulation does not occur, adjustment of *p*H to 6.3 is necessary. The suspension was cooled at −5° overnight. A yield of 1.47 g. was obtained by centrifuging and drying the solid over phosphorus pentoxide.

Further purification consisted of again reprecipitating with picric acid and recovering the picric acid-free solid (1.0 g.) as described before. This solid was dissolved in 50 ml. of water and the solution was boiled with carbon, cooled, and centrifuged. The solution was filtered through a fritted glass filter and poured into 190 ml. of cold ethanol. Coagulation occurred without *p*H adjustment. The suspension was cooled to −5°, centrifuged and the solid dried in a vacuum over phosphorus pentoxide. A yield of 0.79 g. of white solid (CS-13A) was obtained. A 1% solution of CS-13A gave the same reactions as those obtained with CS-13. A dried sample of CS-13A equilibrated with air was used for analysis. *Anal.* Found: C, 43.4; H, 6.78; ash, 0.51; N, 18.1 (micro Kjeldahl); S, 2.04, 2.09 (micro); H_2O, 9.4; P, neg. CS-13A diluted $1:10^6$ gave strong cutaneous reaction on cottonseed-sensitive patients.

Summary

1. The active component of the protein picrate obtained from a concentrate of allergenic constituents from cottonseed embryo was adsorbed quantitatively on aluminum oxide.

2. The adsorbed picrate fractions were eluted and recovered without loss of allergenic activity.

3. A protein possessing an unusual combination of chemical and physiological properties was recovered from the active picrate. The term natural proteose is suggested to designate proteins of this class.

4. Unfractionated aqueous extracts of cottonseed contain a substance or substances other than those present in CS-5 capable of inducing positive reactions in sites passively sensitized with serum from cottonseed-sensitive patients.

The Reduction of α-Bromo-ketones by Aluminum Isopropylate with a Note on the Isomeric Amino-alcohols of the Ephedrine Series

BY PHILIP G. STEVENS, OWEN C. W. ALLENBY AND ADRIAN S. DUBOIS

In an earlier communication we[1] reported the reduction of α-bromo-ketones with aluminum isopropylate. Thus α-bromopropiophenone yielded the bromohydrin and halogen-free products. The former with methylamine gave a mixture of isomeric amino-alcohols, one of which was *dl*-pseudo-ephedrine. No *dl*-ephedrine was isolated.[2] The other isomeric amino-alcohol has now been found to be the *dl*-isoephedrine of Emde and Runne.[3] Inasmuch as this substance and *dl*-pseudo-ephedrine yield the same oxide, according to the boiling points recorded by Rabe and Hallensleben,[4] very likely it has the pseudo configuration, and so should be called *dl*-pseudo-isoephedrine.

In view of the discovery of Winstein and Lucas[5] that replacement by bromine of the hydroxyl group of certain bromohydrins involves a cyclic intermediate, with net retention of configuration, we believe that a similar series of reactions takes place here, rather than direct replacement with inversion. This would mean that both isomeric amino-alcohols are derived from the *threo*-bromohydrin through the *erythro*-oxide. We have no satisfactory explanation for the failure to obtain *dl*-ephedrine, unless the bromohydrin was principally the *threo*- form, or the *threo*-oxide gave complex products instead of the expected *dl*-ephedrine.[6] Work on this problem is now in progress.

The secondary reduction products of the bromo-ketone are lower boiling, and bromine-free. The higher boiling of these turned out to be a mixture of carbinols, one of which was methylbenzylcarbinol. This carbinol undoubtedly arises from further action of aluminum isopropylate on the bromohydrin for, actually, purified bromohydrin yields appreciable amounts of the carbinol when treated separately with the alcoholate. Probably this transformation involves the oxide as an intermediate, which then must rearrange to phenylacetone,[7] followed by further reduction. It was puzzling, however, to understand how this could occur so easily in an aluminum isopropylate solution, until we found that part of the hydrobromic acid removed from the reaction products appeared as isopropyl bromide. The acid could not then be completely neutralized, and was still available, possibly in the form of $AlBr(OC_3H_7\text{-}i)_2$, for either reactions with alcohols, or isomerization of the oxide.

To test this, we treated the oxide with the isopropylate containing aluminum bromide. Rearrangement and simultaneous reduction occurred readily, and the products appeared to be the same mixture of carbinols with methylbenzylcarbinol predominating. We therefore prefer this oxide-rearrangement mechanism in this case, to that suggested by Winstein,[8] which would involve disproportionation of the bromo-ketone to propiophenone and the dibromo-ketone, because this should yield ethylphenylcarbinol and not methylphenylcarbinol. While it is possible that such disproportionation occurred, yet it must have been to a very small extent only, since Kröhnke[9] has shown that the equilibrium between dibromopropiophenone and propiophenone in the presence of hydrobromic acid is almost completely on the side of the monobromo ketone.

The carbinol fraction obtained both from reduction of the bromo-ketone and the oxide boiled over a wide range. This was not due to the other possible rearrangement reduction product of the oxide, hydratropic alcohol,[10] but to another non-isomeric hydroxy compound. This substance was obtained almost exclusively from the oxide and aluminum isopropylate without any aluminum bromide. Its composition corresponded to $C_{12}H_{18}O_2$, and it formed a *p*-nitrobenzoate and phenylurethan melting[11] at 100 and 95.5°, re-

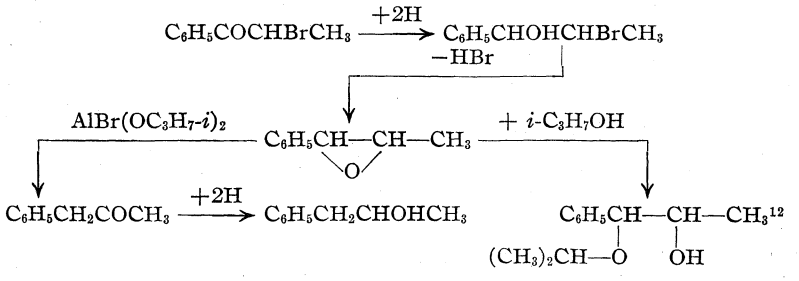
spectively. The substance is possibly a mixture of mono isopropyl ethers of α-phenylpropylene glycol, formed by the addition of isopropyl alcohol to the oxide. The reduction reaction can then be represented as follows:



The lower boiling secondary product has not yet been identified. From its odor it cannot be the intermediate oxide. Because of the poor yields, we turned to α-bromoisobutyrophenone. As expected, reduction in the usual way gave products of very low bromine content (3–7%), and from these could be separated similar bromine-free products in much better yields. The higher boiling of these was a carbinol, $C_{10}H_{14}O$, not yet identified. By analogy it was a mixture of alcohols formed from the oxide.[13]

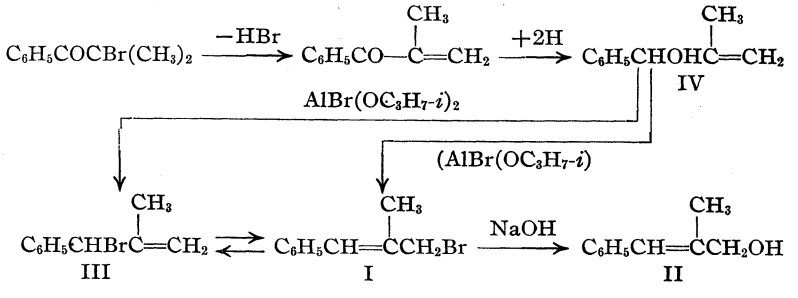
The lower boiling substance again was not the oxide. Its composition corresponded to $C_{13}H_{20}O$, and so it might be an isopropyl ether of some carbinol. Work on both alcohol and ether fractions is now in progress.

The most interesting development with α-bromoisobutyrophenone lay in its reduction with aluminum isopropylate at 33° *in vacuo*. Here the reduction took an entirely different course. In place of the usual products, the main product contained 37.2% bromine, with the composition $C_{10}H_{11}Br$. Oxidation with chromic acid yielding benzoic acid, and hydrolysis with sodium hydroxide to 2-methylcinnamyl alcohol II, indicated that the substance was 2-methylcinnamyl bromide I, or its isomer 1-phenylmethallyl bromide III. The bromide however had a higher boiling point (117°, 8 mm.) than 1-phenylmethallyl alcohol (100°, 8 mm.), strong evidence for the primary structure, as Claisen and co-workers[14] first pointed out with the isoprenyl bromides. Furthermore, the exaltation of the molecular refractivity was in good agreement with the primary structure:

	MR calcd.	MR found	Me
$C_6H_5CH{=}C(CH_3)CH_2OH$	45.84	46.94	+1.10
$C_6H_5CHOH{-}C(CH_3){=}CH_2$	45.84	45.70	−0.14
$C_6H_5CH{=}C(CH_3)CH_2Br$	52.08	52.72	+0.64

There is therefore little doubt but that the bromide is mainly the primary one. The original crude bromide, however, may well be an equilibrium mixture of both allylic isomers.

The formation of this primary bromide shows that at 33° reduction is very slow, and the aluminum isopropylate acts first to withdraw halogen acid. At 80–85°, however, it acts mainly to reduce the carbonyl group, the bromohydrin formed then undergoing secondary reactions. The steps in the former case can be written thus



This mechanism was tested by treating the carbinol IV with aqueous hydrobromic acid. The bromide formed, on hydrolysis with sodium hydroxide, yielded the isomeric primary alcohol II. Attempts to duplicate these reactions with α-bromopropiophenone at 33° were unsuccessful, for little if any reaction occurred. However, it is likely that both types of reaction occur whenever α-bromo-ketones with β-hydrogen are treated with aluminum isopropylate, the main course of the reaction depending on the conditions of the experiment, and the structure of the bromo-ketone.

We have also tried the reduction of a cyclic ketone[8] with secondary α-bromine. With 2-bromocholestanone, the more stable of the two α-bromocholestanones, according to Butenandt and Wolff,[15] reduction certainly occurred, but apparently no bromohydrin (if formed) survived.

Experimental Part

Reduction of α-Bromopropiophenone.—126 grams of the bromo-ketone, b. p. 127–129.5° (10 mm.), was added to a

solution of 33.0 g. of aluminum as isopropylate in 1200 cc. of isopropyl alcohol, and the solution boiled under a reflux distilling column for nine hours. The acetone was removed by fractional distillation. The combined distillate on treatment with alcoholic silver nitrate gave a precipitate of silver bromide equivalent to approximately 8% of the total bromine, indicating the presence of isopropyl bromide. Propylene was also present as evidenced by rapid reduction by aqueous permanganate. Most of the isopropyl alcohol was removed *in vacuo*, and the residual pasty mass poured onto ice and dilute sulfuric acid, extracted with ether, washed with dilute acid, water, potassium carbonate, sodium hydroxide, water, dried over anhydrous potassium carbonate and distilled: first fraction up to 75° (0.1 mm.), second fraction, 44 g., b. p. 75–95° (0.1 mm.). The black tarry residue weighed 42.7 g. Redistillation of the second fraction yielded the bromohydrin, a somewhat viscous yellow-brown oil, b. p. 73–75° (0.1 mm.), $n^{25}D$ 1.5611. *Anal.* Calcd. for $C_9H_{11}OBr$: Br, 37.2. Found: Br, 34.8.

Another reduction was made using 60 g. of bromoketone, 26 g. of aluminum and 1730 ml. of isopropyl alcohol, the solution being approximately one-half as concentrated as above. The solution was boiled for nine hours. Very little isopropyl bromide was formed. The reaction product was worked up as before, and yielded 45 g. of a distillate passing at 70–73° (0.03 mm.). This was not homogeneous, however, and redistillation at 0.02 mm. of 69.5 g. gave the following fractions: (1) 5 g., 45–57°; (2) 7.8 g., 57–58°; (3) 20.8 g., 58–62°; (4), 25 g., 62–68°. The first two fractions were mainly the carbinols, etc., and the last was fairly pure bromohydrin, $n^{25}D$ 1.5643; d^{25}_4 1.429; MR calcd., 49.45; found, 48.96. *Anal.* Calcd. for $C_9H_{11}OBr$: C, 50.2; H, 5.1; Br, 37.2. Found: C, 49.9; H, 5.1; Br, 38.0. The bromohydrin was not very stable, redistillation always yielding considerable tarry residue. Freshly distilled bromohydrin was yellowish, but turned dark green on standing.

The Reduction Side-Reaction Products.—The more volatile material from the reduction of 126 g. of bromoketone boiled from 73–98° (8 mm.) of which the carbinol fraction boiled at 104–111° (16 mm.). This was redistilled taking the fraction b. p. 106–108° (16 mm.). Treatment with phenyl isocyanate yielded the phenylurethan of methylbenzylcarbinol, crystallizing from Skelly Solve B in fine silky needles, m. p. 87.0–87.5° (mixed m. p., 87–88°). The lower boiling substance was not investigated further.

Synthesis of Methylbenzylcarbinol.—This carbinol, b. p. 102–103° (16 mm.), $n^{25}D$ 1.5191, was prepared from phenylacetaldehyde and methylmagnesium iodide. The yield was poor, due to the formation of condensation products. The phenylurethan crystallized as fine needles from Skelly Solve B, m. p. 87–88°.[16]

One of the condensation products crystallized from ether and Skelly Solve A as fine long needles, m. p. 126.5–127.0°. *Anal.* Calcd. for $C_{17}H_{20}O_2$: C, 79.7; H, 7.8. Found: C, 79.8; H, 7.6. Its composition and reactions indicated a glycol structure. Oxidation with chromic acid yielded a yellow-brown oil which gave a deep wine color with ferric chloride, but no copper derivative with copper acetate. Very likely the substance is the aldol condensation product of phenylacetaldehyde which has reacted with methylmagnesium iodide, with the structure $C_6H_5CH_2CHOHCH—CHOHCH_3$, with C_6H_5 on the CH.

Action of Methylamine on the Bromohydrin.—27.2 grams of bromohydrin (34.8% Br) was treated with 40 g. of methylamine dissolved in absolute methanol. After twenty-eight days in the dark at 20–25°, the excess amine was removed *in vacuo*. The entire mass, now solid, was shaken with ether and water, and then extracted four times with dilute hydrochloric acid. The acid solution was extracted twice with ether, and then neutralized with cold concentrated sodium hydroxide. The liberated amine, partially crystalline, was extracted thrice with ether, dried over anhydrous potassium carbonate and the ether evaporated, thus yielding crystals. These were washed with cold Skelly Solve A, weight 7.7 g., yield 33%. After four recrystallizations from Skelly Solve B, the silky crystals melted 116.5–117° with preliminary sintering. A mixed melting point with an authentic sample of *dl*-pseudoephedrine (prepared from *dl*-ephedrine by heating with 25% hydrochloric acid, and recrystallized from Skelly Solve B, m. p. 116.5–117.2°) was 116.5–117°. Recrystallized from water, the melting point was 117–117.7°. The hydrochloride crystallized from alcohol and ether as needles, m. p. 162–163°.

The filtrate from the *dl*-pseudoephedrine was evaporated, yielding 10 g. of a red oil, 43% yield. This was taken up in ether, extracted with dilute hydrochloric acid, neutralized to a faint acid reaction using congo red, and evaporated in a current of air, then over potassium hydroxide *in vacuo*, yielding 13 g. of a dry salt. This salt was crystallized from isopropyl alcohol from which after 6–8 recrystallizations it separated as hexagonal plates, m. p. 188–190.5°. It was much more soluble than *dl*-ephedrine hydrochloride. *Anal.* Calcd. for $C_{10}H_{15}ON$: C, 59.6; H, 7.9. Found: C, 59.8; H, 8.1. A mixed melting point with an authentic specimen[17] of *dl*-pseudoisoephedrine hydrochloride (m. p. 188–190°) was 188–190°. A mixed melting point with *dl*-ephedrine hydrochloride, m. p. 184–185°, was 155–175°. The mother liquors contained in substantial amounts the basic complex products, which did not lend themselves to purification, and so were not further investigated.

Action of Aluminum Isopropylate on the Bromohydrin.—A solution of 10.75 g. of bromohydrin, b. p. 62–68° (0.02 mm.) in 150 cc. of isopropyl alcohol containing 4 g. of aluminum was boiled for fifteen hours. At first the distillate gave a heavy silver bromide precipitate with silver nitrate, and a copious test for acetone. At the end of the reaction these tests were faint. The products were worked up as usual and distilled at 16 mm., yielding 2.8 g. of a liquid, b. p. 66–120°, and much tar; redistillation at 16 mm., first fraction 0.7 g., b. p. 68–100° (mostly 72–74°); second, 1.1 g., 100–109°. This fraction formed a phenylurethan, m. p. 86–87° (mixed m. p. 86.5–88.0°).

α-Methyl-β-phenylethylene Oxide.—21.5 grams of α-phenylpropylene (prepared by the method of Gauthier[18]

(16) Emde and Runne reported 88–89° (ref. 3).

(17) Prepared according to the direction of Emde and Runne, ref. 3.

(18) Gauthier and Gauthier, *Bull. soc. chim.*, [4] **53**, 323 (1933).

and Gauthier) b. p. 79–82° (20 mm.) was added to 37 g. of perphthalic acid (prepared following the directions of Böhme[19]), dissolved in one liter of ether. After twenty-four hours at −1°, and four days at 20–25°, the ether solution was decanted from the phthalic acid, washed thoroughly with aqueous sodium carbonate and water, dried over anhydrous potassium carbonate, and distilled. The oxide fraction, b. p. 74–75° (9 mm.) weighed 15 g., 61% yield. Several batches of oxide were combined and redistilled, b. p. 77–78.8° (10 mm.), $n^{20}D$ 1.5207, $n^{25}D$ 1.5189.

Action of Aluminum Isopropylate on the Oxide. (a) **Without Aluminum Bromide.**—Fifteen grams of the oxide was added to a 1 molar solution of aluminum isopropylate (9 g. of aluminum), and the solution boiled under a reflux column for twelve hours. Fractions were removed at intervals. The reaction of the oxide was very slow, as evidenced by the slow formation of acetone. After eight hours, no more acetone could be detected. The products were worked up as usual. There was no odor of any remaining oxide. Distillation at 16 mm.: first fraction, 1 g., b. p. 118–121°; second, 14 g., 121–124°, viscous residue 1–2 g. Obviously there was very little if any methylbenzylcarbinol, b. p. 102–103° (16 mm.), or hydratropic alcohol, b. p. 111–112° (16 mm.). Redistillation at 11 mm.: b. p. 114–116°, $n^{25}D$ 1.4924, d^{25}_4 0.9877; MR calcd. 57.18; found 57.05. *Anal.* Calcd. for $C_{12}H_{18}O_2$: C, 74.2; H, 9.3. Found: C, 73.4; H, 9.1. The substance contained a hydroxyl group, as it formed a *p*-nitrobenzoate, crystallizing from ethyl alcohol, m. p. 99.5–100°. *Anal.* Calcd. for $C_{19}H_{21}O_5N$: N, 4.1. Found: N, 4.2. The phenylurethan crystallized from Skelly Solve A as feathery needles, m. p. 94.5–95.5°. *Anal.* Calcd. for $C_{19}H_{23}O_3N$: N, 4.5. Found: N, 4.6. The ease of formation of these derivatives suggests the α-ether structure rather than the β.

(b) **With Aluminum Bromide.**—The same quantities were used here as in (a), adding 4.5 g. of aluminum bromide. The isomerization and reduction were quite rapid, as acetone was evolved readily. After thirteen hours of boiling, the products were worked up in the same way and distilled at 16 mm., first fraction, 0.2 g., b. p. 85–107; second fraction, 9.35 g., b. p. 107–118°, third fraction, 3.85 g., b. p. 118–124°. There was very little residue. Obviously here the product was essentially a mixture of methylbenzylcarbinol, and the higher boiling so-called glycol ether. Fraction 2 was converted to the phenylurethan, m. p. 87–88° (mixed m. p. 87–88°).

Reduction of α-Bromoisobutyrophenone. (a) **At 80–85°.**—This bromo-ketone is easily prepared from isobutyrophenone by simple bromination. In spite of its tertiary bromine atom it reacts extremely slowly with alcoholic silver nitrate, a faint opalescence appearing only after fifteen to twenty minutes at 20–25°. This inactivity, it appears, is quite normal for α-bromo-ketones, for α-bromopropiophenone and α-bromopentamethylacetone likewise react very slowly. Unlike the former, but similar to the latter, α-bromoisobutyrophenone has almost no lachrymatory power. It boils about 10° lower than α-bromopropiophenone, b. p. 119–120° (10 mm.), $n^{25}D$ 1.5550, d^{25}_4 1.3663.

Sixty-eight grams of bromo-ketone was reduced by boiling with 27.5 g. of aluminum as isopropylate in 1000 cc. of isopropyl alcohol for seven hours. The amount of isopropyl bromide formed was approximately 30%. The products were worked up as usual, and distilled, b. p. 25–75° (0.03 mm.). This product was separated by repeated distillation into two fractions, (1) b. p. 81–87° (9 mm.) and (2) b. p. 100–103.5° (9 mm.). The first was refractionated through a reflux column packed with glass helices, and so yielded a substance with an odor somewhat reminiscent of geraniol, b. p. 83.8–84.5° (9 mm.),[20] $n^{25}D$ 1.4756, d^{25}_4 0.8985. It gave no precipitate with hot alcoholic silver nitrate, but reduced aqueous permanganate to some extent. *Anal.* Calcd. for $C_{13}H_{20}O$: C, 81.2; H, 10.4. Found: C, 81.0; H, 10.3.

The carbinol fraction contained about 5% bromine, and so was purified through the phthalate. It still boiled over the range 100–104° (9 mm.) but was bromine-free. The fraction of b. p. 101–103° (9 mm.) was possibly a mixture of carbinols. *Anal.* Calcd. for $C_{10}H_{14}O$: C, 80.0; H, 9.3. Found: C, 80.2; H, 9.5.

(b) **At 33°** *in vacuo*.—Thirty-four grams of bromo-ketone was added to a solution of 13.8 g. of aluminum in 865 cc. of isopropyl alcohol, and distilled through a reflux column at 63–65 mm. The bath temperature was 33–34°. The distillation was continued for about fifteen hours, and the reaction products stood two nights at 20–25°. Finally the test for acetone in the distillate was very faint. Very little if any isopropyl bromide could be detected. The product was worked up as usual and distilled, yielding 28.5 g. of an oil, b. p. 65–85° (0.02 mm.). The residue was only 1.7 g. Redistillation in a modified Claisen flask at 0.04 mm. yielded the following fractions, (1) 2.0 g., b. p. 30–64°; (2) 4.6 g., b. p. 64–73°; (3) 18.9 g., b. p. 73–74°. This last was redistilled at 8 mm. taking the following fractions (1) b. p. 80–107°, (2) b. p. 107–115°, (3) b. p. 115–117°. The third fraction represented 70% of the total, $n^{25}D$ 1.5921, d^{25}_4 1.323, MR calcd. 52.08, found 52.72. The bromohydrocarbon, a mild lachrymator, reacts instantly with alcoholic silver nitrate, and reduces permanganate rapidly. It did not absorb bromine in carbon tetrachloride, but did so slowly in acetic acid. *Anal.* Calcd. for $C_{10}H_{11}Br$: C, 56.9; H, 5.2; Br, 37.9. Found: C, 56.9; H, 5.1; Br, 37.2. Oxidation with chromic acid in hot acetic acid was rapid, and a lachrymator was evolved. The acid fraction was isolated in the usual way, yielding copious amounts of benzoic acid, m. p. 121–122°.

Hydrolysis of the Unsaturated Bromide.—One gram of the bromide was boiled for several hours with dilute aqueous sodium hydroxide, the oil extracted with ether, dried, the ether evaporated, and the residual oil distilled *in vacuo*. The distillate was colorless, bromine-free, and had a fine odor. It reduced permanganate instantly, and absorbed bromine in carbon tetrachloride rapidly. The dibromide crystallized from Skelly Solve B as needles, m. p. 86–87° (mixed m. p., 86–87°). The phenylurethan crystallized in long needles from Skelly Solve B, m. p. 78.2–78.8° (mixed m. p. 78.2–78.8°).

2-Methylcinnamic Aldehyde.—This aldehyde was prepared from propionaldehyde and benzaldehyde according to the directions of Miller and Kinkelin[21] with only slight

(19) Böhme, *Ber.*, **70**, 379 (1937).

(20) α,α-Dimethyl-β-phenylethylene oxide boils at 74° (10 mm.).

(21) Miller and Kinkelin, *Ber.*, **19**, 526 (1886).

modifications. The aldehyde, purified through the semicarbazone, m. p. 206–208°, boiled at 113° (12 mm.).

2-Methylcinnamyl Alcohol.—Reduction of the above aldehyde was carried out with aluminum isopropylate. The unsaturated alcohol boiled at 124–124.3° (8 mm.), $n^{25}D$ 1.5697, d^{25}_4 1.034, MR calcd. 45.84, found 46.94. On cooling it solidified, m. p. 19–21°. *Anal.* Calcd. for $C_{10}H_{12}O$: C, 81.1; H, 8.1. Found: C, 80.9; H, 8.1. The dibromide crystallized from Skelly Solve A as needles, m. p. 86.0–87.0°. *Anal.* Calcd. for $C_{10}H_{12}OBr_2$: Br, 51.9. Found: Br, 51.8. The phenylurethan crystallized from Skelly Solve B, m. p. 78.5–79.3°. *Anal.* Calcd. for $C_{17}H_{17}O_2N$: N, 5.6. Found: N, 5.5.

1-Phenylmethallyl Alcohol.—This isomeric alcohol was prepared from α-methylacrolein and phenylmagnesium bromide in the usual way, b. p. 99.8–100.0° (8 mm.), $n^{25}D$ 1.5361, d^{25}_4 1.010, MR calcd. 45.84, found 45.70. *Anal.* Calcd. for $C_{10}H_{12}O$: C, 81.1; H, 8.1. Found: C, 81.2; H, 8.3.

The dibromide was an oil. The phenylurethan crystallized from Skelly Solve B, m. p. 79.5–79.9° (mixed m. p. with the phenylurethan of its isomer above (m. p. 78.5–79.3°) was 57–65°). *Anal.* Calcd. for $C_{17}H_{17}O_2N$: N, 5.6. Found: N, 5.6.

Action of Hydrobromic Acid on 1-Phenylmethallyl Alcohol.—Fifteen grams of the alcohol was treated with 30 ml. of constant boiling hydrobromic acid for one hour, with frequent shaking. The alcohol layer became olive-green. The upper layer was separated, washed with cold sodium bicarbonate, dried over sodium sulfate and distilled, b. p. 165–165.5° (30–26 mm.), 10.3 g. The bromide was now boiled with dilute aqueous sodium hydroxide for four hours, and then worked up as usual. The unsaturated alcohol was distilled, b. p. 147–150° (33 mm.), and converted to the phenylurethan, m. p. 78.0–78.5° (mixed m. p. with the phenylurethan of 2-methylcinnamyl alcohol (m. p. 78.5–79.3°) 78.5–79.0°).

Reduction of 2-Bromocholestanone.—One-half gram of the bromo-ketone, m. p. 169–170°, prepared according to the directions of Butenandt and Wolff[15] was treated with 55 ml. of a 0.2 molal aluminum isopropylate solution. The ketone did not appear to dissolve even after four and one-half hours boiling. The product, recovered in the usual way, was a gum, which gave only a faint opalescence with boiling alcoholic silver nitrate. It was not investigated further.

Summary

1. Reduction of α-bromopropiophenone yielded the bromohydrin and halogen-free products, one of which was methylbenzylcarbinol.

2. The bromohydrin with methylamine gave *dl*-pseudo-ephedrine and *dl*-pseudo-isoephedrine. No *dl*-ephedrine was isolated.

3. Reduction of α-bromoisobutyrophenone at 80–85° yielded principally bromine-free compounds.

4. Reduction of α-bromoisobutyrophenone at 33° *in vacuo* yielded 2-methylcinnamyl bromide, the result of a loss of hydrogen bromide, reduction and replacement by halogen accompanied by an allylic rearrangement.

5. Reduction of 2-bromocholestanone occurred with complete removal of bromine.

[CONTRIBUTION FROM THE RESEARCH LABORATORY OF ORGANIC CHEMISTRY, MASSACHUSETTS INSTITUTE OF TECHNOLOGY, NO. 222]

Intermediate Complexes in the Friedel and Crafts Reaction

BY JAMES F. NORRIS AND JOHN EDWARD WOOD, III[1]

In a former paper[2] a number of complexes were described which contained aluminum halides, aromatic hydrocarbons and hydrogen halides. The complexes differed in stability when submitted to diminished pressure. When the one having the composition $Al_2Br_6 \cdot 2C_6H_5(C_2H_5)_3 \cdot HBr$ was held at 0.002 mm. pressure until constant weight was obtained, one-half of the hydrocarbon was lost. We accordingly attempted to prepare directly a complex which contained its components in molecular ratio of $1Al_2Br_6$ to 1 *s*-$C_6H_3(C_2H_5)_3$. When a mixture of these compounds in the above ratio was treated with hydrogen bromide, a compound was formed which was shown by analysis to have the composition represented by the formula $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3 \cdot HBr$. A compound of similar composition containing aluminum bromide, mesitylene and hydrogen bromide also was prepared.

The previous work of Norris and Ingraham indicated that a complex could be formed in which ethyl bromide replaced the hydrogen bromide. We have isolated complexes which have the formulas $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3$, C_2H_5Br and $Al_2Br_6 \cdot s\text{-}C_6H_3(CH_3)_3 \cdot C_2H_5Br$. We were unsuccessful in attempts to prepare complexes of definite composition containing only aluminum halides and

(1) From the thesis of John Edward Wood, III, presented in partial fulfillment of the requirements for the degree of Doctor of Philosophy, 1939.

(2) Norris and Ingraham, THIS JOURNAL, **62**, 1298 (1940).

hydrocarbons. As far as the work has progressed it appears that a third component is necessary.

The complex which contained ethyl bromide was stable for several days. When it was heated or treated with additional ethyl bromide, hydrogen bromide was eliminated and the hydrocarbon was ethylated. This fact furnishes an explanation of the observation previously reported[3] that when methyl chloride was passed into a mixture of *m*-xylene and aluminum chloride at the temperature of a steam-bath no hydrogen chloride was evolved until about two-thirds of the methyl chloride had been added. It is probable that a ternary complex was first formed and later decomposed with the formation of alkylated benzenes or that the hydrogen chloride formed combined with the hydrocarbon and aluminum chloride to form a ternary complex.

The action of carbon dioxide on several complexes was studied since it has been shown[4] that when a mixture of benzene and aluminum chloride is treated under pressure with carbon dioxide, benzoic acid is formed. When the complex $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3 \cdot HBr$ was allowed to stand with carbon dioxide at about 60 atmospheres pressure for fifty hours, no reaction took place. Under the same conditions the complex which contained two moles of triethylbenzene gave very small yields of what appeared to be the corresponding acid and ketone. When aluminum bromide and mesitylene without hydrogen bromide were used, 26% of the hydrocarbon was converted into *s*-trimethylbenzoic acid and 47% into the ketone. It was evident that the presence of hydrogen bromide in the complex interfered with the carbonation reaction. It is possible that the intermediate in this case contains aluminum bromide, hydrocarbon and carbon dioxide. If this is the case the hydrogen bromide must be removed before reaction takes place.

In order to gain information which might be of value in the interpretation of the structural relationships of the complexes, the compound having the formula $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3 \cdot HBr$ was subjected to electrolysis. Wohl and Wertyporoch[5] have reported on the electrolysis of a compound to which they assign the formula $[Al(C_2H_5Br)n(C_6Et_6)_4]^{+++}3(AlBr_4)^-$.

In a preliminary experiment the conductivities were measured of a solution of aluminum bromide in toluene and of a similar solution after hydrogen bromide had been passed into it to form a complex. The conductivity of the latter was over 1000 times as great as that of the simple solution.

The complex $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3 \cdot HBr$ was electrolyzed in a cell containing a porous cup. When the voltage between the anode and cathode was 18 volts and the current 0.1 ampere, gases were formed at both electrodes. After nine hours the material around the cathode and that around the anode were analyzed. Pure triethylbenzene separated at the cathode only. Analyses of the heavy oils in the two compartments of the cell for hydrocarbon, aluminum and bromine showed that a part of the aluminum bromide had been transferred from the catholyte to the anolyte. The oil from the latter yielded an organic product which consisted of *s*-triethylbenzene and higher boiling substances which contained bromine.

The results indicate that the complex studied is an ionized compound, that the positive ion contains hydrocarbon, and the negative ion aluminum and bromine, that the negative ion is transferred more rapidly than the positive ion, and that the reaction at the anode involves bromination. Whether or not a part of the aluminum bromide is present in the positive ion can be determined only by additional work which is to be done. The simplest formula which could be assigned to the complex with the present knowledge is $[C_6H_3(C_2H_5)_3H]^+Al_2Br_7^-$.

In the paper by Norris and Ingraham it was stated that when the complexes which contained aluminum bromide were treated with hydrogen chloride the bromine of the bromide was replaced by chlorine and a complex containing aluminum chloride was formed. It was of interest to find out whether a similar replacement took place when the aluminum halide was combined with other organic molecules. We have shown that similar replacements take place when the complex contains benzene or toluene. When hydrogen bromide was passed into the complex $AlCl_3 \cdot C_6H_5NO_2$ the chlorine was replaced by bromine, and the complex so formed was converted into the one containing aluminum chloride when it was heated with hydrogen chloride. A small amount of a by-product was formed. When hydrogen iodide was used some triiodoaniline was isolated.

The complexes containing aluminum halides and nitrobenzene are oxidizing agents. It should be noted the complex $2AlCl_3 \cdot C_6H_5NO_2$ must be

(3) Norris and Rubinstein, THIS JOURNAL, **61**, 1169 (1939).
(4) British Patent 307,223.
(5) Wohl and Wertyporoch, *Ber.*, **64B**, 1357 (1931).

handled with care. Once during its preparation it was heated too hot and an explosion occurred. When it was treated with benzene the mixture ignited. It is possible that under controlled conditions a mixture of aluminum chloride and nitrobenzene might prove to be a valuable oxidizing agent to be used in the absence of water.

In the study of the mechanism of the condensation of acyl chlorides with aromatic hydrocarbons by the Friedel and Crafts reaction, it is usually considered that the halogen in the halogen hydride formed is the halogen present in the acyl halide. To test this view the condensation of acetyl chloride with benzene by means of aluminum bromide and the condensation of acetyl bromide with benzene by means of aluminum chloride were studied. In the two cases both hydrogen chloride and hydrogen bromide were formed. When acetyl chloride and aluminum bromide were used 70 mole per cent. of the mixture of gases evolved was hydrogen bromide. When acetyl bromide and aluminum chloride were used, 77 mole per cent. of hydrogen chloride was obtained. Much the larger part of the halogen liberated as the halide was the halogen which was originally in combination with the aluminum. These facts lead to conclusions which will be tested.

Details of Experiments

The Complex $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3 \cdot HBr$.—Aluminum bromide was distilled under anhydrous conditions into a flask and *s*-triethylbenzene was added. The weights used were 17.811 g. of Al_2Br_6 and 5.564 g. of hydrocarbon (mole ratio 1:1). When the mixture was heated to 100° a solution was obtained from which about one-half of the bromide crystallized out on cooling. Hydrogen bromide was passed into the mixture at room temperature as long as it dissolved. The increase in weight was 2.997 g. equivalent to 1.10 moles of hydrogen bromide. When the product which was an oil was held at 15 to 25 microns pressure for 1.4 hours, the loss in weight was 0.373 g. The hydrogen bromide left in the complex was equivalent to 0.970 mole. The complex was held at the same pressure for an additional eight and one-third hours; the loss in weight was 0.04 mole. A control experiment showed that under the same conditions a saturated solution of aluminum bromide in *s*-triethylbenzene lost 1.1 g. in seven hours. A repetition of the preparation in which 32.3 g. of Al_2Br_6 was used gave closely checking results.

Samples of the complex after evacuation were analyzed in the way described by Norris and Ingraham with the following results: % hydrocarbon, 20.21, 19.45; bromine, 70.4, 70.6; aluminum 7.56, 7.52. Calcd.: 20.85, 72.07, 6.97, respectively.

The Complex $Al_2Br_6 \cdot s\text{-}C_6H_3(CH_3)_3 \cdot HBr$.—The compound was prepared in a way similar to that described above. The product after the removal of excess hydrogen bromide was found to contain 0.95 mole of hydrogen bromide.

The Complex $Al_2Br_6 \cdot s\text{-}C_6H_3(CH_3)_3 \cdot C_2H_5Br$.—A mixture was made at 0° of equal molecular quantities of the components, Al_2Br_6, 23.58 g., mesitylene, 4.98 g., and ethyl bromide, 4.59 g. The mixture was shaken for one hour; at the end of this time a homogeneous red liquid was formed. This oil was held at 12 mm. pressure for three and one-quarter hours; the loss in weight was 0.02 g. The pressure was then reduced to 15–30 microns. At the end of a total of four and one-half hours the loss in weight was 0.03 g. To gain further evidence as to whether the ethyl bromide was chemically combined, the product was shaken with about 10 cc. of petroleum ether and the latter after separation and washing with water was tested for bromine with a copper wire. No halogen was found. A control experiment with a mixture of petroleum ether and ethyl bromide gave a positive test.

The Complex $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3 \cdot C_2H_5Br$.—A sample of this complex was made in the way described above and the same tests were applied. Petroleum ether did not remove any ethyl bromide. The complex was slowly decomposed under diminished pressure; 41.5 g. of the complex which contained 5.65 g. of ethyl bromide when held at 15–30 microns pressure lost 0.10 g. in one-quarter hour and 0.40 g. in 5.5 hours.

A sample of this complex which weighed 30.6 g. and contained 3.45 g. of ethyl bromide stood at room temperature in a closed tube for seventeen days with no apparent change. At the end of this time 5 cc. of ethyl bromide was added; the complex dissolved at once. In a few minutes hydrogen bromide was evolved freely.

The Reaction of the Complexes with Carbon Dioxide.—In all the experiments the substances in a glass vessel were placed in an autoclave. After the air was displaced by carbon dioxide, the autoclave was connected directly with a cylinder containing liquid carbon dioxide. When 31.9 g. of the complex $Al_2Br_6 \cdot 2s\text{-}C_6H_3(C_2H_5) \cdot HBr$ was kept for fifty hours at 50° in contact with carbon dioxide, carbonation took place to a very small extent. Enough *s*-triethylbenzoic acid was obtained to make its identification possible by the melting point of the acid and its amide. A very small amount of a substance which probably was the corresponding ketone also was isolated.

Experiments with the complex $Al_2Br_6 \cdot 3s\text{-}C_6H_3(CH_3)_3 \cdot HBr$ yielded unsatisfactory results. A small amount of the dimesityl ketone was isolated, but no acid was identified.

The complex $Al_2Br_6 \cdot s\text{-}C_6H_3(CH_3)_3 \cdot HBr$ when treated with carbon dioxide at room temperature for fifty hours gave no ketone and no acid; 96.5% of the mesitylene in the complex was recovered.

The Carbonation of Mesitylene in the Presence of Aluminum Bromide.—A mixture of 51.3 g. of aluminum bromide and 23.1 g. of mesitylene (mole ratio $1AlBr_3$ to 1 hydrocarbon) was treated with carbon dioxide for sixty hours at room temperature. The product was decomposed by water in the way described above, and steam distilled; 6 g. of mesitylene was recovered. The aqueous part of the distillate was returned to the flask from which it had been distilled and the mixture was cooled in an ice-bath. The solid was separated by filtration and digested

with 10 g. of sodium hydroxide dissolved in 200 cc. of water. The insoluble residue weighed 11.5 g. The alkaline solution after acidification and cooling gave 8.5 g. of an acid. The material insoluble in alkali was crystallized three times from petroleum ether; it melted at 138.5–139.1°. The recorded melting point of dimesityl ketone is 136–137°. The acid formed was crystallized once from a mixture of alcohol and water and twice from petroleum ether; it melted at 152.0–152.4° (short range standardized thermometer). The recorded melting points of *s*-trimethylbenzoic acid vary from 147 to 155°. A sample of the acid which melted at 152.3° was converted into the amide; this melted at 185–186° (recorded m. p. 187–188°). The neutralization equivalent of the acid was 162.7 (theoretical 164.1). The yield of dimesityl ketone was 44.9% of the theoretical and of *s*-trimethylbenzoic acid 26.9%; 26.3% of the mesitylene used was recovered. When 2 moles of $AlBr_3$ and 1 mole of mesitylene were used the yields were 47.2% ketone, 26.4% acid, and 19.6% hydrocarbon.

Electrolysis of the Complex $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3 \cdot HBr$.—In a preliminary experiment two solutions of aluminum bromide in toluene (mole ratio 1:1) were prepared. One solution was converted into the complex by passing into it hydrogen bromide until no free toluene was present. The conductivities of the solution and of the complex were determined in a conductivity cell of the usual type. The conductance of the simple solution was 1.5×10^{-4} mhos; that of the complex was 0.18 mho.

In another experiment the complex $Al_2Br_6 \cdot s\text{-}C_6H_3(CH_3)_3 \cdot C_2H_5Br$ was placed in a conductivity cell and a potential of 6 volts was applied. The current produced measured 0.05 ampere. For comparison a 0.1 *N* solution of sodium chloride was placed in the cell and a potential of 6 volts was applied; the current measured 0.18 ampere.

The complex $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3 \cdot HBr$ was prepared and placed in a cell consisting of a 100-cc. beaker and a thin-walled alundum cup. Platinum electrodes were used. During the electrolysis a stream of dry nitrogen was passed over the cell. A potential of 18 volts across the electrodes was applied; the current was 0.1 ampere. Bubbling and darkening of the material was observed at both electrodes; no aluminum was deposited. At the end of nineteen hours the material at the cathode was a dark viscous substance and a light colorless oil which was shown to be *s*-triethylbenzene by the melting point of its trinitro derivative. There was no separation of hydrocarbon in the anode compartment of the cell.

The dark viscous material from the anode compartment and that from the cathode compartment were analyzed separately for aluminum, bromine and hydrocarbon. The results were as follows: anode, % Al, 8.29, 8.34; % Br, 74.3, 74.9; % hydrocarbon 14.0, 14.6; mole ratio Al:Br, 1 to 3.0. Cathode, % Al, 6.69, 6.54; % Br, 65.8, 63.5; % hydrocarbon 25.4, 27.6; mole ratio Al:Br, 1:3.3. Seven cc. of the insoluble oil obtained as the result of decomposition of the anolyte with water was distilled through a 2-inch (5 cm.) Podbielniak column; there were obtained 5.5 cc. of a liquid which boiled at 215° (*s*-triethylbenzene) and 1 cc. of a higher boiling fluorescent fraction which was shown to contain bromine.

Halogen Interchange in Complexes.—When hydrogen chloride is passed into a mixture of benzene and aluminum chloride a complex is formed very slowly; when, however, hydrogen bromide is used an oily complex soon begins to separate at room temperature. Hydrogen bromide was passed at room temperature into a mixture of 45 g. of aluminum chloride and 132 g. of benzene which was stirred (mole ratio Al_2Cl_6 to C_6H_6, 1:3). At the end of sixteen hours the heavy oily layer was separated from the benzene and aluminum chloride that had not reacted. The product contained chlorine and bromine in the atomic ratio of approximately 1:1. The treatment with hydrogen bromide was continued until all the aluminum chloride had passed into the lower layer; eleven hours were required. The atomic ratio in the complex was approximately bromine 4 to chlorine 1. Continued treatment with hydrogen bromide did not appreciably alter the ratio.

A similar replacement of chlorine by bromine took place when toluene and aluminum chloride were used. In this case the reaction was more rapid; with benzene twenty-seven hours were required to effect solution of the aluminum chloride, whereas with toluene two hours were sufficient.

The complex having the formula $AlCl_3 \cdot 2C_6H_5NO_2$ was kept at 90–100° and treated with hydrogen bromide for eleven hours. It was then held at diminished pressure for several hours to remove any dissolved hydrogen halides. The product was decomposed by water; it contained about 43% bromine and 2% chlorine; 92% of the chlorine had been replaced by bromine.

The complex $AlCl_3 \cdot C_6H_5NO_2$ was treated with hydrogen bromide for eight hours; at the end of this time 85% of the chlorine had been replaced by bromine. Hydrogen chloride was then passed into the product for eight hours at room temperature. The treatment increased the percentage of chlorine from 6.4 to 24.4%.

In an experiment in which $AlCl_3 \cdot C_6H_5NO_2$ was treated with hydrogen bromide for thirty hours at 90–100°, a small amount of a precipitate appeared in the solution. This was separated and treated with water. The product was shown by its melting point and that of its acetyl derivative to be 2,4-dibromoaniline.

About 39 g. of the complex $AlCl_3 \cdot C_6H_5NO_2$ was made in a tube and treated with hydrogen iodide at dry-ice temperature until 20 g. of the gas condensed. The tube was sealed and stood at room temperature for ten days. It was then heated at 65° for twenty hours. From the product was isolated a small amount of 2,4,6-triiodoaniline.

The Condensation with Benzene of Acetyl Chloride in the Presence of Aluminum Bromide and of Acetyl Bromide in the Presence of Aluminum Chloride.—The two reactions were carried out under the same conditions and equal molecular quantities were used. The molecular ratio was 1 aluminum halide, 1 acyl halide, 5 benzene. The weight of acetyl bromide was 45 g. During the reaction the flask containing the reactant was surrounded by ice and the contents were stirred. The aluminum halide was added slowly to the acyl halide and the benzene was allowed to drop, during one hour, onto the mixture. The evolved gases were collected in water. When the reaction was complete the flask was heated on a steam-bath until the evolution of gas ceased. The mixture of hydrogen halides in the water was analyzed. When acetyl bromide and aluminum chloride were used the mole per-

centage of hydrogen bromide was 23 and of hydrogen chloride 77; for each mole of hydrogen bromide there was formed 3.3 moles of hydrogen chloride. When acetyl chloride and aluminum bromide were used the mole percentage of hydrogen chloride was 30 and of hydrogen bromide 70; for each mole of hydrogen chloride there was 2.3 moles of hydrogen bromide. The yields of acetophenone in the two cases were nearly the same, 72 and 76%, respectively.

Summary

1. The preparation and some of the properties of the complexes having the following formulas are described: $Al_2Br_6 \cdot s\text{-}C_6H_3(CH_3)_3 \cdot HBr$, $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3 \cdot C_2H_5Br$, $Al_2Br_6 \cdot s\text{-}C_6H_3(CH_3)_3 \cdot C_2H_5Br$.

2. The complex $Al_2Br_6 \cdot s\text{-}C_6H_3(C_2H_5)_3 \cdot HBr$ did not react with CO_2 at 60 atmospheres, but a mixture of Al_2Br_6 and $s\text{-}C_6H_3(CH_3)_3$ under the same conditions gave high yields of the dimesityl ketone and *s*-trimethylbenzoic acid.

3. When a complex which contains aluminum chloride and benzene, toluene, triethylbenzene or nitrobenzene was treated with hydrogen bromide at room temperature an exchange of halogen atoms took place. When the complex which contained aluminum bromide was treated with hydrogen chloride, exchange also took place.

4. When acetyl chloride was condensed with benzene by means of aluminum bromide 77 mole per cent. of the hydrogen halides formed was hydrogen bromide. When acetyl bromide and aluminum chloride were used the mole per cent. of hydrogen chloride was 70.

The Preparation of Nitriles and Amides. Reactions of Esters with Acids and with Aluminum Chloride. The Use of the Salt $NaCl \cdot AlCl_3$ in the Friedel and Crafts Reaction

BY JAMES F. NORRIS AND ALBERT JOHN KLEMKA[1]

In a former paper[2] the preparation was described of benzonitrile from benzamide or ammonium benzoate by means of aluminum chloride. Since the results were satisfactory, the method has been studied further and applied to the preparation of a number of typical compounds. As a guide in the use of the method the steps involved in the reaction were investigated. The results are indicated as follows

$$C_6H_5CONH_2 + AlCl_3 \xrightarrow{\text{heated}}$$

$$HCl + C_6H_5CONHAlCl_2 \xrightarrow{\text{higher temperature}} C_6H_5CN + HCl + AlOCl$$

In one experiment a part of the product formed after the first evolution of hydrogen chloride had ceased was decomposed by water; benzamide was recovered. The second part was heated to a higher temperature; more hydrogen chloride was formed and the nitrile distilled.

Eleven nitriles were prepared by this method; the yields were from 63 to 97%. In most cases, the double salt of aluminum chloride and sodium chloride ($NaCl \cdot AlCl_3$) was used. This compound can be prepared easily, is convenient to handle and has the added advantage that it gives higher yields and does not melt during the reaction and cause frothing. The method cannot be applied to amides containing functional groups which react with aluminum chloride; unsatisfactory yields were obtained from amides of dibasic acids.

A simple procedure was devised for a semi-micro method to be used in the identification of certain amides by converting them into nitriles and determining the melting point of the latter; about 10 milligrams of the amide is sufficient for the identification.

When ammonium salts of the acids were used the yields were low. It was shown that the first step in the reaction with aluminum chloride was not the formation of an amide.

Since this method of preparing nitriles involved the use of amides, the preparation of the latter directly from acids was studied. Biehringer and Borsum[3] have reported the interaction of an acid and an amide, as the result of which there is an interchange of the hydroxyl and amino groups. The reactions were carried out in sealed tubes at a high temperature and the yields were low.

In our experiments a mixture of the acid and acetamide was heated in a flask and the volatile material was condensed and collected; the latter consisted chiefly of acetic acid.

When the method was applied to 2,6-dichlorobenzoic acid a quantitative yield of *m*-dichlorobenzene was obtained in two hours. The acid was heated with acetamide at the temperature (225–235°) at which decomposition takes place to a slight extent in six hours. The effect of acetamide on other acids that lose carbon dioxide when heated will be investigated.

The interchange reaction between an acid and amide was shown to be a reversible one; an interchange took place between benzoic acid and acetanilide as the result of which benzanilide was formed. Certain esters were shown to interchange groups with acids; for example, benzoic acid and phenyl acetate were converted by heating into phenyl benzoate and acetic acid.

The use of the compound of aluminum chloride and sodium chloride in Friedel and Crafts condensations was studied in a few cases. Since the reagent was found to be much less reactive than aluminum chloride, it could be used with advantage in the case of halogen compounds that are decomposed by aluminum chloride. A good yield of diphenylmethane was obtained from benzyl chloride. With chloroform and carbon tetrachloride the condensation took place to a slight degree only.

A number of miscellaneous reactions related to the work being done in this Laboratory are described in the Experimental Part of this paper. These include the reaction between ethyl 2,6-dichlorobenzoate and aluminum chloride as the result of which the ester was quantitatively converted into a salt of the acid and ethyl chloride; the reaction between benzoyl chloride and ammonium chloride; and the condensation of benzoic acid with toluene.

Details of Experiments

Preparation of Nitriles.—The double salt $NaCl \cdot AlCl_3$ was prepared as follows. Thirty grams of dry sodium chloride was intimately mixed with 68 g. of pulverized aluminum chloride (equal molecular quantities) and heated in a flask for one hour at 230–250°. The liquid was poured into a beaker and stirred as it solidified to a meal. The product was kept in a tightly stoppered bottle and ground before use.

The process used in making nitriles was as follows. A mixture of the amide and the salt $NaCl \cdot AlCl_3$ was heated in a flask connected with a condenser and a receiver. The mixture was heated cautiously with a free flame until the evolution of hydrogen chloride had nearly ceased; it was then heated at a higher temperature until no more distillate was obtained and a charred solid remained in the flask. The volatile product was the nitrile in pure condition. The liquids were redistilled to free them from a small amount of dissolved hydrogen chloride. The boiling and melting points agreed closely with those given in the literature.

The yields of pure nitriles were as follows. CH_3CN (b. p. 81–82°) 91% (moles amide to moles $NaCl \cdot AlCl_3$, 0.2 to 0.26; decrease in $NaCl \cdot AlCl_3$ gave lower yields; aluminum chloride alone, 0.2 to 0.2 mole gave 43%). $(C_6H_5)_2CHCN$ (m. p. 72–73°) 52% (0.031 to 0.044 mole). *n*-$C_5H_{11}CN$ (b. p. 158–159°) 63% (0.052 to 0.068 mole). C_6H_5CN (b. p. 190.7° (cor.) (97% (0.2 to 0.2 mole). *o*-ClC_6H_4CN (m. p. 43–44°) 93% (0.03 to 0.036 mole). *p*-$CH_3C_6H_4CN$ (b. p. 217–220° (cor.)) 89% (0.062 to 0.077 mole). *p*-$NO_2C_6H_4CN$ (m. p. 149–150°) 29%. 2,6-$Cl_2C_6H_3CN$ (m. p. 142.5–143.5°) 67% (0.026 to 0.029 mole). 2,4,6-$Cl_3C_6H_2CN$ (m. p. 75–76°) (50 mg. of acid used). α-$C_{10}H_7CN$ (m. p. 31–32°) 79% (1 g. of amide used). β-$C_{10}H_7CN$ (m. p. 65–66°) 80% (2 g. amide and 2.3 g. $NaClAlCl_3$).

In the study of the mechanism of the reaction, equal molecular quantities of benzamide and $NaCl \cdot AlCl_3$ were heated; when the temperature reached 140–150° hydrogen chloride began to be evolved. When the reaction ceased the temperature was raised to 290–295° before any more gas was formed. At this temperature hydrogen chloride was evolved freely and benzonitrile distilled from the flask; two moles of hydrogen chloride was formed.

Equal molecular quantities of benzamide and aluminum chloride were heated. At the melting point of the amide hydrogen chloride was evolved and the aluminum chloride dissolved in the liquid. The product, after solidification, was hydrolyzed by water; 86% of the amide was recovered.

p-Nitrobenzamide was heated with $NaCl \cdot AlCl_3$ (equal moles) at 180° until one mole of hydrogen chloride was formed. More of the salt was added but no additional hydrogen chloride was formed. The product was steam distilled; no nitrile was obtained. The amount of amide recovered was 94% of the amount used.

The Semi-micro Procedure.—The following procedure is recommended. A powdered mixture of 10 mg. of the amide and the equivalent weight of $NaCl \cdot AlCl_3$ or aluminum chloride is introduced into a 6-mm. tube closed at one end. In order to prevent the mixture from coming into contact with the sides of the tube, it is introduced through a second tube drawn out so that it can be placed in the reaction tube. The latter is then heated about 4 cm. from the closed end and drawn down to the diameter of a melting point tube. The mixture is heated cautiously above a flame until the hydrogen chloride has been given off. It is then heated slowly at a higher temperature until the nitrile formed has sublimed into the narrow part of the tube. When cold, the narrow tube is cut off and the melting point of the nitrile determined in a melting point block. The observed and the recorded melting points (in parentheses) are given of the nitriles made in this way; *o*-ClC_6H_4 45–46° (42–43°); 2,6-$Cl_2C_6H_3CN$ 144.5–146.5° (143°); 2,4,6-$Cl_3C_6H_2CN$ 75–76° (77.5°); 4-$NO_2C_6H_4CN$

144.5–146.5° (149°); α-$C_{10}H_7CN$ 31–32° (33.5°); β-$C_{10}H_7CN$ 63–64° (66°).

Nitriles from Ammonium Salts.—Attempts were made, without success, to isolate an amide as an intermediate product in the formation of nitriles from ammonium salts. In all cases the acid was recovered, although much hydrogen chloride was formed. The yields of acetonitrile (50%) and benzonitrile (48%) were about one-half of those obtained from the amides, when the ammonium salts and $NaCl \cdot AlCl_3$ were heated together in the molecular ratio of 1 to 2.

The Reaction between Acids and Amides.—The reactions were carried out in a 125-cc. distilling flask in the neck of which was placed a 3 cm. layer of glass beads. The latter served to prevent the acetamide used from distilling from the flask which was connected with a condenser and heated in a metal-bath.

One-tenth mole of benzoic acid was heated for two and one-half hours at 220–230° with 0.125 mole of acetamide. The distillate contained a little water, acetic acid and a small amount of benzonitrile. The benzamide formed in three experiments was 46, 51, and 53% of the theoretical yield. When equal molecular quantities of the acid and amide were refluxed for seven hours, the yield of benzamide was 30%.

The reaction was shown to be a reversible one. When equal molecular quantities of acetic acid and benzamide were refluxed for twenty-four hours, 42% of the benzamide and 31% of the acetic acid were recovered. The amount of benzoic acid formed showed that the interchange had taken place to the extent of 35%.

o-Chlorobenzoic acid gave 39% of its amide when heated with acetamide. The acid which did not react was recovered. When 16.1 g. of 2,6-dichlorobenzoic acid was heated at 225–235° for six hours with acetamide, the distillate was 93% of the theoretical yield of *m*-dichlorobenzene. When aliphatic dibasic acids were heated with acetamide the yield of amides was small. When formamide or urea was substituted for acetamide the yields were unsatisfactory.

An interchange of groups took place when benzoic acid was heated with acetanilide for three hours at 230–240°. The acetic acid formed was 65% of the theoretical and the benzanilide 50% after recrystallization.

Interchange between an Acid and an Ester.—An interchange of groups took place when 0.1 mole each of benzoic acid and phenyl acetate and 4 drops of sulfuric acid were heated at 175–177° for two and one-half hours; 49% of the benzoic acid was converted into phenyl benzoate.

The interchange reaction between benzoic acid and ethyl acetate gave 15% ethyl benzoate. No reaction took place between benzoic acid and phenetole.

The Use of the Compound $NaCl \cdot AlCl_3$ in Friedel and Crafts Condensations. Preparation of Diphenylmethane.—Into a mixture of 32 g. of $NaCl \cdot AlCl_3$ and 100 cc. of benzene was allowed to drop, during one hour, a solution of 63 g. of $C_6H_5CH_2Cl$ in 75 cc. of benzene, the temperature being held at 15–20°. Dry air was drawn over the mixture for one hour. It was then hydrolyzed. The product was distilled at 33 mm. pressure. The yield of diphenylmethane (b. p. 154–155°) obtained was 44 g. Diphenylmethane, which is converted into a tar by aluminum chloride, was not appreciably affected when a solution of 5 g. of the hydrocarbon in 15 cc. of benzene was allowed to stand with 3.5 g. of $NaCl \cdot AlCl_3$ for one hundred hours at room temperature. Stilbene and phenanthrene are rapidly changed by aluminum chloride; they were unaffected by $NaCl \cdot AlCl_3$ at room temperature.

Benzene condensed with chloroform or carbon tetrachloride in the presence of $NaCl \cdot AlCl_3$ at room temperature to only a very slight extent. The salt was active enough to bring about the usual reaction between benzene and alkyl halides.

Benzoyl Chloride and Ammonium Chloride.—The acyl chloride (0.20 mole) was refluxed with 0.34 mole of ammonium chloride for two hours; at the end of this time the odor of benzoyl chloride was no longer apparent. The product was treated with a solution of sodium hydroxide; the oil formed (9.8 g.) was shown to be benzonitrile; 10.2 g. of benzoic acid was recovered from the alkaline solution. An explanation of the reaction was evident from the results of Titherly and Holden,[4] who showed that benzoyl chloride and benzamide react and form benzonitrile and benzoic acid. In our experiment the benzamide probably formed from the chloride and ammonium chloride reacted with benzoyl chloride. The yield of nitrile obtained was close to that theoretically possible.

Reaction between Esters and Aluminum Chloride.—The study of this reaction[5] has been extended. Ethyl benzoate (0.1 mole) and aluminum chloride (0.1 mole) were mixed and heated cautiously in a flask, placed in a metal-bath, until the heat generated by the formation of the molecular compound had been given off. The flask was connected with a receiver cooled by dry-ice. The temperature was raised at the rate of about 1° per minute. At about 150–155° the solid melted. At 165° ethyl chloride began to condense. At the end of five hours the reaction ceased. The ethyl chloride obtained was 95% of the theoretical yield. The residue in the flask melted at 245°. When twice the amount of aluminum chloride was used only a few drops of ethyl chloride were obtained; a viscous mass was left in the flask.

Ethyl 2,6-Dichlorobenzoate and Aluminum Chloride.—The ester was prepared by treating the acid with thionyl chloride, removing the excess of the latter by heating and final heating with alcohol. The yield of the pure ester was 82%. To 7.1 g. of the ester 4.5 g. of aluminum chloride was added slowly while the mixture was cooled. The molecular compound melted at 90–95°; at 110° the rate of formation of ethyl chloride was appreciable. The temperature was raised to 120–130°. At the end of two and one-half hours reaction ceased. The weight of ethyl chloride formed was 91% of the theoretical. The residue was treated with water and acidified. The weight of 2,6-dichlorobenzoic acid (m. p. 141.5–142.5°, recorded 139–140°) was 92% of the theoretical yield. It should be noted that this ester of a diortho acid reacted with aluminum chloride at a much lower temperature than did ethyl benzoate or ethyl acetate. This fact is added evidence of the lability of the alkyl–oxygen bond produced by two groups in the ortho position to the carboxyl group. Treatment of these esters with hydrobromic acid or aluminum chloride

(4) Titherly and Holden, *J. Chem. Soc.*, **101**, 1876 (1912).

(5) Norris and Arthur, THIS JOURNAL, **62**, 874 (1940).

appears the best method of converting them into acids, since hydrolysis is effected with difficulty.

The ester and acetamide were distilled slowly at 200–210° for three hours to discover whether an interchange of groups would take place. Twenty-eight per cent. of the ester was converted into *m*-dichlorobenzene and the rest was recovered. The temperature used (200–210°) was below that at which the acid first loses carbon dioxide (235°).

Phenyl Tolyl Ketones from Toluene and Benzoic Acid.—Groggins[6] has shown that chlorobenzophenone can be prepared by condensing chlorobenzene with benzoic acid by means of aluminum chloride. We have applied the reaction to toluene. A mixture of 0.20 mole of benzoic acid, 0.40 mole of aluminum chloride and 0.44 mole of toluene was refluxed for six hours. About two-thirds of the 60% yield of ketones was a mixture which contained *p*-tolyl phenyl ketone and a smaller amount of the ortho isomer. When benzene was used with benzoic acid about 90% of the acid was recovered.

Summary

1. Eleven examples are given of the preparation with excellent yields of nitriles by the reaction between amides and aluminum chloride or the compound $NaCl \cdot AlCl_3$. The process can be used on a semi-micro scale as an aid in the identification of amides.

2. It has been shown that a reversible reaction takes place between an acid and an amide as the result of which the NH_2 and OH groups exchange places.

3. 2,6-Dichlorobenzoic acid loses its carboxyl group quantitatively when heated with acetamide at a temperature at which it is relatively stable when heated alone. The ester of the acid is quantitatively converted into the acid and ethyl chloride when it is heated at 110° with aluminum chloride.

4. The following are described: the reaction between benzoyl chloride and ammonium chloride, the use of the compound $NaCl \cdot AlCl_3$ in the Friedel and Crafts reaction and the condensation of benzoic acid with toluene by means of aluminum chloride.

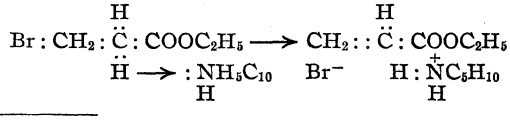
The Reaction of Organic Halides with Piperidine. V. Negatively Substituted Ethyl Bromides

BY E. LEON FOREMAN AND S. M. MCELVAIN

In the preceding paper[1] of this series it was shown that esters with a β-bromo substituent are very much more reactive toward piperidine than are other types of bromo-esters. Also it was shown that the reaction involves, first, the elimination of hydrogen bromide from the β-bromo-ester, and then the addition of piperidine to the resulting acrylic ester. The mechanism by which the acrylic ester is formed was thought to be the removal of a proton from the α-carbon atom of the bromo-ester by the nucleophilic reagent, piperidine, followed by the release of the bromide ion from the molecule,[2] thus



On the basis of such a mechanism it is obvious that the reactivity of β-substituted ethyl bromides, YCH_2CH_2Br, should parallel the electronegativity of the group Y.

The present paper reports the preparation and reactivity of a number of such negatively substituted ethyl bromides with piperidine. In the cases that Y is carbethoxy, cyano or benzoyl the rate of reaction of the bromide with piperidine is so rapid (*e. g.*, ethyl β-bromopropionate reacts to the extent of 94% in fifteen minutes at room temperature) that it cannot be measured readily. For this reason negatively substituted phenylethyl bromides, $YC_6H_4CH_2CH_2Br$, were used. These vinylogs of the more simply substituted ethyl bromides are, in most cases, more easily prepared and generally show a lower and more readily determined reaction rate.

Experimental

Preparation of β-Substituted Ethyl Bromides.—Ethyl β-Bromopropionate was prepared from ethylene cyano-

(1) Drake and McElvain, THIS JOURNAL, **56**, 697 (1934).

(2) A similar idea as to the mechanism of this type of elimination reaction has been expressed in a footnote of a paper by Noller and Dinsmore, *ibid.*, **54**, 1025 (1932), and also by Hauser and coworkers, *ibid.*, **57**, 1056 (1935); **59**, 1823 (1937).

hydrin.[3] **β-Bromopropionitrile**[4] was prepared by the reaction of ethylene cyanohydrin with phosphorus tribromide in benzene solution. The yield of product, boiling at 68–69° (7 mm.), d^{25}_4 1.6234, $n^{25}D$ 1.4789, was 43% of the theoretical. **β-Bromopropiophenone.** This compound had been prepared several years ago in this Laboratory by Frederick Beyerstedt and William Rinelli according to the following procedure. In a 2-liter round-bottom, 3-neck flask, fitted with a reflux condenser, an efficient stirrer and a dropping funnel were placed 500 ml. of carbon bisulfide, 100 g. of thiophene-free benzene and 260 g. of anhydrous aluminum chloride. The flask was set in an ice–salt mixture, stirring started, and 171 g. of β-bromopropionyl chloride[5] added through the dropping funnel at such a rate that the carbon bisulfide refluxed gently. After the addition of the halide, the ice-bath was removed and stirring continued until no more halogen acid was evolved. The reaction mixture then was poured carefully onto a mixture of ice and hydrochloric acid and, after thorough stirring, the carbon bisulfide layer separated. This layer was washed well with water and the solvent removed by distillation from a steam-bath. The remaining residue on cooling solidified. The yield of crude product amounted to 200 g. (93%). After recrystallization from petroleum ether the product melted at 58–59°.

Anal. Calcd. for C_9H_9OBr: Br, 37.5. Found: Br, 37.7.

Preparation of Substituted β-Phenylethyl Bromides. β-Phenylethyl Bromide.—This compound was prepared from Eastman Kodak Co. β-phenylethyl alcohol by the procedure of Norris.[6] The product boiled at 86° (8 mm.); $n^{25}D$ 1.5545.

***o*- and *p*-Nitrophenylethyl Bromide.**—A mixture of 204 g. of acetic anhydride and 120 g. of acetic acid was chilled to 0° in a 1-liter 3-necked flask equipped with a stirrer, thermometer and dropping funnel. There was added slowly 126 g. of fuming nitric acid, after which the mixture was chilled to −5°. One hundred and eighty-five grams of phenylethyl bromide was added slowly (three hours) through the dropping funnel, while the temperature was maintained below 0°. Stirring was continued for two and one-half hours after the addition was complete. The reaction mixture was then poured into a suspension of 265 g. of sodium carbonate in 2 liters of ice water. The yellow product was taken up in benzene and thoroughly washed with water and then with a saturated sodium bicarbonate solution. The benzene was removed as completely as possible on the steam-bath, the final portion under reduced pressure. The remaining product was recrystallized from 3 liters of petroleum ether (b. p. 60–68°). A yield of 124 g. (54% of the theoretical) of the *p*-nitro compound, m. p. 69–70°,[7] was obtained.

The solvent was removed from the mother liquors and the residue fractionally distilled under reduced pressure. Seventy grams (30.4% of the theoretical) of the *o*-nitro compound boiling at 115–120° (0.5 mm.) with some decomposition was obtained. After recrystallizing from petroleum ether, the product melted at 36–38°. This product on oxidation with potassium permanganate yielded *o*-nitrobenzoic acid. An additional 18 g. of the *p*-nitro compound may be recovered from the still residues, if desired. These two compounds were previously prepared by Sobotka,[7] who, however, did not obtain the ortho isomer in pure form.

Anal. Calcd. for $C_8H_8NO_2Br$: Br, 34.7. Found: Br, (ortho) 34.3, (para) 34.5.

***p*-Acetylphenylethyl Bromide.**—In a 1-liter 3-necked flask equipped with an efficient stirrer, dropping funnel, and reflux condenser were placed 83 g. of anhydrous aluminum chloride, 300 ml. of carbon disulfide, and 47 ml. of acetyl chloride. The flask was set in an ice-bath and a solution of 124 g. of phenylethyl bromide in 95 ml. of acetyl chloride added as rapidly as possible. Stirring was continued until no more hydrogen chloride was evolved (two to two and one-half hours), after which the reaction product was decomposed with a mixture of concentrated hydrochloric acid and crushed ice. The carbon disulfide layer was removed and the aqueous layer extracted twice with benzene. The combined benzene and carbon disulfide layers were washed with dilute hydrochloric acid, water, 10% sodium hydroxide solution, and again with water. The solvent was removed and the product fractionally distilled under reduced pressure. A recovery of 22.5 g. of phenylethyl bromide was effected, so that the 101.5 g. of product boiling at 117–118° (0.1 mm.) amounted to 83% of the theoretical based on the phenylethyl bromide actually used; $n^{25}D$ 1.5724; d^{25}_4 1.3784; MD calcd. 53.26, found 52.91. Permanganate oxidation converts this product to terephthalic acid.

Anal. Calcd. for $C_{10}H_{11}OBr$: Br, 35.2. Found: Br, 35.2.

***p*-Carboxyphenylethyl Bromide and *p*-Carbethoxyphenylethyl Bromide.**—An alkaline hypobromite solution prepared in a 1-liter 3-necked flask from 48 g. of the bromine and 33 g. of sodium hydroxide dissolved in 280 ml. of water and 200 ml. of dioxane, was chilled to 0° and 23 g. of *p*-acetylphenylethyl bromide added with stirring. Stirring was continued until the hypobromite was exhausted (2 hours), the temperature being maintained below 0°. The solution was acidified with an excess of hydrochloric acid and the precipitated acid filtered from the aqueous solution and bromoform, washed with water and dried. The yield of *p*-carboxyphenylethyl bromide was 20 g. (87%). After crystallization from a mixture of petroleum ether and benzene, the acid melted at 205–207°.

Anal. Calcd. for $C_9H_9O_2Br$: Br, 34.9. Found: Br, 35.0.

The acid was converted to the ester in 79% yield by first converting it to the acid chloride with a slight excess of thionyl chloride, then refluxing the crude chloride with ethanol. The ester boils at 111–114° (0.1 mm.); d^{25}_4 1.2918; $n^{25}D$ 1.5404; MD calcd., 59.19; obsd. 62.84.

Anal. Calcd. for $C_{11}H_{13}O_2Br$: Br, 31.1. Found: Br, 30.5.

***p*-Cyanophenylethyl Bromide.**—*p*-Carboxyphenylethyl bromide (64 g.) was converted to the corresponding acyl chloride by refluxing with a slight excess of thionyl chloride. This crude chloride was poured into cold concentrated ammonia water. The precipitated amide was

filtered off, dried, and converted to the nitrile by refluxing with a mixture of 100 ml. of benzene and 100 ml. of thionyl chloride according to the procedure of Michaelis and Siebert.[8] When the reaction was complete, the excess thionyl chloride and solvent was removed on the steam-bath, the remaining product taken up in benzene and the insoluble residue discarded. The benzene solution was washed with water and saturated sodium bicarbonate solution, after which the solvent was removed by distillation. The yield of *p*-cyanophenylethyl bromide amounted to 35.5 g. (60% of theoretical) after recrystallization from petroleum ether and melted at 49–50°.

Anal. Calcd. for C_9H_8NBr: Br, 38.1. Found: Br, 38.5.

Reaction of Negatively Substituted Ethyl Bromides with Piperidine.—Ethyl β-bromopropionate, β-bromopropionitrile and β-bromopropiophenone each react too rapidly with piperidine to allow for rate determinations. The least reactive of these compounds, ethyl β-bromopropionate, was found to react practically completely with piperidine in fifteen minutes at room temperature. Determinations of the course of these reactions by the procedure described below in each case showed that the rate at which piperidine added to the resulting unsaturated compound to form the tertiary amine was practically as rapid as that at which the unsaturated compound was formed from the bromide. As may be seen from the table such is not the case with the negatively substituted phenylethyl bromides.

Reaction of Substituted Phenylethyl Bromides with Piperidine.—Due to the insolubility of these compounds in petroleum ether, the procedure used to follow the course and extent of the reaction was modified slightly from that previously reported.[1]

To 10 ml. of *M* solution of the bromide in benzene, contained in a test-tube prepared for sealing, was added two equivalents of piperidine by means of a calibrated pipet. The tubes were then sealed and immersed in the thermostat for the desired length of time, after which they were cooled and opened. The precipitated piperidine hydrobromide was washed onto a filter with petroleum ether and the washings made up to 50 ml. with petroleum ether. Unreacted piperidine was determined by treating an aliquot of this solution with phenyl isocyanate and collecting the piperidinoformanilide as described previously,[9] except that no corrections were applied.

After drying, the piperidine hydrobromide was dissolved in water and made up to 100 ml. An aliquot of this solution was titrated for bromide ion with standard silver nitrate solution.

It is believed that the results in column B of Table I are accurate to about 1%, while those in column C are probably less than 5% in error.

Discussion of Results

It may be seen from columns A and B of Table I that the reactivity of the substituted phenylethyl bromides increases with the negativity of the substituent in the benzene nucleus. Such a result would be expected from a reaction mechanism of the type postulated in the introductory portion of the paper. Inspection of columns D and E in the above table shows that the percentage of tertiary amine in the amine–olefin mixture of reaction products increases with a decrease in the negativity of the substituent groups. This fact indicates that the mechanism involving the elimination of hydrogen bromide is replaced, to an increasing extent, by one that operates directly at the carbon atom holding the bromine.[10] This

(8) Michaelis and Siebert, *Ann.*, **274**, 312 (1893).

(9) Semb and McElvain, THIS JOURNAL, **53**, 690 (1931).

(10) Another alternative, which would require the rate of addition of piperidine to the olefin to increase with a lowering of the negativity of the substituent, was readily eliminated by the failure of piperidine to add to styrene under the conditions of the reaction. Also the high yields of tertiary amine (the formation of which certainly involves the addition of piperidine to the olefin (*cf.* ref. 1)) in the cases of negatively substituted ethyl bromides, which were discussed in the experimental part of the paper, show that the strongly negative group promotes rather than hinders the addition of piperidine to an adjacent carbon to carbon double bond.

other mechanism may involve the approach of the reagent to the carbon holding the bromine, the ionization of the bromine, or some other mode of reaction. Similar transitions from one mechanism to another have been noted in other series of variously substituted bromides.[11]

A strong indication that the elimination reaction under discussion first involves a removal of a proton from the carbon in the β-position to the bromine is the striking difference in the reactivities of the negatively substituted phenylethyl bromides of the present paper and similarly substituted benzyl bromides. With the latter type of bromide it has been found that an increase in the negativity of the substituent group causes a *decrease* in the reactivity of the benzyl bromide with such bases as pyridine and aniline[11a] as well as with aqueous alcohol.[12] This behavior has been taken to indicate that the bromine is removed from the molecule of the benzyl bromide as a negative ion because such an ionization would be hindered by the presence of a substituent in the benzene ring which, by both an inductive and an electromeric effect, is strongly electron attracting.

(11) (a) Baker, *J. Chem. Soc.*, 1128 (1933); (b) Gleave, Hughes and Ingold, *ibid.*, 238 (1935).

(12) Shoesmith and Slater, *ibid.*, 214 (1926); Olivier, *Rec. trav. chim.*, **42**, 775 (1923).

The fact that such a negative group has just the opposite effect on the reactivity of a phenylethyl bromide with piperidine suggests that the opposite type of ion, *viz.*, a positive proton, is removed from the carbon adjacent to the benzene nucleus by the reagent. There seems to be no reason to believe that the electrophilic character of such a substituent group would not exert some of the same hindering effect on the reactivity of a bromine in the β-position to the ring as it does on the bromine of a benzyl bromide. If this be true, then a carbon–hydrogen bond adjacent to the aromatic nucleus is the only apparent point at which a negative substituent in the nucleus can activate a phenylethyl bromide for reaction with a base such as piperidine.

Summary

The rate and course of the reaction of some negatively substituted ethyl bromides with piperidine have been determined. Evidence is presented to show that the removal of a proton from the carbon atom in the α-position to the negative substituent (and in the β-position to the bromine) is the initial step in the elimination of hydrogen bromide from such a negatively substituted bromide.

The Reaction of Organic Halides with Piperidine. VI. Some Branched Chain β-Bromo-esters

BY E. LEON FOREMAN AND S. M. MCELVAIN

If the high reactivity of the β-bromo-esters with piperidine, reported in the fourth paper[1] of this series, is due, as suggested, to the presence of a hydrogen on the α-carbon atom of the ester, a study of the behavior of branched chain β-bromo-esters, particularly those having no α-hydrogen, should be of some interest. The present paper reports the behavior of two such esters, ethyl bromopivalate and ethyl α,α-dimethyl β-bromobutyrate (1 and 2 in the table below) in this reaction. Since such esters are halides of the neopentyl type, which are known to be very unreactive,[2] it seemed necessary to study also ethyl β-bromo-isocaproate and ethyl γ,γ-dimethyl-β-bromovalerate (3 and 4). These esters contain the unreactive isobutyl bromide[3] and neopentyl bromide structure, respectively, and also have hydrogens on the α-carbon atom and a bromine on the β-carbon atom to the carbethoxy group.

In the first paper[3] of this series cyclohexyl bromide, of all that were studied, was found to be the most inert toward piperidine. In order to ascertain the effect of a carbethoxy group in the β-position to the bromine atom on the reactivity of this bromide, ethyl 2-bromocyclohexanoate (no. 6) was included in the present study.

Experimental

Preparation of the Bromo-esters

Ethyl bromopivalate is best prepared by esterification of bromopivalic acid.[4] The treatment of ethyl hydroxypiva-

late[5] with phosphorus tribromide according to the procedure of Lease and McElvain[6] gives only a poor yield of the desired ester. The ethyl bromopivalate used boiled at 62–63°[4] (7 mm.); d^{25}_4 1.2713; $n^{25}D$ 1.4469; MD calcd., 43.91; found, 44.21.

Ethyl α,α-Dimethyl-β-bromobutyrate.—After chilling each in an ice-bath, a solution of 54 g. of phosphorus tribromide in 100 ml. of benzene was added to a solution of 80 g. of ethyl α,α-dimethyl-β-hydroxybutyrate[7] in 100 ml. of benzene. The mixture was allowed to stand in an ice-bath and gradually to come to room temperature as the ice melted. After standing for six days at room temperature, the benzene solution was poured into 500 ml. of ice water and the benzene layer separated, washed with water, then with a saturated solution of sodium bicarbonate and finally with water. On fractionation 28 g. (25% of the theoretical) of the bromo-ester, boiling at 90–92° (20 mm.) was obtained. In addition to this product 36 g. of the phosphite ester of the starting hydroxy ester remained as an undistilled residue. From this residue additional α,α-dimethyl-β-bromobutyric acid could be recovered by slow distillation with 48% hydrobromic acid.

The bromo-ester as prepared above was found to contain some of an isomeric ester, presumably ethyl α,β-dimethyl-α-bromobutyrate, a rearrangement product analogous to that obtained by Whitmore and Johnston[8] by the replacement of the hydroxyl group of methylisopropylcarbinol by halogen. This isomeric bromo-ester was removed readily from the desired product by reaction with piperidine. A solution of 20 g. of the crude bromo-ester and 25 ml. of piperidine in 50 ml. of benzene was refluxed for two hours. After this time the benzene solution was fractionated, whereupon 4 g. of a product boiling at 145–150° and 12 g. of a product boiling at 70–74° (8 mm.) were obtained. The lower boiling fraction was unsaturated and corresponded in properties to trimethylacrylic ester.[9] On refractionation the desired ethyl α,α-dimethyl-β-bromobutyrate boiled at 72–74° (8 mm.); d^{25}_4 1.2430; $n^{25}D$ 1.4531; MD calcd., 48.51; found, 48.58.

Anal. Calcd. for $C_8H_{15}O_2Br$: Br, 35.8. Found: Br, 35.4.

Ethyl β-Bromoisocaproate.—In a 3-liter round-bottomed flask were placed 960 g. (6 moles) of diethyl malonate, 50 g. of piperidine acetate and 432 g. (6 moles) of isobutyraldehyde. After stirring until homogeneous, the mixture was allowed to stand for forty-two hours at room temperature. Then 600 ml. of benzene was added and the aqueous layer separated. The benzene layer was washed with four 200-ml. portions of water and then fractionally distilled.

The yield of isobutylidene malonic ester[10] boiling at 117–119° (13 mm.) amounted to 629 g. (48% of the theoretical). To a hot solution of 450 g. of potassium hydroxide in 450 ml. of water was added slowly with stirring 428 g. (2 moles) of isobutylidenemalonic ester. After standing for two hours on the steam-bath without a reflux condenser, the hydrolysis mixture was chilled in an ice-bath and a cold solution of 450 g. of concentrated sulfuric acid in 450 ml. of water added. The precipitated potassium sulfate was filtered off and washed thoroughly with isopropyl ether. The aqueous solution was extracted with four 250-ml. portions of isopropyl ether and the combined ethereal extracts washed once with a little saturated sodium sulfate solution and then dried over anhydrous sodium sulfate. After removal of the ether, the malonic acid was decarboxylated by heating at 150° in an oil-bath and under a pressure of 20 mm. The monocarboxylic acid which distilled over was then fractionally distilled under reduced pressure. A yield of 46 g. (20.2%) of isocaprolactone[11] boiling at 96–98° (18 mm.), $n^{25}D$ 1.4312, and 48 g. (21%) of isobutylideneacetic acid[11] boiling at 114–115° (18 mm.), $n^{25}D$ 1.4466, neutral equivalent 114, was obtained. A portion of the acid on oxidation with cold 2% potassium permanganate yielded isobutyric acid, which was identified through its *p*-bromophenacyl ester. The isobutylideneacetic acid (42 g.) was esterified by refluxing it for two hours with 100 ml. of absolute ethanol using 2 ml. of concentrated sulfuric acid as a catalyst. The yield of ethyl isobutylideneacetate,[12] boiling at 171–173°, $n^{25}D$ 1.4301, amounted to 44 g. (84% of the theoretical).

Dry hydrogen bromide was passed into a cold solution of 14.2 g. (0.1 mole) of ethyl isobutylideneacetate in 100 ml. of chloroform until twice the amount theoretically required for addition to the unsaturated ester had been absorbed. The flask was then tightly stoppered, allowed to stand in the ice-bath and gradually to come to room temperature after the ice had melted. After six hours, the reaction mixture was poured into cold water and the chloroform layer separated, washed with water, then sodium bicarbonate solution, and finally with water. After drying over calcium chloride, the chloroform was removed at room temperature under reduced pressure and the product distilled at 0.1 mm. pressure so as to minimize the possibility of thermal rearrangement. The yield of ethyl β-bromoisocaproate amounted to 19.3 g. (86.5%); b. p. 63–64° (0.1 mm.); d^{25}_4 1.2464; $n^{25}D$ 1.4557; MD calcd., 48.51; found, 48.89.

Anal. Calcd. for $C_8H_{15}O_2Br$: Br, 35.8. Found: Br, 35.3.

An attempted preparation of this ester from the corresponding hydroxy ester and phosphorus tribromide yielded a product which appeared to be a mixture of the β- and γ-bromo-isocaproic esters, judging from the incompleteness of the reaction of this product with piperidine. In order to make the comparison, ethyl γ-bromo-isocaproate was prepared from isocaprolactone by the procedure of Bredt.[13] This bromo-ester distilled with some decomposition at 57–58° (0.1 mm.) and was found to contain 34.6% instead of the required 35.8% bromine. Previous workers[13,14] have reported it as undistillable. When this γ-bromo-ester was allowed to react with piperidine under the conditions used for the other bromo-esters listed in Table I it showed only 31% reaction in four hours.

Ethyl γ,γ-Dimethyl-β-bromovalerate.—Trimethylacetaldehyde[15] was condensed with diethyl malonate in 50%

		4	90	.90	1.09	2	88

[a] For some reason, as yet undetermined, the values of unreacted piperidine in column C, from which the yields of tertiary amine in column D were calculated, were consistently low. The most obvious explanation of such a result, *viz.*, amide formation, could not be substantiated.

[b] These values carry no rate significance. As pointed out in the fifth paper of this series (ref. 1b) an ethyl bromide with a carbethoxy, cyano or benzoyl group as a β-substituent is much too reactive toward piperidine to allow for rate determinations at or above room temperature. The values are included in the above table to show that the reaction is complete insofar as the elimination of bromine from the ester molecule is concerned.

yield, using the process of Cope and Hancock,[16] except that the refluxing time was reduced from sixty to thirty-six hours. Trimethylethylidenemalonic ester boils at 138–140° (23 mm.); $n^{25}D$ 1.4449; d^{25}_4 0.9347; M_D calcd., 60.46; found, 65.24; exaltation, 4.78.

Anal. Calcd. for $C_{12}H_{20}O_4$: C, 63.12; H, 8.83. Found: C, 63.13; H, 8.86.

The malonic ester was saponified and the acid decarboxylated in 89% yield, using the procedure described above for the preparation of isobutylideneacetic acid. The 4,4-dimethyl-2-pentenoic acid boils at 126–131° (23 mm.), and melts at 62–63° after recrystallization from petroleum ether. The yield of recrystallized acid, neutral equivalent 127, amounted to 73% of the theoretical. A portion of the acid on oxidation with cold 2% potassium permanganate yielded trimethylacetic acid, which was identified by its *p*-bromophenacyl ester.

A solution of 25.6 g. (0.2 mole) of the dimethylpentenoic acid in 100 ml. of absolute ethanol was chilled in an ice-salt-bath and saturated with dry hydrogen bromide. After standing at room temperature for twelve hours, the reaction mixture was poured onto crushed ice, extracted with benzene, and worked up as described above for ethyl β-bromo-isocaproate. The yield amounted to 35.5 g. (75% of theoretical) of product boiling at 65–66° (0.1 mm.); d^{25}_4 1.2149; $n^{25}D$ 1.4588; M_D calcd., 53.29; found, 53.17.

Anal. Calcd. for $C_9H_{17}O_2Br$: Br, 33.8. Found: Br, 32.9.

Ethyl 2-bromocyclohexanoate was prepared in 50% yield from ethyl hexahydrosalicylate[17] by the procedure used above for ethyl α,α-dimethyl-β-bromobutyrate. It boils at 75–76° (0.1 mm.); d^{25}_4 1.3272; $n^{25}D$ 1.4909; M_D calcd., 51.17; found, 53.66.

Anal. Calcd. for $C_9H_{15}O_2Br$: Br, 34.0. Found: Br, 33.8.

Reaction of Bromo-esters with Piperidine.—A ratio of two moles of piperidine to one of the bromo-esters was used. The general procedure for the determination of the extent and course of this reaction was the same as that described in the fifth paper of this series.[1b] The results of these determinations are summarized in Table I. It is believed that the values in column A can be duplicated within 1%, and that the maximum error for the values in column C is 5%.

Discussion of Results

It is apparent that those β-bromo-esters (1 and 2) that have no hydrogen on the α-carbon atom are very unreactive toward piperidine. It also should be noted that these particular bromo-esters show practically the same amount of reaction after ninety-six hours, even though one is a primary and the other a secondary bromide. With the simple alkyl halides there is a considerable difference in the reactivity of these two types.[3] In this connection mention should be made of Bouveault's observation[18] that ethyl α,α-dimethyl-β-chlorobutyrate is not attacked by alcoholic potassium hydroxide.

The high reactivities of the bromo-esters 3 and 4 show that the neopentyl bromide type of structure is not responsible for the low reactivity of esters 1 and 2. There is practically no difference in the rate at which esters 3 and 4 and ethyl β-bromopropionate[5] lose their bromine when allowed to react with piperidine. This fact definitely shows the powerful effect of the presence of an α-hydrogen, as well as the negligible effect of substitution

(18) Bouveault, *Bull. soc. chim.*, [3] **21**, 1064 (1899).

of such generally deactivating groups as isopropyl or *t*-butyl for a β-hydrogen atom of ethyl β-bromopropionate, on the reactivity of the halogen of β-bromoesters. It should be noted, however, that while the presence of these alkyl groups does not materially affect the rate at which these esters give up their bromine, such substitution does greatly affect the rate of addition of piperidine to the olefinic ester to form a tertiary amine.

The substitution of a carbethoxy group in the β-position to the halogen of cyclohexyl bromide changes it from an extremely inert halide to one with a quite high reactivity toward piperidine However, the ethyl 2-bromocyclohexanoate is not as reactive as the other β-bromo-esters with an α-hydrogen that have been studied and the resulting olefin, ethyl cyclohexenoate, shows a surprising inability to add piperidine across its double bond.

Summary

The rate and course of the reaction between piperidine and a number of β-bromo-esters with branched chains are reported. It is shown that those β-bromo-esters that have no α-hydrogen atom are extremely inert, while those that have such a hydrogen atom are very reactive regardless of the nature of the branching of the carbon chain. Such branching, however, greatly reduces the ability of the unsaturated ester that is formed from the bromo-ester to add piperidine to form a tertiary amine.

Vicinal Substituted Resorcinols. I. Alkyl Resorcinols. The Synthesis of γ-Ethyl, γ-*n*-Propyl and γ-*n*-Butyl Resorcinols

BY ALFRED RUSSELL, JOHN R. FRYE AND WM. L. MAULDIN

The occurrence of γ-isoamylresorcinol as a fission product of natural rotenone, the possible value as antiseptics of γ-alkyl resorcinols and the potential usefulness as initial materials in various types of syntheses of γ-substituted resorcinols make it of considerable interest to exploit possible routes to such compounds.

It is comparatively easy to obtain good yields of β-substituted derivatives of resorcinol; thus by treatment of resorcinol by a modification of the Gattermann process[1] it is possible to obtain upward of 90% of the theoretical amount of β-resorcylaldehyde; by carboxylation of resorcinol[2] some 60% of the theoretical amount of β-resorcylic acid may be obtained; again treatment of resorcinol with aliphatic acids and anhydrous zinc chloride gives good yields of alkyl β-resorcyl ketones, a process that involves ester formation followed by a Fries rearrangement; moreover, the ketones so obtained reduce readily by the Clemmensen method to the corresponding β-alkylresorcinols and this process is actually used in the manufacturing of hexylresorcinol.[3] There has also recently been described[4] the synthesis of some *n*-5-(or α)-alkyl resorcinols through the intermediate ketones obtained by the action of appropriate Grignard reagents on 3,5-dimethoxybenzamide.

However, the preparation of vicinal (or γ) substituted resorcinols has been attended with such difficulty that very few such compounds have been made and the yields have been poor. The tedious synthesis of 2,6-dihydroxyacetophenone[5] or vicinal resacetophenone starting with *m*-dinitrobenzene gives a yield amounting at the best to only a few per cent. of the theoretical. The synthesis of γ-resorcylaldehyde which has been described recently gives only a small yield of aldehyde.[6]

The synthesis of 4-methyl-7-hydroxy-8-acetylcoumarin (III, R = CH_3) is on record[7] and from this compound by fission with alkali 2,6-dihydroxyacetophenone[8] is obtained in better than 90% yield. It is obvious that a Clemmensen reduction of 2,6-dihydroxyacetophenone would give γ-ethylresorcinol and such a reduction of 2,6-dihydroxyisovalerophenone recently has been described[9] yielding γ-isoamylresorcinol.

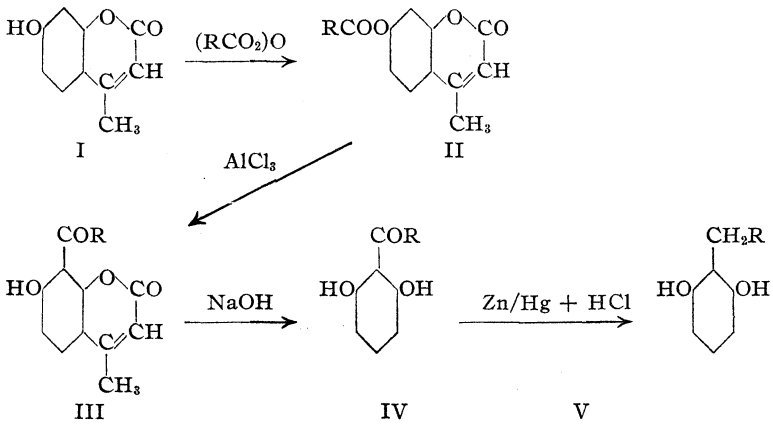
This general route to γ-alkyl resorcinols appears to be very satisfactory and has now been applied to the preparation of γ-ethyl-, γ-*n*-propyl- and γ-*n*-butylresorcinols. Attempts to prepare the corresponding γ-*n*-hexylresorcinol have not been successful up to the present as the intermediate 4-methyl-7-caproyloxycoumarin did not undergo the Fries rearrangement.



Preliminary tests[10] indicate that saturated aqueous solutions of each of the three alkyl resorcinols described are ineffective against *B. typhosus* and *Staph. aureus*. Further tests are in progress and will be described in a later report.

Experimental Part

4-Methyl-7-hydroxycoumarin.—A mixture of acetoacetic ester (260 g.) and resorcinol (220 g.) was added in portions to 2000 cc. of concentrated sulfuric acid in a round-bottom flask which had been immersed in an ice-bath and mechanically stirred until the temperature of the sulfuric acid was below 5°. Mechanical stirring was continued during the addition of the acetoacetic ester–resorcinol mixture. The temperature was kept below 10° until the end of the addition and it was allowed to stand overnight at room temperature.

The mixture was poured, with stirring, onto ice (6 kg.) in a beaker. The product was filtered, washed twice with water, dissolved in 5% sodium hydroxide (1500 cc.) filtered and reprecipitated by the slow addition of dilute hydrochloric acid with mechanical stirring.

The precipitate was washed thoroughly with water and air-dried overnight. It recrystallizes from 95% ethanol in white needles, m. p. 187°, yield 290 g.

4 - Methyl - 7 - acetoxycoumarin.—4 - Methyl - 7 - hydroxycoumarin (286 g.) was refluxed with twice its weight of acetic anhydride for one and one-half hours. The reaction mixture was poured into cold water with stirring. The 4-methyl-7-acetoxycoumarin was collected, washed thoroughly with cold water to remove all acetic acid and the product air-dried for four days, when it was sufficiently pure for the next step, yield 333 g. Recrystallized from alcohol it formed slender white needles, m. p. 151°.

4-Methyl-7-hydroxy-8-acetylcoumarin.—Dry 4-methyl-7-acetoxycoumarin (200 g.) was thoroughly mixed with powdered anhydrous aluminum chloride (450 g.) in a 5-liter round-bottom flask, this immersed in an oil-bath at 125° and the temperature raised slowly over two and one-half hours to 170°. The reaction mixture was cooled, and 2400 cc. of dilute hydrochloric acid (1 hydrochloric acid to 7 water) added dropwise over a period of about five hours. It was then heated on a steam-bath for one-half hour while being stirred mechanically. The product was filtered, washed, recrystallized from 95% ethanol and dried; yield 197 g. It forms golden yellow leaflets, m. p. 163°.

2,6 - Dihydroxyacetophenone.—4 - Methyl - 7 - hydroxy - 8 - acetylcoumarin (197 g.) was placed in a 5-liter three-neck flask fitted with a dropping funnel, reflux condenser, and tube leading to the bottom of the flask. The solid was covered with water and nitrogen was passed in until the air was displaced. One and one-half times the theoretical quantity of sodium hydroxide solution of such concentration (165 g. of sodium hydroxide in 1350 cc. of water) that the final solution was about 12% sodium hydroxide, was added. The reaction mixture was heated on a steam-bath for five hours and then cooled. The alkaline mixture was neutralized with dilute sulfuric acid, and the precipitated 2,6-dihydroxyacetophenone collected, washed, and dried, yield 127 g. On recrystallization from water it forms stout yellow needles, m. p. 154–56°.

Vicinal Ethylresorcinol.—2,6 - Dihydroxyacetophenone (18 g.) was mixed with amalgamated zinc (45 g.) and hydrochloric acid (90 cc., 12% HCl) added. The whole was refluxed vigorously for five hours, with the addition of concentrated hydrochloric acid (15 cc.) at the end of each hour, cooled and extracted with ether. The ethereal extract was dried, the ether removed and the residue vacuum distilled. The solid distillate recrystallized from gasoline in long, slender, glittering needles, m. p. 94.5°; yield 8.5 g. *Anal.* Calcd. for $C_8H_{10}O_2$: C, 69.5; H, 7.25. Found: C, 69.4; H, 7.22.

4-Methyl-7-propionoxycoumarin and 4-Methyl-7-butyroxycoumarin.—From 220 g. of 4-methyl-7-hydroxycoumarin and 450 cc. of propionic anhydride, by refluxing for two hours, 262 g. of the propionoxy derivative was obtained as white needles from ethanol, m. p. 148.5°. Using the same amount of butyric anhydride and heating at 180° for three hours, 240 g. of the butyroxy derivative resulted as white needles from methanol, m. p. 91°. *Anal.* (propionoxy) Calcd. for $C_{13}H_{12}O_4$: C, 67.2; H, 5.18. Found: C, 66.9; H, 5.22. (butyroxy) Calcd. for $C_{14}H_{14}O_4$: C, 68.3; H, 5.7. Found: C, 68.3; H, 5.63.

4 - Methyl - 7 - hydroxy - 8 - propionylcoumarin and 4 - Methyl - 7 - hydroxy - 8 - butyrylcoumarin.—From 120 g. of the propionoxy compound and 300 g. of aluminum chloride heated to 120° and then over three hours to 170°

(10) Arranged through the courtesy of the Röhm and Haas Company, Inc.

there was obtained 90 g. of the rearrangement product as yellowish leaflets from ethanol, m. p. 187°. In a like manner 13 g. of the butyroxy compound gave 9.6 g. of rearrangement product as yellowish leaflets from ethanol, m. p. 141°. *Anal.* (propionyl) Calcd. for $C_{13}H_{12}O_4$: C, 67.2; H, 5.18. Found: C, 67.2; H, 5.34. (butyryl) Calcd. for $C_{14}H_{14}O_4$: C, 68.3; H, 5.7. Found: C, 68.1; H, 5.8.

2,6-Dihydroxypropiophenone and 2,6-Dihydroxybutyrophenone.—155 grams of the propionyl derivative treated with one liter of 12% aqueous sodium hydroxide for six hours on the steam-bath and in a nitrogen atmosphere gave, after cooling and acidification, 66 g. of 2,6-dihydroxypropiophenone, yellow needles from 25% aqueous methanol, m. p. 133.5°. By analogous treatment 16 g. of the butyryl derivative gave 9.4 g. of 2,6-dihydroxybutyrophenone as yellow needles from 25% aqueous methanol, m. p. 106°. *Anal.* (propiophenone) Calcd. for $C_9H_{10}O_3$: C, 65.1; H, 6.0. Found: C, 64.8; H, 6.0. (butyrophenone) Calcd. for $C_{10}H_{12}O_3$: C, 66.7; H, 6.7. Found: C, 66.9; H, 6.8.

Vicinal Propylresorcinol and Vicinal Butylresorcinol.—Clemmensen reduction of 36 g. of 2,6-dihydroxypropiophenone for six hours using 90 g. of amalgamated zinc, hydrochloric acid (180 cc. 12%) and with the addition of 15 cc. of concd. hydrochloric acid each hour gave, after separation, vacuum distillation and recrystallization from gasoline, 23 g. of vicinal propylresorcinol as white lustrous needles, m. p. 92.5°.

Using proportionate quantities, and continuing the reduction for seven hours, 60 g. of 2,6-dihydroxybutyrophenone yielded 44 g. of vicinal butylresorcinol as slender white needles from gasoline, m. p. 83°. *Anal.* (propyl) Calcd. for $C_9H_{12}O_2$: C, 71.1; H, 7.9. Found: C, 70.8; H, 8.0. (butyl) Calcd. for $C_{10}H_{14}O_2$: C, 72.3; H, 8.44. Found: C, 72.1; H, 8.5.

4-Methyl-7-caproyloxycoumarin.—4-Methyl-7-hydroxycoumarin (17 g.) was dissolved in dry pyridine (25 cc.) and the solution treated with caproyl chloride (35 g.). The whole was heated at the temperature of the steam-bath for ten minutes, cooled and poured into cold water (500 cc.) with good stirring. The solid was collected, washed, dried and recrystallized from methanol. It forms white prisms, m. p. 72°, yield 15.3 g. *Anal.* Calcd. for $C_{16}H_{18}O_4$: C, 70.0; H, 6.6. Found: C, 70.0; H, 6.9.

Summary

6- or β-substituted resorcinols are obtained easily in good yield whatever the nature of the substituting group. Moreover, methods are available for obtaining good yields of resorcinols substituted in the 5- or α-position. However, although some vicinal substituted resorcinols are known, up until the present no easy method has been exploited whereby substituents could be introduced into the resorcinol nucleus in the inaccessible 2-, γ- or vicinal position. Such a process is now described for obtaining vicinal alkyl resorcyl ketones and the corresponding vicinal alkyl resorcinols.

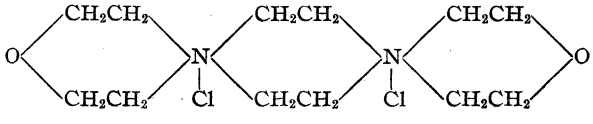
Preparation and Polymerization of β-4-Morpholinoethyl Chloride

BY J. PHILIP MASON AND HARRY W. BLOCK[1]

The only morpholinoethyl halide derivative which we have found described in the literature is β-4-morpholinoethyl bromide hydrobromide obtained by Prelog and Blozek[2] by heating triethanolamine hydrobromide with 64% hydrobromic acid in a sealed tube at 160°. Their yield was 25%. We have prepared β-4-morpholinoethyl chloride hydrochloride by treating β-4-morpholineëthanol hydrochloride with thionyl chloride, obtaining a yield of 63.5%, and also by treating β-4-morpholineëthanol with thionyl chloride, obtaining yields varying from 73 to 88%. Treatment of this hydrochloride with alkali yielded a colorless liquid, β-4-morpholinoethyl chloride. After standing for a few days, a solid appeared in the liquid, and the amount of solid increased slowly on standing. It was found that the formation of the solid could be accelerated by refluxing an alcohol solution of β-4-morpholinoethyl chloride. This solid was found to be a dimeric quaternary ammonium salt having the formula



and which can be named N,N′-dispiromorpholinopiperazonium dichloride or N,N′-di-[1,5-(3-oxapentylene)]-piperazonium dichloride. Knorr[3] previously had prepared β-chloroethyldimethylamine and had found that it polymerized on standing or on refluxing in alcohol solution to N,N′-tetra-

(1) Taken from the thesis to be submitted by Harry W. Block to the faculty of the Graduate School of Boston University in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(2) Prelog and Blozek, *C. A.*, **29**, 4011 (1935).

(3) Knorr, *Ber.*, **38**, 3136 (1905); **39**, 1420 (1906).

methylpiperazonium dichloride. Knorr's proof of structure consisted in determining the decomposition products obtained when the compound was heated with concentrated potassium hydroxide solution. He obtained acetylene, symmetrical tetramethyldiaminoethane and dimethylaminoethanol. Knorr's quaternary piperazonium salt can decompose in two ways, (a) to yield acetylene and tetramethyldiamineëthane, and (b) to yield dimethylvinylamine which was apparently hydrated to form dimethylaminoethanol. If our compound is analogous to Knorr's compound, it should decompose on treatment with potassium hydroxide to yield (a) acetylene and 1,2-dimorpholinoethane and (b) β-4-morpholineëthanol. We have obtained both acetylene and 1,2-dimorpholineëthane, but did not obtain any morpholineëthanol. In this connection, we have tried, unsuccessfully, to make vinylmorpholine by the catalytic dehydration of β-4-morpholineethanol. It is, of course, possible that our quaternary piperazonium salt decomposes in only one way, to yield acetylene and 1,2-dimorpholinoethane.

When β-4-morpholinoethyl chloride was digested with absolute alcohol, the yield of N,N'-di-[1,5-(3-oxapentylene)]-piperazonium dichloride obtained after refluxing for forty-eight hours was about 34%, and the formation of the solid had practically ceased. Evaporation of the alcohol yielded a solid which was identified as the hydrochloride of β-4-morpholinoethyl ether. Since we obtained more of this solid than of the dimer, the reaction between β-4-morpholinoethyl chloride and the solvent alcohol proceeds more rapidly than the polymerization reaction.

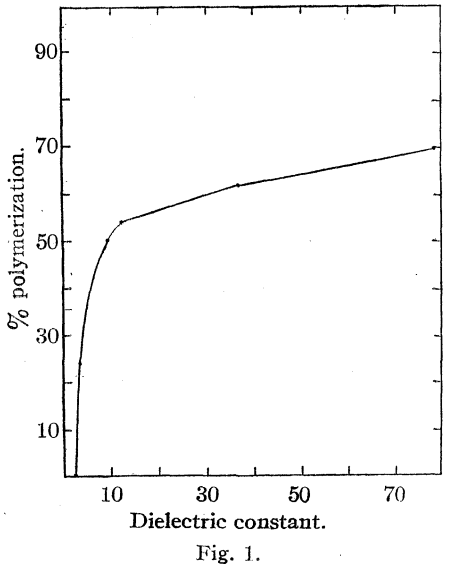


Fig. 1.

β-4-Morpholinoethyl chloride was then refluxed with separate portions of propyl alcohol, acetone and benzene. With propyl alcohol, a yield of 26.6% of the dimer was obtained after 218 hours of refluxing. β-4-Morpholinoethyl propyl ether hydrochloride was obtained after evaporation of the alcohol. Polymerization in acetone occurred very slowly, only 5% of the dimer being obtained after refluxing for a period of four months. There was no evidence of any reaction between β-4-morpholinoethyl chloride and acetone. A benzene solution of β-4-morpholinoethyl chloride was refluxed for one hundred eight hours without forming any trace of solid. At the end of this period, the benzene was distilled and 97% of the original β-4-morpholinoethyl chloride was recovered. In this connection, it is interesting to note that when benzene is used in place of ether for the extraction of β-4-morpholinoethyl chloride from the alkaline solution in which it is prepared, the β-4-morpholinoethyl chloride obtained does not form a solid as quickly as when ether is used for the extraction.

The above observations concerning the polymerization of β-4-morpholinoethyl chloride suggested the possibility that the extent of polymerization was dependent upon the dielectric constant of the solvent. Consequently, a number of polymerizations were carried out in water, dioxane and mixtures of these solvents. The results are given in Table I and represented graphically in Fig. 1.

TABLE I

% Dioxane	Dielectric constant[a]	β-4-Morpholinoethyl chloride used, g.	Dimer,[b] g.	Dimer, %
100	2.2	5	0	0
93.6	4.4	5	1.2	24
85.0	9.0	5	2.5	50
80.0	12.0	5	2.7	54
47.0	37.0	5	3.1	62
0	78.6	7.6	5.3	69.7

[a] Kraus and Fuoss, THIS JOURNAL, 55, 21 (1933).
[b] All mixtures refluxed for twenty-four hours.

It is to be noted that whenever water is present in the solvent, hydrolysis occurs, causing the formation of β-4-morpholineëthanol hydrochloride. In spite of this competing reaction, the evidence does indicate that, for this particular pair of liquids, the extent of dimerization of β-4-morpholinoethyl chloride is a function of the di-

electric constant of the solvent. That no general conclusion can be drawn concerning the extent of dimerization and the dielectric constant is shown by the following facts: (a) absolute ether and benzene, with dielectric constants of 4.35 and 2.28, respectively, did not cause any dimerization in twenty to twenty-four hours; (b) acetone, with a dielectric constant of 21.3, caused only slight polymerization (5%) in four months; (c) ethyl alcohol and propyl alcohol, with dielectric constants of 25.8 and 22, respectively, yielded 34% (forty-eight hours of refluxing) and 22.6% (two hundred and twenty-eight hours refluxing), respectively, of polymer. However, when comparing the dimerization of β-4-morpholinoethyl chloride in alcohols and in dioxane–water mixtures, it should be remembered that our evidence indicates that dimerization proceeds faster than hydrolysis but slower than alcoholysis. The possibility that some relationship exists between the rate of dimerization and the dielectric constant of the solvent is being studied further, using solvents which do not react with β-4-morpholinoethyl chloride.

When it was first planned to make β-4-morpholinoethyl chloride, we intended to make the Grignard reagent, β-4-morpholinoethylmagnesium chloride, and to cause that to react with various carbonyl compounds. All of our attempts to make this Grignard reagent have proved unsuccessful. It is interesting to note that while β-4-morpholinoethyl chloride does not polymerize in absolute ether when the solution is refluxed for twenty-four hours, it does polymerize appreciably (10%) in a few hours in absolute ether solution when magnesium is present. The rate of polymerization is much slower than the rate of formation of most Grignard reagents. Inasmuch as other work in this Laboratory indicates that the chlorine in β-4-morpholinoethyl chloride is a fairly reactive chlorine, we are puzzled over the inability of this compound to form a Grignard reagent.

Experimental Part

β-4-Morpholinoethyl Chloride Hydrochloride. (A) **From β-4-Morpholineëthanol and Thionyl Chloride.**—Two moles (262 g.) of redistilled β-4-morpholineëthanol was dissolved in 200 cc. of chloroform[4] in a three-necked flask equipped with a mercury sealed mechanical stirrer, a reflux condenser and a dropping funnel. A gas absorption bottle was connected to the top of the condenser. By means of a water-bath the solution was warmed to 40°, while stirring, and a few drops of a solution of 2.75 moles (200 cc.) of thionyl chloride in 200 cc. of chloroform[4] was added. After the initial reaction had abated, the thionyl chloride solution was added dropwise at such a rate that the temperature of the reaction mixture did not rise above 55°. After the first thirty minutes, the thionyl chloride solution could be added at the rate of two drops a second. After the first hour, the thionyl chloride was added more rapidly and external heating was necessary to keep the reaction mixture at 50–55°. About two hours was required for the addition. After all of the thionyl chloride solution was added, the reaction flask was heated very slowly and intermittently, until the mixture refluxed smoothly and the refluxing was continued for an hour. After cooling, the white crystals were removed by filtration and recrystallized from one liter of absolute alcohol, using 20 g. of Norit to decolorize the solution; yield, 263.6 g. (70.9%). The alcohol filtrate was concentrated to a volume of about 100 cc. An additional 26 g. was obtained, making a total yield of 289.6 g. (78%), m. p. 182–182.5°.

Anal. Calcd. for $C_6H_{13}Cl_2NO$: total Cl, 38.10; ionic Cl, 19.05; N, 7.53. Found: total Cl, 38.28, 38.40; ionic Cl, 18.59, 18.74; N, 7.15, 7.26.

(B) **From β-4-Morpholineëthanol Hydrochloride.**—β-4-Morpholineëthanol hydrochloride was made by adding slowly 56.4 cc. (10% excess) of concentrated hydrochloric acid to 70 g. of β-4-morpholineëthanol with good cooling and stirring. After evaporating to dryness on a steam-bath under reduced pressure, the solid was dissolved in 200 cc. of water and the solution decolorized by two treatments with Norit. Evaporation of the colorless solution under reduced pressure gave a solid which was recrystallized twice from *n*-amyl alcohol (absolute ethyl alcohol can also be used); yield 62.9 g. (70.2%), m. p. 109–110° (softens at 100°). A second crop of 3.4 g. was obtained by concentrating the combined filtrates.

Anal. Calcd. for $C_6H_{14}ClNO_2$: Cl, 21.15. Found: Cl, 20.91, 20.90.

Since β-4-morpholineëthanol picrate has not been reported in the literature, it was analyzed for nitrogen. It melted at 126°.

Anal. Calcd. for $C_{12}H_{16}N_4O_9$: N, 15.60. Found: N, 15.65, 15.66.

Six-tenths of a mole (100.5 g.) of β-4-morpholineëthanol hydrochloride was suspended in 150 cc. of chloroform. A solution of 108 g. of thionyl chloride in 150 cc. of chloroform was added and the mixture digested on the steam-bath for one hour. Complete solution occurred, followed by the separation of some solid. The mixture was then cooled and filtered and the crystals washed with a little chloroform. Two recrystallizations from *n*-amyl alcohol (absolute alcohol can also be used) yielded 67.2 g. of β-4-morpholinoethyl chloride hydrochloride, m. p. 182°. An additional 2.3 g. was obtained by concentrating the amyl alcohol filtrates and recrystallizing from amyl alcohol. Only 1.4 g. of purified product was obtained from the chloroform filtrate. The total yield was 70.9 g. (63.5%).

β-4-Morpholinoethyl Chloride.—Three-fourths of a mole (139.5 g.) of β-4-morpholinoethyl chloride hydrochloride

(4) When the amount of β-4-morpholineëthanol is considerably smaller, *e. g.*, 0.5 mole, the ratio of chloroform to reactants should be doubled in order to prevent the final reaction mixture from solidifying when cooled.

was dissolved in 150 cc. of water and 75 cc. of ether was added. To this mixture, 15% sodium hydroxide solution was added slowly until the aqueous solution was distinctly alkaline. The ether layer was removed and the aqueous solution was extracted with ten 50-cc. portions of ether. The combined ether extracts were dried over potassium hydroxide pellets. After distillation of the ether, the β-4-morpholinoethyl chloride distilled at 93–4° (12 mm.); yield, 95 g. (84.7%). In some later experiments, benzene was used instead of ether to extract the β-4-morpholinoethyl chloride. Five extractions with benzene were sufficient and the product could be kept for a longer period of time before polymerization was observed.

Anal. Calcd. for $C_6H_{12}ONCl$: Cl, 23.70; N, 9.36. Found: Cl, 23.48, 24.09; N, 9.39, 9.36.

β-4-Morpholinoethyl Chloride Picrate.—Since β-4-morpholinoethyl chloride reacts with both water and alcohol, the picrate was made by adding an excess of a saturated solution of picric acid in dry benzene to a solution of 1 cc. of β-4-morpholinoethyl chloride in 2 cc. of dry benzene. The precipitate, which formed immediately, was recrystallized from hot benzene in which it was soluble only to the extent of about 1.5%. However, it appears to be completely insoluble in cold benzene. It melted at 130°. Since the m. p. of β-4-morpholineëthanol picrate is 126°, a mixed melting point determination was made, m. p. 116°.

Anal. Calcd. for $C_{12}H_{15}ClN_4O_8$: N, 14.80. Found: N, 14.85, 14.96.

Reactions of β-4-Morpholinoethyl Chloride in Ethyl Alcohol. (A) N,N'-Di-[1,5-(3-oxapentylene)]-piperazonium Dichloride.—Fifty grams of freshly distilled β-4-morpholinoethyl chloride was refluxed with 250 cc. of absolute alcohol. The precipitated solid was removed by filtration at one, two, four, four, twelve, twelve, twenty-four, and forty-eight hour intervals. The amount of solid formed during the last period of digestion was very small. The total weight of solid was 16.8 g. (34%). This solid was soluble in water, insoluble in organic solvents and did not melt. It was identified by the following data as N,N'-di-[1,5-(3-oxapentylene)]-piperazonium dichloride.

Anal. Calcd. for $C_{12}H_{24}Cl_2N_2O_2$: Cl, 23.70; N, 9.36. Found: Cl, 23.97, 23.76; N, 9.23, 9.16.

Sixteen grams of this dimer was dissolved in a solution of 32 g. of potassium hydroxide dissolved in 32 cc. of water in an Erlenmeyer flask fitted with a tube leading to an ammoniacal silver nitrate solution. The flask was heated on a steam-bath until all of the acetylene had been driven off. The precipitate of silver acetylide was filtered, and a small portion of it exploded when heated on the end of a spatula. A positive test for acetylene also was obtained when the gas was passed into a 1% solution of phenylmercuric bromide in 10% potassium hydroxide solution, using the procedure developed by Spahr, Vogt and Nieuwland.[5]

After all of the acetylene had been liberated, the solution was cooled and extracted first with 100 cc. of ether, followed by eight more extractions, using 50 cc. of ether for each extraction. These extracts were combined and dried over solid potassium hydroxide. The ether solution was concentrated to a volume of about 25 cc. Five grams of Norit was added to decolorize the solution and the colorless filtrate was evaporated to a volume of 15 cc. The ether solution was cooled to about −75° by placing it in a bath of dry-ice in methanol. The solid was filtered and washed with dry ether previously cooled to this temperature. In this way, 4.4 g. of solid was obtained. By concentrating the filtrate and washings to 5 cc. and then cooling to −75° (dry-ice in methanol) an additional 1.0 g. was obtained. The total yield was 5.4 g. (51%) and the solid melted at 71–72°. Recrystallization from ether solution by cooling in a bath of dry-ice and methanol yielded pure 1,2-dimorpholinoethane melting at 73.5°. Knorr[6] reported a melting point of 74° for 1,2-dimorpholinoethane and 230–236° for the picrate. Our picrate melted with decomposition at 234–236°.

Anal. Calcd. for $C_{10}H_{20}N_2O_2$: N, 13.99. Found: N, 14.23, 13.89.

β-4-Morpholinoethyl Ethyl Ether Hydrochloride.—Since only one-third of the β-4-morpholinoethyl chloride was accounted for as the dimer after refluxing with alcohol, the alcohol filtrate was distilled and the residue transferred to an evaporating dish, using a little alcohol to rinse out the flask. This residue was heated on the steam-bath for four hours. On cooling, the mass solidified and weighed 30.7 g. The solid was pulverized, divided into 6 g. portions and each portion extracted repeatedly with hot toluene. In this way, 12.8 g. of solid was extracted, leaving a resinous residue of 4.2 g. which was insoluble in toluene. Five grams of the solid extracted by toluene was recrystallized twice from 250 cc. of toluene. The weight of pure product was 3 g. and it melted at 138°. This solid was very soluble in water, ethyl alcohol and *n*-amyl alcohol, soluble in the hot solvents, acetone, dioxane, cellosolve, diethylene glycol, β,β'-dichlorodiethyl ether, benzene and toluene, but could be recrystallized satisfactorily only from the last two solvents. It was insoluble in ligroin, cyclohexane and ether. That this compound was β-4-morpholinoethyl ethyl ether hydrochloride was shown by analysis and mixed melting point determination with some β-4-morpholinoethyl ethyl ether hydrochloride prepared from β-4-morpholinoethyl ethyl ether. The picrate of our ether melted at 102–3°, the picrate from the commercial ether melted at 103° and a mixture of the two melted at 102°.

Anal. Calcd. for $C_8H_{18}ClNO_2$: Cl, 18.12; N, 7.16; mol. wt., 195.6. Found: Cl, 18.01, 18.06; N, 6.80, 7.02; mol. wt. (acetic acid), 195.5, 198.5.

Picrate.—Calcd. for $C_{14}H_{20}N_4O_9$: N, 14.43. Found: N, 14.46, 14.65.

Reactions of β-4-Morpholinoethyl Chloride in Propyl Alcohol.—Twenty-one grams of freshly distilled β-4-morpholinoethyl chloride was refluxed with 100 cc. of *n*-propyl alcohol. Filtrations were made at two, twelve, thirty-six, sixty, and one hundred and eight hour intervals. At the end of 218 hours, a total of 5.6 g. (27%) of N,N'-di-[1,5-(3-oxapentylene)]-piperazonium dichloride was obtained. This was identified by decomposition with 50% sodium hydroxide solution as described above.

The propyl alcohol was distilled from the filtrate and

(5) Spahr, Vogt and Nieuwland, THIS JOURNAL, **55**, 2465 (1933).

(6) Knorr, *Ber.*, **35**, 4472 (1902).

the residue transferred to an evaporating dish, which was heated to remove the last trace of solvent. When cooled, the entire mass solidified; weight, 21.5 g. The pulverized solid was extracted repeatedly with hot toluene, and the toluene solution was decolorized with Norit. In this way, 10.5 g. of β-4-morpholinoethyl propyl ether hydrochloride was obtained. When recrystallized from toluene and dried, it melted at 130–131°.

Anal. Calcd. for $C_9H_{20}ClNO_2$: C, 51.54; H, 9.61; Cl, 16.91; N, 6.68. Found: C, 51.14, 51.65; H, 10.13, 10.20; Cl, 17.02, 17.12; N, 6.80, 6.82.

Reactions of β-4-Morpholinoethyl Chloride in Acetone.—Twenty grams of freshly distilled β-4-morpholinoethyl chloride was dissolved in 100 cc. of acetone and the solution refluxed. A solid formed very slowly, only 1 g. being obtained after refluxing for four months. During this period acetone was added frequently because of evaporation losses. The solid was identified as N,N′-di-[1,5-(3-oxapentylene)]-piperazonium dichloride by decomposition with 50% sodium hydroxide as described above.

The acetone was removed from the filtrate by distillation and the remaining liquid (3.7 g.) distilled at 91–2° (12 mm.). This corresponds to the b. p. of β-4-morpholinoethyl chloride. The liquid gave a precipitate with alcoholic silver nitrate solution only when heated, which is characteristic of β-4-morpholinoethyl chloride. The loss of β-4-morpholinoethyl chloride during the digestion can be accounted for by assuming that it was carried off by evaporation along with the acetone during the long period of refluxing.

Digestion of β-4-Morpholinoethyl Chloride in Benzene.—Twenty grams of freshly distilled β-4-morpholinoethyl chloride was refluxed for one hundred and eight hours with 100 cc. of benzene. No solid formed. The benzene was removed by distillation and the residue distilled at 91° (12 mm.). The distillate weighed 19.4 g. It was proved to be β-4-morpholinoethyl chloride by analysis for chlorine and nitrogen.

Digestion of β-4-Morpholinoethyl Chloride in Ether.—Three and eight-tenths grams of freshly distilled β-4-morpholinoethyl chloride was refluxed for twenty hours with 50 cc. of absolute ether. No solid appeared. After removal of the ether by distillation, 3.0 g. of β-4-morpholinoethyl chloride, b. p. 87° (7 mm.), was obtained.

Digestion of β-4-Morpholinoethyl Chloride in Dioxane.—Six grams of freshly distilled β-4-morpholinoethyl chloride was refluxed for twenty-four hours with 50 cc. of pure dioxane. Only the slightest trace of solid formed. After removal of the dioxane by distillation, 5.8 g. of β-4-morpholinoethyl chloride was recovered, b. p. 93° (12 mm.).

Reactions of β-4-Morpholinoethyl Chloride in Water.—Seven and six-tenths grams of freshly distilled β-4-morpholinoethyl chloride was refluxed with 50 cc. of water for twenty-four hours. The solution was then evaporated to dryness. The dry solid was pulverized and extracted three times with 10-cc. portions of hot *n*-amyl alcohol. The insoluble residue was washed three times with ether to remove adhering amyl alcohol. It weighed 5.3 g. (70%) and was identified as N,N′-di-[1,5-(3-oxapentylene)]-piperazonium dichloride by decomposing it with 50% sodium hydroxide solution and testing for acetylene with ammoniacal silver nitrate solution.

The *n*-amyl alcohol extracts were combined and concentrated to a volume of 10 cc. When cooled, a solid precipitated. When recrystallized from *n*-amyl alcohol, washed with ether and dried, 2.6 g. of solid was obtained which melted at 110°. This was identified as β-4-morpholineëthanol hydrochloride by means of a mixed melting point determination (109°) with some known β-4-morpholineëthanol hydrochloride. The weight of β-4-morpholineëthanol hydrochloride obtained is equivalent to 2.2 g. of β-4-morpholinoethyl chloride and accounts for 29% of the original chloride.

Reactions of β-4-Morpholinoethyl Chloride in Dioxane–Water Mixtures.—Five grams of freshly distilled β-4-morpholinoethyl chloride was refluxed for twenty-four hours in 50 cc. of the dioxane–water mixtures listed in Table I. A solid separated in each case except when the 47% dioxane–water solution was used. However, all mixtures were treated in the same way. After evaporation to dryness, the solids were extracted three times with 10-cc. portions of hot, 95% ethyl alcohol to remove β-4-morpholineëthanol hydrochloride. The insoluble N,N′-di-[1,5-(3-oxapentylene)]-piperazonium dichloride was washed with ether, dried and weighed. The results are given in Table I and Fig. 1.

Behavior of β-4-Morpholinoethyl Chloride on Standing and when Heated.—Fifty grams of freshly distilled β-4-morpholinoethyl chloride was placed in a tightly stoppered Erlenmeyer flask and stored in a dark closet. At the end of three months, 1.3 g. of solid was removed by filtration. At the end of an additional three months, 0.75 g. of solid was obtained. The remaining liquid was identified as β-4-morpholinoethyl chloride since it distilled at 92° (13 mm.) and left no residue. The solid was identified as N,N′-di-[1,5-(3-oxapentylene)]-piperazonium dichloride by the procedure described above.

Twenty-one grams of freshly distilled β-4-morpholinoethyl chloride was placed in a large test-tube in a flask of water which was heated on a steam-bath. The temperature of the water in the flask was 86° and the heating was continued for one week. When cold, the mixture was filtered and 1.2 g. of solid was obtained. This was identified as N,N′-di-[1,5-(3-oxapentylene)]-piperazonium dichloride and the remaining liquid distilled at the boiling temperature of β-4-morpholinoethyl chloride.

β-4-Morpholinoethyl Chloride and Magnesium.—Freshly distilled samples of β-4-morpholinoethyl chloride were added to magnesium in absolute ether, benzene and anisole. Even after adding iodine and refluxing for some time, no color test[7] indicating the presence of a Grignard reagent could be obtained. The use of activated catalysts[8,9] failed to cause the formation of any Grignard reagent. In some of these experiments, a white solid appeared. To determine the nature of the white solid, 9.5 g. of magnesium and 5 cc. of absolute ether were placed in a three-necked flask equipped with a mercury-sealed mechanical stirrer, a dropping funnel and a reflux condenser. At the top of the reflux condenser was placed a drying tube containing anhydrone. The flask was warmed on a steam-bath until the ether was refluxing and then a

solution of 26.4 g. of freshly distilled β-4-morpholinoethyl chloride in 30 cc. of absolute ether was added slowly. The mixture was refluxed for one hour, allowed to stand overnight and refluxed for three hours the next day. After filtration, the white solid was dissolved in 10 cc. of water. Evaporation to dryness yielded 2.8 g. which was purified by dissolving in water, decolorizing with Norit, evaporating to 5 cc. and adding alcohol and ether to precipitate the solid. It was identified as N,N′-di-[1,5-(3-oxapentylene)]-piperazonium dichloride by decomposition with 50% sodium hydroxide solution as described above.

Summary

β-4-Morpholinoethyl chloride hydrochloride has been prepared from β-4-morpholineëthanol and also from β-4-morpholineëthanol hydrochloride.

The free base has been obtained and has been found to polymerize on standing. When refluxed with benzene, ether, dioxane, or acetone, it either does not polymerize or polymerizes extremely slowly. When refluxed with alcohols or water, it not only polymerizes but also reacts with the solvent. In dioxane–water solutions, the rate of polymerization appears to be related to the dielectric constant of the solvent.

Ethers and Amines from β-4-Morpholinoethyl Chloride

BY J. PHILIP MASON AND SAUL MALKIEL[1]

The preparation of β-4-morpholinoethyl chloride has been described by Mason and Block.[2] They found the chlorine in β-4-morpholinoethyl chloride to be fairly reactive because hydrogen chloride is removed when the chloride is refluxed with alcohol or water. Since the chlorine in β-chloro ethers is known to be quite unreactive toward some reagents,[3] we considered it worth while to investigate the reactivity of the chlorine in β-4-morpholinoethyl chloride toward a number of reagents which react with alkyl halides.

This communication describes the preparation of a number of ethers and amines. Two ethers of this series have been reported previously, namely, the ethyl ether[2,4] and the propyl ether.[2] Sand[5] reported a melting point of what he thought might be the picrate of β,β′-dimorpholinoethyl ether. He was doubtful about it, however, and we have shown that his picrate was actually the picrate of β-4-morpholinoethanol. Two of the amines have been reported in the literature, namely, dimorpholinoethane[6] and β-4-morpholinoethyl amine.[7]

The method used for the preparation of the ethers was essentially a Williamson synthesis. Since β-4-morpholinoethyl chloride polymerizes on standing, we used the more stable, solid β-4-morpholinoethyl chloride hydrochloride. The results are given in Table I.

The β-4-morpholinoethyl amines were made simply by heating the amine with freshly distilled β-4-morpholinoethyl chloride. The results are given in Table II. Swallen and Boord[3] obtained β-ethoxyethylaniline (no yield given) from β-chloroethyl ether and aniline after heating for ten hours.

Experimental

β-4-Morpholinoethyl Methyl Ether.—To 100 cc. of methanol in a 500-cc. wide-mouth Erlenmeyer flask was added 0.1 mole (2.3 g.) of metallic sodium. After all the sodium had dissolved, sufficient glass wool was added to cover the bottom of the flask. In an underwriter's extraction thimble was placed 0.05 mole (9.3 g.) of β-4-morpholinoethyl chloride hydrochloride. An underwriter's coil condenser was used in the top of the flask. The β-4-morpholinoethyl chloride hydrochloride dissolved in the condensed methanol and as soon as it reached the sodium methoxide solution a precipitate of sodium chloride appeared. About fifteen minutes was required for complete extraction of the β-4-morpholinoethyl chloride hydrochloride. The reaction mixture was refluxed for an additional five minutes and the excess methanol was removed as completely as possible by distillation. When the residue was cool, 100 cc. of 30% sodium hydroxide solution was added. After separation of the two layers, the aqueous solution was extracted with three 25-cc. portions of ether. The ether extracts and the original upper layer were combined and dried over Drierite. The ether and alcohol were removed by distillation and the residue was

transferred to a 50-cc. Claisen flask whose side arm was well "vigreuxed" and was also packed with asbestos. After fractionation under reduced pressure, the high boiling fraction was dried over sodium and redistilled. The yield was 5.5 g. (76%) and the ether distilled at 105.3–107.3° (46 mm.).

The above procedure was used for the preparation of the ethyl, propyl, isopropyl, butyl, *s*-butyl, *t*-butyl, phenyl and benzyl ethers. All of the ethers were colorless mobile liquids possessing a strong ammoniacal odor. The methyl, ethyl, isopropyl, *s*-butyl and *t*-butyl ethers were soluble in water and typical organic solvents such as alcohol, ether and benzene. The butyl, benzyl and phenyl ethers were insoluble in water and soluble in the organic solvents just mentioned.

β,β'-Dimorpholinoethyl Ether.—Because of the high boiling point of β-4-morpholineëthanol (227°), 0.05 mole (7.5 g.) of β-4-morpholinoethyl chloride was added to 100 cc. of β-4-morpholineëthanol in which 0.05 mole (1.15 g.) of sodium had been dissolved. The mixture was heated to 200° in an oil-bath and kept at that temperature for twenty minutes. The separation and purification was carried out as described above. Dimorpholinoethyl ether is soluble in water and the above mentioned organic solvents.

β-4-Morpholinoethylamine.—To an excess of concentrated ammonium hydroxide (40 cc.) in a round-bottom flask was added 0.05 mole (7.5 g.) of freshly distilled β-4-morpholinoethyl chloride and sufficient water (45 cc.) to effect complete solution. A cork stopper was wired to the flask, which was then placed in an oven at 93–98° for five hours. After cooling, 80 cc. of 40% sodium hydroxide solution was added to the reaction mixture. The small upper layer was removed and the aqueous layer was extracted with three 25-cc. portions of ether. The ether solution was dried over Drierite, the ether removed by distillation and the residue distilled fractionally under reduced pressure. β-4-Morpholinoethylbutylamine was made by the same procedure, using 0.055 mole (4.0 g.) of *n*-butylamine. The results are given in Table II.

β-4-Morpholinoethylaniline.—A solution of 0.055 mole (5.2 g.) of aniline and 0.05 mole (7.5 g.) of freshly distilled β-4-morpholinoethyl chloride was heated under a reflux air condenser for two hours in an oil-bath at 200°. After cooling, the solution was treated with an excess of 40% sodium hydroxide solution and extracted three times with 25-cc. portions of benzene. The benzene solution was dried over Drierite, the benzene removed by distillation and the residue distilled using a fractionating column under reduced pressure. β-4-Morpholinoethylmethylaniline was made by the same procedure using 0.055 mole (5.5 g.) of methylaniline. When dimorpholinoethane was made by this procedure, a residue was left after distillation of the benzene. This was dissolved in hot ligroin, decolorized with Norit and recrystallized from ligroin. The results are given in Table II.

With the exception of dimorpholinoethane the amines are colorless liquids possessing an ammoniacal odor. The β-4-morpholinoethylamine and the β-4-morpholinoethylbutylamine are soluble in water and in the previously mentioned organic solvents. The β-4-morpholinoethylaniline and the β-4-morpholinoethylmethylaniline are

viscous liquids, insoluble in water but soluble in the organic solvents. Dimorpholinoethane is a white, water soluble solid.

Summary

The β-4-morpholinoethyl ethers of methyl, ethyl, propyl, isopropyl, butyl, *s*-butyl, *t*-butyl, benzyl and β-4-morpholinoethyl alcohols and phenol have been prepared from β-4-morpholinoethyl chloride and the corresponding sodium alkoxide or phenoxide. β-4-Morpholinoethyl amines have been made by the interaction of β-4-morpholinoethyl chloride with ammonia, *n*-butylamine, aniline, methylaniline and morpholine.

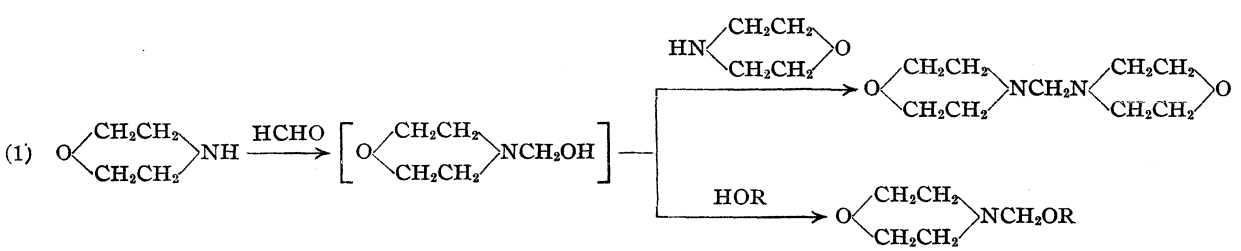
4-Morpholinomethyl Alkyl Ethers and N-Substituted Morpholines

BY J. PHILIP MASON AND MORRIS ZIEF[1]

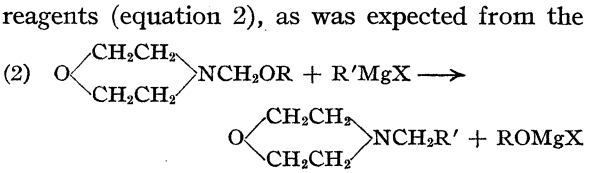
Dialkylaminomethyl alkyl ethers have been prepared by McLeod and Robinson[2] by the condensation of secondary amines with 40% aqueous formaldehyde solution and various alcohols. Stewart and Bradley[3] used paraformaldehyde instead of 40% aqueous formaldehyde solution. We have made a number of 4-morpholinomethyl alkyl ethers using the method described by Stewart and Bradley[3] with certain modifications.



It will be seen from equation (1) that there are two reactions possible when the three reactants are mixed. In order to increase the yield of the ether, we used two equivalents of alcohol to one each of morpholine and formaldehyde.

Table I shows the percentage of morpholine converted into the 4-morpholinomethyl alkyl ether and dimorpholinomethane, together with the boiling points, nitrogen analyses and neutral equivalents. Increasing yields of ether were obtained with increasing molecular weight of the primary alcohols from methyl to *n*-propyl and *n*-butyl. This may be due to the fact that the ethers obtained from higher alcohols are hydrolyzed less readily than those from lower alcohols.[2] Evidence that the hydrogen of the water split off during the formation of the ether comes from the alcohol and the hydroxyl from the hypothetical 4-morpholinemethanol is found in the lower yields of ethers obtained when secondary and tertiary alcohols were used. Picrates of these ethers could not be obtained by the usual method because all of the ethers hydrolyzed to form morpholine, and morpholine picrate was the only compound obtained.

These ethers reacted readily with Grignard reagents (equation 2), as was expected from the



work of McLeod and Robinson.[2] The results are reported in Table II.

Experimental

4-Morpholinomethyl Ethyl Ether.—Fifteen grams of paraformaldehyde (equivalent to 0.5 mole of formaldehyde), 23 g. (0.5 mole) of absolute ethyl alcohol and 100 cc. of dry benzene were placed in a 500-cc. three-necked flask which was equipped with a mercury-sealed mechanical stirrer, a separatory funnel and a fractionating column attached to a condenser for distilling the ternary mixture. The flask was heated in a water-bath kept at 85°. A mixture of 43.5 g. (0.5 mole) of morpholine and 23 g. (0.5 mole) of absolute ethyl alcohol was dropped slowly into the reaction mixture, which was stirred continuously. During this addition, which was completed in one hour,

the ternary mixture of water, alcohol and benzene distilled at 65°.[4] After all of the morpholine was added, the temperature of the water-bath was raised to 100° and the remaining benzene and alcohol were distilled. The residue was transferred to a 500-cc. round-bottom flask to which was attached an efficient fractionating column. The distillate which came over up to 58° at 6 mm. pressure was discarded. The following fractions were collected.

Fraction	B. p., °C. (6 mm.)	Wt., g.	Neut. equiv.
I	58–63	26.7	144.8
II	63–110	24.3	120.5
III	110–113	4.1	97.3

Fraction I is pure 4-morpholinomethyl ethyl ether (neutral equivalent 145) while fraction III consists chiefly of dimorpholinomethane (neutral equivalent 93). If we make the reasonable assumption that fractions II and III are mixtures of the ether and dimorpholinomethane, it is possible to determine the amount of each component from the titration data and simultaneous equations. For example, 0.2546 g. of fraction II required 20.71 cc. of 0.1024

[a] No benzene used. Mixture was fractionally distilled after addition of morpholine was complete. First fraction was a binary mixture of the alcohol and water. [b] 0.75 mole of alcohol used.

N hydrochloric acid for neutralization. One gram of 4-morpholinomethyl ethyl ether requires 68.36 cc. of this acid and 1 g. of dimorpholinomethane requires 104.98 cc. of this acid for neutralization. Solving the simultaneous equations

$$x + y = 0.2546$$
$$68.36x + 104.98y = 20.71$$

x equals 0.1641. Therefore 64.5% of fraction II is 4-morpholinomethyl ethyl ether. This type of analysis was used in all subsequent experiments to determine the per-

(4) Jordan, "Technology of Solvents," Chemical Publishing Company, New York, N. Y., pp. 324–325.

centages of morpholine converted to the ether and dimorpholinomethane reported in Table I.

The other 4-morpholinomethyl alkyl ethers were made by the method described above, with the modifications given in the footnotes of Table III which summarizes all of the experimental data.

N-Substituted Morpholines.—The Grignard reagents were prepared in the usual way using 0.12 mole of magnesium and 0.12 mole of halide in 100 cc. of absolute ether. One-tenth mole of 4-morpholinomethyl ethyl ether dissolved in 50 cc. of absolute ether was then added slowly to the solution of Grignard reagent, the mixture refluxed for thirty minutes and allowed to stand overnight. The mixture was hydrolyzed with 10 cc. of concentrated sulfuric acid dissolved in 100 cc. of water. The ether layer was extracted with three 20-cc. portions of 20% sulfuric acid. Ten grams of ammonium chloride was added to the combined acid extracts to which concentrated ammonium hydroxide (about 65 cc.) was added until the solutions were alkaline. The alkaline solution was extracted with four 40-cc. portions of ether. The combined ether extracts were dried over calcium sulfate, the ether distilled and the remaining oil was distilled under reduced pressure. The results are given in Table II.

Summary

The preparation of eight new 4-morpholinomethyl alkyl (or aralkyl) ethers has been described and the amount of dimorpholinomethane formed by a competing reaction has been indicated in each preparation.

Five alkyl (or aralkyl) morpholines have been prepared from 4-morpholinomethyl ethyl ether and Grignard reagents.

The Thermal Decomposition of the Acetate of 2,2-Dimethyl-3-pentanol

BY PAUL L. CRAMER AND VERLE A. MILLER

The dehydration of primary and secondary alcohols containing a neopentyl group to form the corresponding olefin is accompanied by a skeletal rearrangement.[1] Thus, the alcohol–olefin–paraffin method in many instances is not applicable in the synthesis of the tetra-alkylmethanes. The thermal decomposition of the methyl xanthate of the alcohol has provided a successful modification of the above method for the preparation of this type of hydrocarbon.[2]

The thermal decomposition of the acetate rather than the methyl xanthate of the alcohol has been employed in the synthesis of 3,3-dimethyl-1-butene.[1,3] The acetate gives much higher yields of the olefin than those obtained by the methyl xanthate procedure. Also the acetate method offers a more simple procedure in which no solvent is required. The main disadvantage of this method is the high temperature required to decompose the acetate, which would be expected to enhance the possible formation of isomeric olefins or other undesirable side reaction products. Thus, it seemed desirable to further test the acetate method as a possible general procedure for the synthesis of the above type of olefins and the corresponding paraffins.

In the present investigation a study has been made of the thermal decomposition of the acetate of 2,2-dimethyl-3-pentanol. As in the case of the acetate of 3,3-dimethyl-2-butanol,[3] a temperature of 400° is required to bring about an 80% conversion at contact times of reasonable length. Only about 12% conversion is obtained at 350°. The reaction is remarkably free of side reaction products, and the unchanged acetate may be recovered almost quantitatively.

4,4-Dimethyl-2-pentene is the principal olefin (93%) formed in the decomposition of the acetate of 2,2-dimethyl-3-pentanol. In contrast with the results obtained with the acetate of 3,3-dimethyl-2-butanol,[1,3] rearrangement occurs in this reaction to the extent of about 7%.[4] The rearranged products consist of a mixture containing about equal amounts of two olefins boiling in the 2,3-dimethylpentene and the 2,4-dimethylpentene range. Due to the very small amounts of these rearranged olefins, their separation and further identification by fractionation was unsuccessful.

(1) For references see Whitmore and Meunier, THIS JOURNAL, **55**, 3721 (1933).

(2) (a) Fomin and Sochanski, *Ber.*, **46**, 246 (1913); (b) Schurman and Boord, THIS JOURNAL, **55**, 4930 (1933).

(3) Cramer and Mulligan, *ibid.*, **58**, 373 (1936).

(4) To demonstrate that the rearranged olefins were not the result of the decomposition of the 2,2-dimethyl-3-pentanol contained as an impurity in the acetate, the pure alcohol, obtained by the saponification of a portion of the acetate, was found to be stable under the conditions employed in the decomposition of the acetate.

However, from the corresponding heptanes, obtained by the hydrogenation of the rearranged olefin mixture, pure 2,3-dimethylpentane was separated by fractionation. Thus, one of the rearranged olefins is identified as 2,3-dimethylpentene. The boiling point range, and in particular the refractive index curve for the second hydrogenated rearranged product, offer strong evidence in favor of the 2,4-dimethyl isomer. The above distillation analysis is shown in Fig. 1.

It is of interest to note that in the case of the principal olefin, 4,4-dimethyl-2-pentene, only a very small amount of evidence was obtained to indicate the presence of both *cis* and *trans* isomers. The entire distillation range, carried out in a column having an effectiveness equivalent to 100 plates, was only 0.1°. The refractive index of the first 20% of the distillate was slightly higher than that of the main portion. Hydrogenation of the first portion gave pure 2,2-dimethylpentane, Fig. 1. Thus, it seems reasonable to assume that the 4,4-dimethyl-2-pentene obtained by the above method is comprised largely of one form, presumably the higher boiling isomer.

A comparison of the results obtained by the acetate and the methyl xanthate methods in the synthesis of 4,4-dimethyl-2-pentene is shown by the following data: acetate, yield based on the carbinol 70.5%, b. p. 76.6–76.7°, d^{20}_4 0.6884, $n^{20}D$ 1.3983; methyl xanthate,[2b] 44%, 76–76.1°, 0.6881, 1.3986. No rearranged olefins have been reported for the methyl xanthate procedure.

Experimental

Materials.—2,2-Dimethyl-3-pentanol was prepared in the usual manner, namely, the reaction of *t*-butyl-magnesium chloride with propionaldehyde. The yield of the alcohol, b. p. 132–135°, was 35%.

The acetate of 2,2-dimethyl-3-pentanol, previously prepared by the acetylation of the alcohol with acetic anhydride,[5] was prepared here by the acetylation of the alcohol by a 10% excess of acetyl chloride. The acetyl chloride was added slowly to the alcohol with stirring. The reaction mixture finally was heated at 100° for two hours. The acetate was distilled from the reaction mixture. It was washed with water and with sodium bicarbonate solution, and dried over calcium chloride. The yield of acetate, b. p. 153–158°, containing a small amount of unchanged carbinol, was 80%.

The Thermal Decomposition of the Acetate of 2,2-Dimethyl-3-pentanol.—These reactions were carried out in a pyrex tube packed with glass wool, and heated in the conventional type of electric furnace. The reaction products were collected at 0°. The olefin containing unchanged acetate was separated from the acetic acid by washing with water and with sodium bicarbonate solution. After drying over calcium chloride, the olefin was separated by distillation.

(5) Favorsky, *J. prakt. Chem.*, (2) **88**, 672 (1912).

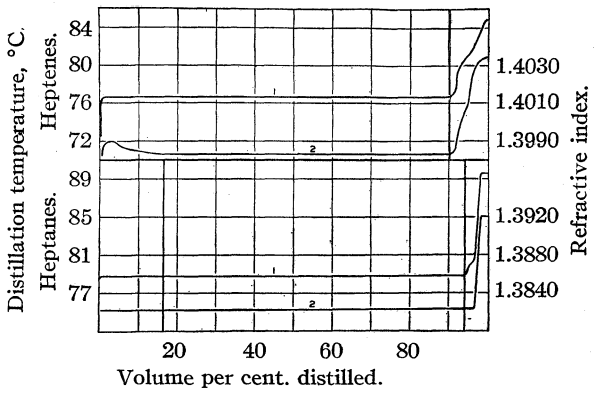

Fig. 1.—Distillation analyses of the heptenes and the corresponding heptanes obtained by the thermal decomposition of the acetate of 2,2-dimethyl-3-pentanol: curves 1, distillation temperature; curves 2, refractive index.

The decomposition of the acetate (238 g.) at 349° with a contact time of one hundred and nine seconds yielded 11.5% olefin. At 401° and a contact time of ninety-nine seconds the yield from 214 g. of the acetate was 77%.

The main portion of the acetate (538 g.), in which the olefins were analyzed by fractionation, was decomposed at 400° and a contact time of one hundred seconds. The yield of olefin, including that obtained from the second passage of the recovered acetate from the main run, was 88%. The main portion of the olefin (90.5%), pure 4,4-dimethyl-2-pentene, was separated by fractionation in a 100-plate column. The hold-up from this column, amounting to about 50 cc., was transferred to a small column having an effectiveness equivalent to 28 plates. In the latter column only a partial separation of a mixture (38 cc.) of 4,4-dimethyl-2-pentene, and two rearranged products, boiling in the 2,3- and 2,4-dimethylpentene range, was effected. The distillation analysis of the heptenes is shown in Fig. 1. The physical constants for 4,4-dimethyl-2-pentene are presented elsewhere in this paper.

The Hydrogenation of the Heptenes.—The hydrogenation of the heptenes was carried out in three separate batches: namely, the first 20%, the middle 70.5% and the last 8% of the total heptene distillate. The hydrogenation was effected by the use of Raney nickel catalyst in the absence of a solvent. The hydrogenated products in each case were purified by washing with water, concd. sulfuric acid, and finally by refluxing and fractionation over sodium. The fractionation was carried out in the 28-plate column. The distillation analysis of the heptanes is shown in Fig. 1. The physical constants for the pure heptanes thus obtained are as follows: 2,2-dimethylpentane, b. p. 78.8°, $n^{20}D$ 1.3823; 2,3-dimethylpentane, b. p. 89.6°, $n^{20}D$ 1.3920.

Summary

A study has been made of the thermal decomposition of the acetate of 2,2-dimethyl-3-pentanol

to yield 4,4-dimethyl-2-pentene and acetic acid.

About 7% rearrangement occurred in this reaction. One of the two rearranged olefins obtained in this reaction was identified as a 2,3-dimethylpentene.

In the case of the principal olefin, 4,4-dimethyl-2-pentene, little evidence was obtained of the presence of both *cis* and *trans* isomers.

2,2-Dimethylpentane, 2,3-dimethylpentane and an unidentified isomer were obtained by the hydrogenation of the heptenes.

The Ternary Systems Involving Cyclohexene, Water, and Methyl, Ethyl, and Isopropyl Alcohols

BY E. ROGER WASHBURN, C. LOREN GRAHAM,[1] GEORGE B. ARNOLD AND LAURENCE F. TRANSUE

In continuation of a series of investigations of similar binary and ternary systems the solubility relationships for the systems formed from cyclohexene, water and methyl, ethyl and isopropyl alcohols have been studied at 25.0°. In order to provide an indication of the changes to be expected with changes in temperature the system involving isopropyl alcohol was also studied at 15.0 and 35.0°. The proportions in which the alcohols are distributed between the water-rich and cyclohexene-rich layers have been measured.

Materials.—Good commercial grades of methyl and ethyl alcohol, and isopropyl alcohol from Eastman Kodak Company were dried by refluxing over active lime for many hours. The alcohols were then distilled from the lime into a carefully dried all-glass still. They were then slowly distilled from this still through an efficient fractionating column and preserved in carefully dried glass-stoppered bottles. The specific gravities and refractive indices of the purified materials are listed in Table I.

Several studies carried out in this Laboratory indicate that both the density and the refractive index of cyclohexene change with the passage of time if the material is in contact with oxygen. That this is probably due to the formation of a peroxide is indicated by the fact that while the freshly distilled material fails to liberate iodine from an iodide, the material which has been in contact with oxygen for some time gives positive results when added to an acidified potassium iodide–starch solution. Accordingly our cyclohexene, the better of the two grades sold by Eastman Kodak Company, was repeatedly fractionated through a carefully controlled Snyder column[2] in an atmosphere of purified nitrogen. It was collected in carefully dried, nitrogen-filled bottles and kept under nitrogen until used. It was our experience that the specific gravity and refractive index were constant at the values indicated in Table I as long as tests with potassium iodide and starch indicated no peroxide.

There is little consistency in the recorded values for the specific gravity, or for the refractive index, of cyclohexene. Therefore, since considerable effort was made in this work to obtain material of a high degree of purity, more than the usual amount of interest may attach to the value which we record. In one distillation these observations were made. Three hundred twenty-five cc. of stock material of d^{25}_4 0.80919 was distilled. The first 50 cc. collected had a value of d^{25}_4 of 0.80558, the second fraction (210 cc.) had a specific gravity of 0.80566, while the 50 cc. of residue showed the high value of 0.82152. The second fraction was then fractionated yielding 35 cc. with d^{25}_4 of 0.80564, 55 cc. of 0.80562 and leaving 50 cc. of residue of 0.80576.

A large number of similar distillations carried out by different investigators in this Laboratory lead us to believe that the specific gravity of cyclohexene d^{25}_4 is 0.8056 ± 0.0001.

TABLE I

Material	Specific gravity, d^{25}_4	Refractive index $n^{25}D$
Methyl alcohol	0.7866	1.32659
Ethyl alcohol	.7851	1.35942
Isopropyl alcohol	.7809	1.37487
Cyclohexene	.8056 d^{15}_4 0.8151	1.4434

Procedure and Results.—The ternary solubility curves were determined by a titration method similar to that described elsewhere.[3] The titrations were carried out at the temperatures

(1) Present address: Eastman Kodak Company, Rochester, New York.

(2) Hill and Ferris, *Ind. Eng. Chem.*, **19**, 379 (1927).

(3) THIS JOURNAL, **62**, 579 (1940).

indicated within ±0.05°. Weighed quantities of the components were used, the titrant being added from a weight pipet. Care was taken to avoid overstepping the end-point and also to avoid confusing the opalescence obtained with certain proportions of the components with the true end-point as indicated by the appearance of a second phase. The angle and intensity of the illumination was varied so as to provide conditions most favorable for the particular titration. To make certain that the end-point had been reached the titration mixture was shaken automatically in the constant-temperature bath for at least fifteen minutes and then reëxamined.

The determinations of the refractive indices of the saturated solutions containing methyl alcohol were particularly difficult with the solutions where the end-point was preceded by an opalescence. In order to overcome this difficulty these solutions were warmed to 30.0° in order to clear up the solutions and the refractive indices were determined at that temperature. These values are indicated in Table I. When solutions in this range of concentrations were encountered in the distribution studies they were, of course, also heated to 30.0° for the refractive index determination.

The results of these determinations of solubilities and refractive indices are recorded in Tables II to VI. The concentrations of the conjugate solutions are recorded in Tables VII to XI.

methyl alcohol is found in the cyclohexene layer, even when a considerable portion of the system is alcohol. A slightly larger proportion of ethyl alcohol is found in the hydrocarbon layer especially when the alcohol content is high. As has been found with other systems containing isopropyl alcohol, the proportion of it found in the

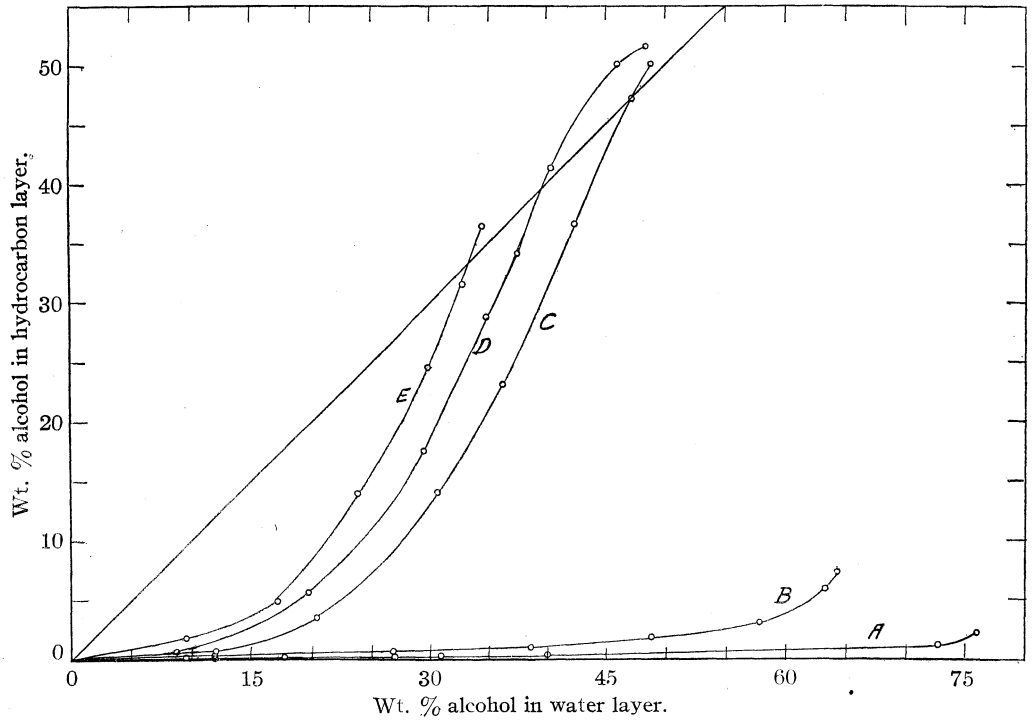

Fig. 1.—A, methyl alcohol; B, ethyl alcohol; C, D, E, isopropyl alcohol at 15, 25, 35°, respectively.

hydrocarbon layer increases rapidly with increasing total amount of alcohol until the tie lines change the sign of their slope. These facts are clearly indicated in Fig. 1 in which the % of alcohol in the cyclohexene layer is plotted against the % of alcohol in the water layer.

Increasing the temperature from 15 to 35° causes very little change in the area in which conjugate solutions are found; the area is slightly larger at the lower temperature. The slopes of the tie lines change by a large amount. The plait point at 15° is not far from the highest point of the solubility curve, while at 25° it is farther down on the water-rich side of the curve. It was experimentally difficult to approach very closely to the plait point at 35° but the indications are that at this temperature it is still farther down on the water side of the curve.

Summary

The solubility relationships for the ternary systems containing water and cyclohexene and methyl, ethyl or isopropyl alcohol have been determined at 25°. The system containing isopropyl alcohol has been investigated at 15 and 35°.

Hydration Mechanism of the Clay Mineral Montmorillonite Saturated with Various Cations[1]

BY S. B. HENDRICKS,[2a] R. A. NELSON[2b] AND L. T. ALEXANDER[2b]

Introduction

The hydrous magnesium aluminum silicate mineral montmorillonite, because of its unusual properties and widespread occurrence in clays and soils, has attracted the attention of workers in many fields. It is extremely plastic when moist and can be dispersed in water, readily forming thixotropic gels at moderate concentrations. The dispersed material upon drying reorganizes, forming a crystalline material one lattice constant of which depends upon the humidity. Montmorillonite is a salt of a moderately strong acid, from which other salts and the free acid can be prepared by cation replacement, that is, base exchange. It strongly absorbs organic bases with formation of the corresponding salts and also shows marked adsorption for neutral organic compounds, which is the basis for its use as a clarifying agent. Many reactions are catalyzed by montmorillonite.

Study of montmorillonite as a base exchange complex has come about largely because it is a component of many soils showing high base exchange capacity. Replacement of one cation by another has been investigated to a considerable extent and several series have been set up showing ease of replacement. The one generally accepted shows[3,4]: $H^+ > Ba^{++} > Sr^{++} > Ca^{++} > Mg^{++} > Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$; thus, for example, a greater fraction of the K^+ ions is displaced at equivalent concentrations by Ca^{++} than by Li^+. These differences usually have been attributed to "ionic hydration."[5] A successful correlation has been found with zeta potentials[6] derived from migration velocities of clay micelles in suspensions. No attempt has been made, however, to determine the environment of the ion in the clay, which is fundamental to understanding the nature of the replacements.

For a number of years the authors have been interested in the identification and structures of minerals present in clays. During the course of this work it became evident that a study of water sorption by the various salts of montmorillonite probably would go far toward determining the environment of the replaceable cation. The material is one of the few in which sorption can be followed by means of lattice changes.

Methods and Materials

Since montmorillonite might be expected to differ in behavior depending upon its origin, samples were obtained from several localities. All of these were bentonites, that is, they were formed by devitrification of volcanic ash. One was a commercial material from Wyoming, sold under the trade name "Volclay," which is known to contain finely divided quartz and appreciable silica that can be dissolved in weak bases. This particular sample has not been ana-

lyzed. Two other samples were furnished by Dr. C. S. Ross and Dr. P. G. Nutting of the U. S. Geological Survey. One was a fine white specimen from Otay, California (Sample G in 7) and the other was a slick yellowish material from the vicinity of Laurel, Mississippi (Sample B in 7). Both are considered to be very pure montmorillonite and analyses for them have been published.[7]

The clays were electrodialyzed to obtain the free acids and these were titrated to *p*H 8.0 with dilute calcium hydroxide or sodium hydroxide solutions to form the corresponding salts. Cesium, potassium, and barium salts of the Mississippi sample were made by titration of the free acid obtained by treatment of the clay for short times with successive lots of dilute (1:10) hydrochloric acid in large excess which was removed by washing with water. Lithium, magnesium, strontium (Miss.), and cerium (Calif.) salts were prepared from the original clays (predominantly the calcium salt) by base exchange from neutral chloride solutions. Base exchange capacities, expressed in milliequivalents per gram, of the three clays as obtained by titration of the hydrogen clays to *p*H 8.0 with sodium hydroxide solution are as follows: Mississippi 0.95, California 0.80, Wyoming 0.85.

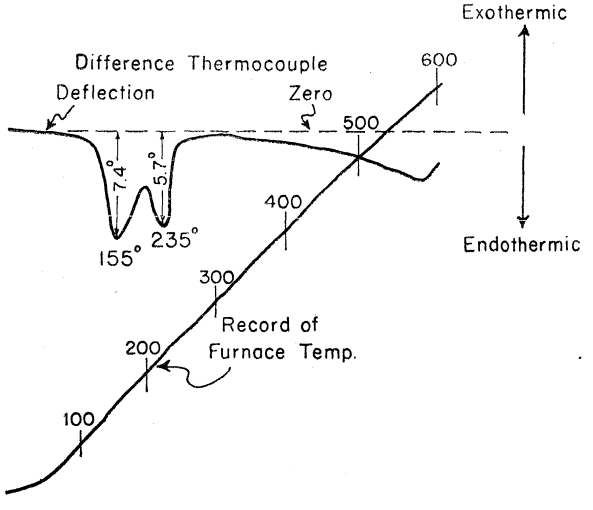

Fig. 1.—Photographic record from differential thermal analysis apparatus.

The clay salts were dried over phosphorus pentoxide in vacuum to constant weight and were then exposed at 30° to water vapor, at various relative humidities, for a week or longer. Amounts of water adsorbed were recorded and samples were removed for differential thermal analysis and for X-ray examination. The samples for X-ray examination were protected from change in water content by sealing them with plastocene in small tubes, 0.5 mm. in diameter, made from Lindemann glass. Unoriented samples were used since the procedure was simple and gave satisfactory results, even though it was realized that oriented samples would have been preferable. Nickel Kα radiation was used throughout.

Differential thermal analyses were made, according to the Le Chatelier[8] method, in an apparatus similar to that described by Norton.[9,10] In this method the temperature of a sample relative to that of an inert material is followed as the two are heated at an equal and approximately constant rate. An endothermic change, such as accompanies loss of water from a clay, results in a temperature lag relative to the inert material. The heating rate used was approximately 12° per minute which is rapid; a photographic record from the apparatus is reproduced as Fig. 1.

Some Structural Features of Montmorillonite.—The approximate crystal structure of montmorillonite, the essential mineral component of bentonites, was suggested by Hofmann, Endell and Wilm.[11] They showed that the lattice consisted of superimposed silicate sheets, similar to those found in the mineral pyrophyllite, having the ideal composition $(OH)_2Al_2Si_4O_{10}$, with replacement of Al^{+++} by Mg^{++}, Fe^{+++} and Fe^{++}, and silicon by aluminum. There is perfect cleavage between the sheets. Water sorption was shown to result in increase of the lattice spacing normal to the cleavage, (001). The water molecules were thus presumably located on the surfaces of the sheets.

Montmorillonite differs from pyrophyllite in having a smaller particle size, a more variable composition, a larger amount of water lost above 300°, and in showing base exchange. The replaceable ions are apparently external to the silicate sheets and usually amount to slightly less than 1 m. e. per gram, which is equivalent to about one-third the amount of potassium in muscovite. Their presence indicates that the sheets have some deficiency of positive ions resulting in an over-all negative charge. Attempts to locate the replaceable ions relative to the lattice have largely been speculative. Hofmann and Bilke[12] assumed that these ions were chiefly around the edges of the layers and to a lesser extent between the layers. Marshall[13] considered them to be between the layers and to be associated with water molecules. The behavior of organic salts of montmorillonite[14] when analyzed in detail shows that the exchangeable ions are predominantly between the silicate sheets. Gieseking, who has carried out the most extensive study of these salts, actually reproduces a drawing due to Hofmann and Bilke, without particular comment, but it is not to be thought that his results support their hypothesis. Results obtained in the present work also show that the most of the ions, probably more than 80%, are between the silicate sheets.

There has been some discussion of the manner in which water molecules are arranged between the silicate layers. A considerable body of opinion contends that they are in some type of close packed arrangement.[15] However, there are several arguments against this hypothesis, the simplest of which is that water usually has tetrahedral coordination. A suggested arrangement of water molecules which is supported by the known structure of vermiculite and which explains the observations that have been made on montmorillonite is shown in Fig. 6. A water layer of this type is of such a structure that if preserved would

propagate the lattice as a whole which is a very strong argument in its favor. If it is assumed that the upper surfaces of all silicate layers in montmorillonite are covered by a single water sheet of this type then 0.10 g. of water will be required for 1.0 g. of mineral.

Addition of a layer of water molecules results in a change of about 3.0 Å. in the separation of the silicate layers. The first layer hydrate would thus have a spacing of about 12.0–13.0 Å., and a hydrate with two water layers about 15.0–16.0 Å.[16] Bradley, Grim and Clark have shown that definite hydrates can at least be formed for a sample of hydrogen Wyoming montmorillonite that they studied. Others have failed to repeat this observation, which, however, does not detract from its possible validity. The more usual situation, and one in accord with all except a single observation made in this work, is that the characteristic cleavage spacing varies continuously but not uniformly with water content.[12] This apparently is a result of an averaging effect from a lattice that contains various numbers of water layers in different parts.[15]

Results and Discussion

Previous studies of water sorption by clays have largely been restricted to measurement of lattice constants and weight increases as functions of humidity or loss on drying to constant weight at fixed temperatures. With one exception, which will be discussed later (note reference 16), the results indicated that water was gained or lost in a monotonous way. Differential thermal analyses, however, carried out in this Laboratory for identification of clay minerals indicated that probably more than one process was involved in water sorption since the low temperature endothermic region had considerable structure (note Fig. 1).

Results obtained by differential thermal analysis for the various clays are reproduced in Figs. 2–5. Curves in these figures show the galvanometer response, in series with the differential couple, as the sample is heated. Ordinates thus are proportional to lag in temperature of the sample, behind the reference body, which depends upon the rate of energy uptake accompanying evolution of water.

(16) W. F. Bradley, R. E. Grim and G. L. Clark, *Z. Krist.*, **97**, 216 (1937).

Energy of desorption is constant to within 10% irrespective of the temperature of water evolution. Thus the area under a curve is a measure of the amount of water associated with each component curve provided it is referred to a uniform dry weight of sample. Values listed in the second line beneath the curves were obtained in this manner and can probably be trusted to within 20%. Amounts of water adsorbed per gram of dry material at room temperature, which of course are accurate, are shown in the first line beneath the curves. Results of X-ray diffraction measurements are given in the third line.

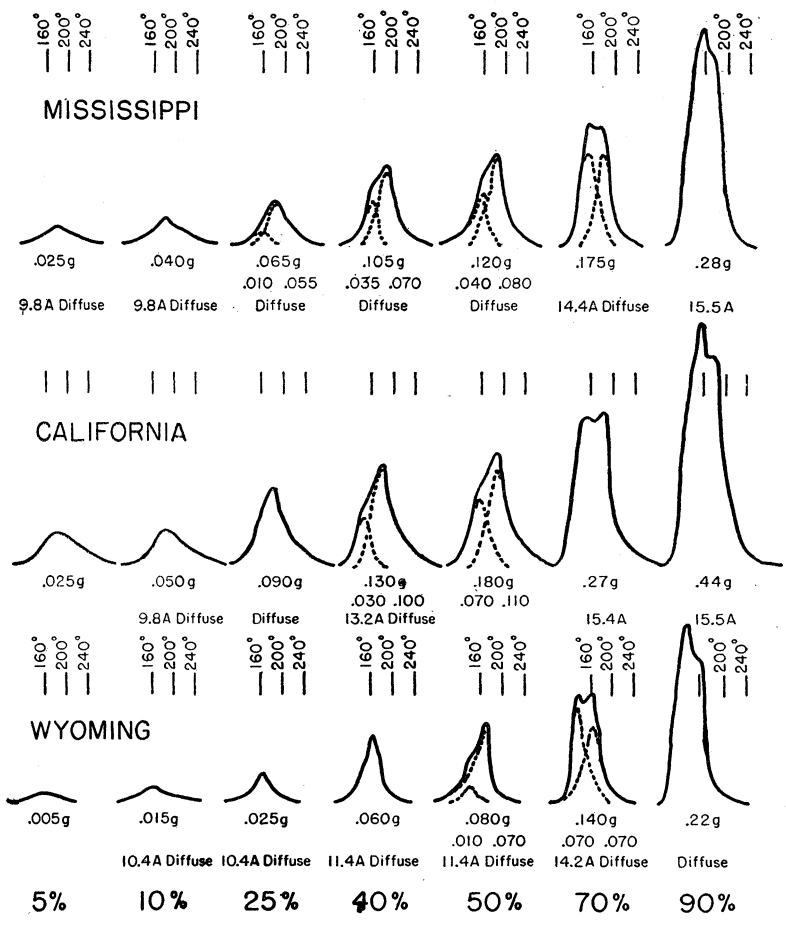

Fig. 2.—Thermal analysis curves of the sodium salts of various montmorillonites. Amounts of adsorbed water and values of the apparent cleavage spacing are given below the curves.

Although differential thermal analysis is a crude method measuring no real physical constant of a system, it enables one to distinguish variations in the binding of water even though such variations might be very small. Temperature of maximum rate of energy absorption is perhaps the best meas-

ure of order of binding energy. Maxima produced by loss of water adsorbed at low humidities occur at the higher temperatures, which is evidence that such water has the higher heat of binding.

Differential thermal analysis curves of the sodium and calcium clays from different localities are reproduced in Figs. 2 and 3. It can perhaps be seen that origin of material is relatively unimportant. For this reason only salts of the Mississippi material were prepared for further examination. Results obtained from them are reproduced in Figs. 4 and 5.

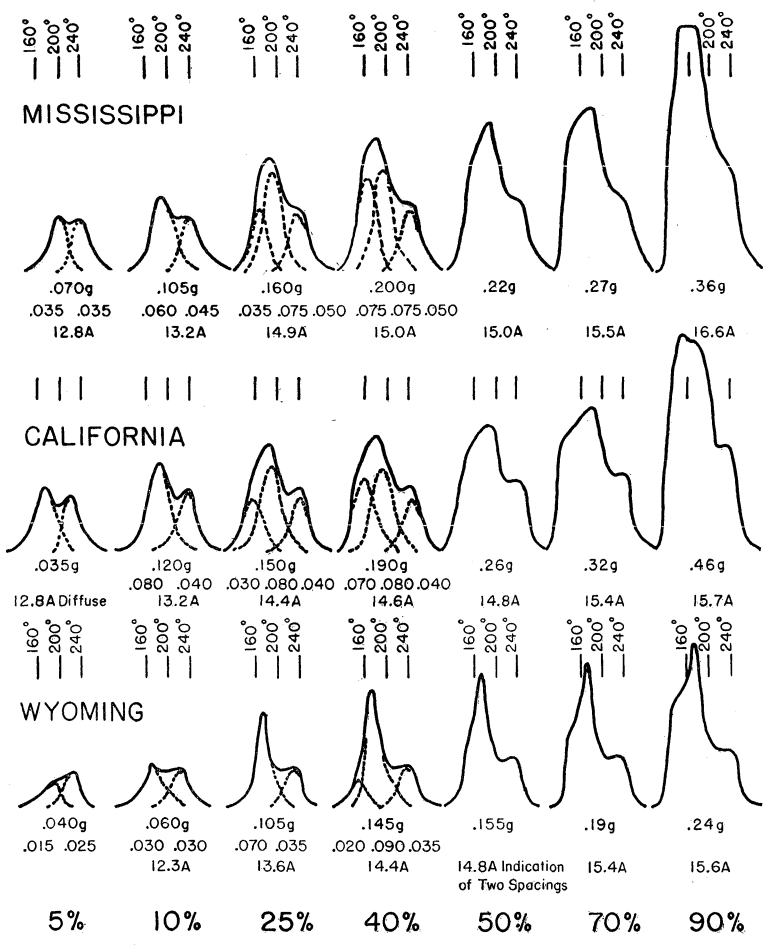

Fig. 3.—Thermal analysis curves, amounts of adsorbed water and values of the apparent cleavage spacing of the calcium salts of various montmorillonites.

An attempt was made, as shown in the figures, to resolve some of the curves into ones with single maxima. This presented some difficulties, but was aided by the fact that the contribution to one maximum was rather well completed before that to another had started. An example will be discussed to illustrate the general procedure. At a 5% R. H. (relative humidity as given at the bottom of the charts) the magnesium salt of Mississippi montmorillonite has a curve that comparison with the alkaline earth salts at the same R. H. indicates is formed from two incompletely resolved components. Moreover, the shape of the curve on the high temperature side shows that the high temperature component is somewhat smaller than the other. At 10% R. H. the second component has increased with little accompanying change of the high temperature component since that part of the curve above 240° has changed but slightly. The slightly convex shape of the low temperature part of the curve, below 180°, suggests that a third component is appearing. This is questionable at 10% R. H. but at 25% R. H. the third component is prominent and apparently accounts for the added water sorption as it also does at 40% R. H. Although the curves of samples with high water content obviously have several components, it was not considered justifiable to attempt the resolution. Attention is called to the cesium salt of Mississippi montmorillonite where the presence of two component curves between 40% and 70% R. H. is indicated by the shifting of the apparent single maximum and the shape of the curve above 180°.

The total area under the two peaks with highest maximum lags in temperature (max. T°C.) of the magnesium and calcium salts of Mississippi montmorillonite represents about 0.12 g. of adsorbed water which is approximately the amount, 0.10 g., required for formation of a single layer of water molecules arranged in the manner shown in Fig. 6. Moreover, the cleavage spacings of the hydrates are between 13.0 and 13.5 Å. which is but slightly more than the expected value, 12.0 to 13.0 Å., for a silicate sheet covered by a single layer of water molecules. Thus it would seem that at least two distinct processes are involved in the formation of the first layer hydrate.

It appears that the peaks having the highest max. T°C. for the magnesium and calcium Mississippi montmorillonites are to be correlated with hydration of the exchangeable cations. The base exchange capacity of this clay is about 0.95 milliequivalent per gram, the actual value varying slightly with the method used for determining it. This is equivalent to 0.00047 mole of Ca^{++} which would require 0.050 g. of water to form a hexahydrate. From the curves it appears that about 0.045 g. of water is associated with the peak having the highest max. T°C. The remaining water contributing to the formation of the first layer hydrate must be that required to hydrate the surface not contiguous to the exchangeable cations. It apparently is held somewhat less strongly since the max. T°C. of the peak associated with it is about 40° lower than the first peak.

Strontium and barium salts of Mississippi montmorillonite show characteristics similar to those discussed above. It is necessary, however, to go to higher humidities in order to have water sorption equivalent to that of the magnesium and calcium salts. As would be expected, accordingly, corresponding max. T°C. peaks are shifted to somewhat lower temperatures, about 20°, for the strontium and barium compounds. This shift makes it difficult to effect the resolution of the experimental curve into three maxima at the higher humidities and thus to determine the point at which the second peak is completed.

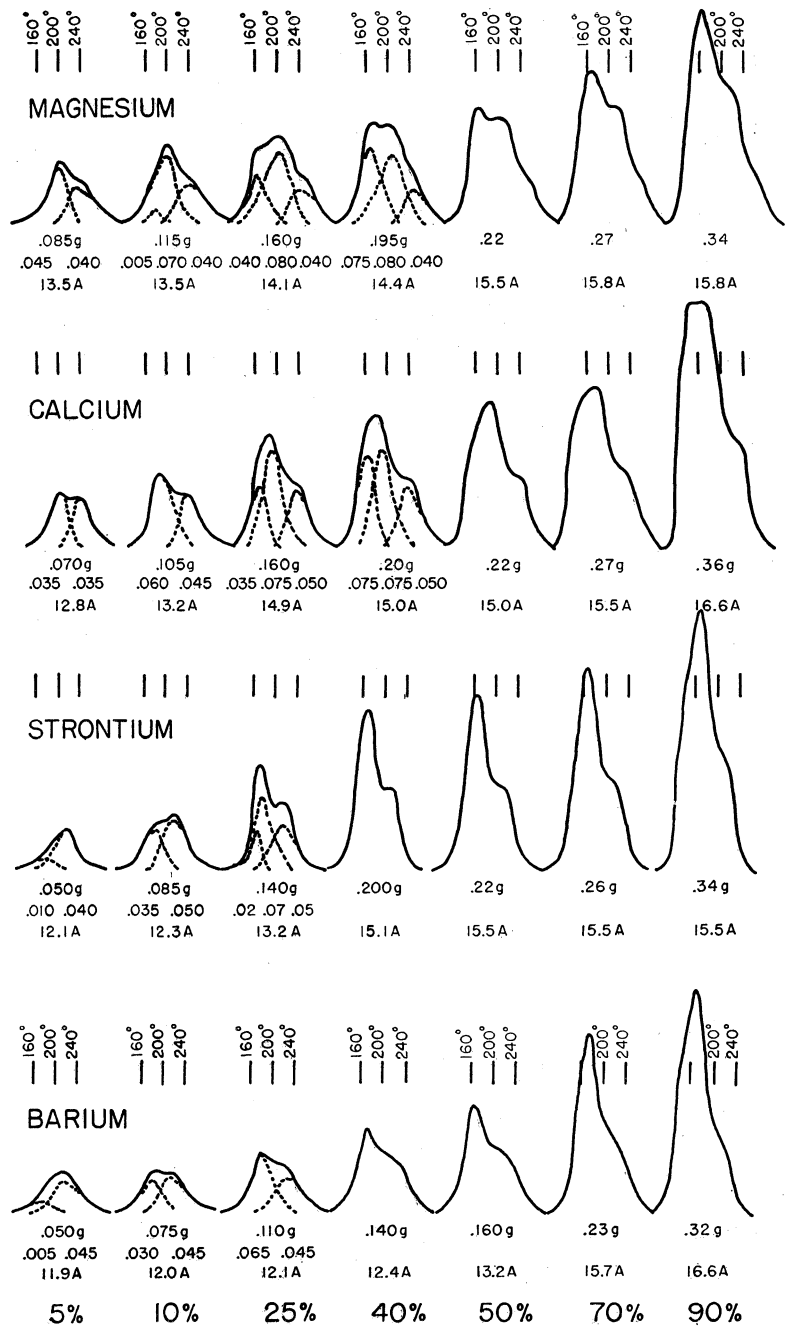

Fig. 4.—Thermal analysis curves, amounts of adsorbed water and values of the apparent cleavage spacing of magnesium, calcium, strontium and barium salts of Mississippi montmorillonite.

Lithium Mississippi montmorillonite is somewhat like the alkaline earth salts in behavior. At low humidities two well-resolved peaks are present. The peak with the highest max. T°C. (235°), which is almost complete at 5% relative humidity, corresponds to about 0.055 g. of water. This is about three (actually 3.3) water molecules for each Li^+ ion, which is the amount expected for plane coördination about a small ion. The second peak has a considerably lower max. T°C. (170°) than does the second peak of the alkaline earth salts. This, as was the case for the strontium and barium salts, makes it difficult to determine when the third peak begins to appear. The

cleavage spacing, however, is constant, as far as can be told, between 5 and 25% relative humidities but increases at 40%.[17] It would appear that the third peak must contribute to the curve at 40% relative humidity and that the second peak is essentially complete at 25%. The total water sorption at 25% relative humidity is about 0.12 g. which again is approximately the same as that required for a single layer of water molecules. While the six-fold coordination of magnesium and the alkaline earth ions would be expected to enhance the stability of a layer of the type shown in Fig. 6, there would possibly be some disrupting effect of lithium. This effect, however, need not completely destroy the structure in the water layer.

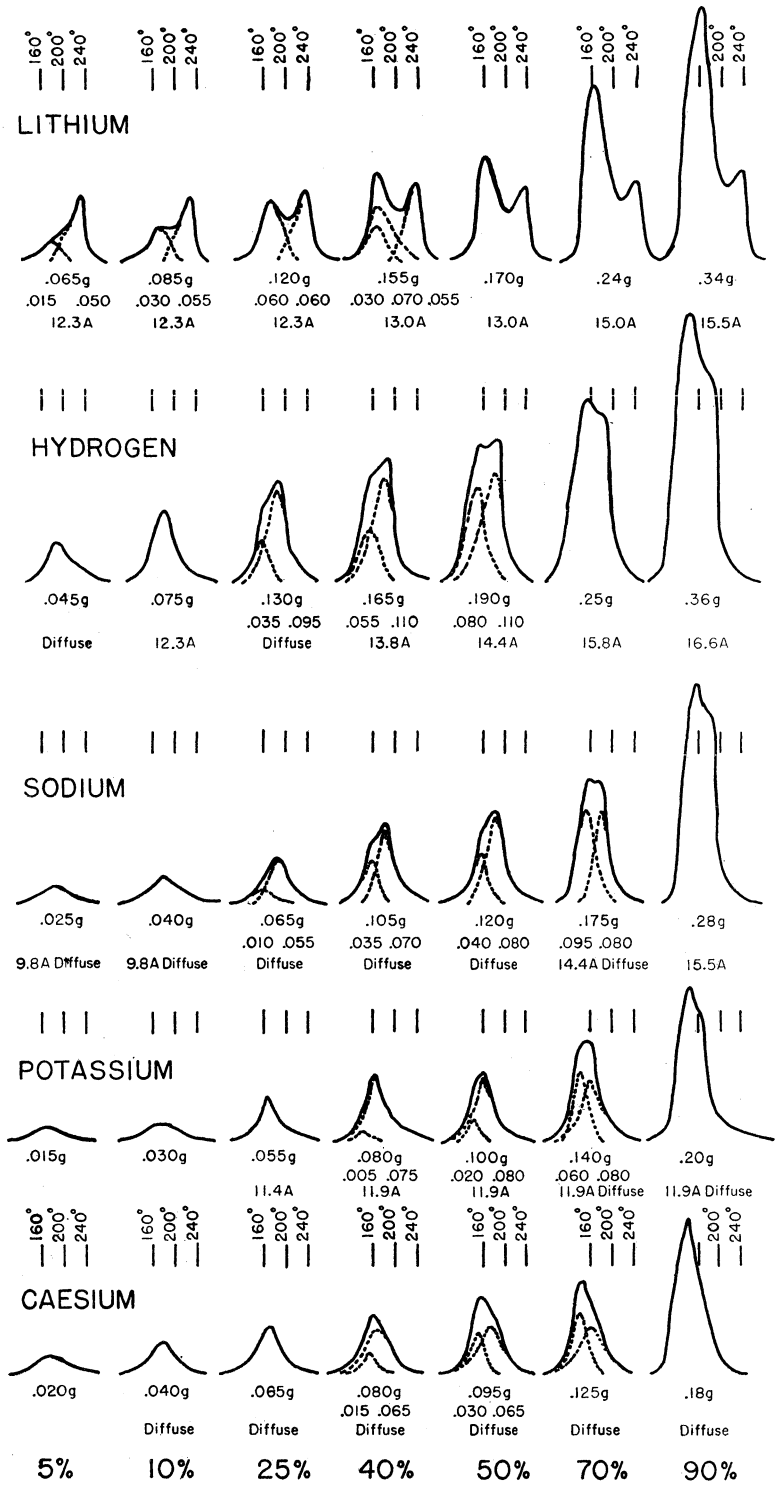

Fig. 5.—Thermal analysis curves, amounts of adsorbed water and values of the apparent cleavage spacing of lithium, hydrogen, sodium, potassium and cesium salts of Mississippi montmorillonite.

The third peak that appears for the lithium, magnesium and alkaline earth salts is probably to be associated with introduction of another layer of water molecules since the cleavage spacing increases, finally reaching a value of 15.0 to 16.0 Å., as the relative humidity is increased. Introduction of a second layer of water molecules is not a particularly simple process since it must influence the energy of binding of water that is already present. As a second layer is started molecules of the first layer are probably redistributed, some of the hydrated ions being in one layer and some in the other. Since the analysis is really made by successive removal of water it does not show what the binding conditions are before any water is removed. Finally at high relative humidities increased water sorption does not further change

(17) It is outside the scope of this work to discuss the crystal structures of montmorillonite and its hydrates in detail, but attention should be called to several facts. The measured interplanar spacings recorded on the figures are definitely not those of the first observed order (n) for some of the lithium, calcium, and hydrogen samples, but rather appear to be the second order ($2n$) since an apparent third order ($3n$) is present. We suspect, without analysis, that this is a result of the averaging effect previously mentioned.

the apparent cleavage spacing. Either the additional water is not between silicate layers or the diffraction pattern is due to only a minor part of the total sample. Both actually seem to play a part.

The most striking difference in the behavior of the sodium, potassium and cesium salts of Mississippi montmorillonite from that of the salts already considered is that only a single peak is present at low humidities. Furthermore, the value of max. T °C. is about the same for this peak, about 180°, as for the second peak of the strontium and barium salts. The two are completed at about the same value of the relative humidity and correspond to approximately the same amount of water, 0.06 to 0.08 g. These features indicate that the exchangeable cation is probably not hydrated in the sodium, potassium and cesium salts, although this interpretation is open to some question. Such a result might be expected for the cesium ion[18] from its behavior in solutions and to a lesser extent for the potassium ion.

Sodium, potassium and cesium salts are further characterized by a very poor degree of organization, as evidenced by the diffuseness of the X-ray diffraction patterns. Even at 90% relative humidity the potassium salt although containing enough water for two layers still shows the spacing of a single layer hydrate. The general character of these photographs, however, indicates that probably only a small portion of the material is sufficiently organized to give a diffraction pattern. This organized portion then is the single layer hydrate, which is indicative of an even more difficult formation of the multiple layer hydrate. The sodium salt is well enough organized to show the expected increase in X-ray spacing when a considerable amount of the double layer hydrate is present.

The free acid of the Mississippi clay has perhaps the simplest behavior of any of the materials examined. A single peak with a max. T °C. of 180° corresponding to the second peak of the alkaline earth salts is completed at about 25% relative humidity. The cleavage spacing is that of a single layer hydrate and the degree of organization as judged by diffuseness is high. Water sorption associated with this peak is about 0.10 g., which is the amount required for hydration of a layer according to the structure shown in Fig. 6. It would appear therefore that the hydrogen ion has little influence on the hydration. This is

(18) J. D. Bernal and R. H. Fowler, *J. Chem. Phys.*, **1**, 515 (1933).

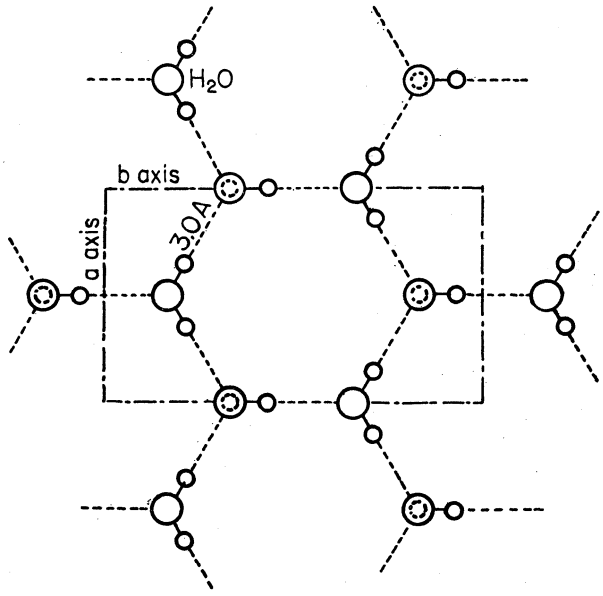

Fig. 6.—Possible arrangement of water molecules in a hydrated layer of vermiculite or montmorillonite.

reasonable when it is remembered that the hydrogen ion, being very small, is probably embedded in the silicate sheet near the site of the effective negative charge. There is no indication of hydration of the proton with formation of a hydronium $(H_3O)^+$ ion which in turn would hydrate.

Consideration of the preceding discussion shows that the evidence for the base exchange ions being between the silicate layers in montmorillonite is rather conclusive.

The total surface of water sorption by montmorillonite is about 8×10^6 sq. cm. per g., which is of the order of fifty times the observed surface for sorption of gases such as nitrogen and oxygen.[19] In other words, the internal surface reached by water in montmorillonite, as might be expected, is not available for van der Waals adsorption of most gases. Adsorption of nitrogen and oxygen rather measure the external surface area of the organized montmorillonite crystal which would not be greatly changed in formation of the internally hydrated material. Comparison of these areas shows that the individual montmorillonite crystals contain fifty to a hundred silicate layers, which is within the range indicated by electron diffraction and interference of visible light.

Summary

The water sorptions at relative humidities between 5 and 90% were measured for the Li^+, Na^+,

(19) B. Makower, T. M. Shaw and L. T. Alexander, *Proc. Soil Sci. Soc. Am.*, **2**, 101 (1937).

K^+, Cs^+, Mg^{++}, Ca^{++}, Sr^{++}, and Ba^{++} salts as well as the free acid of the clay mineral montmorillonite. Variations in X-ray diffraction patterns and behaviors upon differential thermal analyses were determined for the materials at the various relative humidities.

Results obtained indicate that the exchangeable cations are located between the silicate layers of which the mineral is formed. In the magnesium and alkaline earth salts, the first step of water sorption is the hydration of the cation with six molecules of water which is followed by completion of a water layer having a hexagonal type structure. A second water layer of similar structure is taken up at high relative humidities. Similar results were obtained for the lithium salt except that only three molecules of water were required for the hydration of the lithium ion. In sodium, potassium, and cesium salts the cation apparently was not hydrated. This was also true for the hydrogen ion in the clay acid.

The methods used in the work although inexact give a clear picture of the sorption process for water, which is entirely different from van der Waals adsorption of gases such as nitrogen.

The Heats of Dilution, Heat Capacities, and Activities of Urea in Aqueous Solutions from the Freezing Points to 40°[1,2]

BY FRANK T. GUCKER, JR., AND HUGH B. PICKARD

Introduction

In the study of solutions of non-electrolytes, a number of thermodynamic properties of aqueous solutions of urea have been determined in this Laboratory. We have found that, up to a concentration of 3 *M*, the apparent molal volume[3] of urea at 25 and 30° and the apparent molal expansibility[4] at 27.5° are linear functions of the first power of the concentration. Such a relationship is to be expected for many properties of non-electrolytes. Redlich and Klinger[5] found that it was the limiting law for the apparent molal volume of sucrose, and work in this Laboratory showed that it also was the limiting law for the apparent molal heat capacity[6] and heat content[7] of sucrose. An exhaustive study of the specific heats of aqueous solutions of urea[8] failed to determine unequivocally what limiting law was obeyed by the apparent molal heat capacity of urea. Heats of dilution can be measured in very dilute solutions, the specific heats of which differ from unity by an amount too small to measure directly. Hence the limiting value of the apparent molal heat content can be determined more accurately than that of the heat capacity. We therefore undertook a study of the heats of dilution of solutions of urea in order to find the limiting law for this property.

Our results also provide the final thermal data necessary for an accurate calculation of the change of the osmotic and activity coefficients of urea over a temperature range from 2 to 40°. Thus we can compare the results of vapor pressure measurements at different temperatures, and of freezing point depressions, with recent precise measurements of the vapor pressures of aqueous solutions of urea at 25°.

Heats of Dilution at 25°

Materials and Solutions.—The urea used in experiments 1–6 had been purified and used in the density determinations carried out in this Laboratory. It had been reclaimed several times by precipitation from 50% alcohol, as described in this work.[3] The urea used in experiments 7–23 was prepared from Mallinckrodt analytical reagent. It was recrystallized once from water, washed once with 95% alcohol, filtered on a sintered glass filter and dried overnight in a vacuum desiccator connected to a water aspirator. After being ground in an agate mortar, it was dried for seven or eight hours *in vacuo* at 50–60°. This purified material showed a conductance corresponding to only 0.004% electrolyte calculated as sodium chloride.

The distilled water used in making up the solutions had a specific conductance of 3×10^{-6} reciprocal ohm or less.

(1) Most of the material in this paper was presented before the Division of Physical and Inorganic Chemistry at the Boston Meeting of the American Chemical Society, September 14, 1939.

The solutions used in experiments 1, 5, 7–10, 13, 14, 16 and 19–23 were made up determinate. Those used in the other experiments were the products of previous dilutions.

Experimental Methods.—The twin-calorimeter apparatus, sensitive to 1 microdegree, which was used to measure the heats of dilution of urea, has been described in a previous paper.[7] The experimental procedure was the same except for a few slight modifications. In order to increase the rate of heating, the 50-ohm calorimeter heaters were replaced by 25-ohm heaters in experiments 19–23.

In our apparatus, electrical heating cannot always be supplied rapidly enough to balance the heat of dilution at each instant. Since the thermal conductance constant is very low, no appreciable error is caused by heat leakage unless a heat change of more than a quarter of a calorie is involved. In these experiments, the pipet is opened not at the *beginning* but in the *middle* of the heating period.

Two types of experiment were carried out. In the first, a small amount of water (2.8–58 ml.) in the pipet was added to a large volume of solution (900 ml. to 1 liter) in the calorimeter. This caused a small change in molality, Δm, and gave a short chord on the heat content–molality curve. In the second type of experiment, a small quantity of solution was diluted with a large amount of water, giving a long chord on the heat content–molality curve.

In most of the experiments, the pipets were only partially filled with liquid. For example, in experiments 13 and 14 at 3 m, the pipets contained only about 3 ml. of water and 57 ml. of air. This introduced unexpected complications. The air is saturated with water vapor, at the vapor pressure of pure water, p_0. After the pipet is opened, this same air is in contact with the *solution*, having a vapor pressure $(p_0 - \Delta p)$. A small quantity of water therefore will condense and the heat of condensation will be added to the observed heat of dilution. This is practically the same as the heat of condensation of the same amount of water vapor on pure water, since the values of $\bar{L}_1$ which we calculate later are quite small. Taking the recent value of Osborne, Stimson and Ginnings[9] for the latent heat of vaporization of water at 25°, the heat evolved for V ml. of air in the pipet is

$$-\delta q = \frac{273}{298} \times \frac{\Delta p}{760} \times \frac{V}{22{,}400} \times 10{,}510$$
$$= 0.000566\, V \Delta p \text{ cal.}_{15}$$

Values of the vapor pressure of urea solutions, which are very nearly those calculated from Raoult's law, were taken from the paper of Scatchard, Hamer and Wood.[10] This correction then was applied to the experimentally measured values of q to give the actual heat effect caused by the dilution.

In experiments 13, 14, and 19–23, a small amount of solution was added to a large amount of water. In this case δq was positive (heat was absorbed) since the vapor pressure of the final 0.01 m solution was greater than that of the 3 m solution over which the air originally stood. In experiments 3–7 the volume of air in the pipet was 10 ml. or less and Δp was small so that δq was negligible and no correction was applied.

Experimental Results.—The experimental results are summarized in Table I, which includes all but eight dilutions. Seven of these could not be completed, because of mechanical failures. One dilution of experiment 13 was rejected. This result was very low, probably because the valves of the pipet leaked.

The temperature at which the dilution took place was read from a standardized Beckmann thermometer. This temperature seldom varied from 25° by more than 0.03° and never by more than 0.05°. No correction was necessary for this difference, since the slope of the apparent molal heat capacity curve for urea at 25° is small.

We analyzed the results by the same methods we had used for sucrose.[7] The values of $\Delta H/\Delta m$ obtained from the short chord experiments, when plotted against m, were found to lie along a smooth curve, which could be represented by the equation

$$\Delta H/\Delta m = -85.87 + 12.88\, m - 0.795\, m^2 \qquad (1)$$

The coefficients of this equation were determined by the method of least squares, weighting each experiment in proportion to the heat change which was measured. The experimental results, together with the graph of this equation, are plotted in Fig. 1. The chords are short, corresponding to a change of only 0.01 in m, so that they are plotted simply as points. The satisfactory agreement is apparent from the graph.

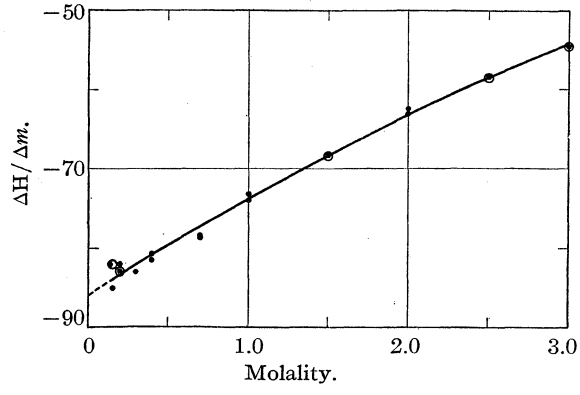

Fig. 1.—Slopes of dilution curve for urea at 25°.

Integration of equation (1) gave for the apparent relative heat content the equation

$$\Phi L_2 = \Phi H_2 - \Phi H_2^0 = -85.87\, m + 6.44\, m^2 - 0.265\, m^3 \qquad (2)$$

From this equation we calculated the values of q which are given in column 5 of Table I. The values for the two dilutions of an experiment usu-

ally were slightly different, because different quantities were used in the two calorimeters, although the change in concentration was the same. As the figures in column 6 show, equation (2) reproduces the experimental results up to 3 m very satisfactorily, with an average deviation of ±3.3 microdegrees. The equation shows increasing deviations, however, when applied to our later results at higher concentrations. When all of our results were employed to calculate the coefficients by the method of least squares, the resulting cubic equation gave better agreement at high concentrations but yielded a limiting slope inconsistent with our experiments at low concentration.

Finally we obtained a fourth degree equation, retaining the limiting slope of equation (2) and calculating the other coefficients from the results of experiments 13 and 14, 20 and 23 at 3, 8 and 12 m. This equation was

$$\Phi L_2 = -85.87\, m + 6.815\, m^2 - 0.4569\, m^3 + 0.01471\, m^4 \quad (3)$$

Values of q for each dilution, calculated from this equation, are included in column 7 of Table I. As the figures in column 8 show, this gives reasonably satisfactory agreement with all our experimental results. Up to 1.5 m concentration, the difference averages ±2.7 microdegrees, and over the whole range it averages ±7.6 microdegrees.

From equation (3), the partial relative molal

heat contents of urea and water were calculated by the methods used in our previous work.[7] The results are plotted in Fig. 2.

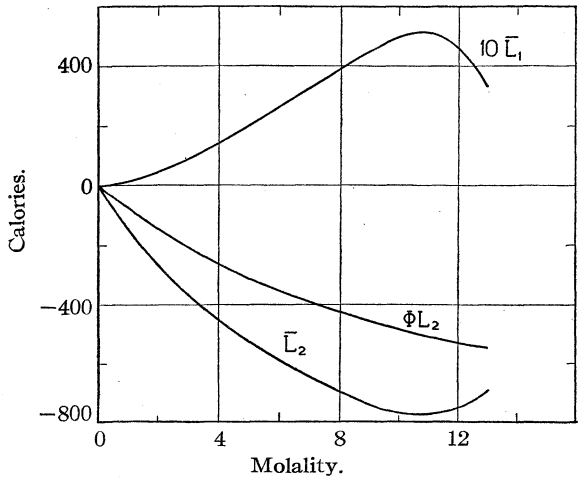

Fig. 2.—Apparent and partial relative molal heat contents for urea and water at 25°.

Discussion of the Heats of Dilution.—In magnitude, the heat of dilution of urea is even smaller than that of sucrose, showing that urea is more nearly an ideal solute. Our results are in general agreement with those of Naudé[11] at 18°, as we shall show in more detail after a discussion of the heat capacities.

In dilute solutions, the apparent molal heat content of urea is a linear function of the first power of the molality. It therefore parallels the volume properties. This is to be expected on the basis of what little theory has been developed for such solutes. For instance, Fuoss[12] has calculated the free energy of a dipolar solute of small dipole moment. From his theory, we can show that the apparent molal heat content of such a solute should be a linear function of the first power of the concentration. The surprising thing about the results is the *sign* of the heat of dilution. The separation of electrical dipoles, like that of ions, should cause a *liberation* of heat in a solvent having a dielectric constant with a temperature coefficient like that of water. It is hard to see how any purely electrostatic forces could account for a negative limiting slope. However, we have found the same negative slope in the case of glycine, which we expect to publish shortly.

(12) Fuoss, THIS JOURNAL, **58**, 982 (1936).

Apparent Molal Heat Capacities

Since the apparent molal heat content is a linear function of the molality at low concentrations, its temperature coefficient, the apparent molal heat capacity, doubtless obeys the same limiting law and should be expressed by a power series in m

$$\Phi C_{p_2} = \Phi C^0_{p_2} + am + bm^2 + cm^3 + \ldots \quad (4)$$

Accordingly we took the data of Ayres[6] and plotted the apparent molal heat capacity against the molality at each of the six temperatures he investigated. The results, as shown in Fig. 3, lie along smooth curves. The best coefficients for cubic equations in m were determined by the method of least squares. Each value of the apparent molal heat capacity was weighted in proportion to its accuracy, assuming the same precision for the specific heat s at all concentrations.

The resulting equations reproduced all 74 of the experimental points satisfactorily. Only one deviation was greater than 0.03% in s, seven were between 0.02 and 0.03%: and eighteen between 0.01 and 0.02%. The average deviation, $\pm 0.007\%$ in s, is slightly smaller than the average of $\pm 0.0085\%$ from the third degree equations in $m^{1/2}$ which were used in the original publication[6]

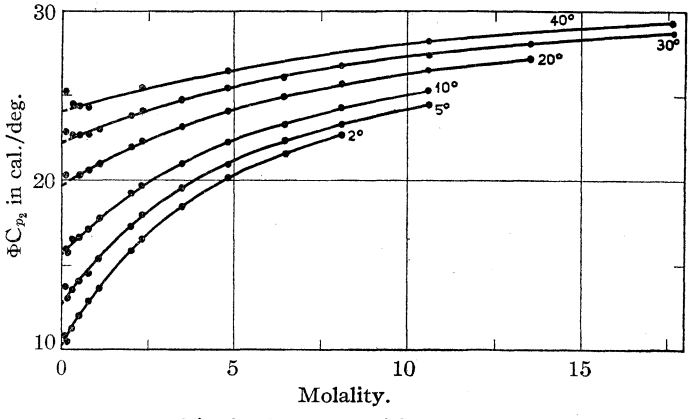

Fig. 3.—Heat capacities of urea.

of these data. This comparison emphasizes the difficulty in determining the limiting law from specific heat measurements. However, it shows that the limiting slope linear in m, indicated by the more sensitive measurements of heats of dilution, is consistent with the specific heats.

The coefficients of equation (4) are measured in calories at the experimental temperature. In order to be combined with our heats of dilution they are first changed to 15°-calories, using the values of the heat capacity of water at different

temperatures recently determined by Osborne, Stimson and Ginnings at the National Bureau of Standards.[13] The coefficients then were plotted against the centigrade temperature, t. As shown in Fig. 4, all four change in about the same way with temperature. The values of $\Phi C^0_{p_2}$ and b increase more rapidly at low temperatures, while those of a and c decrease correspondingly. Assuming the change of each coefficient is a quadratic function of $(t - 25)$, *e. g.*

$$\Phi C^0_{p_2} = \Phi^0_{25} + k_1(t - 25) + k_2(t - 25)^2 \qquad (5)$$

we evaluated the constants k_1 and k_2 by the method of least squares, weighting each according to the accuracy with which it was calculated from the original data. Thus the value of c, the coefficient of m^3 in equation (4), is fixed 20 times as accurately at 30°, by the series of fourteen experiments extending up to 17.6 m, as at 2°, where the twelve experiments extended only to 8.1 m. The differences in the accuracy of the coefficients of the lower powers of m were progressively less.

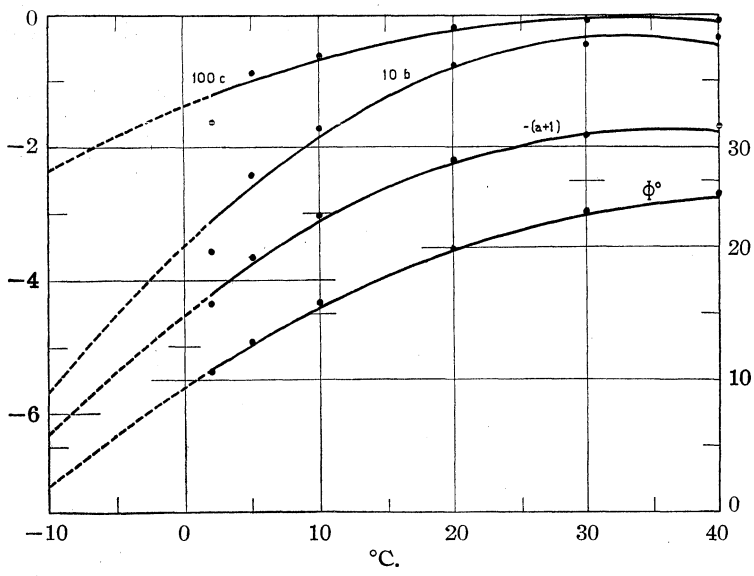

Fig. 4.—Constants for heat capacities of urea.

The curves of Fig. 4 represent these equations. The deviations, which appear to be random, average ±0.236 in $\Phi C^0_{p_2}$, ± 0.0898 in a, ±0.0175 in b and ±0.00120 in c. Because of the decreased accuracy of the coefficients of higher powers of m at low temperatures, the scattering in Fig. 4 is more pronounced at low temperatures. Fortunately the importance of these coefficients also decreases at low temperature, because of the decreased solubility of urea. Using the equations thus derived, coefficients of equation (4) were calculated at all six temperatures. Values of specific heats, calculated from these smoothed equations, were compared with the original experiments. The average deviation was ±0.033%. The two largest deviations, −0.236 and −0.500%, were for the 17.6 m solution at 30 and 40°. The average deviation of all the other results, up to and including 13.5 m, was ±0.024%. Of the individual deviations, 22 are less than 0.01%, 26 lie between 0.01 and 0.02%, 4 between 0.02 and 0.03%, 7 between 0.03 and 0.04%, 5 between 0.04 and 0.05%, 4 between 0.05 and 0.06%, 2 between 0.06 and 0.07% and 1 (13.5 m at 20°) is 0.22%. At any one temperature, the deviations are of the same sign, but the average net deviation is only −0.01%.

These figures indicate that, up to 12 m, which is the limit of the heats of dilution, the results can be expressed fairly satisfactorily by means of quadratic equations in the temperature, over the range from 2 to 40°. The values plotted in Fig. 4 indicate, however, that the coefficients of equation (4) approach zero at higher temperatures, instead of going through a maximum value and then decreasing as demanded by a quadratic equation in the temperature. A different type of equation might be required to fit the results of a series of heat capacity measurements extended to higher temperatures. At the lower temperatures, our equations are consistent with the experimental results and seem reasonable bases for extrapolation. Also, the decreased solubility at low temperatures limits the range to which the equations can be applied, and this helps to compensate some of the uncertainty of extrapolation.

Apparent and Partial Relative Heat Contents at Different Temperatures.—From equation (4) we can obtain the apparent relative heat capacity of the solute, $\Phi C_{p_2} - \Phi C^0_{p_2}$. Since this is the temperature coefficient of the apparent relative heat content, and a, b and c are known functions of temperature, we can integrate to obtain the apparent relative heat content at any temperature between 2 and 40°. The equation is

(13) Reference 9, Table 6.

$$\Phi L_2 = \Phi L_2'' + \Delta\Phi C_{p_2}(t - 25) + \Phi P_2(t - 25)^2 + \Phi Q_2(t - 25)^3 \quad (6)$$

where $\Phi L_2''$ at 25° is given by equation (3), and the other terms are

$$10^3\Delta\Phi C_{p_2} = 940.0\ m - 49.4\ m^2 + 1.11\ m^3 \quad (7)$$

$$10^5\Phi P_2 = -2306\ m + 236.9\ m^2 - 1.88\ m^3 \quad (8)$$

$$10^7\Phi Q_2 = 7423\ m - 955\ m^2 + 1.71\ m^3 \quad (9)$$

In 1928, Naudé[11] studied the heats of dilution of urea from 1 to 0.001 M, at temperatures near 18°, using one of the first microcalorimeters. Previous work in this Laboratory[3] has shown that the apparent molal volume of urea changes very little with temperature, hence the difference between molarity (moles per liter) and molality, m, is practically the same at 18 as at 25°. On this basis we have converted Naudé's results to 25°. For dilutions from 0.333 M (0.340 m) to 0.0067 M (or m) at 18.51°, he found $\Delta H = 28.5$ cal./mole. From equation (6) the value should be 2.4 cal./mole less, or 26.1 cal./mole at 25°. Our equation (3) gives 27.8 cal./mole for this dilution. His value of 14.0 for the dilution from 0.1 to 0.003 M is decreased by 0.8 to 13.2 cal./mole, compared to 8.3 calculated from equation (3). These differences of −1.7 and +4.9 cal./mole correspond to −11 and +15 microdegrees. This agreement was typical of the five results up to 0.5 M. His 2 results at 1 M gave larger deviations of about 60 microdegrees.

From equation (3) for the apparent relative heat content of urea, the equations for $\bar{L}_2$ and $\bar{L}_1$, the partial relative heat contents of urea and water are calculated by the general thermodynamic relations. If G represents any extensive property of a solution of n_1 moles of water and n_2 of solute, and G_1 is the corresponding molal property of the water, the apparent molal property, ΦG_2 is defined by the equation

$$G = n_1G_1 + n_2\Phi G_2 \quad (10)$$

If ΦG_2 is represented by the equation

$$\Phi G_2 = \Phi G_2^0 + am + bm^2 + cm^3 + \ldots \quad (11)$$

the corresponding equations for $\bar{G}_2$ and $\bar{G}_1$, the partial molal properties of solute and water, respectively, are

$$\bar{G}_2 = \Phi G_2^0 + 2\ am + 3\ bm^2 + 4\ cm^4 + \ldots \quad (12)$$

$$\bar{G}_1 = G_1 - 0.018016[am^2 + 2\ bm^3 + 3\ cm^4 + \ldots] \quad (13)$$

These relationships hold for the arguments of equations (3), (7), (8) and (9).

The Change of Activity with Temperature

The difference between the activity a' of any component of a solution at a temperature T' and its activity a'' at a temperature T'' is given by the well-known thermodynamic equation[14]

$$\log a'' - \log a' = \frac{-0.43429}{R}\int_{T'}^{T''}\frac{\bar{L}}{T^2}\,dT \quad (14)$$

where R is the gas constant and $\bar{L}$ the partial relative heat content. If $\bar{L}$ is a cubic function of T, the integrated form of equation (14) is

$$\log a'' - \log a' = K_1\bar{L}'' + K_2\Delta\bar{C}_p'' + K_3\bar{P} + K_4\bar{Q} \quad (15)$$

where

$$K_1 = \frac{-0.43429}{R}\frac{\Delta T}{T'T''}, \text{ where } \Delta T = T'' - T' \quad (16)$$

$$K_2 = \frac{0.43429}{R}\left[\frac{\Delta T}{T'} - \ln\left(\frac{T''}{T'}\right)\right] \quad (17)$$

$$K_3 = \frac{-0.43429}{R}\left[\Delta T + T''\left\{\frac{\Delta T}{T'} - 2\ln\left(\frac{T''}{T'}\right)\right\}\right] \quad (18)$$

$$K_4 = \frac{0.43429}{R}\left[3T'\Delta T + 4.5(\Delta T)^2 + \frac{(\Delta T)^3}{T'} - 3T''^2\ln\left(\frac{T''}{T'}\right)\right] \quad (19)$$

The coefficients K_1, etc., are functions only of the temperatures involved. The first can be evaluated easily by direct substitution but the rest cannot, since the logarithmic term differs from the sum of the others by only 4, 0.1 and 0.005%, respectively. However, on expanding the logarithm in series, many of the largest terms cancel and we obtain the following expressions for the coefficients, chiefly in terms of the variable $v = \Delta T/T'$.

$$K_2 = \frac{0.43429}{R}v^2[1/2 - v/3 + v^2/4 + \ldots] \quad (20)$$

$$K_3 = -\frac{0.43429}{R}v^3[T' - 2T''/3 + 2\Delta T(1 + v)\,(1/4 - v/5 + v^2/6 + \ldots)] \quad (21)$$

$$K_4 = \frac{0.43429}{R}v^4\left[\frac{T'^2}{4} - \frac{T'\Delta T}{10} - \frac{9(\Delta T)^2}{20} - \frac{3(\Delta T)^2v}{5} + 3(\Delta T)^2(1 + v)^2\,(1/6 - v/7 + v^2/8 + \ldots)\right] \quad (22)$$

In evaluating the coefficients, only four or five terms of each power series in v are necessary to give results to 0.01%. In Table II we have recorded values of these coefficients for changes from the given initial temperatures T' to the standard temperature $T'' = 298.16°$.

The values of K_1 are 0.03% higher than those tabulated by Lewis and Randall (p. 615), because of our use of $R = 1.9869$ cal.$_{15}$ deg.$^{-1}$ mol.$^{-1}$ for the gas constant and 273.16° A. as the freezing point of water.[15] Our values of K_2 agree with

(14) Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., Inc., New York, N. Y., 1923, p. 289.

(15) These values were obtained from a critical compilation by Dr. F. D. Rossini, privately communicated to us through Professor Scatchard.

TABLE II[a]

[a] The energy unit of this table is the 15°-calorie, which is used throughout this paper: 1 $cal._{15}$ = 4.1858 abs. j. (ref. 9, p. 238).

those of Lewis and Randall, but are carried two places farther. T. F. Young,[16] in his excellent treatment of the calculation of activities from freezing points, has taken account of the quadratic change of $\bar{L}$ with temperature. He has tabulated values of Ω, the coefficient defined in equation (10) of his paper, which is equal to $-1/2\ K_3$. This unpublished tabulation, extending from −25 to 0°, he kindly sent to us in a private communication.

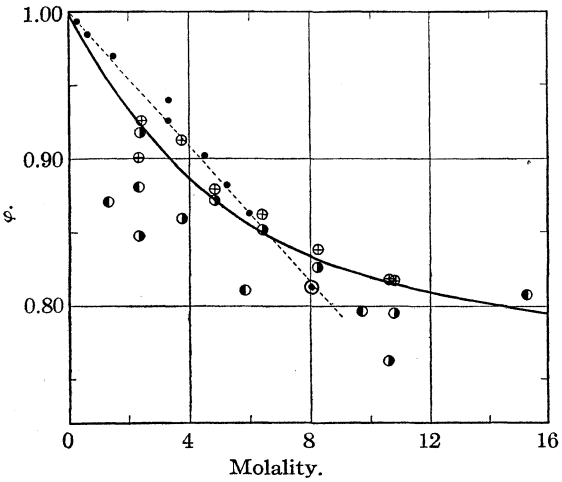

Fig. 5.—Osmotic coefficients of urea at 25° (curve from Scatchard, Hamer and Wood); ◑, Fricke at 0°; ⊕, Fricke at 10°; ◐, Perman and Lovett at 50°; ● and ○, Chadwell and Politi at f. p. (The first point represents 2 results.)

In describing the behavior of the solvent in an aqueous solution, Bjerrum's osmotic coefficient

$$\varphi = -\frac{55.506}{m} \ln a_1 \qquad (23)$$

is a convenient function since it can be calculated directly from measurements of the vapor pressure or freezing point of the solution.

The activity coefficient is related to the osmotic coefficient by the isothermal equation

$$\ln \gamma = (\phi - 1) + \int_0^m (\phi - 1)\, d \ln m \qquad (24)$$

If values of ϕ or γ at any temperature are known at definite concentrations, and the thermal terms are also known, the values of ϕ or γ at any other temperature can be calculated. If either ϕ or γ at any temperature is known as a function of m, and the thermal terms are also known as functions of m, ϕ or γ at any other temperature in the experimental range can be determined as a function of m by algebraic addition of the necessary equations. These methods are applicable to the results of isothermal vapor pressure measurements.

When solvent activities are determined from freezing points, they corrrespond to the temperature of the freezing point, which decreases with concentration. Knowing ϕ' at a definite freezing point, we can interpolate values of the coefficients from Table II and calculate ϕ at 25° from our thermal data.

The Osmotic Coefficient of Urea at 25°

Scatchard, Hamer and Wood[10] have made a very careful study of isotonic solutions at 25°. By intercomparison with the best results for several standard substances, they have determined the vapor pressure and tabulated the osmotic coefficient of urea at this temperature. The smooth curve of Fig. 5 represents their results. Our thermal data allow a comparison between their results and other studies at different temperatures, excluding the early work, in which the experimental uncertainty is large.

Fricke[17] has measured the vapor pressure of urea solutions at 0 and 10°. From these data we have calculated ϕ, first at the experimental temperature and then, by means of equations (15) and (23), at 25°. The resulting values are plotted in Fig. 5. The deviations from the curve corresponded to

(16) T. F. Young, *Chem. Rev.*, **13**, 103 (1933).

(17) Fricke, *Z. Elektrochem.*, **33**, 441 (1927); **35**, 631 (1929).

average differences of +0.010 mm. in the vapor pressure at 0° and −0.004 mm. at 10°, which appear to be within the experimental error. Perman and Lovett[18] measured vapor pressures at 50° and higher. We calculated values of ϕ from their results at 50°, which did not involve too great extrapolation of our thermal data. The points, plotted in Fig. 5, show an average deviation from the curve of +0.18 mm. in the vapor pressure, which also appears to be within the experimental error. The results of these three series of vapor pressure measurements therefore corroborate the curve of Scatchard, Hamer and Wood.

Recently, Chadwell and Politi[19] have determined the freezing points of aqueous solutions of urea from 0.3 to 8.08 *m*, the eutectic, and calculated ϕ', the osmotic coefficient at the freezing point. After interpolating the coefficients from Table II, we used equations (15) and (23) to calculate the corresponding values of ϕ, at 25°, which we plotted in Fig. 5. The deviations in ϕ are smaller than those among the vapor pressure measurements, but they are systematic. The points all lie along the dotted straight line which crosses the curve of Scatchard, Hamer and Wood at about 7 *m*. Below this concentration, the freezing point depressions observed by Chadwell and Politi are *higher* than those which would be expected from the vapor pressure and thermal data, while their two concordant results at 8.08 *m* are *lower*. The deviation is only +0.004° in the 0.3 *m* solution, but it increases to +0.25° at 3.4 *m* and −0.32° at 8.1 *m*.

We have estimated the part of this discrepancy which might be due to our thermal measurements, as follows. From the differences between the heats of dilution observed and those calculated from equation (3), the corresponding differences in $\bar{L}_1$ were determined at a series of even concentrations. The uncertainty in $\Delta\bar{C}_{p_1}''$ at the same concentrations was then estimated as the average difference between $\Delta\bar{C}_{p_1}$ at each temperature, calculated from the original equation (which best fitted the measured specific heats) and the final equation (which smoothed the results at all temperatures). The corresponding uncertainty in $\bar{P}_1$ and $\bar{Q}_1$ was estimated by assuming an error in $\Delta\bar{C}_{p_1}$ at 2 and 40° equal to that in $\Delta\bar{C}_{p_1}''$ at 25°, but opposite in sign. The resulting differences in these three terms, multiplied by the appropriate factors, gave the corresponding differences in ϕ. The sum of these differences, taken as a generous estimate of the error in the thermal terms, was 2, 3, 4, 5, 20 and 44 × 10^{-4} at 0.5, 1, 2, 4, 6 and 8 *m*. Up to 4 *m*, the three heat capacity terms made up 80–90% of the whole uncertainty, but at 6 and 8 *m* their contribution had fallen to about 50%. Up to 4 *m*, these figures would account for only 2% of the observed differences between ϕ calculated from freezing points and from vapor pressure measurements at 25°. At 6 and 8 *m* they would account for 38 and 20% of the difference. The remaining difference, at all but the lowest concentrations, is far larger than would be expected from the sensitivity of the measurements involved, and from the agreement between the results of freezing point and e. m. f. measurements in the case of hydrochloric acid, reported by Chadwell a few years ago.[20] We considered the possibility of solid solution of the urea in the ice, but this would lead to a negative error in ϕ at all concentrations.

Acknowledgments.—In addition to the grants-in-aid from the Penrose Fund of the American Philosophical Society and from the Graduate School of Northwestern University, it is a pleasure to acknowledge the courtesy of Professors George Scatchard and T. F. Young in reading the manuscript and making helpful suggestions in connection with it.

Summary

We have used a calorimeter sensitive to one millionth of a degree in measuring the heats of dilution of aqueous solutions of urea at 25°, from 12 *m* to 0.005 *m*. At low concentrations the heat of dilution is a linear function of *m*.

Combining these results with the heat capacities of urea from 2 to 40°, previously determined in this Laboratory, yields equations for the heat of dilution and the partial relative molal heat contents of urea and water as cubic functions of temperature.

These data are used to calculate ϕ, the osmotic coefficient at 25°, from measurements of freezing points and of vapor pressures at 0, 10 and 50°. The necessary equations are given and the numerical coefficients for the integration are tabulated.

The results of vapor pressure measurements

agree within their own rather large experimental uncertainty with the recent precise isotonic measurements of Scatchard, Hamer and Wood. The results calculated from freezing points show smaller but systematic deviations, which apparently are considerably beyond the experimental error of the thermal measurements.

The System Magnesium Sulfate, Cadmium Sulfate and Water at 25 and 40°

BY W. C. VOSBURGH, VERNON H. DIBELER, HELEN C. PARKS AND WILLIAM J. MILLER

In the study of modified Weston cells[1] some difficulty was experienced in the preparation of a double salt of magnesium and cadmium sulfates. Schiff[2] prepared a double salt with the composition $MgSO_4 \cdot CdSO_4 \cdot 14H_2O$ in 1857, but no mention of later work on this compound has been found. Attempts to make the double salt by slow evaporation at room temperature of a solution containing the two component salts failed, and it was apparent that further study of the system magnesium sulfate, cadmium sulfate and water was desirable.

Mixtures were prepared of carefully weighed quantities of recrystallized magnesium and cadmium sulfates and water and brought to equilibrium in closed tubes which were rotated in an air-bath at 25 ± 0.1°. The time allowed for equilibrium varied considerably, but in only a few cases was it less than forty-eight hours. Often it was much longer than this, and the consistency of the data is an indication that equilibrium was attained in the time allowed.

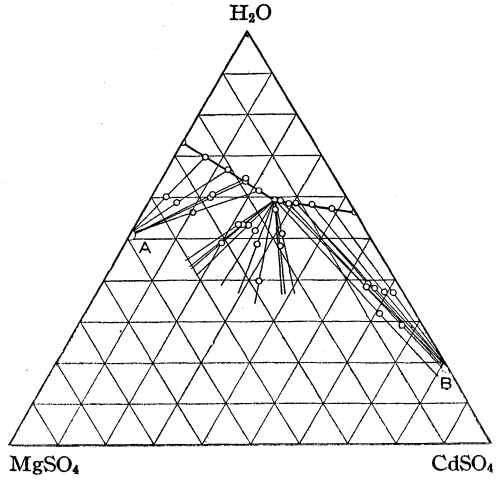

Fig. 1.—The system magnesium sulfate, cadmium sulfate and water at 25°. Points A and B represent the calculated compositions, in weight percentage, of hydrated magnesium and cadmium sulfates, respectively.

After sufficient rotation, the saturated solution was drawn off through a glass-wool filter, this operation being carried out within the air-bath. The solution was weighed, diluted to a known volume and aliquot portions taken for analysis. Total solids were determined by evaporation to dryness and ignition in a muffle at 500°. Other samples were acidified with sulfuric acid, the cadmium was precipitated as sulfide, and the magnesium sulfate determined in the filtrate by evaporation, ignition at 500° and weighing. The cadmium sulfide was dissolved by hydrochloric acid, and the solution evaporated to dryness after addition of an excess of sulfuric acid. The cadmium sulfate was ignited at 500° and weighed.

(2) Schiff, *Ann.*, **104**, 327 (1857); **107**, 73 (1858).

The compositions of the original mixtures and saturated solutions are given in Table I and plotted in Fig. 1.

It is apparent from Fig. 1 that no double salt was formed at 25°. Consequently, some experiments were carried out to see whether a transition temperature could be detected, since the temperature range within which the double salt of Schiff[2] is capable of existence might not include 25°. Two modified Weston cells[1] were constructed with an electrolyte saturated with magnesium and cadmium sulfates and with an excess of both hydrated solids present. On measurement of the electromotive force at several temperatures between 20 and 40° it was found that the temperature coefficient ($\Delta E/\Delta T$) changed abruptly and considerably at about 30°. The reproducibility and constancy of the cells were not good, and the error might amount to a few tenths of a degree. Following this, equimolecular quantities of magnesium and cadmium sulfates and a little water were rotated together for several days at 40° and a cooling curve for the mixture determined. It gave clear evidence of an evolution of heat at about 30.2°.

TABLE II

COMPOSITIONS OF SATURATED SOLUTIONS AND ORIGINAL MIXTURES AT 40°

Saturated solutions		Original mixtures	
$CdSO_4$, wt. %	$MgSO_4$, wt. %	$CdSO_4$, wt. %	$MgSO_4$, wt. %
2.6	29.6	2.0	36.0
5.0	28.8	3.2	36.5

38.8	9.2	37.7	13.2
39.6	9.2	40.3	14.8
40.1	8.8	44.7	13.8
40.9	7.7	57.1	4.7
42.7	4.5	59.4	2.5

The solubilities were determined again at a temperature of 40 ± 0.2°, and the data in Table II (shown graphically in Fig. 2) obtained. It is clear that a double salt can exist at 40° in equilibrium with solutions of a wide range of compositions. Point C in Fig. 2 represents the calculated composition of the compound $MgSO_4 \cdot CdSO_4 \cdot 14H_2O$ while D represents that of a double salt with twelve molecules of water. Points A and B represent $MgSO_4 \cdot 7H_2O$ and $3CdSO_4 \cdot 8H_2O$, respectively, in both Figs. 1 and 2. The solubilities of these salts in water were taken from "International Critical Tables."

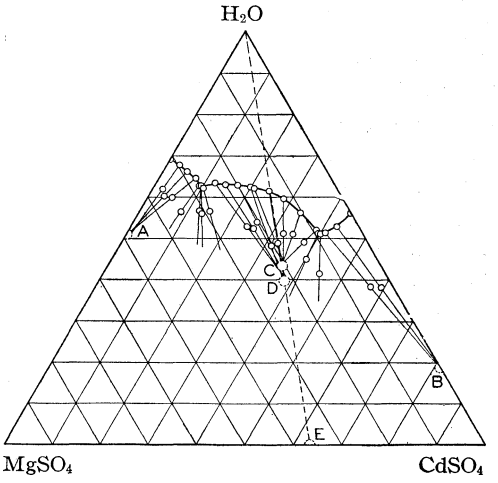

Fig. 2.—The system magnesium sulfate, cadmium sulfate and water at 40°. Points A and B are the same as in Fig. 1. Point C represents the calculated composition of the compound $MgSO_4 \cdot CdSO_4 \cdot 14H_2O$, point D a double salt with twelve molecules of water and point E the anhydrous double salt.

As a further check on Schiff's formula for the double salt, samples of the salt were prepared by rotation of equimolecular mixtures of hydrated magnesium and cadmium sulfates with some excess water at 40° and filtering and drying in the air-bath at the same temperature. Determination of water lost at 500° and of magnesium and cadmium sulfates gave the following results for three different preparations of the double salt.

	Calcd. for $CdSO_4 \cdot MgSO_4 \cdot 14H_2O$	Observed 1	2	3
$MgSO_4$, %	20.72	20.74	20.76	20.83
$CdSO_4$, %	35.88	35.85	35.83	35.87
H_2O, %	43.41	43.41	43.39	43.40

Summary

A double salt of magnesium and cadmium sulfates, $MgSO_4 \cdot CdSO_4 \cdot 14H_2O$, can exist in equilibrium with saturated solutions at 40°, but not at 25°. A transition point for the system was found at about 30.2°.

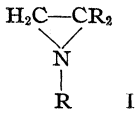
The Stability toward Racemization of Optically Active Compounds—with Especial Reference to Trivalent Nitrogen Compounds

BY JOHN F. KINCAID AND F. C. HENRIQUES JR.

Although a tremendous amount of work has been done in attempts to resolve trivalent nitrogen compounds into optically active forms, the attempts have been uniformly unsuccessful.[1] On the other hand, other compounds in which the central atom is surrounded by only three groups have been resolved. Thus active forms of the sulfoxides, sulfinic esters, and sulfonium salts have been obtained. The present investigation was undertaken in order to explain this apparent anomaly as well as to gain information which would lead to a prediction of the stability toward racemization of a substituted ethyleneimine of the type (I), which is being investigated at the present time by Dr. T. L. Cairns of this Laboratory.[2]



I

Since all previous attempts to prepare optically active nitrogen compounds have proved fruitless, the energy required to bring about a planar configuration, through vibrations, must be low. The computations which are to follow are based on the fact that one of the normal modes of vibration, ν_3 of Fig. 1, leads to such a configuration. A

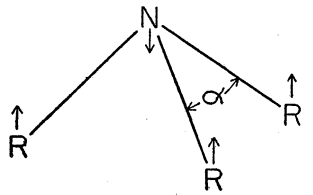


Fig. 1.—A diagrammatic representation of the normal vibration ν_3.

similar type of calculation by Rice and Teller[3] of the amount of energy required to bring three of the hydrogen atoms of the methane molecule into a plane containing the carbon has led to an approximately correct value of the activation energy of the reaction $D + CH_4 \rightarrow CH_3D + H$.[4]

Let us consider a compound of the type R_3N. If the nitrogen is not in the plane of the R groups, then the potential energy of the molecule as a function of the distance of the nitrogen atom from the plane of the other groups will have the form illustrated by the dotted curve in Fig. 2.

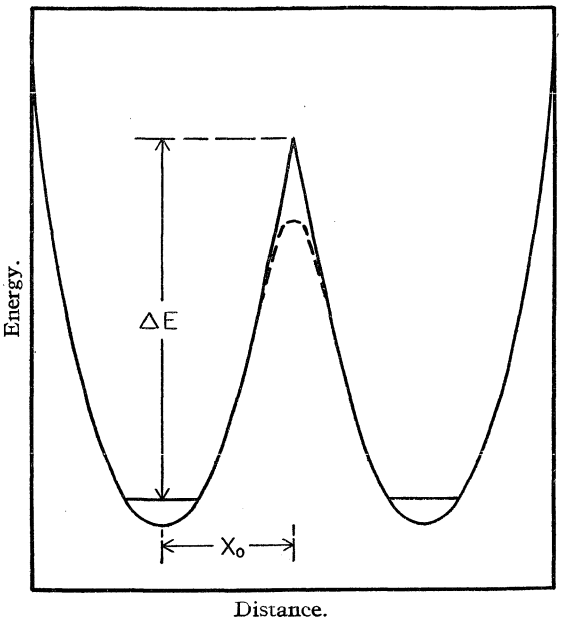

Fig. 2.—The energy, V, as a function of the displacement, x, for the normal vibration ν_3.

Therefore, racemization may take place either by passing over or through the potential hill. The rate of racemization by either of these mechanisms is determined by the dimensions of the barrier, the frequency ν_3, and the temperature. For ammonia several methods have been employed to obtain these dimensions.[5,6,7] By far the simplest of these leading to agreement between theory and experiment is that employed by Wall and Glockler[7]; and it is this function which has been used in these computations. Their expression for the potential energy, V, is

$$V = {}^1/_2k(|x| - |x_0|)^2 \qquad (1)$$

where x is the distance of the nitrogen from the

$C(CH_3)_4$[h]	C–C = 1.54[13]	α = 111.5°[13]	0.87	377	9.6	88

[a] The angle β, see Fig. 3, is uniquely determined by the bond distances. Since the C–C bond distance in cyclopropane has been found to be 1.53 Å.,[13] it is quite reasonable to assume that the above bond distances for ethyleneimine are correct. Angle α, see Fig. 3, has been assumed to have the normal tetrahedral value. This assumption is substantiated by the value of 110° found for the C—N=N angle of azomethane by Boersch.[15] [b] This distance has been calculated from the covalent radii of the atoms.[14] [c] From a comparison of homologous compounds, values of 100° for the HPH angle and 109.5° for the C–S–C angle are upper limits. A smaller angle would only make the calculated activation energies higher. [d] All of the experimental frequencies are those summarized by Hibben.[16] [e] Since the vibrational levels for ethyleneimines are unknown, the value for $N(CH_3)_3$ has been used. Due to the formation of a three-membered ring the actual frequency for this vibration must be somewhat greater; however, this would only lead to a higher activation energy than that calculated. [f] The vibrational spectrum of this ion has not been determined. Since the C–C bending frequencies,[16] 377 cm.$^{-1}$ for $(CH_3)_2CH_2$ and 413 cm.$^{-1}$ for $(CH_3)_2NH$ are very close to the respective values of the normal mode corresponding to ν_3, 372 cm.$^{-1}$ for $(CH_3)_3CH$ and 374 cm.$^{-1}$ for $(CH_3)_3N$; a good approximation for ν_3 of $(CH_3)_3S^+$ can be obtained from the 648 cm.$^{-1}$ bending frequency of dimethyl sulfide. 600 cm.$^{-1}$ is probably a lower limit, and a higher value would only tend to increase the activation energy. [g] The vibrational frequencies for this compound are also unknown. A comparison of ν_3 for PH_3 and NH_3 together with the known value for $N(CH_3)_3$ (see table) yield 390 cm.$^{-1}$ for $P(CH_3)_3$. A similar comparison using the corresponding frequencies[16] of 1304 cm.$^{-1}$ and 372 cm.$^{-1}$ for methane and isobutane, respectively, yields a value of 300 cm.$^{-1}$. An average value, 340 cm.$^{-1}$, has been used; even if ν_3 were as low as 300 cm.$^{-1}$, the calculated ΔE would still be 55 kcal. [h] The method of calculating the activation energy for this compound is given later. α is the C–C–C angle in propane, and ν_3 its bending frequency; x_0 is the height of one carbon from a line joining the other two; $1/\mu \approx (1/14) + 1/(2 \times 15)$.

plane of the R groups, x_0 is this distance at equilibrium, and k, the force constant, is given by the expression

$$k = 4\pi^2\nu_3^2\mu \qquad (2)$$

where ν_3 (Fig. 1) is the frequency leading to inversion of the molecule and μ is the reduced mass defined by

$$\mu \approx 3ab/(3a + b) \qquad (3)$$

where a is the mass of the R group and b that of nitrogen.[8]

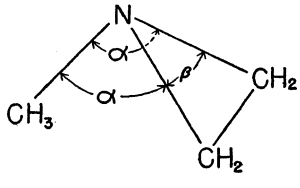

Fig. 3.—A diagrammatic representation of N-methyl ethyleneimine.

The results of the computations are given in Table I. A necessary condition for resolution is that the intramolecular first order rate constant for racemization be less than 10^{-5} sec.$^{-1}$. Thus

(8) It is a well-known fact that a potential curve of the form illustrated in Fig. 2 leads to a quantum mechanical interaction, *tunneling*, and gives rise to a separation of the ν_3 vibrational levels into doublets. Previous investigations have been made with the view in mind of obtaining these observed doublet separations. In order to obtain the observed separation of the first vibrational level of ν_3, Wall and Glockler[7] used an arbitrary equilibrium distance, x_0, for ammonia. It is of interest to compare their activation energy of 9.5 kcal./mole with our value for ammonia of 11 kcal. Both these values are possibly high since the form of the curve given by equation (1) is that of the solid curve rather than the dotted curve of Fig. 2. The more elaborate function, $V = A(\csc^2\Theta - \csc^2\Theta_0)^2$, was employed by Manning and gives rise to a smooth curve. The arbitrary parameters in this function were chosen so as to give the observed doublet separations of the zero-th and first vibration levels. Manning[6] obtained 6 kcal./mole for the height of the potential hill, 0.38 Å. for x_0, and 1050 cm.$^{-1}$ for ν_3 (see also Howard, *J. Chem. Phys.*, **3**, 208 (1935)). Although this value of 6 kcal./mole is considerably lower than our value, it should be noted that Manning's values for x_0 and ν_3 are both too high. Since the doublet separation for a fixed reduced mass is a function of the area under the barrier, it is clear that a more reasonable value for x_0 and the correct value for ν_3 would lead to a considerably higher activation energy. These considerations lead to the conclusion that about 8 kcal./mole is the most probable barrier height for ammonia.

one readily obtains from the Arrhenius equation

$$k \approx 10^{13} \exp.(-\Delta E/RT) \qquad (4)$$

that ΔE must be greater than 25 kcal./mole if resolution at room temperature is to be possible. For the moment tunneling through the barrier has been neglected. It will be shown later that for room temperature and above the effective activation energy for tunneling is only a few % lower than the height of the barrier.

Before discussing specific cases it should be emphasized that our method of obtaining ΔE leads to rather approximate results and values which are too high. However, the relative values are undoubtedly quite significant. An estimate of the probable error may be obtained by comparing our value of 11 kcal. for ΔE for NH_3 with the more reasonable value of 8 kcal.[8] Due to mutual repulsions, neopentane is an exception, the calculated ΔE being too low.

Compounds Similar to Trimethylamine.—The activation energy obtained for trimethylamine is 15 kcal./mole. One would expect other compounds of the type $NR_1R_2R_3$ to have a somewhat lower value for the following reasons. (1) The activation energy calculated for ammonia is less than that of trimethylamine. Thus if R_1, R_2, or R_3 is a hydrogen atom, ΔE should be slightly less than 15 kcal. (2) If R_1, R_2, and R_3 are aliphatic groups, the force constant, k, which appears in equation (1) will be approximately independent of the weight, *i. e.*, an increase in the reduced mass will be compensated by a corresponding decrease in the numerical value of ν_3. However, due to mutual repulsions, x_0, the height of the pyramid, will actually tend to decrease with increasing size of the R groups, thus lowering ΔE. Hence, three large normal saturated aliphatic groups attached to nitrogen would not lower the activation energy as much as would branched groups, such as *t*-butyl radicals. (3) Aromatic groups attached directly to nitrogen tend to lower ΔE through making the molecule more planar both because of the size of the groups, and the contribution to the stability of the compound through the resonance structure involving a double bonded nitrogen. This effect has been pointed out by Pauling.[17] (4) A comparison of ΔE for PH_3, PCl_3, and PBr_3 indicates that the attachment of an electronegative group to the central atom will not result in an appreciable increase in stability.

(17) Gilman, *loc. cit.*, p. 334.

The resolution of a compound of the type $NR_1R_2R_3$ is impossible at room temperature.

From the reasons given above, the activation energy for inversion of these compounds is certainly no more than 15 kcal./mole. This value almost suffices for resolvability at −80° (dry-ice temperature). Since, however, 15 kcal./mole is an upper limit for the activation energy, it appears very improbable that these compounds can be resolved even at dry-ice temperatures.[1]

Cyclic Compounds.—The activation energy obtained for N-methyl ethyleneimine was 38 kcal./mole. Even if rounding off the barrier should decrease it as much as 10 kcal., this compound would be stable with respect to racemization at room temperature. It can be shown that the increase in the rate of racemization through tunneling is negligible.[18] Thus a substituted ethyleneimine containing an asymmetric nitrogen atom appears to offer an excellent possibility for the resolution of a trivalent nitrogen compound.

Many attempts have been made to resolve cyclic compounds in which the nitrogen is enclosed in a five- or six-membered ring.[1] From simple considerations of strain it is evident that such systems will be only slightly more stable than the analogous open chain compounds.

Trivalent Phosphorus Compounds.—Although no examples of activity due to trivalent phosphorus have been reported, the values of ΔE recorded in Table I for these compounds are so high that it appears certain that they can be

(18) The B. K. W. approximation for tunneling rate is given by Rojansky ("Introductory Quantum Mechanics," Prentice-Hall, New York, N. Y., 1938, p. 221).

$$T_{\epsilon_i} = f(\epsilon_i) \exp.\left(-(4\pi/h)\int_{x_1}^{x_2}\sqrt{2\mu(V-\epsilon_i)}\,dx\right)$$

where T_{ϵ_i} is the probability of penetration through the barrier for a harmonic oscillator with energy ϵ_i, and V is defined by equation (1). It is easy to show that in our case $f(\epsilon_i)$ is about two. Assuming a Boltzmann distribution, the rate constant for tunneling is

$$k_t = c\nu_3 \sum_i T_{\epsilon_i} \exp.(-\epsilon_i/kT) \Big/ \sum_i \exp\,(-\epsilon_i/kT)$$

where ν_3 has been previously defined and c is the velocity of light. From the above equations it is found that for trimethylamine the ratios of the rate of tunneling to that of going over the barrier, k_t/k, at 300, 200, and 150°K. are 60, 3×10^3, and 10^3, respectively. The numerical values of k_t at these temperatures were, respectively, 10^3, 10^{-1} and 6×10^{-5} sec.$^{-1}$ and resolution should be possible only at or below 150°K. For the ethyleneimine considered, k_t/k at 300, 400, and 500°K. is 300, 30, and 10, respectively. Since the rate in the reverse direction has been neglected, these computations are an upper limit for the rate of tunneling. It should be pointed out that if the calculations had been based on the type of potential function illustrated by the dotted line in Fig. 2, the tunneling rate would be much smaller, but the thermal rate would be correspondingly greater. Thus for the type of barrier employed, the effect of tunneling is essentially to round off the barrier.

resolved if the chemical difficulties can be overcome. Comparison of the values recorded for $P(CH_3)_3$, phosphorus trichloride, and phosphorus tribromide lead to the conclusion that the most favorable case is one in which three alkyl groups are attached directly to phosphorus.[19]

Active Sulfonium Salts.—The calculated activation energy is so high that racemization through an intramolecular conversion is out of the question. In fact, not only have these compounds been resolved,[20] but it has also been demonstrated that the mechanism by which they racemize is dissociation of the molecule, $R_3S^+X^-$, into the compounds R_2S and RX.

Asymmetric Carbon Atoms.—A mechanism which has been suggested[21] for the racemization of a compound of the type $CR_1R_2R_3R_4$ is one in which the four R groups and the asymmetric carbon atom are postulated to assume momentarily a planar configuration during inversion. Computations of the energy required show that this mechanism is entirely unreasonable.

From inspection of models it is clear that ΔE for this mechanism should be approximately twice the energy required to bend the propane molecule so that the three carbons lie on a line. Using the carbon bending frequency for propane[16] and the appropriate reduced mass, ΔE is found to be 88 kcal./mole. A value computed directly from data for neopentane is even higher. Since the attachment of groups other than methyls would not be expected to reduce greatly this value it may be stated *that the racemization of an asymmetric carbon cannot occur except through some process which results in the breaking of a bond attached to the central carbon.* A search through the literature has revealed no clear-cut experimental evidence for inversion through an intramolecular process.

(19) Sutherland, Lee and Wu (*Trans. Faraday Soc.*, **XXXV**, 1373 (1939)) have recently computed about 4 kcal./mole for the height of the barrier in PH_3 from a doublet observed by Fung and Barker (*Phys. Rev.*, **45**, 238 (1934)) at 990 cm.$^{-1}$. The separation of 2.4 cm.$^{-1}$ was interpreted as arising from a splitting of the ν_2 vibrational levels. We do not agree with this interpretation since it leads to a ten-fold reduction in the barrier height, thus necessitating an unreasonable anharmonicity. It should be noted that if the same anharmonicity were employed in the calculation of ΔE for R_3S^+, a value of 10 kcal./mole would be obtained compared to a minimum value of 25 kcal./mole required for stability at room temperature. There is no reason to expect much difference in the behavior of S^+ and P since the orbitals available for bond formation are the same in each case.

(20) (a) Gilman, *loc. cit.*, p. 344; (b) Balfe, Kenyon and Phillips, *J. Chem. Soc.*, 2554 (1930).

(21) Gilman, *loc. cit.*, p. 177.

Summary

1. Approximate calculations of activation energy from spectroscopic data have shown that no compound of the type $NR_1R_2R_3$ can be resolved into active forms at room temperature.

2. Substituted ethyleneimines appear to offer the best possibility for the resolution of trivalent nitrogen compounds since the calculated activation energy is considerably above the minimum value required for stability.

3. Trivalent compounds of phosphorus can be resolved if the chemical difficulties can be overcome.

4. The calculations provide an explanation of the observation that the mechanism of racemization of active sulfonium salts is through dissociation of the molecule, $R_3S^+X^-$, into RX and R_2S, rather than through an intramolecular mechanism.

5. It is concluded that the activated complex for racemization of a compound of the type $CR_1R_2R_3R_4$ cannot be a planar structure, and thus that the racemization of a compound of this type cannot occur except through some process which results in the breaking of a bond attached to the central atom.

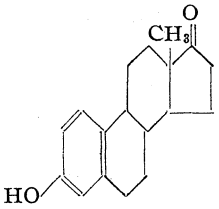
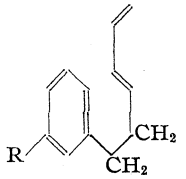
Experiments on the Synthesis of Oestrone. I. The 2-(β-Phenylethyl)-furans as Components in the Diene Synthesis

BY ROBERT BURNS WOODWARD[1,2]

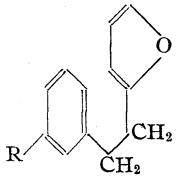
The synthetic approach to substances of the hormone or sterol group, culminating in the brilliant synthesis of equilenin by Bachmann, Cole and Wilds,[3a] and of a stereoisomer of oestrone by Dane,[3b] has attracted much attention in recent years. The investigation undertaken in this Laboratory had as its ultimate object the synthesis of oestrone (I) or a stereoisomer. In view of its wide applicability in the synthesis of cyclic systems, the diene synthesis of Diels and Alder was investigated as a favorable vehicle for such a



I



II



III

project. Other investigators[4] have explored the possibilities of this method. Cohen[4a] was able to add maleic anhydride to 1-(β-phenylethyl)-$\Delta^{1,3}$-butadiene (II, R = H). The yield, however, was small and the extension of the reaction to the pertinent case of 1-[β-(*m*-methoxyphenyl)-ethyl]-$\Delta^{1,3}$-butadiene (II, R = OCH_3) was unsuccessful. The use of 1-vinylnaphthalenes[4b] and 1-vinyl-$\Delta^{1,2}$-dihydronaphthalenes[4c] has been attended with more success.

Cohen attributed his difficulties to isomerism to derivatives of 1-vinyl-tetralin, and their subsequent polymerization. Our success in view of his failure is easily explained on this basis. The choice of 2-(β-phenylethyl)-furans (III) as diene components affords compounds whose individual double bonds are not active enough to be subject to prototropic isomerization, but whose diene character is still so marked as to permit their participation in the Diels and Alder reaction.

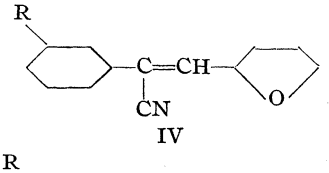
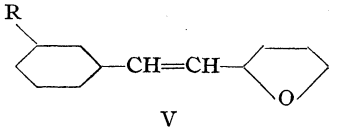
The parent compound, 2-(β-phenylethyl)-furan (III, R = H) had been prepared by Freund and Immerwahr.[5] Phenylacetonitrile was condensed with furfural to give α-phenyl-β-(2-furyl)-acrylic nitrile (IV, R = H). The reduction of the latter substance by molten sodium and absolute alcohol gave the desired compound in addition to β-phenyl-γ-(2-furyl)-propylamine.



IV



V

Since this method involved two concurrent reactions, one of which gave a product unsuitable for further synthetic work, it was hoped that a more direct method could be used. Two alternatives were investigated. The reaction of benzylmagnesium chloride with furfuraldehyde proceeded smoothly but it was impossible to obtain a homogeneous sample of benzyl-(2-furyl)-carbinol, water being split to some extent even on distillation in a high vacuum. Dehydration of the crude carbinol gave the new stilbene isolog α-phenyl-β-(2-furyl)-ethylene (V, R = H), characterized by the ease with which it forms a beautifully crystalline dibromide, and by its catalytic hydrogenation to the desired 2-(β-phenylethyl)-furan. The over-all yield of the latter substance obtained by this method, however, was slightly less than that obtained by the older process.

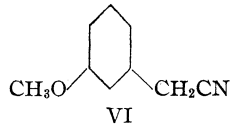
Again, the reaction of benzylmagnesium halide with 2-furfuryl bromide was the subject of considerable investigation. Certain 2-substituted furans had been prepared in this manner by Paul.[6] This investigator found that unless a large excess of the Grignard reagent was used, a small quantity of unchanged 2-furfuryl bromide invariably induced conjunct polymerization during the working up of the reaction mixture, with the result

(5) Freund and Immerwahr, *Ber.*, **23**, 2847 (1890).

(6) Paul, *Compt. rend.*, **200**, 1481 (1935).

that no product was obtained. Such a procedure was not feasible when a relatively rare substance such as *m*-methoxybenzyl bromide was being used. Accordingly the device was adopted of using equimolecular proportions of the (un)substituted benzyl halide and of 2-furfuryl bromide, and adding a large excess of butylmagnesium bromide after the reaction was complete to destroy the sensitive 2-furfuryl bromide. It was found also that greater success was obtained with this type of reaction if certain variations were made in the original preparation[7] of 2-furfuryl bromide. While Zanetti and Paul freed the crude bromide of water, unchanged 2-furfuryl alcohol, and other impurities, a better product is obtained by treating the crude ethereal solution with a small molar proportion of freshly prepared methylmagnesium iodide or butylmagnesium bromide. The separation of small amounts of 2-ethyl- or 2-(*n*-amyl)-furans formed by this process from the desired 2-(β-phenylethyl)-furans is easily effected by distillation. If these conditions are carefully observed, it is possible by this method to obtain better yields of the 2-(β-phenylethyl)-furans than by the older process. On the other hand, since the reactions of the latter method may be carried out more easily and quickly, it is the better method for preparative purposes.

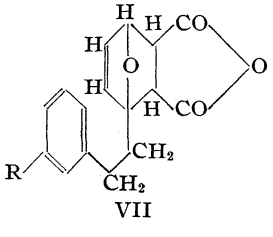
m-Methoxyphenylacetonitrile (VI) was obtained in 70% over-all yield by the following four-step process. *m*-Hydroxybenzaldehyde[8] was methylated according to Reimer[9] with methyl sulfate in dilute alkaline solution. The methylation of the aldehyde by means of diazomethane was unsatisfactory.[10] The methoxybenzaldehyde was reduced quantitatively by hydrogen using the Adams catalyst with ferrous ions to *m*-methoxybenzyl alcohol. The conversion of the alcohol into *m*-methoxybenzyl bromide by the action of hydrogen bromide in benzene proceeded essentially as described by Lapworth.[11] The bromide gave an excellent yield of *m*-methoxyphenylacetonitrile (88%) (VI) on treatment in the usual manner with aqueous alcoholic potassium cyanide.



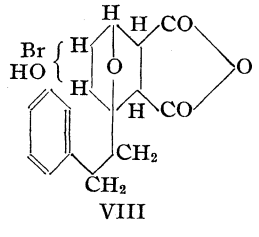
VI

The condensation of *m*-methoxyphenylacetonitrile with furfural to α-(*m*-methoxyphenyl)-β-(2-furyl)-acrylic nitrile (IV, R = OCH_3) proceeded smoothly; the product, an oil, may if desired be isolated by distillation *in vacuo*, but it was more convenient for synthetic work to reduce the crude condensation product directly by molten sodium and absolute alcohol to 2-[β-(*m*-methoxyphenyl)-ethyl]-furan (III, R = OCH_3).

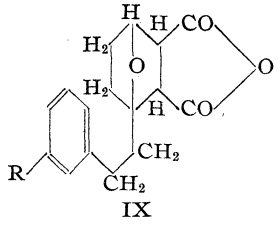
2-(β-Phenylethyl)-furan reacted on standing with pure maleic anhydride in anhydrous ether to give a beautifully crystalline addition product, 3-(β-phenylethyl)-3,6-endoxo-Δ^4-tetrahydro-*o*-phthalic anhydride (VII, R = H). This substance on heating above the melting point alone or in solvents dissociated into its components. On dissolving in ligroin, particularly, a clear solution was obtained which deposited crystals of maleic anhydride on standing in the ice-box for a short time. Again, the colorless solution in dimethylaniline on heating developed the characteristic orange color of maleic anhydride in this reagent. When the substance is warmed on the steam-bath in a current of nitrogen, maleic anhydride sublimes into the condenser. A bromo-hydroxy derivative (VIII) of the addition product was prepared by the action of bromine on a neutralized solution of the addition product in sodium carbonate. As would be expected, this latter substance exhibited no tendency to dissociate.



VII



VIII



IX

Similar phenomena are observed in the reaction of 2-[β-(*m*-methoxyphenyl)-ethyl]-furan with maleic anhydride. A beautifully crystalline addition product, 3-[β-(*m*-methoxyphenyl-)-ethyl]-3,6-endoxo-Δ^4-tetrahydro-*o*-phthalic anhydride

(7) Zanetti, THIS JOURNAL, **49**, 1066 (1927).

(8) The *m*-hydroxybenzaldehyde used in this research was obtained through the kindness of the General Aniline Company of New York.

(VII, R = OCH_3) is obtained in excellent yield. This substance, like the unsubstituted adduct, dissociates readily into its components.

The original synthetic plan involved the catalytic hydrogenation of the addition products to dihydro derivatives (IX, R = H, OCH_3), theoretically susceptible of isomerization to substances possessing a substituted hydrophenanthrene template similar to oestrone or its degradation products. In practice the addition products were found to be remarkably resistant to hydrogenation. 3-(β-Phenylethyl)-3,6-endoxo-Δ^4-tetrahydro-*o*-phthalic anhydride was unaffected on shaking with hydrogen for long periods in ethyl acetate solution, in the presence of palladium or platinum black. Hydrogenation in glacial acetic acid with a platinum catalyst over a period of twelve hours gave succinic acid as sole crystalline product, dissociation evidently taking place. Similar difficulties were experienced in reducing the methoxylated addition product.[12]

Experimental

α-Phenyl-β-(2-furyl)-acrylic nitrile (IV, R = H) was obtained by Frost's method[13] from phenylacetonitrile and furfuraldehyde in the presence of alcoholic sodium ethylate. The substance crystallized from aqueous alcohol as slightly yellow needles, m. p. 42–43°.

2-(β-Phenylethyl)-furan (III, R = H).—(a) The material was first prepared according to Freund and Immerwahr.[5] The substance was purified more easily by steam distillation than by the procedure recommended by these authors. From 63 g. of the nitrile an average of 30 g. of the furan, b. p. (760 mm.) 241–243°, was obtained as a colorless oil of pleasant aromatic odor, reminiscent of stilbene.

(b) 9.6 grams of freshly turned magnesium was dissolved in 50 g. of benzyl chloride and 200 cc. of anhydrous ether in a three-necked flask equipped with dropping funnel, reflux condenser, and mercury seal with mechanical stirrer. To the large excess of benzylmagnesium chloride obtained in this manner, 2-furfuryl bromide, prepared as described below from 40 g. of 2-furfuryl alcohol, was added slowly with good stirring. A white or slightly yellow precipitate began to form immediately and precipitation continued throughout the course of the reaction. When the addition was complete, the reaction mixture was decomposed in the usual manner with ammonium chloride solution, the yellow ethereal extract was washed with water and dried over anhydrous sodium sulfate. After removal of the ether, the residual oil was fractionated. Twenty grams of 2-(β-phenylethyl)-furan was obtained, identical with that obtained by the method outlined in (a).

The preparation could also be carried out using equimolecular proportions of the reactants if the precautions mentioned in the theoretical part are observed (*cf.* 2-[β-(*m*-methoxyphenyl)-ethyl]-furan, (b), below).

α-Phenyl-β-(2-furyl)-ethylene (V).—To the Grignard solution from 12.2 g. of magnesium, 63 g. of benzyl chloride and 300 cc. of anhydrous ether, 48 g. of furfuraldehyde was added slowly, with mechanical stirring. When the addition had been completed, the reaction mixture was heated on the steam-bath for a short time. There was now suspended in the ether a yellow crystalline precipitate. The whole was poured into ice and stirred well to effect decomposition. The ethereal solution was separated, the residual sludge of magnesium oxychloride was dissolved by the addition of dilute acetic acid, and the resulting solution was extracted with ether. The ether extract was dried over anhydrous sodium sulfate, and the ether was removed. The deep yellow residual oil (35 g.) was distilled *in vacuo* over 20 g. of pure potassium hydrogen sulfate, or 7 g. of anhydrous aluminum sulfate. The fraction b. p. (3 mm.) 150–165° solidified on cooling and was purified further by crystallization from alcohol. Ten grams of α-phenyl-β-(2-furyl)-ethylene was obtained in long yellowish needles, of pleasant aromatic odor, reminiscent of stilbene (m. p. 49–50°).

Anal. Calcd. for $C_{12}H_{10}O$: C, 84.7; H, 5.88. Found: C, 84.6; H, 5.93.

2-(β-Phenylethyl)-furan (III, R = H) is obtained readily from the above substance by shaking with hydrogen in the presence of Adams catalyst. The reduction is complete in less than one-half hour, and the product is identical in every respect with that obtained above.

Dibromide.—One-half gram of the ethylenic compound was dissolved in 15 cc. of pure chloroform, 0.5 g. of bromine was added, and the reaction mixture allowed to stand for three days. At the end of this time magnificent crystals of the dibromide had separated as long transparent prisms, m. p. 232.0–232.3°, reminiscent in appearance of hydroxylamine hydrochloride.

Anal. Calcd. for $C_{12}H_{10}OBr$: Br, 48.48. Found: Br, 48.5.

***m*-Methoxybenzaldehyde** was obtained in 83% yield by the methylation of *m*-hydroxybenzaldehyde in weakly alkaline solution by means of dimethyl sulfate. The yield of pure product obtained when the crude aldehyde is distilled *in vacuo* in a current of nitrogen is appreciably higher than that obtained when no precaution is taken to protect the substance from oxidation (b. p. (30 mm.) 129–130°).

***m*-Methoxybenzyl alcohol** was prepared in quantitative yield by the catalytic hydrogenation of the aldehyde. In a typical experiment, 40 g. of *m*-methoxybenzaldehyde, 200 cc. of reagent ethyl alcohol, 0.2 g. of freshly prepared Adams platinum oxide, and 2.0 cc. of 0.1 *M* ferrous sulfate solution were placed in the pressure bottle of the Adams hydrogenation apparatus. Shaking was started at three atmospheres. Within ten minutes, the theoretical absorption (0.294 mole = 23 lb.) had taken place. It was possible to use the same catalyst for a second or third reduction, but the time required for complete hydrogenation in this case was considerably longer. The alcohol was removed by distillation under reduced pressure, and the residual oil distilled *in vacuo* in a current of nitrogen.

(12) More recent work which will be described in a subsequent communication has led to the quantitative hydrogenation of 3-[β-(*m*-methoxyphenyl)-ethyl]-Δ^4-tetrahydro-*o*-phthalic anhydride by shaking a suspension in methyl alcohol with hydrogen in the presence of platinum black.

(13) Frost, *Ann.*, **250**, 159 (1888).

m-Methoxybenzyl alcohol is a clear colorless liquid of peculiar odor, b. p. (25 mm.) 150°.

***m*-Methoxybenzyl Bromide.**—167 grams of *m*-methoxybenzyl alcohol was dissolved in 300 cc. of dry thiophene-free benzene, and saturated with dry hydrogen bromide in the cold. Water collected under the clear benzene solution of the bromide which was decanted and allowed to dry overnight over calcium chloride. The benzene was removed *in vacuo* in a current of dry nitrogen; 238 grams of *m*-methoxybenzyl bromide, b. p. (8 mm.) 116° was obtained. The substance is a clear, highly refractive liquid which rapidly turns green or greenish purple on standing. Care must be taken not to inhale the substance nor allow it to come in contact with the skin, since it is an extremely irritating lachrymator and vesicant.

***m*-Methoxyphenylacetonitrile** (VI).—100 grams of *m*-methoxybenzyl bromide was refluxed for two and a half hours with 32 g. of sodium cyanide, 30 cc. of water and 55 cc. of reagent ethyl alcohol. At the end of this time the alcohol was distilled *in vacuo* from the orange-brown mixture, the residual sludge was shaken with water, and the oil which separated dried over a small amount of anhydrous sodium sulfate. On distillation 64 g. (87.5%) of *m*-methoxyphenylacetonitrile, b. p. (20 mm.) 164–165°, was obtained as a highly refractive liquid, of faint characteristic nitrile odor.

Anal. Calcd. for C_9H_9ON: C, 73.5; H, 6.10; N, 9.50. Found: C, 73.6; H, 6.3; N, 9.6.

α-(*m*-Methoxyphenyl)-β-(2-furyl)-acrylic Nitrile (IV, R = OCH_3).—To a mixture of 64 g. of *m*-methoxyphenylacetonitrile and 42 g. of furfural, 20 cc. of 20% alcoholic sodium ethylate was added, in small portions, with shaking. A good deal of heat was liberated, and the color of the reaction mixture deepened considerably. From time to time the flask was cooled under the tap. Considerable water separated on the sides of the vessel. When the reaction was complete, the dark brown oil was washed several times with water, dried over a small amount of anhydrous sodium sulfate and distilled in a high vacuum (b. p. (1 mm.) 180°). Ninety grams of α-(*m*-methoxyphenyl)-β-(2-furyl)-acrylic nitrile was obtained as a clear yellow oil. For conversion into 2-(β-(*m*-methoxyphenyl)-ethyl)-furan, the purification was superfluous. The crude brown oil gave satisfactory results.

Anal. Calcd. for $C_{14}H_{11}O_2N$: C, 74.8; H, 4.98; N, 6.23. Found: C, 74.6; H, 5.2; N, 6.4.

2-[β-(*m*-Methoxyphenyl)-ethyl]-furan (III, R = OCH_3).—(a) (The preparative method.) Ninety grams of α-(*m*-methoxyphenyl)-β-(2-furyl)-acrylic nitrile was dissolved in 1200 cc. of absolute ethyl alcohol and poured onto 138 g. of metallic sodium cut into chips (this was an excess of two and a half times the theoretical amount for complete reduction to β-(*m*-methoxyphenyl)-γ-(2-furyl)-*n*-propylamine). A three-necked flask equipped with two reflux condensers and one stopper was used for the reduction. If the reaction became too violent, the clogging of the condensers was easily remedied by removing the stopper for a moment. The flask was set in a pail, or in the sink, so that cold water could be dashed on the sides of the flask in case the reaction got out of control. When the reduction was complete, the greenish reaction mixture was made acid with hydrochloric acid. Since a good deal of free sodium remained in the flask, it was advisable to conduct this operation with considerable care. It was advantageous to place a quantity of dry-ice on the surface of the reaction mixture before each addition of acid. The contents of the flask were then subjected to a vigorous steam distillation, when the desired product passed over as a yellowish oil. Since this process was very slow, it was found that it was quite as satisfactory to extract the contents of the flask with ether, wash with dilute hydrochloric acid, then with water, and evaporate the ether after drying over sodium sulfate. In either case, the oil was distilled *in vacuo*. Thirty-nine grams of 2-[β-(*m*-methoxyphenyl)-ethyl]-furan was obtained as a colorless oil, b. p. (10 mm.) 153°, of aromatic odor, which turned yellow on standing. The same change was noticed with 2-(β-phenylethyl)-furan and 2-(γ-phenyl-*n*-propyl)-furan.

(b) (By the Grignard reaction.) Three grams of magnesium was placed in a dry three-necked flask equipped with dropping funnel, reflux condenser, and mercury seal bearing a mechanical stirrer. A few drops of *m*-methoxybenzyl bromide were allowed to fall onto the magnesium. When the reaction had started, the remainder of the bromide, in all 25 g., dissolved in 60 cc. of anhydrous ether, was added slowly. The reaction was not vigorous. Stirring and refluxing were continued for three hours after the bromide had been added. To the solution of *m*-methoxybenzylmagnesium bromide obtained in this manner, an ethereal solution of 2-furfuryl bromide, prepared from 40 g. of 2-furfuryl alcohol as described below, was added slowly, with good stirring. A shiny purple precipitate of magnesium bromide covered the walls of the flask as the reaction proceeded. When the addition of 2-furfuryl bromide was complete, a large excess of freshly prepared butylmagnesium bromide was added rapidly and the reaction mixture was allowed to stand for one-half hour. Ammonium chloride solution was then added to decompose unreacted Grignard reagents, the yellow ethereal solution was separated, washed with water, and dried over anhydrous sodium sulfate. On fractionation *in vacuo*, 13 g. of 2-[β-(*m*-methoxyphenyl)-ethyl]-furan was obtained, identical in every respect with that prepared by method (a).

Anal. Calcd. for $C_{13}H_{14}O_2$: C, 77.3; H, 7.10. Found: C, 77.1; H, 7.1.

2-Furfuryl Bromide.—Forty grams of freshly distilled 2-furfuryl alcohol dissolved in 400 g. of absolute ether was treated in the course of a half hour with 40 g. of pure phosphorus tribromide dissolved in 60 cc. of anhydrous ether. The flask was cooled from time to time by running water. When the addition had been completed, the reaction mixture was allowed to stand for half an hour before decanting from the waxy precipitate of phosphorous acid which covered the walls of the flask. The decanted solution was treated with a solution of 0.1–0.2 mole of butylmagnesium bromide (from 18 g. of butyl bromide and 4.0 g. of magnesium) in 100 cc. anhydrous ether, and used directly in the reaction described above.

3-(β-Phenylethyl)-3,6-endoxo-Δ^4-tetrahydro-*o*-phthalic Anhydride (VII, R = H).—Three grams of pure maleic anhydride (twice recrystallized from chloroform) and 5.4 g. of 2-(β-phenylethyl)-furan dissolved in the smallest amount of anhydrous ether necessary for complete

solution were allowed to stand in a well-stoppered flask. In a few days the contents of the flask had become a solid mass of beautiful needles. On filtering and washing with anhydrous ether, the addition product was obtained in almost quantitative yield as white needles, m. p. 71–73°. Due to its tendency to dissociate, the substance was difficult to recrystallize. Satisfactory results were obtained, however, by dissolving in cold chloroform, adding petroleum ether, and allowing to stand in the ice-box, when long fine needles gradually separated, m. p. 73–74°.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.2; H, 5.18. Found: C, 71.2; H, 5.3.

If this substance was dissolved in warm ligroin (b. p. 70–90°) and the resulting solution allowed to stand in the icebox, needles separated, which proved to be maleic anhydride, m. p. 57–59°, mixed m. p. 57–59°; orange color on heating with dimethyl- or diethylaniline.

Bromohydroxy Derivative (VIII, R = H).—The addition product (1.0 g.) was dissolved in excess sodium carbonate and the basic solution was exactly neutralized. This solution was shaken vigorously with a slight excess of bromine. Recation took place immediately with the quantitative precipitation of the bromohydroxy acid. After recrystallization from boiling water (Norit) the acid melted at 142–143°, with decomposition.

Anal. Calcd. for $C_{16}H_{15}O_5Br$: C, 52.4; H, 4.18. Found: C, 52.1; H, 4.4.

3-[β-(*m*-Methoxyphenyl)-ethyl]-3,6-endoxo-Δ⁴-tetrahydro-*o*-phthalic Anhydride (VII, R = OCH_3) crystallized quantitatively in beautiful transparent rosets when 31.6 g. of 2-[β-(*m*-methoxyphenyl)-ethyl]-furan and 15.3 g. of pure maleic anhydride were dissolved in the least amount of anhydrous ether necessary for complete solution and allowed to stand for three days. After washing with anhydrous ether, drying and crystallizing by the chloroform–petroleum ether procedure, long, transparent needles were obtained, m. p. 78–80°.

Like the unsubstituted addition product, this methoxy derivative gave maleic anhydride on heating in ligroin, gave no color with dimethylaniline until heated, and was unstable to cold dilute alkaline permanganate.

Anal. Calcd. for $C_{17}H_{16}O_5$: C, 68.0; H, 5.33. Found: C, 68.0; H, 5.4.

Hydrogenation Experiments.—If 1 g. of 3-(β-phenylethyl)-3,6-endoxo-Δ⁴-tetrahydro-*o*-phthalic anhydride dissolved in 30 cc. of glacial acetic acid was shaken with 0.2 g. platinum (palladium) oxide under 3 atmospheres of hydrogen for fifteen hours, succinic acid was obtained after washing the residue from the acetic acid (removed *in vacuo*) with dry benzene; m. p. 186–187°, mixed m. p. 185–187°.

All attempts to isolate other crystalline products from the reaction, or from numerous runs made in ethyl acetate or inert solvents, failed.

Summary

The synthesis of 2-(β-phenylethyl)-furan and 2-[β-(*m*-methoxyphenyl)-ethyl]-furan has been accomplished.

The Diels–Alder reaction has been applied with success to these substances.

Ketene Acetals. VI. The Preparation of Ketene Acetals from α-Bromo-orthoesters[1]

BY PHILIP M. WALTERS AND S. M. MCELVAIN

The procedure which has been used in this Laboratory for the preparation of ketene acetals involves the removal of the elements of halogen acid from a halogenated acetal by means of potassium *t*-butoxide

$$XCH_2CH(OEt)_2 + KOC_4H_9(t) \longrightarrow CH_2{=}C(OEt)_2 + KX + t\text{-}C_4H_9OH$$

By this reaction ketene diethylacetal and various halogenated derivatives of it have been prepared.[2] It is obvious that attempts to apply this procedure to the acetals of the higher α-halogenoaldehydes, $R_2CHCHXCH(OEt)_2$, might be unsuccessful due to the preferential loss of halogen acid from the α- and β-carbon atoms with the resultant formation of the acetals of the unsaturated aldehydes.[3]

Another route to the ketene acetal structure that was partially explored when the problem first was undertaken is the elimination of the elements of ethyl hypohalite, EtOX, from an α-halogenoorthoacetic ester in a manner similar to that used by Boord and co-workers[4] to prepare olefins. A

(1) Paper V of this series is Barnes, Kundiger and McElvain, THIS JOURNAL, **62**, 1281 (1940).

(2) Beyerstedt and McElvain, *ibid.*, **58**, 529 (1936); **59**, 2266 (1937); Magnani and McElvain, *ibid.*, **60**, 2210 (1938).

(3) In the cases of the acetals of the α-halogeno-propionaldehyde, -butyraldehyde and -isobutyraldehyde the larger numbers of hydrogens on the β-carbon atoms makes the α,β-loss of halogen acid much more probable than that between the α-carbon and the aldehyde carbon atom. However in the case of the acetal of α-halogeno-isovaleraldehyde, $(CH_3)_2CHCHXCH(OEt)_2$, in which there is only one hydrogen on the β-carbon atom it seems that there should be some chance of loss of halogen acid from the α-carbon and the aldehyde carbon atom. But Jones (B.S. Thesis, University of Wisconsin, 1939), working along this line found that each of the above acetals (X is Br) gave the corresponding unsaturated acetal, through an α,β-loss of hydrogen bromide, when treated with potassium *t*-butoxide in *t*-butyl alcohol.

(4) Boord, *et al.*, THIS JOURNAL, **52**, 3396 (1930); **53**, 1505 (1931) **54**, 751 (1932); **55**, 3293, 4930 (1933).

study of the reaction of the various ethyl orthohalogenoacetates with both zinc and magnesium showed that the loss of EtOX was not intramolecular to form ketene acetal, but instead was poly-intermolecular to form non-volatile condensation products of high molecular weight.[5]

Wislicenus[6] reported the removal of the elements of ethyl hypochlorite from chloro-acetal by means of sodium to form vinyl ethyl ether according to the following reaction:

$$ClCH_2CH(OEt)_2 + 2Na \longrightarrow CH_2{=}CHOEt + NaCl + NaOEt$$

The yield of the ether obtained was not reported by Wislicenus, but Lunsted[7] in this Laboratory has studied the reaction, using the bromo- instead of the chloro-acetal, and has found that vinyl ethyl ether is produced in yields of 75% of the theoretical.

Because of the success of this reaction with bromoacetal it seemed worth while to apply it to the preparation of ketene acetals from the α-bromo-orthoesters. It has proved to be most satisfactory for this purpose and the present paper reports the preparation of ketene diethylacetal and methylketene diethylacetal from ethyl orthobromoacetate and ethyl ortho-α-bromopropionate. Each of these bromo-orthoesters reacts smoothly with two equivalents of sodium to give the corresponding ketene acetal according to the following reaction:

$$RCHBrC(OEt)_3 + 2Na \longrightarrow RCH{=}C(OEt)_2 + NaBr + NaOEt$$

Ketene acetal (R is H) and methylketene acetal (R is CH_3) were obtained from the above reaction in yields of 66 and 80% of the theoretical, respectively. Methylketene diethyl acetal boils at 133–134°[8] and shows no tendency to rearrange into the isomeric acrolein diethyl acetal, $CH_2{=}CHCH(OEt)_2$ (b. p. 123–124°). It reacts vigorously, with the evolution of heat, with both water and alcohol at room temperature and yields the corresponding esters, ethyl propionate and ethyl orthopropionate.

It seems that this method should be of general applicability. The elements, EtOBr, which are eliminated from the orthoester can only come from the carbon atoms that are to carry the double bond of the ketene acetal, and since it appears from the behavior of methylketene acetal that there is no rearrangement of the ketene acetal into an unsaturated aldehyde acetal, the reaction should be applicable to the preparation of any of the higher homologs of ketene acetal.

(6) Wislicenus, *Ann.*, **192**, 106 (1879).

(7) Lunsted, M.S. Thesis, University of Wisconsin, 1940.

(8) Scheibler, Marhenkel and Nikolic, *Ann.*, **458**, 21 (1927), reported the formation of this acetal in 7% yield from the reaction of sodium ethoxide on ethyl propionate. They list the following physical properties, b. p. 78–81°; d^{13}_4 0.8002; $n^{18}D$ 1.36732 (*cf.* other properties given in the experimental part of this paper).

Experimental

Ketene Diethylacetal from Ethyl Orthobromoacetate.—To a stirred mixture of 9.2 g. (0.4 atom) of powdered sodium and 200 ml. of anhydrous benzene heated under gentle reflux was added dropwise 48.2 g. (0.2 mole) of ethyl orthobromoacetate[5] over a period of forty minutes. After the first few ml. of the bromo-ester had been added, the reaction mixture turned a characteristic deep blue in color. The reaction mixture was stirred for an additional two hours with continued refluxing. The clear supernatant liquid was then decanted from the precipitated blue salts, and the salts thoroughly washed by several triturations with anhydrous benzene. These washings were combined with the filtrate, and the benzene removed under atmospheric pressure with the heating bath temperature not exceeding 120°. The remaining material was distilled under diminished pressure (100 mm.). The yield of ketene diethylacetal was 15.4 g. (66%), b. p. 68° (100 mm.); $n^{25}D$ 1.4110; d^{25}_{25} 0.877.

Ethyl Orthopropionate.—This ester was prepared in yields of 48% of the theoretical from propioniminoethyl ether hydrochloride, m. p. 92°, by the procedure of Sah.[9] It was found advantageous to carry out the distillation of the reaction mixture under diminished pressure sufficient to keep its temperature below 85°. The ethyl orthopropionate obtained boiled at 44° (9 mm.); $n^{25}D$ 1.4000.

Ethyl Orthobromopropionate.—This ester was prepared by the procedure used for the preparation of ethyl orthobromoacetate.[5] The yields amounted to 67% of the theoretical. The product boiled at 73° (8 mm.); $n^{25}D$ 1.4338; d^{25}_{25} 1.181.

Anal. Calcd. for $C_9H_{19}O_3Br$: C_2H_5O, 52.95. Found: C_2H_5O, 53.05.

Methylketene Diethylacetal.—This acetal was prepared from ethyl ortho-α-bromopropionate and sodium in yields of 80% of the theoretical by the same procedure as that given above for the preparation of the lower homolog, ketene diethylacetal. The product obtained boiled at 133–134° or 77–78° (100 mm.); $n^{25}D$ 1.4083; d^{25}_{25} 0.8654.

Anal. Calcd. for $C_7H_{14}O_2$: C, 64.61; H, 10.72; C_2H_5O, 69.23. Found: C, 64.48; H, 10.57; C_2H_5O, 68.50.

A 3-g. sample of methylketene diethylacetal was treated with the theoretical amount of water, and the reaction catalyzed with a trace of concentrated hydrochloric acid. The reaction mixture underwent almost spontaneous reaction and the temperature rose rapidly to 80–85°. The reaction mixture then was dried over anhydrous calcium chloride, and distilled under atmospheric pressure. The ethyl propionate so obtained boiled at 98–100°; $n^{25}D$

(9) Sah, THIS JOURNAL, **50**, 516 (1928).

1.3810; sap. equiv., 103 (calcd. 102); m. p. of the *p*-toluidide of the acid, 122–124°. When this experiment was repeated using absolute alcohol instead of water a decided evolution of heat was noticed and resulting ethyl orthopropionate boiled at 157–158° (752 mm.); $n^{25}D$ 1.4000. The yields of ester in each of these cases were practically quantitative.

Summary

Ketene diethylacetal and methylketene diethylacetal have been prepared in excellent yields by the action of sodium on the corresponding α-bromo-orthoesters. This method appears to be of general applicability for the higher homologs of ketene acetal. The properties of methylketene diethylacetal are described for the first time.

Osage Orange Pigments. IV. Degree of Unsaturation and Flavone Nature[1]

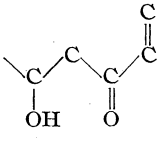
BY M. L. WOLFROM, P. W. MORGAN AND F. L. BENTON

The publication of the determination of the degree of unsaturation of osajin and pomiferin, the two pigments of the fruit of the osage orange (*Maclura pomifera* Raf.), has been withheld until enough data were obtained to warrant a satisfactory explanation. We believe that this can now be done.

Osajin could be hydrogenated catalytically at atmospheric pressure with platinum in a stepwise fashion. One double bond hydrogenated with great ease to yield dihydro-osajin. The second double bond also hydrogenated readily, although more slowly than the first, to yield tetrahydro-osajin. At this point further hydrogenation proceeded very slowly but a hexahydro-osajin was obtained. All of these hydrogenated derivatives showed the presence of the one easily acetylatable and of the one difficultly acetylatable hydroxyl group of the original osajin, a monoacetate and a diacetate of each hydrocompound being obtained. Hydrogenation thus produced no new hydroxyl groups and it was determined also that no carboxyl groups were formed. Similar results were obtained with pomiferin, except that the hexahydropomiferin has not yet been isolated. A diacetate and a triacetate of both dihydropomiferin and tetrahydropomiferin were obtained, this behavior on acetylation being identical with that of pomiferin. No carboxyl groups were produced.

Table I shows the results of the application of the perbenzoic acid titration procedure to the determination of the degree of unsaturation of the two pigments and of their reduction products. Osajin and pomiferin were found to undergo extensive general oxidation with perbenzoic acid, but when protected by acetylation, this effect was minimized, although not eliminated. If we consider the relatively low values given by the tetrahydro derivatives as a subtractable blank, it is seen that the data indicate the presence of two active double bonds in both osajin and pomiferin. The data indicate also that the third unsaturation, as represented by hexahydro-osajin, is of a different type and is not a simple aliphatic double bond. A negative Diels–Alder test with maleic anhydride denoted that the two active double bonds are not conjugated.

The nature of the unsaturation of this third double bond of osajin was therefore a presented problem. It was found that hexahydro-osajin gave a negative result with the boric acid test described by Wilson.[2] On the other hand, Table II shows that osajin and pomiferin and their dihydro and tetrahydro derivatives gave a positive color reaction. According to Wilson, flavanones give no color reaction with boric acid, and the grouping shown below is among those that do give a positive color reaction, the α,β-unsaturated carbonyl and a suitable *peri* auxochromic group, as the hydroxyl, being essential.



A phenolic group *peri* to a carbonyl group in osajin and pomiferin would be in harmony with the known fact of the presence of one hydroxyl group that is difficultly methylatable. This type of phenolic group is also frequently quite acidic and

(1) Previous publications in this series: (a) THIS JOURNAL, **60**, 574 (1938); (b) **61**, 2832 (1939); (c) **62**, 651 (1940).

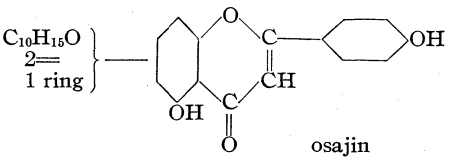
(2) C. W. Wilson, *ibid.*, **61**, 2303 (1939).

would explain the titratable phenolic acidity (one equivalent) of osajin, although pomiferin consumes less than one equivalent of alkali on direct titration.

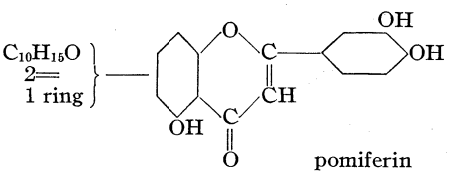
Asahina and co-workers[3] have shown that flavanones are reducible by both sodium amalgam and magnesium and hydrochloric acid; flavones are reducible by sodium amalgam and not by magnesium–hydrochloric acid; flavanols unsubstituted in position three are reducible by magnesium–hydrochloric acid and not by sodium amalgam; flavonols substituted in position three by a methoxyl group or a sugar residue are reducible by both methods. All reduction products exist in or separate from hydrochloric acid solutions as red substances of a flavylium salt nature. Application of these tests to our substances showed that hexahydro-osajin was reducible with magnesium–hydrochloric acid and that osajin, tetrahydro-osajin, pomiferin, and tetrahydro-pomiferin were not reducible by this reagent. Sodium amalgam, however, reduced all of the compounds, as shown in Table III.

The above results are indicative that osajin and pomiferin possess flavone structures and that the third double bond reduced in osajin was that between carbons two and three in a γ-pyrone nucleus, producing a flavanone structure. The absorption spectra obtained[1a,1b] for osajin and pomiferin (one band with maxima at 2730 and 2750 Å., respectively) are in harmony with the presence of a carbonyl group. These conclusions are based on color reactions and must be considered as tentative until supported by definite degradative results. Such confirmation has been obtained in part by the isolation of anisic acid from osajin dimethyl ether and of veratric acid from pomiferin trimethyl ether by oxidation with alkaline hydrogen peroxide.[1c]

If a flavone structure be subtracted from the molecular formulas of osajin ($C_{25}H_{24}O_5$) and of pomiferin ($C_{25}H_{24}O_6$), there is left a $C_{10}H_{15}O$ group. This is a monoterpene residue and would be attached very probably as shown in the formulas below. In this residue there must be two active double bonds which, when saturated, would produce the separate entity $C_{10}H_{20}O$. The one oxygen atom is unreactive, indicative of an oxide linkage. This entity has a deficiency of two atoms of hydrogen, indicative of one ring. On this basis, the formulas of osajin and pomiferin may be developed as shown below, although they are distinctly tentative and must be corroborated by further degradative work.



osajin



pomiferin

Further work on the structure of these two substances is in progress in this Laboratory.

Experimental[4]

Dihydro-osajin.—Platinum dioxide catalyst was freshly prepared and then dried for twenty-four to forty-eight hours in a vacuum desiccator over potassium hydroxide. The catalyst (0.10 g.) was suspended in 10 cc. of absolute ethanol and saturated with hydrogen. A solution of osajin (1 g. in 40 cc. of absolute ethanol) was then introduced and hydrogenation (atmospheric pressure) was stopped when 1 mol of hydrogen (55 cc., S. T. P.) had been absorbed. The time required varied with the activity of the particular catalyst preparation but with the amount of osajin cited it was generally about five minutes.

The catalyst was removed by filtration, the filtrate was concentrated to 30 cc. and the product was crystallized by the addition of water to the hot solution until turbidity appeared; yield 0.9 g. of m. p. 194.5° and 0.05 g. of m. p. 173–175°. The melting point was raised to 197°[5] by repeated crystallization from methanol and was unchanged on further crystallization from methanol, 95% ethanol or propylene chloride; yield 0.74 g.

The substance crystallized from methanol in fine, cottony needles of a light, dull yellow color. It was soluble in ethanol, less so in methanol and was moderately soluble in benzene. In alcoholic solution, it gave a dark green ferric chloride color, turning to a bright wine-red on the addition of ammonium hydroxide. In glacial acetic acid solution, it gave an immediate orange color on the addition of a few drops of concentrated sulfuric acid. In pyridine solution, it reduced Tollens reagent.

Anal. Calcd. for $C_{25}H_{26}O_5$: C, 73.87; H, 6.45; mol. wt., 406.5. Found: C, 73.88; H, 6.32; mol. wt. (Rast), 400, 380.

Dihydro-osajin Monoacetate.—Dihydro-osajin (0.44 g.) was acetylated overnight at icebox temperature with pyridine (10 cc.) and acetic anhydride (15 cc.) and the product obtained crystalline by pouring the acetylation mixture into ice and water; yield 0.48 g., m. p. 155°. Recrystal-

(3) Y. Asahina and M. Inubuse, *Ber.*, **61**, 1646 (1928); **64**, 1256 (1931); Y. Asahina, G. Nakagome and M. Inubuse, *ibid.*, **62**, 3016 (1929).

(4) All experimental work by Mr. P. W. Morgan, except where otherwise noted.

(5) All melting points recorded are uncorrected and were taken on a 360° thermometer with immersion to the −20° mark.

lization from 95% ethanol raised the melting point to 156.5° (yield 0.36 g.), unchanged on further crystallization from 95% ethanol or benzene.

The substance crystallized from ethanol as long, silky needles of a very light yellow tinge. It was very soluble in chloroform and was only moderately soluble in 95% ethanol, acetone and benzene. It gave an apple-green ferric chloride–alcohol test and gave a yellow color with sulfuric acid–acetic acid.

Anal. Calcd. for $C_{25}H_{25}O_5(CH_3CO)$: C, 72.30; H, 6.29; CH_3CO, 2.23 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 448.5. Found: C, 72.25; H, 6.19; CH_3CO,[6] 2.16 cc.; mol. wt. (Rast), 400.

Dihydro-osajin Diacetate.—Dihydro-osajin (0.6 g.) was acetylated by refluxing for three hours with fused sodium acetate (5 g.) and acetic anhydride (30 cc.) and the product isolated by pouring the acetylation mixture into ice and water; yield 0.7 g., m. p. 150°. Recrystallization from 95% ethanol and from methanol raised the melting point to 154° (yield 0.45 g.) unchanged on further recrystallization from 95% ethanol or benzene–petroleum ether; mixed m. p. with dihydro-osajin monoacetate (m. p. 156.5°), 142°.

The substance crystallized in radiating clusters of colorless, elongated plates, was very soluble in acetone and benzene and was only moderately soluble in cold alcohol. It gave no coloration with ferric chloride–alcohol and gave a yellow color slowly with sulfuric acid–acetic acid.

Anal. Calcd. for $C_{25}H_{24}O_5(CH_3CO)_2$: C, 71.03; H, 6.17; CH_3CO, 4.08 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 490.5. Found: C, 71.03; H, 6.01; CH_3CO, 4.16 cc.; mol. wt. (Rast), 460.

Dihydro-osajin diacetate also was obtained by similar treatment of dihydro-osajin monoacetate and was identified by melting point and mixed melting point.

Tetrahydro-osajin.—Osajin (1.0 g.) was reduced with hydrogen (platinum catalyst) at atmospheric pressure as described for the preparation of dihydro-osajin except that the hydrogenation was stopped when 2 mols of hydrogen (111 cc., S. T. P.) had been absorbed. With most catalyst preparations, this point was attained readily (about fifteen minutes) and further reduction proceeded very slowly. The substance was isolated as described for dihydro-osajin; yield 0.78 g., m. p. 198–200°. Pure material was obtained on recrystallization from benzene; yield 0.60 g., m. p. 206°, mixed m. p. with dihydro-osajin (m. p. 197°) 188–190°. This melting point was unchanged on further crystallization from propylene chloride. The substance crystallized from benzene or propylene chloride in the form of long, silky needles of a pale yellow color. If allowed to stand overnight in a benzene–petroleum ether mixture these needles slowly changed to short prisms of a lemon-yellow color, having the same melting point. This change in habit occurred more readily if the material was impure.

The solubilities and properties of the substance were similar to those of dihydro-osajin. In alcoholic solution, it gave an apple-green ferric chloride color, turning wine-red on the addition of ammonium hydroxide.

Anal. Calcd. for $C_{25}H_{28}O_5$: C, 73.50; H, 6.91; mol. wt., 408.5. Found: C, 73.70; H, 6.84; mol. wt. (Rast), 390, 360.

(6) All acetyl analyses recorded were made according to the procedure of K. Freudenberg and M. Harder, *Ann.*, **433**, 230 (1923).

Tetrahydro-osajin also was obtained on further hydrogenation of dihydro-osajin and was identified by melting point and mixed melting point.

Tetrahydro-osajin Monoacetate.—Tetrahydro-osajin (0.25 g.) was acetylated with pyridine and acetic anhydride as described for the preparation of dihydro-osajin monoacetate. Pure material was obtained on recrystallization from benzene–petroleum ether; yield 0.19 g., m. p. 179.5°, unchanged on further crystallization from benzene or ethanol.

The substance crystallized as silky needles of a very light yellow tinge. It was soluble in benzene and propylene chloride and was moderately soluble in ethanol. It gave an apple-green color with ferric chloride–alcohol.

Anal. Calcd. for $C_{25}H_{27}O_5(CH_3CO)$: C, 71.98; H, 6.71; CH_3CO, 2.22 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 450.5. Found: C, 71.96; H, 6.68; CH_3CO, 2.21 cc.; mol. wt. (Rast), 395, 370.

Tetrahydro-osajin was recovered from the acetyl[6] analysis by pouring the alcoholic solution into a large excess of water, removing the separated solid by filtration, and recrystallizing from benzene–petroleum ether (identification by m. p. and mixed m. p.).

Tetrahydro-osajin Diacetate.—Tetrahydro-osajin (0.30 g.) was acetylated with acetic anhydride and sodium acetate as described for the preparation of dihydro-osajin diacetate. The substance crystallized from 95% ethanol as colorless needles; yield 0.21 g. of m. p. 186°, unchanged on further crystallization from methanol. It gave no color with ferric chloride–alcohol.

Anal. Calcd. for $C_{25}H_{26}O_5(CH_3CO)_2$: C, 70.71; H, 6.55; CH_3CO, 4.06 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 492.6. Found: C, 70.89; H, 6.47; CH_3CO, 4.00 cc.; mol. wt. (Rast), 450.

This substance also was obtained by similar treatment of tetrahydro-osajin monoacetate (identification by m. p. and mixed m. p.). Tetrahydro-osajin was recovered from the acetyl analysis (identification by m. p. and mixed m. p.).

Hexahydro-osajin.[7]—This substance was prepared by the reduction of osajin (1.5 g.) with an active catalyst as described for the preparation of dihydro-osajin but allowing the hydrogenation to proceed until 3 mols of hydrogen (250 cc., S. T. P.) were absorbed. This required about three hours. It was isolated in the same manner and was purified by crystallization from methanol–water and benzene–petroleum ether; yield 1.0 g. of m. p. 162°.

The substance crystallized in the form of pale yellow needles. When impure, it crystallized with difficulty. It was water-insoluble but was soluble in the common organic solvents except low-boiling petroleum ether. It gave a dark dull-green color with ferric chloride–alcohol, turning to a dull wine-red color with ammonium hydroxide. In acetic acid solution, it gave an immediate yellow color on the addition of a few drops of concentrated sulfuric acid. In pyridine solution it reduced Tollens reagent. The compound was recovered unchanged on refluxing with either a pyridine or an alcoholic solution of hydroxylamine for two hours.

Anal. Calcd. for $C_{25}H_{30}O_5$: C, 73.15; H, 7.37; mol. wt., 410.5. Found: C, 73.16; H, 7.30; mol. wt. (Rast), 380.

(7) Preliminary experimental work by Mr. W. W. Hess.

The substance absorbed one equivalent of alkali when titrated directly in acetone solution according to the procedure described for osajin.[1a] This behavior is identical with that observed for osajin and accordingly no acid groups were formed in the reduction.

Hexahydro-osajin was obtained on further hydrogenation of tetrahydro-osajin (identification by m. p. and mixed m. p.).

Hexahydro-osajin Monoacetate.—This substance was prepared from hexahydro-osajin (0.50 g.) as described for the preparation of dihydro-osajin monoacetate and was purified by crystallization from 95% ethanol; yield 0.45 g., m. p. 138°, unchanged on recrystallization from benzene–petroleum ether.

The substance crystallized in radiating clusters of needles possessing a slight yellow tinge and was soluble in the common solvents except water and petroleum ether. It gave an apple-green color with ferric chloride–alcohol.

Anal. Calcd. for $C_{25}H_{29}O_5(CH_3CO)$: C, 71.66; H, 7.13; CH_3CO, 2.21 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 452.5. Found: C, 71.57; H, 7.03; CH_3CO, 2.28 cc.; mol. wt. (Rast), 390.

Hexahydro-osajin was recovered from the acetyl analysis (identification by m. p. and mixed m. p.).

Hexahydro-osajin Diacetate.—This substance was prepared from hexahydro-osajin (0.20 g.) as described for the synthesis of dihydro-osajin diacetate and was purified by crystallization from 95% ethanol; yield 0.17 g., m. p. 190°, unchanged on crystallization from benzene–petroleum ether, mixed m. p. with tetrahydro-osajin diacetate (m. p. 186°) 170–174°.

The substance crystallized in radiating clusters of fine, colorless needles. Its solubilities were similar to those of hexahydro-osajin monoacetate. It gave no color with ferric chloride–alcohol.

Anal. Calcd. for $C_{25}H_{28}O_5(CH_3CO)_2$: C, 70.44; H, 6.93; CH_3CO, 4.04 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 494.6. Found: C, 70.39; H, 6.82; CH_3CO, 4.01 cc.; mol. wt. (Rast), 450.

This substance also was obtained by similar treatment of hexahydro-osajin monoacetate (identification by m. p. and mixed m. p.). Hexahydro-osajin was recovered from the acetyl analysis (identification by m. p. and mixed m. p.).

Dihydropomiferin.[8]—This substance was prepared from pomiferin (2 g.) as described for the preparation of dihydro-osajin. It was purified by crystallization from propylene chloride, trichloroethylene and from ethanol–water; yield 1.3 g. of m. p. 212°.

The substance crystallized from ethanol–water as fine, lustrous, light yellow needles. It was very soluble in acetone, methanol and ethanol; moderately so in benzene and propylene chloride; and was insoluble in water. It gave an apple-green color with ferric chloride–alcohol, turning deep violet with ammonia. The compound gave an orange color with acetic acid–sulfuric acid.

Anal. Calcd. for $C_{25}H_{26}O_6$: C, 71.07; H, 6.20; mol. wt., 422.5. Found: C, 70.75; H, 6.10; mol. wt. (Rast), 390.

The substance consumed less than one equivalent of alkali when titrated directly in acetone solution according to the procedure described for osajin.[1a] This behavior is identical with that observed for pomiferin.

Dihydropomiferin Diacetate.—Dihydropomiferin (0.50 g.) was acetylated as described for the preparation of dihydro-osajin monoacetate and the product was purified from 95% ethanol; yield 0.50 g. of m. p. 166°, unchanged on crystallization from benzene–petroleum ether.

The compound formed long, silky needles of a slight yellow tint. It was readily soluble in acetone, benzene and chloroform; moderately so in 95% ethanol and carbon tetrachloride; practically insoluble in water and petroleum ether. The substance gave an apple-green color with ferric chloride–alcohol. It gave a deep yellow color with acetic acid–sulfuric acid.

Anal. Calcd. for $C_{25}H_{24}O_6(CH_3CO)_2$: C, 68.77; H, 5.97; CH_3CO, 3.95 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 506.5. Found: C, 68.80; H, 5.90; CH_3CO, 3.91 cc.; mol. wt. (Rast), 450.

Dihydropomiferin Triacetate.—Dihydropomiferin (0.60 g.) was acetylated as described for the preparation of dihydro-osajin diacetate and the product was purified from 95% ethanol and from methanol; yield 0.59 g. of m. p. 165.5°, unchanged on crystallization from benzene–petroleum ether, mixed m. p. with dihydropomiferin diacetate (m. p. 166°) 142–149°.

The substance crystallized from methanol as glistening plates and from benzene–petroleum ether as clusters of radiating needles. It was very soluble in benzene; moderately so in acetone, ethanol and methanol; practically insoluble in water and petroleum ether. It gave no color with ferric chloride–alcohol.

Anal. Calcd. for $C_{25}H_{23}O_6(CH_3CO)_3$: C, 67.84; H, 5.88; CH_3CO, 5.47 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 548.6. Found: C, 68.06; H, 5.85; CH_3CO, 5.41 cc.; mol. wt. (Rast), 520.

This substance also was produced by similar treatment of dihydropomiferin diacetate (identification by m. p. and mixed m. p.).

Tetrahydropomiferin.—This substance was prepared from pomiferin (1 g.) as described for the preparation of tetrahydro-osajin and the product was purified by crystallization from trichloroethylene–petroleum ether; yield 0.91 g. of m. p. 201.5°, unchanged on crystallization from 95% ethanol or benzene–petroleum ether.

The substance crystallized from trichloroethylene–petroleum ether as yellow plates. Its solubilities and properties were similar to those of dihydropomiferin. The substance was recovered unchanged on refluxing with a pyridine solution of hydroxylamine hydrochloride for four hours.

Anal. Calcd. for $C_{25}H_{28}O_6$: C, 70.71; H, 6.65; mol. wt., 424.5. Found: C, 70.71; H, 6.57; mol. wt. (Rast), 380.

The substance consumed less than one equivalent of alkali when titrated directly in acetone solution according to the procedure described for osajin.[1a] This behavior is identical with that observed for pomiferin. Tetrahydropomiferin also was obtained by further hydrogenation of dihydropomiferin (identification by m. p. and mixed m. p.).

Tetrahydropomiferin Diacetate.—Tetrahydropomiferin (0.35 g.) was acetylated as described for the preparation of

(8) Preliminary experimental work by Mr. F. L. Benton.

dihydro-osajin monoacetate and the product was purified from methanol; yield 0.35 g. of m. p. 154.5°, unchanged on crystallization from 95% ethanol or benzene–petroleum ether.

The compound crystallized from methanol as very long, radiating needles of a slight yellow tinge. Its solubilities and properties were similar to those of dihydropomiferin diacetate.

Anal. Calcd. for $C_{25}H_{26}O_6(CH_3CO)_2$: C, 68.49; H, 6.34; CH_3CO, 3.93 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 508.6. Found: C, 68.65; H, 6.41; CH_3CO, 3.96 cc.; mol. wt. (Rast), 500, 480.

Tetrahydropomiferin was recovered from the acetyl analysis (identification by m. p. and mixed m. p.).

Tetrahydropomiferin Triacetate.—Tetrahydropomiferin (0.50 g.) was acetylated as described for the preparation of dihydro-osajin diacetate and the product was purified from 95% ethanol; yield 0.62 g. of m. p. 181.5°, unchanged on crystallization from propylene chloride–petroleum ether or benzene–petroleum ether.

The compound crystallized from 95% ethanol as fine, colorless needles. Its solubilities and properties were similar to those of dihydropomiferin triacetate.

Anal. Calcd. for $C_{25}H_{25}O_6(CH_3CO)_3$: C, 67.62; H, 6.22; CH_3CO, 5.45 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 550.6. Found: C, 67.56; H, 6.15; CH_3CO, 5.38 cc.; mol. wt., 540, 490.

This substance was produced by similar treatment of tetrahydropomiferin diacetate and also was obtained by reduction of pomiferin triacetate[1b] (identifications by m. p. and mixed m. p.). Tetrahydropomiferin was recovered from the acetyl analysis (identification by m. p. and mixed m. p.).

Maleic Anhydride Treatment of Osajin and Pomiferin.—Osajin (0.30 g.) was recovered unchanged (0.20 g., identification by m. p. and mixed m. p.) on refluxing for two hours in xylene (20 cc.) containing 0.7 g. of maleic anhydride. Similar results were obtained with pomiferin.

Flavone and Flavanone Color Tests.—The substance to be tested[9] (10 mg.) was dissolved in 3 cc. of 95% ethanol, a small drop of mercury and 5 drops of concentrated hydrochloric acid were then introduced and the mixture heated to 40° and maintained at that temperature. Powdered magnesium was then added and from time to time more powdered magnesium and a few drops more of hydrochloric acid were added in order to maintain a constant evolution of hydrogen. A quercitin control gave a cherry-red coloration in ten minutes. No colorations were developed in five hours time by osajin, tetrahydro-osajin, pomiferin and tetrahydropomiferin. Hexahydro-osajin, however, developed on orange color in twenty minutes. This color deepened to a reddish-orange in one hour and when observed at five hours, the color was a dark cherry-red.

The sodium amalgam reductions were performed according to the general directions of Asahina and co-workers.[3] The substance (10 mg.) to be tested was dissolved in 3 cc. of 95% ethanol and the air displaced with nitrogen. Sodium amalgam (3%) was added and the tube stoppered. Standing at room temperature for ten hours or heating at 40° for two hours gave the same results. At the end of this treatment, the solution was decanted quickly from the excess amalgam and acidified with an excess of concentrated hydrochloric acid. The colored precipitates obtained were formed on dilution with water. Sodium chloride sometimes separated but redissolved on dilution. The results obtained are tabulated in Table III and indicate that osajin, pomiferin and their tetrahydro compounds possess the flavone structure and that hexahydro-osajin has the flavanone structure.

TABLE III

SODIUM AMALGAM REDUCTION OF OSAJIN, POMIFERIN AND THEIR HYDRO COMPOUNDS

Substance	Color of final HCl soln.	Color of ppt.
Osajin	Bright red	Dark red
Tetrahydro-osajin	Reddish-orange	Rust
Hexahydro-osajin	Reddish-orange	Brick-red
Pomiferin	Dark red	Purple
Tetrahydropomiferin	Cherry-red	Purple

We are indebted to Mr. John Walker (W. P. A. Project 18062) for assistance rendered in the analytical determinations and to Messrs. E. J. Penka and J. H. Tracht (N. Y. A. Project O. S. U. 181) for assistance in preparing the plant material.

Summary

1. Osajin has been hydrogenated stepwise to produce a dihydro, tetrahydro and hexahydro derivative, each of which has been characterized as a monoacetate and diacetate.

2. Pomiferin has been hydrogenated stepwise to produce a dihydro and a tetrahydro derivative,

each of which has been characterized as a diacetate and triacetate.

3. Perbenzoic acid titrations and non-reactivity with maleic anhydride indicate the presence of two non-conjugated, active double bonds in both osajin and pomiferin.

4. By a combination of the Wilson boric acid color reaction and the Asahina reduction tests, it is shown that a flavanone structure for hexahydro-osajin and a flavone structure for osajin and pomiferin are probable.

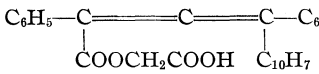
Optically Active α,γ-Diphenyl-α-carbomethoxy-γ-naphthylallene

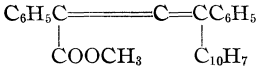
BY ELMER P. KOHLER AND WENDELL J. WHITCHER[1]

The glycolic acid ester of α,γ-diphenyl-γ-naphthylallene carboxylic acid (I) was recently



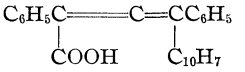
(I)

resolved in this Laboratory,[2] and we now describe the preparation and behavior of the optically active forms of the corresponding allenic methyl ester (II).



(II)

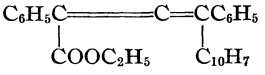
The solid inactive glycolic acid ester (I), with diazomethane, yielded its methyl derivative, but the active forms of (I), on similar treatment, or when subjected to hydrolysis in the attempt to prepare active forms of the simple allenic acid (III), gave only oily products.



(III)

The optically active methyl esters of the simple allenic acid (II), however, were synthesized by at least two of the following methods: (1) the active glycolic acid ester (I) was hydrolyzed by a large excess of alcoholic potassium hydroxide, the active form of the simple allenic acid (III) was converted into the silver salt, and the latter, with methyl iodide, to the active methyl ester (II); (2) the active allenic acid (III), prepared by the hydrolysis of active (I), was treated with diazomethane and yielded the active methyl ester (II); and (3) the active glycolic acid ester (I) was converted to the active methyl ester (II) by absolute methyl alcoholic potassium hydroxide.

A study of the formation of the active and inactive methyl esters (II) by the third method, as well as the rapid conversion of the inactive glycolic acid ester (I) to the inactive ethyl ester (IV)

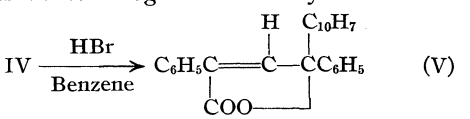


(IV)

by ethyl alcoholic potassium hydroxide, indicated that the reaction proceeded by ester interchange. The pure methyl esters (II) were obtained in yields increasing with the amount of potassium hydroxide used up to two equivalents. With 1.1 mole of potassium hydroxide (0.08 *M*), during one hour, 62% yield of methyl ester was obtained, but 80% was obtained with two moles (0.25 *M*) during a quarter hour. The sign of rotation of each optically active ester was the same as that of the parent glycolic ester no matter which method of transformation was employed.

That these enantiomeric methyl esters retained the allenic system was demonstrated by dissolving together equimolecular quantities of each in ether, and isolating from the solution only an inactive ester which proved to be identical with the inactive methyl ester (II) prepared by a method leaving no doubt as to its structure.[2]

Solutions of the active forms of the glycolic acid ester (I) and of the methyl ester (II) in benzene and in ethyl acetate remained optically active during long periods when kept in the dark, but on exposure to sunlight for a few days the solution developed a yellow color, became inactive, and the inactive form of (I) or (II) (50–60% yield) was isolated together with a yellow resin.



(V)

It has been shown that the inactive ethyl ester (IV) with hydrogen bromide in benzene solution yields the crotono lactone[3] (V).

(1) The experimental work described in this manuscript was completed before the death of Professor Kohler. The present manuscript has been prepared since that time by the junior author.

(2) Kohler, Walker and Tishler, THIS JOURNAL, **57**, 1743 (1935).

(3) Unpublished work of Dr. Max Tishler.

Whereas analogous treatment of the active methyl esters (II) seemingly offered an unprecedented opportunity for the conversion of a molecule with asymmetry due to its structure as a whole into one in which asymmetry is dependent upon a particular carbon atom, the dextro methyl ester, when subjected to this treatment, underwent ring closure as expected, but with complete loss of activity, and only the inactive form of the crotono lactone could be isolated.

Experimental Part

The Methyl Ester of the Glycolic Acid Ester, $C_6H_5C(COOCH_2COOCH_3)=C=C(C_{10}H_7)C_6H_5$.—An ether solution of 2.0 g. of inactive glycolic acid ester (I) was treated with enough diazomethane to esterify 1.2 g. Excess acid ester was removed by sodium bicarbonate extraction and 0.92 g. of crystalline methyl ester was recovered, m. p. 113°.

Anal. Calcd. for $C_{29}H_{22}O_4$: C, 80.16; H, 5.11. Found: C, 80.28; H, 5.32.

Active Methyl Esters of α,γ-Diphenyl-γ-naphthylallene Carboxylic Acid (II). (1) By Way of the Silver Salt.—Hydrolysis of 0.5 g. of levo glycolic acid ester (I) was carried out with excess alcoholic potassium hydroxide. The alcoholic solution was diluted with water, acidified with nitric acid and extracted with ether, from which extract any glycolic acid or unhydrolyzed acid ester was removed by aqueous sodium bicarbonate. The levo allenic acid (III) was taken up in aqueous sodium hydroxide and converted into the silver salt in the manner previously employed[2] in the case of the inactive acid. Boiling the salt with excess methyl iodide in ether led to isolation of 0.16 g. of levo methyl ester (II), m. p. 91°, $[\alpha]_D$ −49.8° in benzene at 25°.

Anal. Calcd. for $C_{27}H_{20}O_2$: C, 86.14; H, 5.36. Found: C, 86.14; H, 5.62.

(2) **By Means of Diazomethane.**—An ether solution of the active form of (III) prepared as above from 0.5 g. of the levo glycolic acid ester (I) when dried and treated with an equivalent quantity of diazomethane deposited 0.1 g. of levo methyl ester (II).

(3) **By Action of Potassium Hydroxide in Methyl Alcohol.**—A solution of 1.32 g. of dextro glycolic acid ester (I) in 25 cc. of a 0.25 *M* solution of potassium hydroxide in absolute methyl alcohol was boiled for fifteen minutes, poured into water and the aqueous solution extracted with ether. Ether and petroleum ether deposited 0.94 g. of the dextro methyl ester, m. p. 91°, $[\alpha]_D$ +49.3° in benzene at 25°.

Conversion of Active Ester to Crotono Lactone (V).—When 0.159 g. of the dextro methyl ester (II) was dissolved in 10 cc. of benzene containing 0.085 g. of hydrogen bromide, the rotation fell rapidly, practically disappearing in twenty minutes. From this solution was recovered 0.10 g. of the crotono lactone (V), m. p. 189°, readily identified by comparison with an authentic sample. A series of such conversions indicated that the rate and extent of lactone formation was dependent on the initial concentration of the hydrogen bromide.

Summary

Although the enantiomeric forms of α,γ-diphenyl-γ-naphthyl-allene carboxylic acid have not been obtained in the solid state, the crystalline methyl esters of this acid have been obtained from the active forms of its glycolic acid ester by three methods: (a) hydrolysis and subsequent treatment with diazomethane, (b) hydrolysis, formation of the silver salt of the acid, and subsequent reaction with methyl iodide, and (c) ester interchange in methyl alcoholic potassium hydroxide.

Whereas acids rapidly isomerize the above acid and its alkyl esters to a crotono lactone with one asymmetric carbon atom, the coversion of the active methyl esters to this lactone by hydrogen bromide in benzene was accompanied by loss of optical activity.

Binary Liquid Systems. II. The Azeotropic Composition of Carbon Tetrachloride–Ethyl Acetate Mixtures as a Function of the Pressure

BY PHILIP W. SCHUTZ AND ROBERT E. MALLONEE

In the first article[1] of this series it was pointed out that, judging from the then existing values for the composition of the azeotrope formed by carbon tetrachloride–ethyl acetate mixtures at different pressures, it appeared that this system was unique since the rate of change of the azeotropic composition with pressure decreased as the pressure decreased.

The rapid change in composition with pressure at higher pressures evidenced by these data would indicate that in the vicinity of 900 mm. a complete separation of these compounds by ordinary fractional distillation would be possible (see curve 1, Fig. 1). As the data were so few in number and the phenomenon an entirely new one, the present work was undertaken in order to obtain a complete set of data over a wider pressure range.

Experimental

The materials and apparatus were identical with those previously described[1] except that a pressure regulator was incorporated, which, with careful operation, controlled the pressure within ±0.3 mm. All runs were made as described earlier. As we were interested only in the composition of the azeotrope and since the quantities of materials were limited, we did not cover the entire range of compositions at any pressure other than 685 mm. The azeotropic composition was determined at each pressure by means of the x–y diagram familiar in the analysis of distillation problems. The composition of the liquid (x) was plotted against that of the vapor (y), both in terms of the same constituent. A forty-five degree line on such a plot represents vapors and liquids of the same composition. The intersection of the curve through the points representing equilibrium compositions of the vapor and liquid on either side of the azeotrope with this forty-five degree line represents the azeotropic composition at the pressure under which the data were obtained. At each pressure, three or more vapor–liquid equilibrium compositions were determined on each side of the azeotropic composition. In every case the intersection was at such an angle as to lead to no uncertainty as to the azeotropic composition. All analyses were made by refractive index ($n^{20}D$) and all compositions are believed accurate to well within ±0.1 mole %.

Discussion of Results

The data obtained are given in Table I and plotted as composition *vs.* pressure in curve 2, Fig. 1. It is apparent from this curve that the rate of change of composition of the azeotrope formed by this system with pressure is increasing as the pressure is decreased. This result is in accord with all available data of a similar nature on other systems. It is also apparent that the present results are not in very good agreement with the three earlier values, indicated by curve 1 of Fig. 1, and we are unable to explain the large discrepancies at the present time. The value of 43 mole per cent. at 760 mm. given by Young[2] and by Lecat[3] has been widely quoted, but it is impossible

TABLE I

AZEOTROPIC DATA AT DIFFERENT PRESSURES

P, mm.	B. p., °C.	Mole % CCl_4
789.2	76.15	55.60
583.7	66.72	60.75
484.5	61.32	63.75
385.2	55.22	67.75
285.7	47.36	72.60

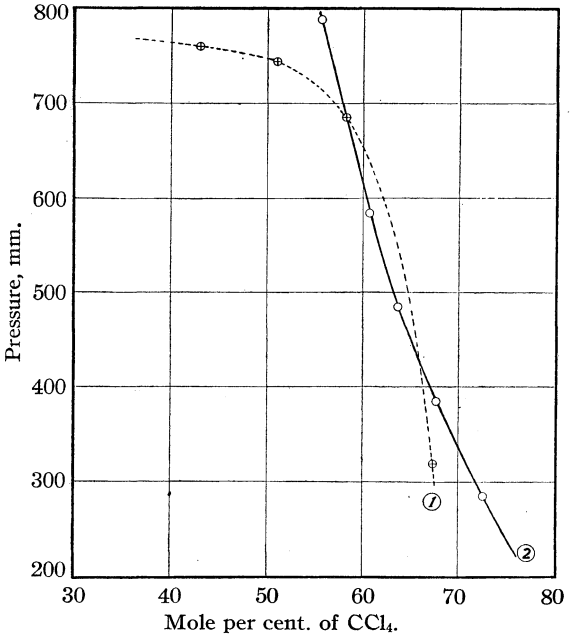

Fig. 1.—Change in composition of the azeotrope formed by the system carbon tetrachloride–ethyl acetate with pressure: 1, plot of data from Reference 1; 2, plot of data from Table I.

(3) Lecat, "l'Azeotropisme," Lamertin, Brussels, 1918, p. 136.

to find the original work in which this value was determined. Young records this value as 57 weight % of carbon tetrachloride. If by chance this should have been 57 mole per cent, the latter value agrees quite well with our results.

Conclusions

1. Data have been presented which show that the system carbon tetrachloride–ethyl acetate behaves in the same manner when subjected to pressure change as do all other systems for which similar data are available. The concentration of carbon tetrachloride in the azeotrope increases as the pressure decreases.

Crystal-Chemical Studies of the Alums. I. Solid Solutions of Potassium Aluminum Alum and Ammonium Aluminum Alum

BY HAROLD P. KLUG AND LEROY ALEXANDER

Solid solution formation by potassium aluminum alum and ammonium aluminum alum was first observed by Krickmeyer,[1] who proved the existence of a continuous series of solid solutions by density measurements. More recently Hill and Kaplan[2] have studied this pair of alums and made analyses of the conjugate liquid and solid solutions. It was noted that the tie-lines pass through the water apex of the ternary diagram, indicating that the ratio of the two alums is the same in the aqueous phase as in the solid phase. The data when plotted with respect to these two ratios fall nearly upon the true diagonal, giving what Hill and Kaplan regarded as an ideal example of Roozeboom's class 1.[3] This appears to be the first example of this type to be noted. In such a case the deviation of the two phases from the properties of ideal solutions, whatever they are, are quantitatively similar.

It seemed of interest to investigate this series of solid solutions further by means of X-ray diffraction to determine whether they were ideal from the standpoint of Vegard's law,[4] which states that for two compounds of the same crystal structure, forming a continuous series of solid solutions, the lattice constants of the solid solutions are a linear function of the composition. The results of such a study are reported in this communication.

Experimental

The materials used were reagent grade alums each of which was recrystallized from conductivity water slightly acidified with sulfuric acid. To produce fine crystals the solutions were shaken vigorously during crystallization. The crystals were washed successively with water, alcohol, and ether, and then air dried overnight. Analyses of these alums for aluminum by precipitation with *o*-hydroxyquinoline, according to the method of Kolthoff and Sandell,[5] were in excellent agreement with the theoretical composition.

The preparation of the solid solutions followed that of Hill and Kaplan[2] each complex being made up in duplicate so that the final equilibrium solid solution was formed in one case (A) from the potassium alum and in the duplicate case (B) from the ammonium alum. The stoppered bottles containing the complexes were turned in a thermostat at 25 ± 0.1° until equilibrium was attained. Contrary to the observations of Hill and Kaplan, equilibrium was reached much more slowly under the conditions of this experiment. It was necessary to introduce four lengths of 8 mm. Pyrex glass rod into each bottle, thereby producing a miniature rod-mill effect, to prevent the crystals from becoming too coarse. Even under these conditions attainment of complete equilibrium required four months. The crystals of the equilibrium solid solution were filtered off with suction, washed successively with alcohol and ether, and air-dried.

The compositions of the solid solutions were determined by analyzing for ammonia by titrating with calcium hypochlorite solution according to the procedure of Kolthoff and Sandell.[5] This method proved to be much more accurate than the usual Kjeldahl method. From the ammonia content the amount of ammonium alum present was calculated, and the potassium alum determined by difference.

Using a Buerger powder camera[6] of 57.3 mm. radius, precision determinations of the lattice constants of the pure alums and their solid solutions were made at 25°. FeK radiation was used with the films in the asymmetric position,[7] and the camera was thermostated as described by Straumanis and co-workers.[8] For control of the air thermostat a hollow cylindrical mercury regulator[9] was

used with a vacuum tube relay circuit. The temperature within the thermostat could be kept constant at 25 ± 0.2°, and the variation in sample temperature was probably considerably less than this.

The sample consisted of 200-mesh powder stuck on the outside of a fine Pyrex glass capillary tube with an adhesive such as glyptal varnish.

Diffraction lines on the films were measured to ±0.02 mm. Then, using only lines with angle θ greater than 60°, the lattice constants were calculated by Cohen's analytical method.[10]

Results

In Table I are the compositions of the pure alums and their solid solutions, and their lattice contants at 25°. The criterion for the attainment of equilibrium in the solid solutions was the close agreement in composition for the two members of a pair, each of which had approached equilibrium from opposite directions.

$NH_4Al(SO_4)_2 \cdot 12H_2O$	3.750	100.0	12.2136

The results are presented graphically in Fig. 1. A straight line has been drawn through the points representing the lattice constants of the pure alums. It is seen that the deviations from Vegard's additivity law are extremely small. The deviations are, however, believed to be real, and the pair can be said to be not quite ideal from the standpoint of their solid solutions and Vegard's law.

(10) Cohen, *Rev. Sci. Instruments*, **6**, 68 (1935); **7**, 155 (1936).

The values of the lattice constants reported above are believed to be accurate to ±0.001 Å. In the case of the pure alums the values may be compared with those of Lipson and Beevers,[11] who report for $KAl(SO_4)_2 \cdot 12H_2O$, 12.133 Å., and for $NH_4Al(SO_4)_2 \cdot 12H_2O$, 12.215 Å., each with an accuracy of ±0.002 Å., but with no indication of the temperature of their observations.

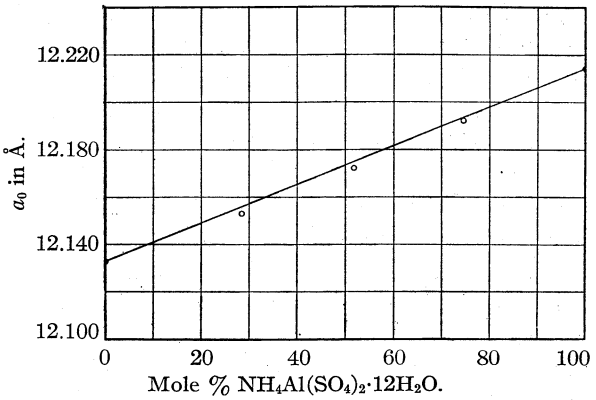

Fig. 1.—Lattice constants as a function of composition for solid solutions of potassium and ammonium alums.

The authors are indebted to G. B. Heisig for the loan of the vacuum tube relay. They also wish to acknowledge gratefully a grant from the Graduate School of the University of Minnesota which made this study possible.

Summary

1. The solid solutions of potassium aluminum alum and ammonium aluminum alum have been studied by means of X-rays and found to deviate slightly from Vegard's law of additivity.

2. The following values are reported for the lattice constants of the pure alums at 25 ± 0.1°:

$KAl(SO_4)_2 \cdot 12H_2O$ $a_0 = 12.133 \pm 0.001$ Å.

$NH_4Al(SO_4)_2 \cdot 12H_2O$ $a_0 = 12.214 \pm 0.001$ Å.

The Distribution of Protons between Water and Other Solvents

BY L. S. GUSS AND I. M. KOLTHOFF

In a study of acid–base indicator equilibria in methanol[1] buffer solutions, it was found that traces of water have a negligible effect upon the equilibrium of the system, unless the water reacts with the indicator itself.[2] In unbuffered solutions of strong acids in alcohols, traces of water have a pronounced effect upon the color equilibrium of an indicator since water is a much stronger base than the alcohols.

Qualitatively, the effect of the addition of water to alcoholic solutions of strong acids is comparable to the effect of ammonia added to aqueous solutions of strong acids. In the present paper, the effect of traces of water added to a dilute solution of a strong acid in an alcohol, ROH, has been studied quantitatively with the aid of a suitable acid–base indicator. In anhydrous alcoholic solution, the strong acid is assumed to be completely ionized into alcoxonium ions, ROH_2^+ and anions. Upon addition of traces of water, the protons distribute themselves between the alcohol and water molecules according to the equation

$$ROH + H_3O^+ \rightleftharpoons ROH_2^+ + H_2O$$

The equilibrium of this reaction is given by

$$K_p = \frac{a_{ROH_2^+} a_{H_2O}}{a_{H_3O^+}}$$

At very small ionic strengths, the activity coefficients of the ROH_2^+ and H_3O^+ ions may be taken equal. When the concentration of the water is very small, the activity of the water may be written equal to the concentration. Hence, under the specified conditions we may write

$$K_p = \frac{c_{ROH_2^+} c_{H_2O}}{c_{H_3O^+}} \qquad (1)$$

The equilibrium between the acid and alkaline forms, I_a and I_b, of an indicator in alcoholic medium is given by the expression

$$\frac{a_{I_b}}{a_{I_a}} = \frac{K_I}{a_{ROH_2^+}}$$

or

$$r = \frac{c_{I_b}}{c_{I_a}} = \frac{K_I}{c_{ROH_2^+}} \frac{f_{I_a}}{f_{I_b} f_{ROH_2^+}} \qquad (2)$$

If c is the concentration of the strong acid in the alcohol and c_{H_2O} the concentration of the water added, we have

$$c_{H_3O^+} + c_{ROH_2^+} = c \qquad (3)$$

From this and equation (1), it is derived that in the water-containing alcoholic solution

$$c_{ROH_2^+} = \frac{K_p c}{c_{H_2O} + K_p} \qquad (4)$$

Introducing this expression in equation (2), we find that

$$r = \frac{c_{I_b}}{c_{I_a}} = \frac{K_I}{c} \left[\frac{c_{H_2O}}{K_p} + 1 \right] \frac{f_{I_a}}{f_{I_b} f_{ROH_2^+}} \qquad (5)$$

If we use a simple indicator base, such as methyl yellow, I_a is a positively charged univalent ion. It has been shown[3] that in such a case f_{I_a} can be taken equal to $f_{ROH_2^+}$ at small ionic strengths. Since I_{I_b} is a neutral molecule we then have, instead of (5)

$$r = \frac{c_{I_b}}{c_{I_a}} = \frac{K_I}{c} \left[\frac{c_{H_2O}}{K_p} + 1 \right] \qquad (6)$$

By plotting values of the indicator color ratio, r, against water concentration, the intercept is K_I/c and the slope, K_I/cK_p, leads to the evaluation of K_p. Since $C_{H_3O^+}$ is negligible, compared with C_{H_2O}, the latter may be taken equal to the concentration of water added.

By studying the change in conductivity of hydrochloric acid solutions on the addition of traces of water, Goldschmidt and co-workers obtained the values of K_p of 0.0583 in ethanol[4] and of 0.235 in methanol.[5] These values are substantiated in this investigation and the method is extended to the solvent *n*-butanol.

Materials.—Methanol and ethanol were purified by methods already described,[1,6] the final product having less than 0.01% of water as estimated from density measurements. *n*-Butanol was dehydrated with aluminum amalgam[7] and distilled from anhydrous copper sulfate. Its density (d^{25}_4) measured with a 100 ml. pycnometer was found to be 0.80579. Methyl yellow was recrystallized from a water–methanol solution.

Dry hydrogen chloride was prepared by dropping concentrated sulfuric acid into concentrated hydrochloric acid, passing the gas through a wash bottle of concentrated sulfuric acid, then through a plug of glass wool. It was

finally washed in the solvent to be used. Such solutions were prepared immediately before use to diminish errors due to esterification. Standard solutions of water were prepared as previously described.[2]

Method.—A measured volume of hydrogen chloride was introduced into a test-tube, 0.5 ml. of methyl yellow solution (0.0001 *M*) added and the volume made up to 5.0 ml. with the pure solvent. The ratio r was measured by the Gillespie method. The procedure was then repeated with the same solution containing known concentrations of water. These data are listed in Tables I, II and III.

Intercept	0.70	0.48	0.32
Slope	23.8	12.8	9.8
K_p	0.029	0.038	0.033

Values of r were plotted against c_{H_2O} and from the curves K_p was evaluated. As an example, the data obtained in methanol are plotted in Fig. 1. For the sake of brevity, the figures referring to the data in ethanol and *n*-butanol are omitted. All determinations were carried out in the temperature range 25 ± 2°.

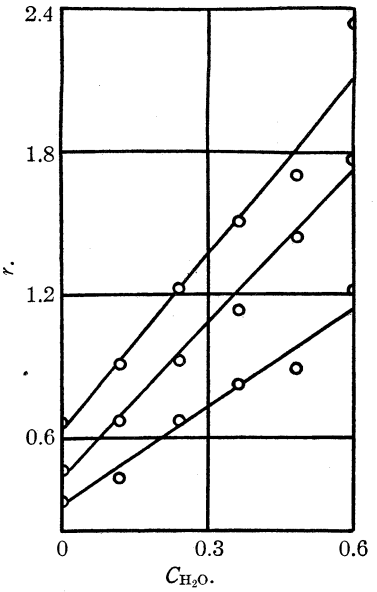

Fig. 1.—Effect of water on methyl yellow in methanol.

Discussion

The average values of K_p obtained by these measurements are 0.23, 0.059 and 0.033 for methanol, ethanol, and butanol, respectively. The first two are in agreement with the values obtained by Goldschmidt of 0.235 and 0.0583. While ethanol is a much weaker base than methanol, *n*-butanol is not much less basic than ethanol.

The fact that all points fall fairly well on straight lines substantiates the validity of the derivation in the introduction. There might, however, be a doubt in the assumption that hydrogen chloride is completely dissociated in such solvents of low dielectric constant. If we take this into consideration, equation 3 would become

$$c = c_{H_3O^+} + c_{ROH_2^+} + c_{HCl} = c_{ROH_2^+}\left[\frac{c_{H_2O}}{K_p} + 1 + \frac{c_{Cl^-}}{K_{HCl}}\right]$$

where K_{HCl} is the dissociation constant of hydrogen chloride. Equation 6 then becomes

$$r = \frac{K_I}{c}\left[\frac{c_{H_2O}}{K_p} + 1 + \frac{c_{Cl^-}}{K_{HCl}}\right]$$

Hence, if the acid were not completely dissociated, we would expect an increase in K_p with an increase in acid concentration. Since the values of K_p check within experimental error in all three cases, our assumption of complete dissociation is valid.

The results of the experiments give us a method of evaluating the dissociation constant of methyl yellow in these solvents. In Table IV are listed

these values, along with values obtained by other methods.

TABLE IV

DISSOCIATION CONSTANT OF METHYL YELLOW

Solvent	pK_I	pK_I (lit.)
Methanol	3.3	3.4[1]
Ethanol	3.1	3.1[a]
Butanol	3.1	2.8[b]

[a] The value reported by us in a previous paper (ref. 5) was erroneously given as 3.55 instead of 3.1. [b] R. B. Mason and M. Kilpatrick, THIS JOURNAL, **59**, 372 (1937).

There is a satisfactory check in the case of methanol and ethanol. The lack of agreement in butanol might be due to the presence of water in the butanol used by Mason and Kilpatrick. The amount of water can be estimated from these data. From equation (6) we find

$$K_I' = K_I \left[\frac{c_{H_2O}}{K_p} + 1\right]$$

where K_I' is the apparent dissociation constant. So

$$pK_I - pK_I' = \log\left(\frac{c_{H_2O}}{K_p} + 1\right)$$

Setting $pK_I - pK_I' = 0.3$, and $K_p = 0.033$, we get $c_{H_2O} = 0.033$ mole per liter, corresponding to 0.075% water in the butanol used by the above authors.

The colorimetric method could be used for the determination of traces of water in ethanol and butanol. From equation (6) it follows that

$$C_{H_2O} = K_p\left(\frac{rc}{K_I} - 1\right)$$

It is seen from Table II that the ratio r increases about 2.5 times when 0.18% water is added to pure ethanol.

Summary

1. The effect of traces of water on the color equilibrium of methyl yellow in dilute solutions of hydrogen chloride in methanol, ethanol and butanol, has been studied.

2. The relative basicities of these solvents have been determined and were found to decrease in the order: methanol, ethanol, butanol.

3. The dissociation constant of methyl yellow in these solvents has been calculated.

The Change with Time of the Surface Tension of Solutions of Sodium Cetyl Sulfate and Sodium Lauryl Sulfate

BY G. C. NUTTING, F. A. LONG AND WILLIAM D. HARKINS

Introduction

The static value of the surface tension of a pure liquid is attained within a very minute time after the surface is formed, for in order to reduce the surface free energy to its minimum value only a reorientation of molecules already present is necessary. With solutions, however, there is in general at equilibrium an excess or deficiency of solute in the surface layer and an appreciable time interval may be required for the transport of solute molecules from the bulk of the solution into the surface or *vice versa*.

Bond and Puls[1] have measured the surface tension of surfaces whose age is about 0.003 sec. and find that for a variety of aqueous solutions, including solutions of inorganic salts and the lower aliphatic alcohols, the surface tension even in so short a time changes to approximately the static value. They have been able to show that their experimental values of the surface tension change agree reasonably well with predicted values if diffusion alone is responsible for the time effect.

In the case of certain other solutions the final surface tension is not reached until days or weeks have passed. Examples are solutions of paraffin chain salts and of other molecules which are in part strongly hydrophobic, yet which dissociate into ions in water.[2] Doss[3] has presented evidence that unhindered diffusion would lead to establishment of equilibrium in the surface in a far shorter time than is observed, and that the rate of diffusion of the ions is slowed up enormously near the surface by the electrostatic repulsion of the ions already present in the surface layer.

In the present paper data are presented on the change with time of the surface tension of solutions of sodium cetyl sulfate and sodium lauryl

(1) W. N. Bond and H. O. Puls, *Phil. Mag.*, **24**, 864 (1937).

sulfate. The time effect has been studied over the interval between two minutes and about six hours, over a wide range of concentrations, and at particular concentrations in the presence of various inorganic salts.

Experimental Methods

Sodium lauryl sulfate and sodium cetyl sulfate are salts of strong acids and are thus much better suited for a study of time effects than are the soaps since with the latter a small change in *p*H, induced perhaps by atmospheric carbon dioxide, has a large effect on the surface tension. Samples of these two salts were generously supplied by E. I. du Pont de Nemours and Co. and were supposedly of high purity. In addition a partial analysis was carried out and the amount of barium sulfate and alcohol formed indicated a purity of 99% or better.

Surface tensions were measured by the ring method, with the apparatus used by Harkins and Jordan.[4] The apparatus was immersed in a thermostat kept at 40.00 ± 0.05°. A slow current of water-pumped nitrogen, saturated with water vapor at the temperature of the thermostat, was passed through the apparatus. That this eliminated evaporation was shown by the fact that the volume of the liquid in the cup did not change measurably in two weeks. The ring used in the measurements was of platinum iridium and its mean radius was 0.6378 cm. After precautions had been taken to prevent condensation of water on the suspension wire, it was found that the weight of the wire and ring remained constant to within 0.1 mg. over a two-day period.

Since it was found that electrolytes in small amounts affected considerably the rate of change of surface tension, much care was taken in preparing the solutions. The water used was conductivity water, redistilled in a quartz still. Solutions were made up in very clean soft glass volumetric flasks by diluting stock solutions of 0.01 *M* alkyl sulfate. The solutions were used shortly after they were prepared since experiments showed that solutions kept for a long time in glass vessels gave results different from either fresh solutions or solutions kept in quartz vessels.

The solutions were brought to 40° and then introduced into the surface tension apparatus. The level of the liquid was adjusted to that of the rim of the cup and at the same time the surface was swept free from bubbles. Initial time was taken as the instant when the surface was swept level and free of bubbles. The first measurement was taken within two to three minutes and then measurements were taken at intervals thereafter. The maximum pull on the ring was determined to 0.1 mg., equivalent to 0.013 dyne per cm.

The suitability of the ring method for measuring surface tensions changing with time has been questioned[3] because of the inevitable disturbance of the surface by the (small) motion of the ring. Tests were made by agitating the surface with the ring as violently as possible and in no case was a change in the surface tension of over 1% observed. It appears from this evidence that solute particles once in the surface-film are averse to reëntering the solution. However, it is still true that a small error is involved in the expansion of the closed surface inside the ring as this is pulled from the surface.

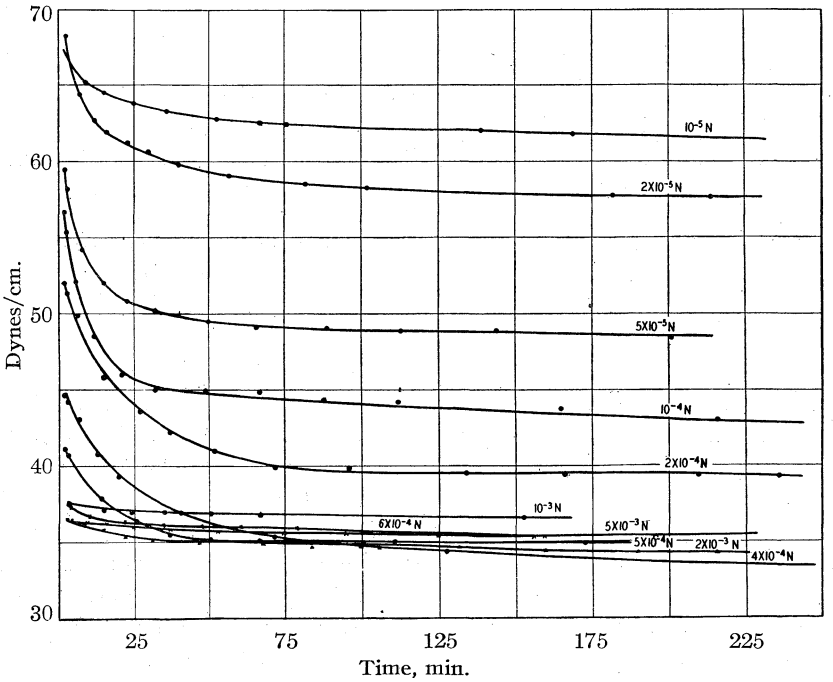

Fig. 1a.—Sodium cetyl sulfate solutions at 40°: surface tension *versus* time curves for various concentrations. At ten minutes time the concentrations of the sclutions are, in order of increasing surface tensions: 2×10^{-3}, 5×10^{-3}, 6×10^{-4}, 10^{-3}, 5×10^{-4}, 4×10^{-4}, 2×10^{-4}, 10^{-4}, 5×10^{-5}, 2×10^{-5}, 10^{-5} mole per liter.

Decrease of Surface Tension with Time

Sodium Cetyl Sulfate.—Surface tension *versus* time curves for sodium cetyl sulfate, $Na(Cet)SO_4$, have been obtained at 19 concentrations between 10^{-5} and 10^{-2} *N*. Most of the curves are shown in Figs. 1a and 1b. It is to be noted that at concentrations below 0.0006 *N* there is a considerable decrease in the surface tension in the first few minutes, while at higher concentrations the tension measured after two minutes is about the same as that measured after several hours. After the initial, more or less rapid, decrease in surface tension a much slower decline sets in which is linear

(4) W. D. Harkins and H. F. Jordan, THIS JOURNAL, **52**, 1751 (1930).

with time and nearly the same for all the solutions. The work of Adam and Shute[2] on cetylpyridinium bromide and cetyltrimethylammonium bromide suggests that the linear decrease may continue for weeks in the case of the more dilute solutions. Figure 1b shows clearly that the form of the surface tension curve at times below fifty minutes changes entirely from a very rapidly decreasing slope at 0.0002 M to an almost flat curve at 0.0007 M. Figure 1a shows that at 4 and 5 $\times$ 10^{-4} M the curve has the same general form as at 2 $\times$ 10^{-4} M. Thus the abrupt change in the time relation occurs very close to 6 $\times$ 10^{-4} M.

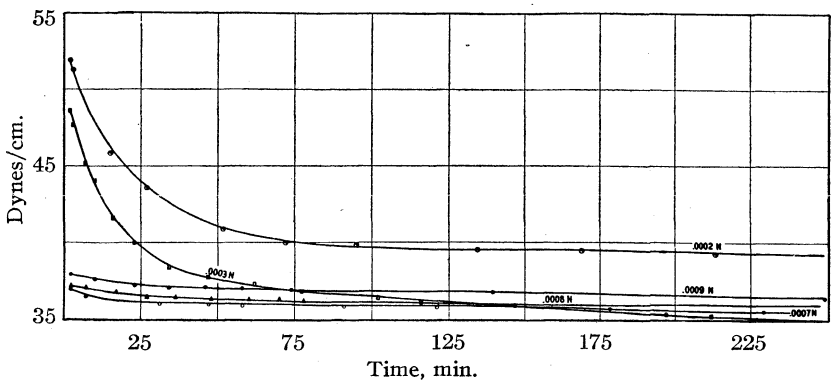

Fig. 1b.—Sodium cetyl sulfate solutions at 40°: surface tension *versus* time curves for various concentrations. At ten minutes the concentrations of the solutions are, in order of increasing surface tension: 7 $\times$ 10^{-4}, 8 $\times$ 10^{-4}, 9 $\times$ 10^{-4}, 3 $\times$ 10^{-4}, 2 $\times$ 10^{-4} mole per liter.

The abruptness with which the large initial drop in surface tension ceases at 0.0006 M is exhibited in Fig. 2 where the ratio of the surface tension after five minutes to that after two hundred minutes, σ $5/\sigma$ 200, is plotted against the logarithm of the concentration. The true value of the surface tension of all the solutions at zero time is doubtless the surface tension of water at 40° (69.6 dynes) and the final value of the surface tension for all concentrations is not far from 35 dynes. The course of the attainment of this final value is very different for different concentrations. Our experiments do not show the true final value of the surface tension but the ratio of σ at five minutes to σ at two hundred minutes serves to show clearly the sharp change in the time decrease of the surface tension which occurs at about 0.0006 M, since it is in the first fifty-minute period that the great differences are manifest.

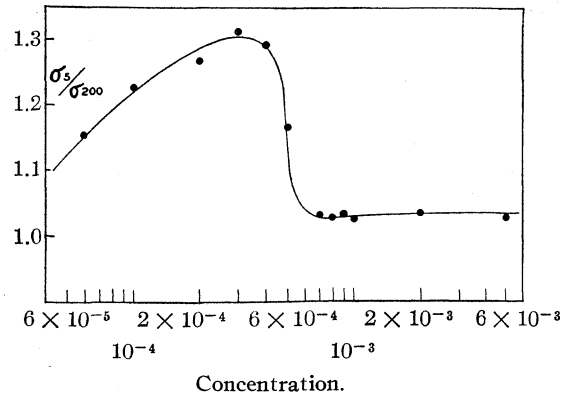

Fig. 2.—Sodium cetyl sulfate solutions at 40°: the ratio of the surface tension at a surface age of 5 min. to the surface tension at 200 min. for various concentrations.

Figures 3a and 3b exhibit the influence of added electrolytes on the rate of change of the surface tension of 0.0004 N Na(Cetyl)SO_4. It is seen from Fig. 2 that there is a large difference between the "initial" and "final" surface tensions of solutions of this concentration, and the primary effect of added electrolytes is to diminish this difference, producing S. T. *vs.* time curves similar to solutions 6 $\times$ 10^{-4} N and stronger. Thus 0.01 N sodium chloride, hydrochloric acid, sulfuric acid and sodium hydroxide give almost identical curves, while the curve of 0.01 N lithium nitrate is similar in shape, but lies above even the curve of the cetyl sulfate solution alone and thus resembles the 0.001 N solution without added electrolyte. Increasing the concentration of the electrolyte lowers and further flattens the curves.

Silver ions are much more effective in lowering the surface tension than the alkali metal ions and H^+, but the greatest effect is shown by Mg^{++} at 10^{-4} and 10^{-3} N. These solutions which contained Mg^{++} were extremely viscous, but clear throughout the experiments, and had surface tensions of about 30 dynes which scarcely changed with time. 10^{-8} N Ca^{++} lowered the surface tension slightly, but 10^{-6} N and higher concentrations raised it considerably. At the highest concentration, 10^{-4} N Ca^{++}, there was visible precipitation during the measurements, and the obvious removal of the alkyl sulfate ions from the solution accounts for the increased surface tension. In other solutions containing polyvalent positive ions, even though permanently free from turbidity, the tight binding

of the metal and cetyl sulfate ions is expressed in the heightened surface tension.

Sodium Lauryl Sulfate ($Na(Lauryl)SO_4$).—Figure 4 presents curves for this salt at ten concentrations from 5×10^{-4} to 5×10^{-2} N. At concentrations below 5×10^{-4} N the results were very erratic and are not reported. The surface tension of the solutions decreases in a rather regular fashion with concentration. The amount of the decrease is not nearly so great at the lower concentrations as with cetyl sulfate. The most remarkable result is that, except for 0.01 N and stronger solutions, whose curves are very flat anyway, the surface tension *vs.* time curves have broad minima which are followed by a rise of gentle, nearly constant upward slope. The surface tension variation of none of the solutions was followed for more than six hours, so that it is not possible to estimate either the value of the static surface tension or the time required to approach it.

Salt effects were observed with 0.004 N solutions. The results are in Figs. 5a and 5b. In none of the solutions, even those containing 0.6 N Na^+, 0.006 N Mg^{++} or 0.001 N Al^{+++}, was there ever any trace of turbidity. The unvarying effect of addition of electrolytes was to decrease the surface tension, sometimes to values nearly 4 dynes lower than observed in even the most concentrated lauryl sulfate solutions. The minimum was displaced both to shorter and longer times and was most often broadened or rendered nonexistent, but a conspicuous exception is provided by the solution which contains 1×10^{-5} N aluminum sulfate.

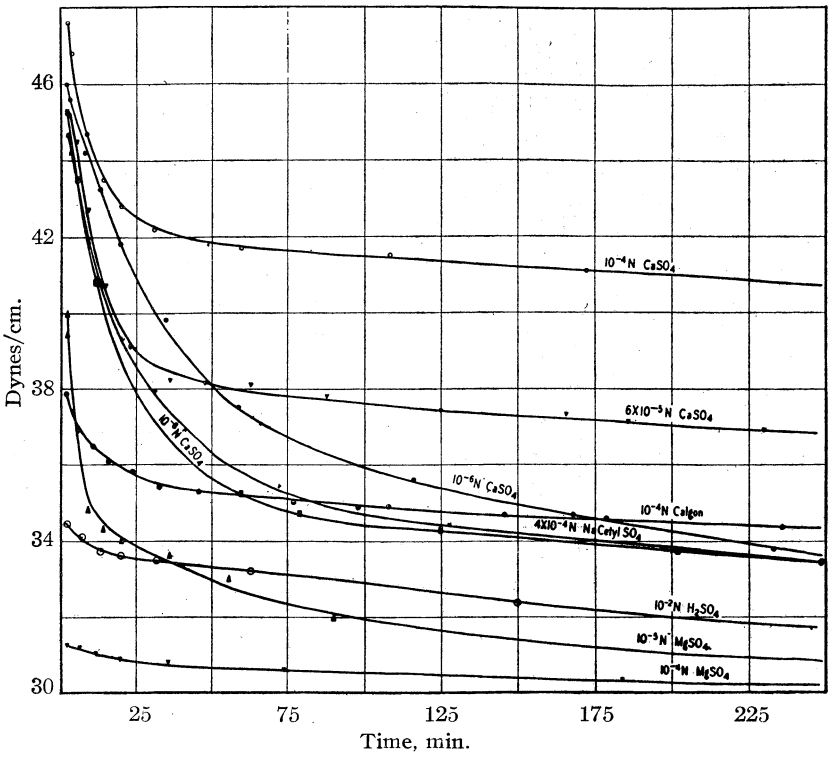

Fig. 3a.—0.0004 N sodium cetyl sulfate solutions at 40°: the effect of added salts on the lowering of the surface tension with time.

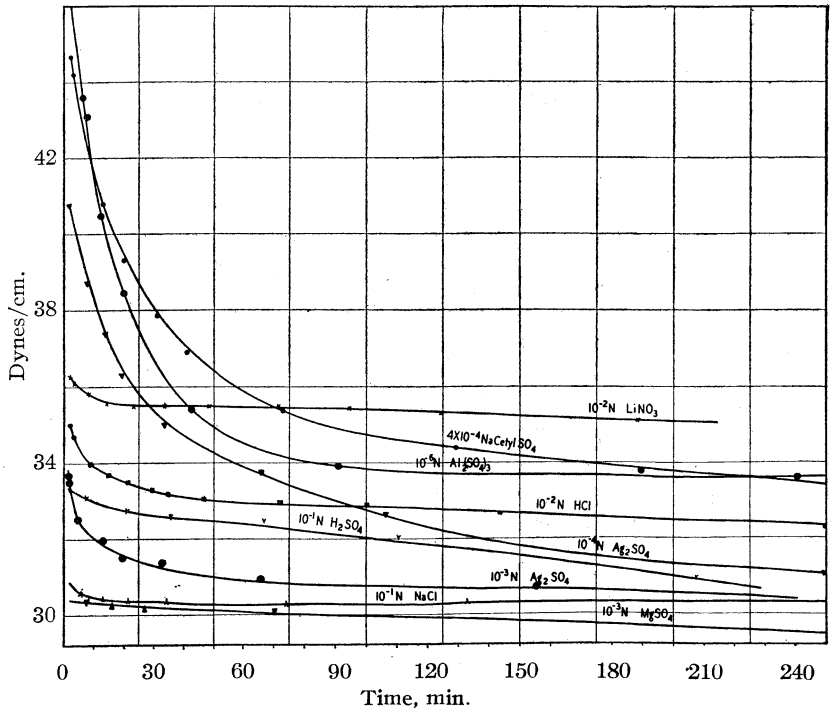

Fig. 3b.—0.0004 N sodium cetyl sulfate solutions at 40°: the effect of added salts on the lowering of the surface tension with time.

Discussion

At the instant of its formation the surface of the strongest alkyl sulfate solution employed contains about five thousand and the most dilute about five million water molecules to each molecule of solute, so that the initial surface tension approximates that of pure water. At all surface concentrations the solute particles adsorbed from the solution presumably behave like a two-dimensional gas in the sense that their cohesional forces are too feeble to produce permanent agglomeration and that they cover uniformly the entire surface area of the solution. Except in the very first stages of adsorption, however, the surface film cannot approach the behavior of an ideal gaseous film, and when the surface is nearly saturated and the film pressure is around 40 dynes per cm. the gas must be highly imperfect.

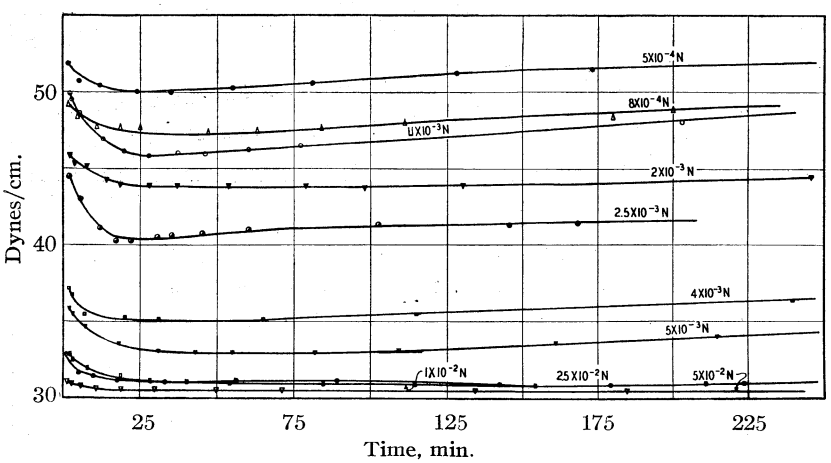

Fig. 4.—Sodium lauryl sulfate solutions at 40°: surface tension *versus* time curves for various concentrations.

The great amount of work which has been done on films of materials which contain long, unbranched paraffin chains, indicates that the area per molecule of films of sodium cetyl and lauryl sulfate under pressures of 40 dynes may fall as low as 20 sq. Å. The number of molecules per sq. cm. is then 5×10^{14}. The depth from which *all* solute would have to be removed in order to thus saturate the surface is inversely proportional to the bulk concentration of the solution and for a 10^{-6} N solution the depth is 0.8 cm.; for a 10^{-3} solution, 0.008 cm. Transfer of solute from such depths to the surface will be by no means instantaneous and attainment of the ultimate surface tension is correspondingly delayed.

Bond and Puls[1] and Doss[3] have given expressions for the order of magnitude of the time necessary for the attainment of the static value of the surface tension of solutions, assuming that the time is determined principally by the rate of diffusion of the surface-active material. The methods of Bond and Puls are not applicable to the present work since they involve a knowledge of the change of the static surface tension with concentration. An application of Doss' equation indicates that the time necessary to half saturate the surface with solute would be of the order of one second for the concentrations employed in this work. The actual times, both from the present investigation on sodium cetyl sulfate and from Adam and Shute's work on cetylpyridinium bromide and cetyltrimethylammonium bromide, are of the order of one thousand times the predicted values. While the assumptions made by Doss are probably not strictly valid no plausible variations could account for this *extreme* disagreement. It should be mentioned that the work of Harkins and King shows that a period of half an hour is required to give equilibrium with the surface in the case of a 0.000067 M solution of decylic acid. Consequently it is quite improbable that the rate of simple diffusion alone can account for the excessively slow accumulation of the solute in the surface layer which was found in our work.

The capillary active material in solutions of the alkyl sulfates is doubtless a collection of alkyl sulfate ions, each with a single negative charge. At a solution–air interface the adsorbed ions are firmly joined to water molecules through the sulfate groups, while the hydrocarbon "tails" above may assume practically any orientation with respect to the surface. At high surface concentrations the tails are closely packed and inclined steeply to the surface, and thus constitute an upper layer of liquid hydrocarbon, and a lower negative ionic layer. Sodium ions must then concentrate below this negative sheet in a diffuse positive layer. The electrical double layer thus set up provides a potential barrier to the entrance of additional alkyl sulfate ions into the surface. The height of the barrier increases with the density of ions in the surface and initially is zero.

An accurate calculation of the effect of this double layer on the speed with which ions diffuse into the surface would undoubtedly be difficult. In a rough calculation Doss, however, has shown that the hindering potential, even when the surface density of ions is small, is probably much larger than kT, the energy magnitude which determines the speed of diffusion of the ions. Thus the first ions could diffuse into the surface with rapidity but the electrical double layer caused by these ions would repel other negative ions and the rate of attainment of the equilibrium surface tension would be considerably delayed.

Evidence which qualitatively confirms this picture of the time effect can be obtained from the work of Schulman and Rideal[5] on mixed films. These investigators worked with partially compressed films of various insoluble substances, cetyl alcohol for example, on an approximately neutral substrate into which they injected very small amounts of sodium cetyl sulfate. The sodium cetyl sulfate was at a concentration (approximately 10^{-5} M) such as to cause the surface tension of water alone to be lowered only slowly, about 5 dynes in the first hour. But this same concentration of sodium cetyl sulfate causes a film of cetyl alcohol, initially present at a film pressure of 10–12 dynes and thus rather highly compressed, to show a surface tension lowering of nearly 50 dynes in a few minutes.

By the use of a different technique Harkins and Florence[6] have obtained an increase in the pressure of the cetyl alcohol film by a much greater factor. A 10^{-5} M sodium cetyl sulfate solution was found to increase its film pressure to about 6 dynes in four hours. The film of this material was then swept off quickly by the use of barriers. Then a few drops of a solution of cetyl alcohol in a low boiling ligroin were put on the surface. The solution spreads rapidly and pushes off any trace of the sodium cetyl sulfate. Even although the amount of cetyl alcohol used on the area gives by itself a pressure of only about 0.2 dyne/cm. the sodium cetyl sulfate diffused into the surface so rapidly that the pressure had risen to over 50 dynes per cm. in less than three minutes.

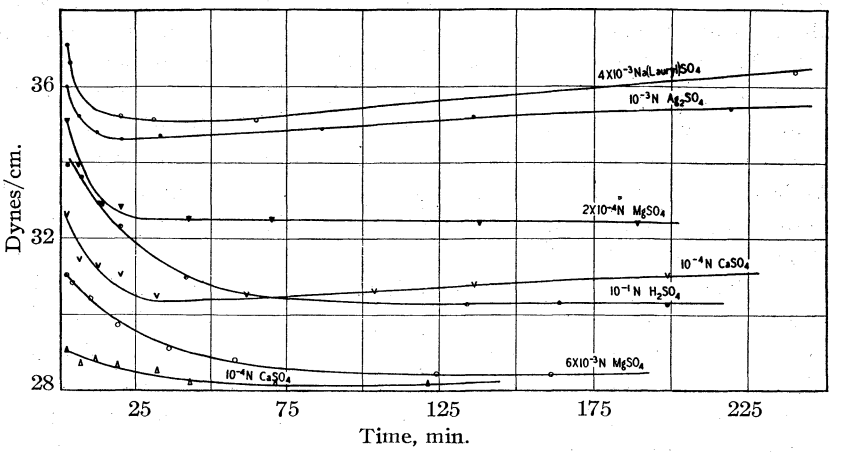

Fig. 5a.—0.004 N sodium lauryl sulfate solutions at 40°: salt effects.

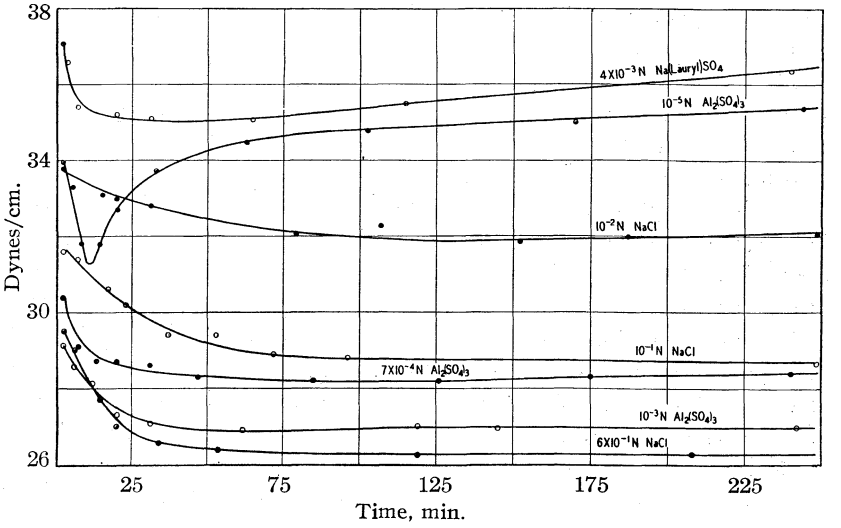

Fig. 5b.—0.004 N sodium lauryl sulfate solutions at 40°: salt effects.

Although in the last experiment described the pressure of the alcohol film alone is very low, nevertheless the surface was almost completely covered by the alcohol since its molecular area was only slightly above that found for a completely condensed liquid film (21.85 sq. Å. for cetyl alcohol at 20°).

Thus in either of the cases cited above the sur-

(6) W. D. Harkins and R. T. Florence, unpublished work.

face was so completely covered by the alcohol that the sodium cetyl sulfate molecules in general moved into holes, in the film, completely surrounded by alcohol molecules. Thus no potential barrier was present to slow down their entrance and the diffusion into the surface was rapid. Also, since very few molecules of the solute were required to fill these holes, the adjacent solution was only very slightly depleted. In such a case both of these factors coöperate to make the rise of film pressure a very rapid one.

In the case of films of the sodium cetyl sulfate by itself a phenomenon appears which is even more spectacular than the time effect itself. This is its sudden cessation at a definite concentration. As is shown in Figs. 1 and 2, the time effect for sodium cetyl sulfate at 40° stops abruptly at about 6×10^{-4} M. For sodium lauryl sulfate the similar change comes at about 7×10^{-3} M. A very similar result has been reported by Adam and Shute for the salts investigated by them. Although the explanation of the time effect as being due to the electrostatic repulsion of the surface layer of ions seems fairly straightforward, the problem as to just why this effect should almost disappear at a definite concentration needs further consideration.

There is a close correlation for a given salt between the concentration at which the time effect stops and that at which the conductivity of the solution of the salt shows an abrupt break. Thus for sodium cetyl sulfate at 40° an abrupt decrease in the conductivity sets in at a concentration of about 5×10^{-4} M and for sodium lauryl sulfate at 6×10^{-3} M.[7]

The concentrations above which the time effect disappears are almost the same, that is, respectively, 6×10^{-4} and 7×10^{-3} M. Other properties of these solutions also show abrupt changes in the same concentration regions.[8]

These sharp changes have been explained by Hartley as due to a formation of ionic micelles, spherical aggregates of around 60 paraffin-chain ions with about half this number of "gegenions" attached more or less firmly to the aggregate. The concentration at which this abrupt change enters has been called the "critical concentration for micelles." And it is clear, not only from our results but from results of other workers on essentially "fresh" solutions,[9] that the surface properties of these solutions also show sharp changes at concentrations close to the critical concentration for micelles. The difference when surface tension is the phenomenon involved is, however, that it is not so much the final value which shows a change but the rate of attainment of the final, equilibrium value.

The results which are presented here on the effect of added salts on the surface tension are just what are to be expected from a consideration of the action of added salts on the critical concentration for micelles. It has been shown[8,10] that the effect of added salt is to lower the critical concentration and this effect is larger for divalent than for monovalent cations. Hence it is not surprising that solutions of 0.0004 M sodium cetyl sulfate which contain added electrolyte show surface tensions similar to solutions of the pure salt of somewhat larger concentrations (Figs. 1 and 3). The observation that small concentrations of magnesium salts have a pronounced action offers still further evidence that divalent cations adhere more strongly to the micelles than do monovalent ones, as they should on the basis of electrostatic theory.

It is not easy to see just why the presence of micelles allows the final surface tension to be attained so much more rapidly, but the change must be due to changes in the bulk of the solution, since it is quite unlikely that there is any essential change in the surface conditions in the small concentration ranges involved. It is plausible, however, that the ease with which an ion in a micelle can get up to the surface is greater than that for the simple ion. In the first place the mobility of a micelle is such that the rate of diffusion per ion is larger for the ions in a micelle than for simple ions. Probably still more important is the condition near the surface in the region of the double layer. The double layer offers a barrier to the simple ion of many times kT. But consider the behavior of a micelle in this region, assuming for convenience a micelle of 60 simple ions with approximately half this many gegenions. As the micelle approaches the surface it will encounter the diffuse region in which gegenions are concentrated. The greater potential gradient at the surface of the micelle (compared to a simple ion) will result in a still larger number of gegenions be-

coming attached to it. Consequently the net charge of the micelle will be reduced as it approaches the surface region. The surface will still offer an electrostatic barrier to the approach of the micelle, but the force per ion will be considerably less than for the simple ion case. As a result the rate at which ions present in micelles reach the surface may be many times that for simple ions.

In addition to these coulombic interactions which tend to hinder the formation of the surface layer, there are undoubtedly short-range noncoulombic forces between the surface layer and the ions or micelles in the solute. The noncoulombic forces will in general be attractive and thus tend to accelerate the formation of the surface layer. If these forces are greater for the micelle than for the simple ions, the result would be that, with micelles present, the height of the potential barrier for entrance into the surface would be decreased and the rate of formation of the surface accelerated. At present, however, it does not seem possible to ascertain whether these forces are of sufficient importance and sufficiently different for the micelles than for the ions to explain the observed results. It is, of course, unlikely that the micelle remains in or even enters the surface as such, since it is strongly hydrophilic and cannot decrease the surface free energy by orientation but only by dissociation. At an air–solution interface the condition essential for the existence of a small spherical micelle which is stable in the bulk of the solution is removed, the micelle dissociates and its fragments orient in the infinitely large two-dimensional micelle.

Lottermoser[7] and McBain[11] have not accepted the concept of Hartley and believe, rather, that the critical concentration for micelles represents a formation, not of ionic micelles, but of neutral colloid. This latter is considered to consist of aggregates of paraffin-chain salt molecules, each aggregate carrying only a very low net charge. This theory, although it does not seem to agree with certain other properties of solutions of paraffin chain salts,[7] allows an easy interpretation of the change in the time effects noted at the critical concentration. An electrical double layer would not be expected to offer any large hindering potential to a neutral or practically neutral aggregate and consequently if neutral colloid is present it could diffuse to the surface and permit the formation of a saturated surface layer in a comparatively short time.

If, as seems likely, the surface layer of these solutions is formed from ions, a comparison of the observed surface tensions with those for neutral molecules is rather difficult. Considerable numbers of gegenions will adhere to the ionic layer, but even so the electrostatic repulsion of like ions will cause the surface layer to be less concentrated. The ionic layer will act in the opposite way to produce a lower surface tension. These two opposing effects must be approximately equal since the final surface tension is about the same as that for neutral molecules of about the same chain length.

An interesting result is obtained from an application of Gibbs' theorem to the surface tension data for paraffin-chain salts or in other cases in which the surface tension though below that of water remains constant, or even increases with concentration. Here, *if the activity is proportional to concentration*, the theorem indicates a zero, or even a negative adsorption. The apparent explanation of this is that the equation gives correctly the adsorption in the whole surface region, but that the organic solute is more concentrated in the monolayer and less just below it, than in the three-dimensional phase.

Behavior like that of the alkyl sulfates might be expected from solutions of the soaps, which we have regarded as less suitable for the present work than the alkyl sulfates since the former hydrolyze. However, Bond and Puls have found that observed and predicted values of $t_{1/2}$ for 1% and 0.25% solutions of Lux are in good agreement. Assuming that the paraffin salt in Lux is sodium stearate and that the weight of water and other electrolyte is negligible, the respective molal concentrations are approximately 0.02 and 0.008.

At these concentrations the soap is largely in micellar form and the time of half-saturation of the surface would be small. That it should be as small as predicted from diffusion theory seems to indicate that the solute in the surface film is not in the form of ions but of fatty acid molecules. These have no potential barrier hindering their entrance into the surface and would pass in preferentially from a mixture of fatty acid ions and molecules. The static surface tension would be that of a liquid hydrocarbon, 25 to 30 dynes, as is observed. The *p*H of the soap solutions is doubtless not far above 7 so that the concentration of

(11) M. L. McBain, *Proc. Roy. Soc.* (London), **A170**, 415 (1939).

neutral particles in the solutions must be considerable. If the *p*H of the Lux solutions were raised, so that the surface active particles were fatty acid ions, it is predicted that the approach to equilibrium would be far slower and that the discrepancy between $t_{1/2}$ as calculated and observed would be as great as in the case of the alkyl sulfates and the pyridinium compounds.

Observations made by the writers on the change of surface tension of sodium nonylate and sodium laurate solutions with *p*H may be reinterpreted on the basis of the time effects which have been discussed.[12] It was found that the surface tension of dilute soap solutions increased markedly with *p*H. The film at *p*H 7 was supposed to consist principally of fatty acid molecules; at *p*H 12 principally of fatty acid ions. It was also supposed that the observed film pressure was characteristic of the film species in the equilibrium proportion at each *p*H. But the surface tension lowering by an ion layer should be comparable to the lowering by a layer of molecules of the same length of hydrocarbon chain. In reporting the increase in surface tension with *p*H it was tacitly assumed that the surfaces at the time of measurements were in all cases saturated. It seems at present likely that at low *p*H, adsorption of the fatty acid molecules was so rapid that the surface at the time of measurement was indeed saturated; while at higher *p*H adsorption of the fatty acid ion was so slow that the measured surface tension corresponded to only a partly filled surface. If the measurements had been postponed for several hours saturation would have been approached and the surface tension probably about the same as for the less alkaline solutions.

Adam and Shute's measurements on sodium lauryl sulfate are not in very good agreement with our own. Their surface tensions are invariably *higher* by 5 or 10 dynes per cm., even though the error to be expected in the ring method used by us is such as to give a value slightly too high. Also, their curves do not have the minima which we have observed. The minima suggest a change in the nature of the adsorbed particles but the character of the change cannot yet be specified.

Summary

The change with time of the surface tension of solutions of sodium cetyl sulfate has been measured in the concentration range 10^{-5} to 10^{-2} N at 40°; and of sodium lauryl sulfate in the range 5×10^{-4} N to 5×10^{-2} N. The changes were followed in the interval two minutes to from three to six hours.

The effects of various uni-, di- and trivalent ions at several concentrations have been measured on 0.0004 N sodium cetyl sulfate and 0.004 N sodium lauryl sulfate.

In the cetyl sulfate solutions without added electrolyte at concentrations below 6×10^{-4} N a rapid fall in tension is found followed by a slow fall, linear with time, at the same rate for all solutions. At concentrations higher than 6×10^{-4} N the initial fall is small and the surface tension soon reaches a value of about 35 dynes per cm. The effect of electrolytes is the same as an increase in cetyl sulfate concentration, namely, greatly to hasten attainment of static values of the surface tension near 30 dynes. The effectiveness of the positive ions increases rapidly with the valence.

In the lauryl sulfate solutions the initial fall is not so marked and is followed usually by a broad minimum surface tension. The nature of this phenomenon cannot now be specified. The effect of electrolytes is again to hasten attainment of a static tension of about 25–30 dynes, and the order of effectiveness is the same as for the cetyl sulfate.

The slow fall is considered due principally to the potential barrier set up against alkyl sulfate ions diffusing into the surface by the ions already in the surface film. No quantitative account of the effect of this electric double layer on the rate of fall of surface tension has yet been possible.

The sudden change in the time effect at a definite concentration has been correlated with the appearance of micelles in the bulk of the solution. The reasons for this change are obscure but a tentative explanation is considered. The effects of added electrolytes are shown to be related to the critical concentration for micelles.

The apparent increase of surface tension of solutions of soaps with increasing *p*H is accounted for on the basis of slow accumulation of fatty acid ions in the surface films at high *p*H, and rapid accumulation of fatty acid molecules by simple diffusion at low *p*H.

Thermal Data on Organic Compounds. XX. Modern Combustion Data for Two Methylnonanes, Methyl Ethyl Ketone, Thiophene and Six Cycloparaffins

BY GEORGE E. MOORE,[1] MELVIN L. RENQUIST AND GEORGE S. PARKS

In a continuation of the thermochemical studies initiated by Richardson and Parks[2] in this Laboratory, we have recently measured very accurately the heats of combustion of 2-methylnonane, 5-methylnonane, methyl ethyl ketone, thiophene, and six cycloparaffins, *viz.*, methylcyclopentane, ethylcyclopentane, cyclohexane, methylcyclohexane, *n*-heptylcyclohexane and *n*-dodecylcyclohexane. These thermochemical results will be summarized in the present paper. In subsequent publications they will be combined with the proper entropy data to yield values for the free energies of the several compounds.

Apparatus and Method

The apparatus and general method were essentially the same as in the previous study of Richardson and Parks. Three cylinders of oxygen were used in this investigation and with each a new series of calibrations of the calorimeter, involving five to eight combustions, was carried out with standard benzoic acid (sample 39e) supplied by the United States Bureau of Standards. For the "standard" conditions of our calorimeter the three series of calibrations yielded the mean results 3211.4 (±0.2) cal., 3211.2 (±0.5) cal., and 3211.3 (±0.2) cal. for the energy equivalent per degree at 25.0°. These values are in excellent agreement with the result (3211.3 ± 0.4 cal.) reported previously.

The combustions were made with the bomb filled with oxygen to a pressure of 30 atm. at 23° and, except in the case of thiophene, with 1 ml. of water initially in the bomb. In general, most of the air originally in the bomb was washed out by two preliminary fillings with oxygen to a pressure of 5 atm. and thus the correction for nitric acid formation was kept down to about 1 calorie in a total of approximately 6000 calories.

In the case of thiophene, however, this washing out was omitted because we found that the air originally in the bomb was very essential as a catalyst for the complete oxidation of the sulfur to sulfuric acid. After each combustion of this substance we analyzed for both nitric acid and nitrous acid and corrected for the small heat effects of these according to the procedure of Huffman and Ellis.[3] In this work with thiophene appropriate corrections were also made on the standard energy equivalent of our calorimetric system (a) for the omission of the 1 ml. of water usually placed within the bomb, (b) for the absence of any vaporization of this water during the average temperature rise of 2°, and (c) for the small amount of water vapor condensed from the air initially in the bomb by the sulfuric acid produced. The sulfuric acid corresponded approximately to the concentration $H_2SO_4 \cdot 1.70H_2O$ and hence for comparative purposes our experimental combustions were always corrected to this exact composition by means of Table III in the paper of Huffman and Ellis.

Because of their volatility all these compounds, save the dodecylcyclohexane, were sealed into thin-walled capsules of soft glass, which in general had volumes of 0.5 to 0.8 ml. and weighed 0.065 to 0.085 g. empty. These capsules were flattened or collapsed on opposite sides so that, when practically filled with the sample to be burned, they would withstand the deformation produced by the oxygen pressure within the bomb. The capsules were made so light because it was found that when they weighed more than 0.100 g. they tended to explode on ignition and the liquid therein was thrown about the bomb with incomplete combustion as a result. Under our conditions the thin glass fused quietly to allow smooth combustion from the liquid surface. As a "promoter" in these combustions about 0.02 g. of *n*-hexadecane was placed within the combustion crucible and always in part on an upturned flat side of the glass capsule so that the ignition took place mainly from above. Hexadecane was chosen for this purpose because of its very small volatility at room temperature and its high, precisely known heat of combustion (11,283 cal. $g.^{-1}$ in air[2]). Its preliminary ignition was always accomplished with the platinum wire and cotton string system described by Richardson and Parks.

Units.—The unit of energy used throughout this paper is the defined conventional calorie which has been derived from the international joule by multiplying by the factor 1.0004/4.185. The unit of mass is the gram true mass which is derived from the weight in air against brass weights by use of a suitable correction factor for buoyancy. The molecular weights are based on the 1939 table of atomic weights.[4]

Materials

The various substances studied had been prepared and purified with great care and were exceptionally high grade. After due allowance is made for the effect of dissolved air in these liquids, the impurities, except possibly in the case of the heptylcyclohexane, should produce no error in the combustion results greater than 0.01%.

Methylnonanes.—The samples of 2-methylnonane and 5-methylnonane were prepared in the Research Laboratory of the Ethyl Gasoline Corporation. Their preparation and properties have been fully described by Calingaert and Soroos.[5]

***n*-Heptylcyclohexane and *n*-Dodecylcyclohexane.**—These substances were prepared in the Chemical Laboratory of Stanford University by Dr. Simon Kinsman, working with Prof. C. R. Noller. The preparations were made

from highly purified intermediates by Grignard syntheses, followed by careful drying and fractional distillations under reduced pressure. Part of these samples were first used in heat capacity measurements at low temperatures and in this connection their fusion behavior was carefully noted.

The *n*-dodecylcyclohexane melted sharply at 12.5° and from its fusion curve we have estimated its purity at 98.8 mole %. Undoubtedly the remaining 1.2% represents for the most part closely related hydrocarbons which produce no appreciable error in the heat of combustion. The *n*-heptylcyclohexane melted at −41.2° but with considerable premelting. Our estimate of its purity was 97.1 mole %. In view of this rather low figure the material was carefully tested for impurities, such as halogens, which might produce an appreciable error in our combustion value. These tests indicated not more than 0.003% chlorine (by weight). Moreover, microanalyses on these two compounds yielded results for carbon and hydrogen corresponding to the theoretical compositions within the limits of experimental error (about 0.1%).

Methyl Ethyl Ketone.—This material was specially prepared for our low temperature specific heat measurements by the Shell Development Company. The fusion behavior indicated a purity of 99.74 mole %. As several months elapsed after our specific heat studies, we again dried and redistilled this material in two batches, just before the combustions, using as drying agents calcium sulfate and calcium oxide, respectively. These two samples yielded identical combustion results within the limits of experimental error.

Methylcyclopentane, Ethylcyclopentane, Cyclohexane, Methylcyclohexane and Thiophene.—All five compounds were specially prepared for this study in the Research Laboratory of the Shell Development Co. Three purity requirements were set up for these preparations: first, that the sample should be free of any elements not present in the molecular formula of the compound; second, that its only permissible impurities should be isomers or closely related homologs; and third, that its absolute purity should be greater than 98 mole %. Careful syntheses and extensive chemical purifications were relied on to meet these first and second requirements and repeated fractional distillations in a Podbielniak column to meet the third. The final criterion of purity adopted was that all portions of the distillate, on refractionation of a "pure" sample, should be of the same refractive index (within ±0.00003) as the charge to the still.

In the case of the ethylcyclopentane three different syntheses were employed before all these requirements were completely met. The second of these preparations, however, contained only 0.012% chlorine and we made a number of combustions with this as well as with the "pure" third sample. Counting this small chlorine content as inert material, we obtained practically identical heats of combustion for these two samples.

For cyclohexane three fractional crystallizations were employed in addition to the foregoing purification methods. The final product melted very sharply at 6.35°.

Table I contains the refractive indices and densities at 20° of the "pure" samples of these five compounds.

TABLE I

REFRACTIVE INDICES AND DENSITIES

Substance	$n^{20}D$	d^{20}_4
Methylcyclopentane	1.4095	0.7482
Ethylcyclopentane	1.4196	.7665
Cyclohexane	1.4262	.7785
Methylcyclohexane	1.4230	.7694
Thiophene	1.5283	1.0638

The Heats of Combustion and Derived Data

After considerable preliminary work on the method of burning with the glass capsules, about sixty precise combustion determinations were made upon these ten compounds. These combustions ordinarily involved gaseous carbon dioxide and liquid water as end-products but in the special case of thiophene the water was replaced by sulfuric acid at the concentration $H_2SO_4 \cdot 1.7H_2O$.

Table II contains a summary of our experimental combustion data together with some important thermal data calculated therefrom. The number of combustions made on each particular compound is given in the fifth column. The resulting mean values for the energy evolved in the isothermal bomb process per g. at 25.0°, represented by the term $-\Delta U_B/m$, and the mean deviations of the individual combustions from these mean values, represented by Δ, appear in the succeeding column. The values of the bomb process were then calculated per mole and corrected to the standard constant-volume process where the reactants and products are each at 1 atmosphere by means of the equations of Washburn.[6] The energy evolved in this hypothetical standard process is designated in the table by the symbol $-\Delta U_R$. From this quantity $-\Delta H_R$, the heat evolved in the isobaric process at 1 atm., was obtained by addition of the proper work term. Finally, $-\Delta H_f^\circ$, the heat of formation of the compounds from the elements (gaseous hydrogen, graphitic carbon and rhombic sulfur) was then calculated from $-\Delta H_R$ by use of 68,318 cal.[7] and 94,030 cal.[8] for the heats of formation of water and carbon dioxide, respectively, and in the case of thiophene by the value $\Delta H = -135{,}010$ cal.[3] for the process

$$S(\text{rhombic}) + 2.7H_2O(l) + 3/2O_2(g) = H_2SO_4 \cdot 1.7H_2O\ (l)$$

In the calculation of the quantity $-\Delta U_R$ from the tabulated $-\Delta U_B/m$ values a correction of +0.02% was made in all cases for the air dis-

[a] This is the mean of the six combustions made on the unboiled samples.

solved in the liquid sample when weighed. This is the correction worked out from the available solubility data by Richardson and Parks to allow for the air dissolved in other liquid hydrocarbons. Whether the same figure should be applied to methyl ethyl ketone, which is considerably more polar, seemed perhaps questionable. Accordingly, we first made six combustions on the two preparations of this substance containing dissolved air and then three more combustions on samples of the same materials which, just prior to weighing, had been boiled under reduced pressure. For $-\Delta U_B/m$ the mean value for these first six combustions, corrected by +0.02%, was 8070.2 (±2.3) cal., while the last three air-free samples yielded a mean of 8071.1 (±0.9) cal. This agreement is highly satisfactory, and therefore we have used 8070.6 cal. as a final mean for this substance in computing $-\Delta U_R$.

The uncertainties attached to the tabulated values of $-\Delta U_R$ have been calculated by use of the "precision error" described by Rossini.[9] This includes not only the "reaction error" for the combustion of the particular compound but also our "calibration error" averaging 0.014%, an "assigned error" of 0.023% on the standardizing substance, and an arbitrary allowance for a 10% uncertainty in the Washburn correction.

Previous Work.—The literature contains no earlier combustion values for five of these compounds. Zubow made determinations on methylcyclopentane, cyclohexane, methylcyclohexane and methyl ethyl ketone. His values, as revised by Swietoslawski,[10] differ from our present data by −0.23%, +0.01%, +0.16% and −0.04%, respectively. More modern combustion results for cyclohexane, obtained by Richards and Barry (revision by Swietoslawski and Bobinska[11]) and by Roth and von Auwers,[12] exceed our present value by 0.41 and 0.10%, respectively. Berthelot's very early result[12] for thiophene apparently differs from ours by +0.54% and that of Thomsen by −0.68%.

Acknowledgment.—Before concluding, we wish to thank Dr. George Calingaert for the gift of the methylnonane samples and the Shell Development Co. for the preparation of six of these ten compounds as well as for financial assistance in this research during the summer of 1939.

Summary

1. A bomb calorimeter has been calibrated and then used for precise measurements of the heats of combustion of the following ten substances at 25° and constant volume: 2-methylnonane, 5-methylnonane, methylcyclopentane, ethylcyclopentane, cyclohexane, methylcyclohexane, *n*-heptylcyclohexane, *n*-dodecylcyclohexane, methyl ethyl ketone and thiophene.

2. From these experimental results the corresponding heats of combustion and heats of formation at constant pressure have been calculated.

Acid-Polymerized Dipinene. I. Dehydrogenation[1]

BY JOHN J. RITTER AND JACOB G. SHAREFKIN[2]

Dipinene, $C_{20}H_{32}$, resulting from the action of acids on alpha- or beta-pinene has been studied by various investigators since its discovery a century ago by Deville,[3] who obtained the substance from turpentine oil and sulfuric acid.[4]

The delayed revival of active interest in the diterpene group is probably due in part to the fact that the diterpenes are comparatively few and their acids quite common, while the converse is true of the sesquiterpenes. Recent workers have made use of sulfur dehydrogenation with inconclusive results in most instances, particularly with the acid-polymerized diterpenes. Up to the present no definite facts bearing upon their structure have appeared. Of the naturally occurring diterpenes alpha-camphorene, distilled from camphor oil[5] and also resulting from myrcene by polymerization,[6] dehydrogenated with sulfur to a product which failed to yield a picrate. Careful fractionation of the unsaponifiable portion of rosin oil[7] gave colophene and diterpenes which were believed to be identical with those prepared by heat and acid polymerization of monoterpenes. Although retene was obtained in the Vesterberg reaction from the colophene fraction, the diterpenes were reported unchanged after this treatment. Neither Aitken[8] nor Blackie[9] obtained an aromatic on sulfur dehydrogenation of the solid diterpene dacrene. The first instance of successful dehydrogenation of a naturally occurring diterpene is Beath's[10] isolation of isoretene from a diterpene which he considered identical with rimunene.

Among the synthetic diterpenes the only reported dehydrogenation resulting in an isolable aromatic is that of dipinene by Dulou,[4] after Kondakow and Saprikin[11] found no aromatic on sulfur dehydrogenation of this substance. Carter, Smith and Read[12] were unable to isolate an aromatic after sulfur dehydrogenation of the closely similar acid-polymerized di-alpha-phellandrene. Dulou's picrate melted at 132° and the hydrocarbon at 64–65°. The latter he stated to be di-isopropyldiphenyl although this compound does not appear in the literature and no proof of structure is given by the author.

We have now reinvestigated the dehydrogenation of dipinene with the immediate view to isolation and identification of a pure aromatic and ultimately arriving at significant facts bearing upon the nature of the carbon skeleton of dipinene. The conditions for most satisfactory dehydrogenation were studied first. High temperature (280°) resulted in complete carbonization while lower temperature (150°) gave no aromatic isolable as picrate. Slow sulfur addition to dipinene at intermediate temperatures (200°) proved most effective in minimizing carbonization; however, the yield of pure aromatic even under the most favorable conditions was of the order of 1.0%. Dilimonene, practically identical with dipinene in physical characteristics, dehydrogenated under the same conditions to the same product. The same product, in yields of the same order, was obtained by the use of diphenyl ether as solvent in the dehydrogenation as well as by slow selenium addition[13] and by the pressure-tube procedure of Ruzicka.[14]

All of the picrates prepared melted at 169.5–170° and showed no depression in mixed melts. From these a solid hydrocarbon was obtained melting at a higher temperature (78.2–78.4°) than that reported by Dulou. This hydrocarbon is not reported in the literature; its analysis and general characteristics indicated a phenanthrene of molecular formula $C_{17}H_{16}$, and its synthesis by an independent method[15] proves it to be 2,6,9-trimethylphenanthrene.

Experimental

Dipinene.—alpha-Pinene was purified by repeated distillation through a 20-cm. column: b. p. 155–156°;

d^{20}_{20} 0.8613; $n^{23}D$ 1.4682; $[\alpha]^{25}D$ +28.12°. Limonene prepared in the same manner gave the constants: b. p. 175.5–175.8°; d^{25}_{25} 0.8395; $n^{23}D$ 1.4710. Phosphoric acid (85%, 500 cc.) is placed in a three-neck flask fitted with a mechanical stirrer, dropping funnel and thermometer; an equal volume of monoterpene is added dropwise with rapid stirring during eight hours while the temperature is held below 30°. After the addition is completed the stirring is continued at room temperature for one hundred and twenty hours. The mixture is then allowed to stand until the layers separate, and the upper layer neutralized with potassium carbonate solution, dried over anhydrous potassium carbonate and distilled. Dipinene, a colorless viscous liquid, is obtained in 71% yield: b. p. 127–128° (1 mm.); d^{25}_{25} 0.9316; $n^{25}D$ 1.5149; $[\alpha]^{25}D$ ±0. *Anal.* Calcd. for $C_{20}H_{32}$: C, 88.15; H, 11.85. Found: C, 87.44; H, 11.71. Dilimonene, prepared in the same way, gave the constants: b. p. 128° (1 mm.); d^{25}_{25} 0.9313; $n^{25}D$ 1.5170; $[\alpha]^{25}D$ ±0. The procedure is that of Carter, Smith and Read[12]; the yields and constants of our products are in agreement with theirs.

Dehydrogenation.—Sulfur (80 g., 2.5 moles) is added to dipinene (136 g., 0.5 mole) in 2–3 g. portions at uniform intervals over a ten-day period, the temperature remaining close to 200° throughout. The resulting black tarry mass is distilled with superheated steam to yield an oil which is extracted from the distillate with ether and distilled at 1 mm. after drying the extract with anhydrous potassium carbonate and removing the ether on the steam-bath. Three fractions are cut: to 140°, 3.7 g.; 140–160°, 36.3 g.; 160° until no further distillation, 32.2 g. Addition of hot saturated alcoholic picric acid to these fractions shows picrate formation only with the latter two.

By the same procedure, 1760 g. of dipinene gave 980 g. of steam-distilled oil which yielded for the three fractions 60, 390, and 375 g., respectively. Redistillation of these through a 20-cm. column at 1 mm. resulted in a fraction of 472 g. at 160–185° which yielded a solid picrate. The crude picrate melted at 137°; after three recrystallizations from alcohol 19.7 g. of pure product, m. p. 169.5–170°, was obtained. *Anal.* Calcd. for $C_{23}H_{19}N_3O_7$: N, 9.35. Found: N, 9.25. The picrate from dilimonene dehydrogenation, m. p. 169–170°, showed no depression in a mixed melting point with that from dipinene. *Anal.* Calcd. for $C_{23}H_{19}N_3O_7$: N, 9.35. Found: N, 9.29. Attempts to increase the yield of the picrate-producing hydrocarbon by re-treatment of the low-boiling fraction from the dehydrogenation with sulfur resulted in failure.

Hydrocarbon $C_{17}H_{16}$.—The picrate from the previous section (23.5 g.) was decomposed in a Soxhlet thimble by refluxing with water for fifteen hours; the 10.5 g. of yellowish solid remaining in the thimble after drying at 40° was extracted with benzene in the Soxhlet apparatus. The extract on evaporation left a solid residue, m. p. 75–75.5°; after three recrystallizations from 95% alcohol colorless tablets, m. p. 78.2–78.4°, were obtained. *Anal.* Calcd. for $C_{17}H_{16}$: C, 92.68; H, 7.32. Found: C, 92.61; H, 7.53.

Summary

A modified Vesterberg reaction was found most suitable for dipinene dehydrogenation.

All dehydrogenation methods tested with dipinene and dilimonene yielded the same hydrocarbon, which has a higher melting point than that previously reported.

Analysis of the hydrocarbon and its picrate rules out the proposed di-isopropyldiphenyl structure of Dulou.

The hydrocarbon has the composition and general characteristics of a phenanthrene.

Acid-Polymerized Dipinene. II. Identification of the Dehydrogenate

BY JOHN J. RITTER AND VIRGIL BOGERT[1]

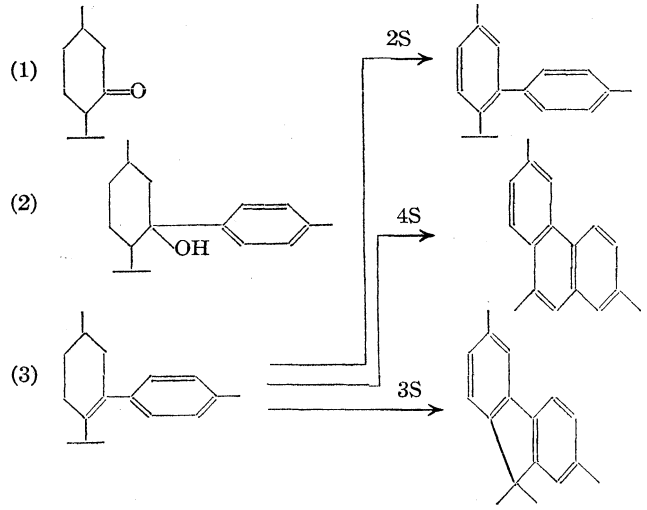
In the preceding paper the isolation of a pure crystalline aromatic hydrocarbon $C_{17}H_{16}$ from the sulfur dehydrogenation of acid-polymerized dipinene $C_{20}H_{32}$ is reported. While the limited amount of this substance at hand curtailed rather severely any extended studies of structure by oxidative or other means, its general characteristics indicated the structure of a phenanthrene. Our inability on repeated attempts to isolate a phenanthraquinone on oxidation was ascribed to the presence of a methyl group on carbon atom 9 or 10. Consideration of antecedent literature dealing with dipinene and the action of acids on alpha-pinene led us to the postulation of a carbon skeleton for the dimer which pointed specifically to 2,6,9-trimethylphenanthrene as the most probable substance resulting from its dehydrogenation. This has now been verified by synthesis and the demonstrated identity of the synthetic product with the dehydrogenate.

We proceeded from *l*-menthone (1) which was condensed with *p*-tolylmagnesium bromide to 3-*p*-tolylmenthol (2); the latter was dehydrated to 3-*p*-tolylmenthene-3 (3), which was dehydrogenated with sulfur to 3,4[1]-dimethyl-6-isopropyl-

(1) Based upon a portion of the dissertation submitted by Virgil Bogert to the Graduate Faculty of New York University in partial fulfillment of the requirements for the degree of Doctor of Philosophy, June, 1940.

diphenyl (4) and also to 2,6,9-trimethylphenanthrene (5). The yield of the phenanthrene was low, the major portion of the product consisting of a liquid aromatic $C_{17}H_{18}$ which appears to be tetramethylfluorene (6). We hope to furnish unequivocal proof of the structure of the latter in a later publication. The tentative assignment of structure to (6) gains added confirmation from the fact that it, like fluorenes generally, forms no crystalline picrate.

The facts here presented serve not only to establish the structure of the dipinene dehydro-



genate but seem also to offer an explanation of the principal difficulty of structure determination by dehydrogenation in the acid-polymerized diterpene group, *i. e.*, the formation, principally, of a non-picrating fluorene along with very small quantities of the more easily recognizable phenanthrene. The synthetic trimethylphenanthrene is formed ultimately by dehydrogenative ring-closure of an *o*-isopropyldiphenyl; in spite of the homogeneity of the latter the yield of phenanthrene is of the same order as that resulting from dipinene dehydrogenation under the same conditions. Previous investigators[2] have uniformly disregarded the non-picrating liquid fractions from dipinene dehydrogenation.

We are at present engaged in further studies of the partial and complete dehydrogenation of dipinene with a view to isolation of diphenyls or fluorenes, as well as the more general problem of dehydrogenative ring-closure of *o*-alkyl diphenyls with sulfur. The results of these investigations will appear shortly in THIS JOURNAL.

Experimental

3-*p*-Tolylmenthol.—*p*-Bromotoluene (129 g., 0.75 mole) is added slowly with mechanical stirring to magnesium (18 g., 0.75 mole) and 400 cc. of absolute ether after the reaction has been started with only 50 cc. of ether. After completion of the reaction on the water-bath the mixture is cooled in an ice-bath; ordinary (1) menthone (80 g., 0.52 mole) in 100 cc. of absolute ether is added slowly with continuous stirring. The reaction product is allowed to stand overnight at room temperature, heated on the water-bath for one hour, and then hydrolyzed with 25% aqueous ammonium chloride solution. The ether layer is separated, dried over sodium sulfate, and the ether removed. Distillation of the residue at 2 mm. yields 28–37 g. of menthone and 64–71 g. of the carbinol: b. p. 127–128° (2 mm.); 140–142° (4 mm.); m. p. 39.5°; d^{25}_4 0.9745; $n^{25}D$ 1.5150; $[\alpha]^{25}D$ −14.49°. *Anal.* Calcd. for $C_{17}H_{26}O$: C, 82.93; H, 10.57. Found: C, 82.81; H, 10.26.

3-*p*-Tolylmenthene-3.—3-*p*-Tolylmenthol-3 (50 g.) is mixed with twice its weight of anhydrous oxalic acid and the mixture heated in an oil-bath at 150° for six to eight hours. Water is added to dissolve the oxalic acid and the upper layer of hydrocarbon separated. Distillation of the product yields 37–40 g. (80–87%) of 3-*p*-tolylmenthene: b. p. 118–120° (2 mm.); 145–147° (10–11 mm.); d^{25}_4 0.9269; $n^{25}D$ 1.5218; $[\alpha]^{25}D$ +49.45. *Anal.* Calcd. for $C_{17}H_{24}$: C, 89.47; H, 10.53. Found: C, 89.59; H, 10.26.

3,4[1]-Dimethyl-6-isopropyldiphenyl.—3-*p*-Tolylmenthene-3 (22.8 g., 0.1 mole) is placed in a 50-cc. round-bottom flask sealed to an air-cooled reflux condenser which is in turn connected with a potassium hydroxide trap to collect the evolved hydrogen sulfide. Sulfur (6.4 g., 0.2 mole) is added in portions of 1–2 g. over a twelve-hour period at 220–230°. The heating is continued for an additional sixty hours or until 6.3–6.7 g. of hydrogen sulfide (93–99% of calcd.) has been collected in the trap: yield, 19 g. (85%); b. p. 108–110° (2 mm.); 130–132° (4–5 mm.); d^{25}_4 0.9619; $n^{25}D$ 1.5579. *Anal.* Calcd. for $C_{17}H_{20}$: C, 91.07; H, 8.93. Found: C, 91.11; H, 9.09.

Trinitro Derivative.—3,4[1]-Dimethyl-6-isopropyldiphenyl is heated for one-half hour on the steam-bath with concentrated nitric–sulfuric acid mixture: m. p. (from alcohol) 164–165°. *Anal.* Calcd. for $C_{17}H_{17}N_3O_6$: N, 11.70. Found: N, 11.76.

Total Dehydrogenation of 3-*p*-Tolylmenthene-3 with Sulfur.—3-*p*-Tolylmenthene-3 (22.8 g., 0.1 mole) is dehydrogenated as in the preceding paragraph with sulfur (12.8 g., 0.4 mole) added in portions of 1–2 g. over a twenty-four hour period. After addition of one-half of the sulfur the temperature is raised from 220–230° to 280–300° and finally to 320–340°, where it is held for thirty-six hours. The total time of dehydrogenation is ninety-six hours, and the weight of hydrogen sulfide collected 12.2 g. Distillation at 2 mm. yields: dimethylisopropyldiphenyl, b. p. 110°, 1.3 g.; 2,6,9,9-tetramethylfluorene, b. p. 123–125°, 5 g.; high-boiling fraction, 130–210°, 1.4 g. The latter yields the picrate of 2,6,9-trimethylphenanthrene; a further quantity of picrate is obtained by alcohol extraction

of the distillation residue and treatment of the extract with alcoholic picric acid. The total yield of picrate is 0.3 g. (0.66%).

Total Dehydrogenation with Selenium.—3-*p*-Tolylmenthene-3 (22.8 g., 0.1 mole) is dehydrogenated with 32 g. of selenium added over thirty-six hours. Heating for an additional seventy-two hours with gradual increase of the temperature from 290 to 360° gives a product which on ether extraction and distillation yields: 3,4¹-dimethyl-6-isopropyldiphenyl, 3.0 g.; 2,6,9,9-tetramethylfluorene, 4.0 g.; fraction 130–210°, 1.5 g. From the latter and also the distillation residue 0.9 g. of picrate, m. p. 169–170°, is obtained (yield, 2%).

2,6,9-Trimethylphenanthrene.—The hydrocarbon is obtained from its picrate by the method described in the previous paper: yield, 1.4% of calculated from 3-*p*-tolylmenthene-3; m. p. 78.5°. Both the picrate and the hydrocarbon show no depression in mixed melts with the corresponding products from dipinene dehydrogenation.

2,6,9,9-Tetramethylfluorene.—B. p. 123–125° (2 mm.); d^{25}_4 0.9893; $n^{25}D$ 1.5811; mol. wt. (Rast, camphor) 225, calcd. 222. *Anal.* Calcd. for $C_{17}H_{18}$: C, 91.89; H, 8.11. Found: C, 91.80; H, 8.20. Monobromo derivative, m. p. 94.5°. *Anal.* Calcd. for $C_{17}H_{17}Br$: C, 67.77; H, 5.64. Found: C, 67.75; H, 5.15. Dinitro derivative (mixed acid at room temperature), m. p. 218° (from alcohol). *Anal.* Calcd. for $C_{17}H_{16}N_2O_4$: N, 8.97. Found: N, 9.15.

Summary

2,6,9-Trimethylphenanthrene has been synthesized, characterized, and shown to be identical with the product of dipinene dehydrogenation.

Mono- and Di-α-furfuryl Glycines

BY J. E. ZANETTI AND J. T. BASHOUR

We have shown the pronounced reactivity of furfuryl bromide in ether solution on the amino group[1] and it appeared of interest to investigate whether the neighboring presence of a carbethoxy group would influence the reaction. Accordingly we have studied its action on the amino group of α-aminoacetic ethyl ester and found it to proceed quite satisfactorily. The free α-furfurylamino acid can be obtained readily from the ester by hydrolysis. We have found that excess of the ethyl aminoacetate to liberate the furfuryl addition compound from its hydro bromide gave better results than the use of sodium or potassium hydroxides for similar purposes. The reaction may then be written as

$$C_4H_3OCH_2Br + 2NH_2CH_2COOC_2H_5 \longrightarrow C_4H_3OCH_2NHCH_2COOC_2H_5 + NH_2HBrCH_2COOC_2H_5$$

The glycine ester hydrobromide precipitates out of the ether, leaving in solution the furfuryl glycine ethyl ester.

As explained in the experimental part, both the mono- and di-α-furfurylglycines can be obtained in one operation by using varying ratios of α-furfuryl bromide to the amino acetate, a procedure which we found unsatisfactory when working with free amines.

Experimental

The general procedure was similar to that already described for the preparation of furfurylalkyl amines.[1] The hydrobromide precipitated and was filtered off in the usual manner. It was also found that the difurfurylaminoacetic ester could be obtained in one operation by slightly increasing the ratio of furfuryl bromide to amine. Two and one-half cc. of ethyl aminoacetate per cc. of furfuryl alcohol used in the bromide synthesis, gives a product consisting of 80% monofurfuryl derivative and 20% difurfuryl derivative. Two cc. of amine per cc. of furfuryl alcohol resulted in approximately equivalent quantities of secondary and tertiary products. Yields were over 80% on the basis of 70% yield of furfuryl bromide.

Ethyl aminoacetate was prepared from glycine through the ester hydrochloride by the methods of Curtius[2] and Fischer.[3] Over-all yields of 65% were readily obtained.

Ethyl Furfurylaminoacetate.—In contrast to glycine ester, this product is quite stable, long standing causing only a slight yellowing with very slight decomposition as determined by redistillation. No diketopiperazine formation was observed. It is soluble in most organic solvents: b. p. 99–101° at 3 mm.; $n^{25}D$ 1.4735; d^{25}_{20} 1.096. The hydrochloride melted at 68–70°. It was recrystallized from absolute alcohol by addition of absolute ether to incipient cloudiness.

Anal. Calcd. for $C_9H_{13}O_3N$: N, 7.65. Found: N, 7.70.

Ethyl Benzofurfurylaminoacetate.—Three cc. of ethyl furfurylaminoacetate was dissolved in 4.2 cc. of benzoyl chloride with cooling in an ice-bath. Thirty cc. of 2.5 *N* sodium hydroxide, ice-cold, was added at once and the mixture shaken for twenty minutes. Ether was added and the aqueous layer discarded. The ether layer was washed with dilute hydrochloric acid and water, and dried overnight with sodium sulfate. After removal of the ether, the product was collected at 157–162° at approximately 1 mm.

(1) Zanetti and Bashour, THIS JOURNAL, **61**, 3133 (1939); **62**, 742 (1940).

(2) Curtius and Goebel, *J. prakt. Chem., N. F.*, **37**, 159 (1888).

(3) Fischer, *Ber.*, **34B**, 436 (1901).

The compound is highly viscous, quite soluble in ether, insoluble in water and petroleum ether. It crystallizes from ether–petroleum ether solution in a dry-ice bath, remelting at once on removal from the bath, $n^{25}D$ 1.5072.

Anal. Calcd. for $C_{16}H_{17}O_4N$: C, 66.9; H, 5.9. Found: C, 66.5; H, 6.1.

Furfurylaminoacetic Acid.—Ethyl furfurylaminoacetate was boiled with ten times the quantity of water until solution was complete (about two and one-half hours). The solution was evaporated to incipient dryness, the residue dissolved in a minimal quantity of water and precipitated in the form of fine needles by the addition of ten volumes of dioxane. It may be recrystallized from boiling alcohol or from four parts of hot water, the latter producing thick, transparent prisms: m. p. 210–212° (corr.) in preheated baths. Slow heating results in much decomposition starting at about 180°.

Anal. Calcd. for $C_7H_9O_3N$: C, 53.8; H, 5.80; N, 9.03. Found: C, 53.7; H, 5.72; N, 8.94.

Ethyl Difurfurylaminoacetate.—B. p. 154–157° at 3 mm.; $n^{25}D$ 1.4691; d^{25}_{20} 1.135; m. p. of hydrochloride, 94–96° (corr.) (recrystallized from absolute ethanol and ether). The ester is soluble in most organic solvents.

Anal. Calcd. for $C_{14}H_{17}O_4N$: N, 5.3. Found: N, 5.6.

Difurfurylaminoacetic Acid.—The preceding ester was hydrolyzed by two methods: (A) 1 g. of ester was boiled for fifteen minutes with 3 g. of barium hydroxide octahydrate and 5 cc. of water. The barium was removed in the usual manner and the filtrate evaporated nearly to dryness; (B) 1 g. of ester was boiled with 5 cc. of 24% sodium hydroxide until solution was complete (ten minutes). It was cooled at once and an equivalent quantity of sulfuric acid was added. After evaporation to dryness the product was extracted with hot ethanol, from which it crystallizes on cooling. It may be recrystallized from hot water, or more conveniently from 10 parts of ethanol and decolorizing with bone black. It is insoluble in ether and benzene; m. p. 140–141° (corr.).

Anal. Calcd. for $C_{12}H_{13}O_4N$: C, 61.3; H, 5.53; N, 5.95. Found: C, 61.3; H, 5.60; N, 6.04.

The authors are indebted to Mr. Saul Gottlieb for the microanalyses of these compounds.

Summary

The following derivatives of glycine have been synthesized by the use of furfuryl bromide, and their properties reported: ethyl furfurylaminoacetate, ethyl benzoylfurfurylaminoacetate, furfurylaminoacetic acid, ethyl difurfurylaminoacetate and difurfurylaminoacetic acid.

The Preparation of 2-Furanacetic Acid

BY JULIUS PLUCKER, III, AND E. D. AMSTUTZ

In the course of other work to be reported shortly, it became necessary to prepare considerable quantities of 2-furanacetic acid. This compound is not accessible by the usual avenues of approach[1] and, although it has been prepared in several ways,[2] either the methods are inconvenient or the yields are low.[3] It was therefore thought to be of interest to investigate the applicability of the rhodanine method.

Julian and Sturgis[4] have repeated some of the elegant work of Gränacher[5] on the aldehyde-rhodanine condensation products and have shown that the rhodanine method offers a valuable way of preparing the acids of one more carbon atom. Gränacher condensed furfural with rhodanine[5] and cleaved the resulting product with alkali to give β-2-furyl-α-thioketopropionic acid (II) which in turn was converted to the oximino acid (IV). In order to prove the applicability of this method therefore it was necessary only to determine whether the oximino acid could be satisfactorily decarboxylated and dehydrated to furanacetonitrile (V). This has been done and it was found that the desired nitrile is obtained in yields consistently above 80% of the theoretical. In this connection it is interesting to note that furanacetaldoxime (VII) is reported to yield only a small amount (12–15%) of the same nitrile on dehydration under essentially the same conditions.[2b] Following is a summary of the reactions involved in the rhodanine method

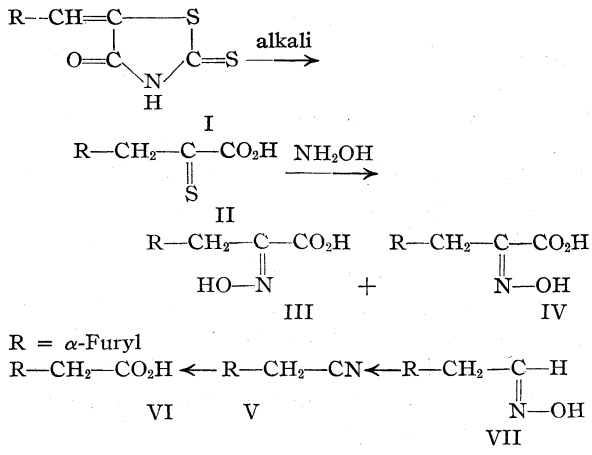
(1) (a) Johnson and co-workers, THIS JOURNAL, **52**, 1284 (1930), and Reichstein, *Ber.*, **63B**, 749 (1930), have shown that when furfuryl chloride is treated with aqueous potassium cyanide the product is composed mainly of 5-methyl-2-furonitrile instead of the expected 2-furanacetonitrile. (b) Gilman, *Rec. trav. chim.*, **51**, 93 (1932), has found that furfuryl chloride could not be made to undergo a smooth reaction leading to the Grignard reagent which, if formed, would be expected to yield the desired acid on carbonation.

(2) By the following reaction sequences: (a) Reichstein, ref. 1a; furoyl chloride → furoyl cyanide → furoyl formic acid → furanacetic acid. Sodium furylglycidate → furanacetaldehyde → furanacetic acid. (b) Johnson, ref. 1a; furfural → furyl nitro ethylene → furanacetaldoxime → furanacetonitrile → furanacetic acid.

(3) R. Robinson, *J. Chem. Soc.*, 718 (1937), mentions the lack of a satisfactory method of preparation of 2-furanacetic acid.

(4) THIS JOURNAL, **57**, 1126 (1935).

(5) *Helv. Chim. Acta*, **5**, 610 (1922).



The oxime of 2-furanpyruvic acid was obtained in two forms, both light yellow microcrystalline powders, m. p. 127–128° dec.[6] and m. p. 143.8–144° dec., tentatively designated[7] as compounds III and IV, respectively. The lower melting form is the more soluble and reacts the less vigorously with acetic anhydride but gives essentially the same yield of the nitrile as the higher melting form. They were not investigated further.

Experimental[8]

Fufuralrhodanine (m. p. 229–231° dec.; yield, 94%) was prepared and cleaved with alkali to 3-α-furyl-2-thioketopropionic acid (m. p. 114.6–115°; yield, 99%) according to the directions of Julian and Sturgis.[4]

3-α-Furyl-2-oximinopropionic Acid.—A solution of 26.6 g. of thioketo acid and 16 g. of hydroxylamine (from 33.8 g. of the hydrochloride and 11.3 g. of sodium) in 325 cc. of absolute ethyl alcohol was refluxed for one-half hour and distilled under diminished pressure till all the alcohol was removed. The brown solid remaining was dissolved in 80 cc. of 5% sodium hydroxide solution and filtered free of sulfur. Cautious acidification of the cooled filtrate with 75 cc. of 10% hydrochloric acid precipitated 8.5 g. (32%) of the acid as a light brown powder, m. p. 143.8–144° dec.; reported, m. p. 145°.[4] The filtrate was extracted with five 50-cc. portions of ether which were combined, dried over anhydrous magnesium sulfate and evaporated. There was obtained in this way an additional 13 g. (49.5%) of acid, m. p. 127–128° dec.; total yield, 21.5 g. or 81.5% of the theoretical.

In a run with twice the quantities used above the alkaline solution of the acid was acidified to congo red in the cold under ether. There was obtained a yield of 49.1 g. (93%) of acid, m. p. 121.5–122° dec.

2-Furanacetonitrile.—A mixture of 49.1 g. of oximino acid (m. p. 121.5–122.0°) and 237 g. of acetic anhydride was warmed till effervescence set in. Upon cessation of the vigorous reaction the dark reddish solution was rapidly steam distilled. The steam distillate was extracted with 300 cc. of ether in several portions which were combined, washed to neutrality with sodium carbonate solution, dried over anhydrous magnesium sulfate and distilled. There was obtained a yield of 27.3 g. (87.7%) of nitrile, b. p. (17 mm.) 84°, $n^{25}D$ 1.4691; reported,[1a] b. p. (20 mm.), 78–80°, $n^{25}D$ 1.4715.

The oximino acid (11.7 g.), m. p. 127–128°, gave 6.1 g. or an 82.5% yield of the nitrile and 7.3 g. of the acid, m. p. 143.8–144°, gave 3.5 g. or 76%. The use of a smaller quantity of the higher melting material is thought to explain the discrepancy in yields.

Hydrolysis of the nitrile in the customary way with 18% aq. potassium hydroxide gave 96% of the theoretical yield of 2-furanacetic acid, white leaflets, m. p. 66.8–67.5° (crude); m. p. authentic specimen,[9] 67–67.5°; mixed m. p. 66.5–67°.

The over-all yield of 2-furanacetic acid from furfural is about 73% of the amount required by theory.

Summary

It has been shown that 2-furanacetic acid may be conveniently prepared in very satisfactory yield from furfural by the rhodanine method.

Benzylalkali Compounds[1]

BY HENRY GILMAN, HENRY A. PACEVITZ AND OGDEN BAINE

Benzylsodium was found to be the most effective organometallic compound of a series examined in the metalation of furan.[2] In extension of interconversion reactions of organometallic compounds, we have examined procedures which might make the highly effective benzylalkali compounds more accessible.

Rearrangement of Sodium in *p*-Tolylsodium.—Bachmann and Clarke[3] isolated benzoic acid (34%), *p*-toluic acid (30%) and phenylacetic acid (0.36%) after carbonation of a reaction mixture of di-*p*-tolylmercury, sodium and benzene which had been allowed to stand for one month. The formation of phenylacetic acid establishes a migration of sodium to benzylsodium, and is an interesting variation of the lateral metalation of toluene by ethylsodium which was first examined by Schorigin.[4] However, it is uncertain in the Bachmann–Clarke experiment whether migration took place directly or involved first the metalation of benzene, used as a medium, inasmuch as phenylsodium must have formed because of the high yield of benzoic acid. We have carried out the same reaction using as a medium petroleum ether, which is not metalated by organosodium compounds, and find that phenylsodium is no necessary intermediate, benzylsodium being formed in quite satisfactory yields.

Ziegler[5] prepared *p*-tolylsodium from *p*-chlorotoluene and found that by omitting strong heating a migration of the metal from the nucleus to the side-chain did not occur. This result is also consistent with the long time, room temperature experiment of Bachmann and Clarke. Apparently the migration of sodium is not only independent of the intermediate formation of phenylsodium, but also takes place very slowly at room temperature. Actually, as we have shown, the reaction can be carried out for a short time and without refluxing to give exclusively *p*-tolylsodium; and, with refluxing, to give exclusively benzylsodium. This is also strikingly illustrated with the reaction of *m*-chlorotoluene and sodium.[6]

Benzylpotassium.—The existence of benzylpotassium has been postulated reasonably in some reactions, but the compound has not hitherto been accessible. Marcus,[7] in some studies with Schlenk, mentioned that 1,1,1,2-tetraphenylethane was cleaved by potassium to triphenylmethylpotassium and benzylpotassium.

$$(C_6H_5)_3CCH_2C_6H_5 + 2K \longrightarrow (C_6H_5)_3CK + C_6H_5CH_2K$$

Subsequently, Ziegler and Thielmann,[8] in an orienting experiment, carried out a similar reaction with sodium–potassium alloy and isolated, subsequent to carbonation, triphenylacetic acid but no phenylacetic acid. Wooster and Mitchell[9] added one equivalent of benzyl bromide to two equivalents of potassium in liquid ammonia. A deep red color developed, and this faded gradually until the solution was colorless. They concluded that the red color was due to benzylpotassium.

We now find that it is possible to prepare benzylpotassium in workable quantities by two different procedures. First, di-*p*-tolylmercury and potassium are heated in petroleum ether.

$$(p\text{-}CH_3C_6H_4)_2Hg \xrightarrow{[K]} p\text{-}CH_3C_6H_4K \longrightarrow C_6H_5CH_2K \qquad [I]$$

Second, toluene is metalated laterally in essential accordance with Schorigin's procedure in which ethylsodium was used. In one of these syntheses phenylpotassium (prepared from benzene and *n*-butylpotassium) was used as the metalating agent.

$$C_6H_5CH_3 + C_6H_5K \longrightarrow C_6H_5CH_2K + C_6H_6 \qquad [II]$$

In the other synthesis, the transitorily formed phenylpotassium was used as the metalating agent.

$$C_6H_5Cl + 2K \longrightarrow [C_6H_5K]$$
$$[C_6H_5K] + C_6H_5CH_3 \longrightarrow C_6H_5CH_2K \qquad [III]$$

Phenylpotassium is most probably formed as an intermediate in reaction [III], although we have not as yet succeeded in interrupting the reaction to capture the phenylpotassium by carbonating to benzoic acid. Our present interpretation is that phenylpotassium is formed from chloro-

benzene and potassium in toluene, and then rapidly metalates the toluene to give benzylpotassium. This reaction, by the way, is one of choice for the preparation of benzylpotassium inasmuch as the 82–84% yield of pure phenylacetic acid indicates an even higher yield of benzylpotassium.

In sharp contrast with the reaction of chlorobenzene and potassium is the related reaction with sodium. Bockmühl and Ehrhart[10] were probably the first to prepare phenylsodium (in 70–80% yields) from chlorobenzene and sodium. We have found that it is possible to prepare phenylsodium in at least an 87% yield, and in a few hours, by appropriately cooling a mixture of chlorobenzene and sodium in toluene. If, however, the mixture is refluxed then the phenylsodium metalates the toluene to give benzylsodium in an 80% yield. Morton and co-workers[11] have prepared benzylsodium by metalation of toluene with amylsodium directly, or with phenylsodium prepared by metalation of benzene by amylsodium.

An examination of the reaction of *p*-chlorotoluene with sodium in some solvents has shown that *p*-tolylsodium can be prepared in 80% yield in toluene. When the reaction mixture is refluxed, a migration of the sodium takes place and benzylsodium is formed in a 79% yield. This migration is not peculiar to *p*-tolylsodium, for we have observed that benzylsodium is also formed from *o*-tolylsodium (prepared from di-*o*-tolylmercury and sodium), and from *m*-tolylsodium (prepared from *m*-chlorotoluene and sodium,[6] as well as from di-*m*-tolylmercury and sodium). As illustrated in reaction [I], *p*-tolylpotassium also undergoes a thermal rearrangement to give benzylpotassium.

Benzyllithium.—Although benzylsodium and benzylpotassium can now be obtained very conveniently and in highly satisfactory yields, benzyllithium is relatively inaccessible. Hein and co-workers[12] have prepared benzyllithium from dibenzylmercury and ethyllithium.

$$(C_6H_5CH_2)_2Hg + 2C_2H_5Li \longrightarrow 2C_6H_5CH_2Li + (C_2H_5)_2Hg \quad [IV]$$

Ziegler and Dersch[13] have used two different reactions for the synthesis of benzyllithium. One of these is the interaction of benzylmagnesium chloride in ether with metallic lithium.

$$C_6H_5CH_2MgCl + Li \longrightarrow C_6H_5CH_2Li + Mg + LiCl \quad [V]$$

The other is probably a two-stage reaction between benzylmagnesium chloride and phenyllithium.

$$C_6H_5CH_2MgCl + C_6H_5Li \longrightarrow C_6H_5CH_2MgC_6H_5 + LiCl$$
$$C_6H_5CH_2MgC_6H_5 + C_6H_5Li \longrightarrow C_6H_5CH_2Li + (C_6H_5)_2Mg \quad [VI]$$

No one of these procedures is quite satisfactory. Reaction [IV] involves the relatively inaccessible dibenzylmercury, and may be incomplete; reaction [V] is quite slow and, if conditions are not followed rigorously, may be erratic; and reaction [VI] produces a mixture of two different but relatively reactive organometallic compounds.

Unfortunately, we have not succeeded as yet in effecting a rearrangement of *p*-tolyllithium to benzyllithium under conditions where *p*-tolylsodium and *p*-tolylpotassium (reaction [I]) rearrange to benzylsodium and benzylpotassium, respectively. It is possible to prepare benzyllithium by metalating toluene laterally with *n*-butyllithium. However, the yield is not much greater than that required to establish definitely that benzyllithium is formed. Interestingly enough, Mr. F. W. Moore has shown that benzene can be metalated by *n*-butyllithium under corresponding conditions to give a 15% yield of phenyllithium. In general, our experience is that alkylsodium and alkylpotassium compounds are distinctly more effective for lateral metalations than are alkyllithium compounds.

Lateral Metalations.—We have extended lateral metalations by organosodium and organopotassium compounds to mesitylene and to β-methylnaphthalene. In the absence of functional groups that would undergo secondary transformations, it is probable that lateral metalation will prove serviceable in effecting indirectly such reactions as oxidation. For example, there is no known procedure for oxidizing a methylcarbazole to a corresponding carbazolecarboxylic acid.[14] Lateral metalation followed by oxidation or carbonation would undoubtedly facilitate conversion of a methyl group to a carboxyl group. Occasional cases of oxidation-resistant methyl groups are

found in other types, for example, dibenzofuran.[15]

Rates of Carbonation.—It has long been known that the kind and ratio of products obtained by carbonation of organometallic compounds are influenced markedly by the rate and temperature of carbonation,[16a] particularly with organolithium compounds.[16b] Low temperature together with a large excess of carbon dioxide, conditions realized by pouring RM compounds on crushed solid carbon dioxide, give predominantly the acid and little of the ketone or tertiary alcohol. Furthermore, carbonation by solid carbon dioxide depresses markedly the formation of malonic acids from benzylmetallic types.[16c] For example, benzylpotassium under such conditions gives an 82% yield of phenylacetic acid and no significant quantity of phenylmalonic acid. However, slow carbonation with gaseous carbon dioxide gives 55% of phenylacetic acid and 23% of phenylmalonic acid. Related observations were made in the carbonation of 3,5-dimethylbenzylpotassium. What probably happens predominantly in such cases is the metalation of the active methylene group formed after the initial carbonation. The following reactions were investigated in some detail by Ivanoff and Spassoff[17] with benzylmagnesium chloride.

$$C_6H_5CH_2MgCl + CO_2 \longrightarrow C_6H_5CH_2COOMgCl \quad [VII]$$

$$C_6H_5CH_2COOMgCl + C_6H_5CH_2MgCl \longrightarrow [C_6H_5CHCOOMgCl][MgCl] + C_6H_5CH_3 \quad [VIII]$$

$$[C_6H_5CHCOOMgCl][MgCl] + CO_2 \xrightarrow{[H_2O]} C_6H_5CH(COOH)_2 \quad [IX]$$

Slow carbonation undoubtedly would facilitate metalation of the methylene group by the RM compound in essential accordance with reaction [VIII]. This mechanism for the carbonation of benzylsodium has been established by Morton and co-workers.[11c]

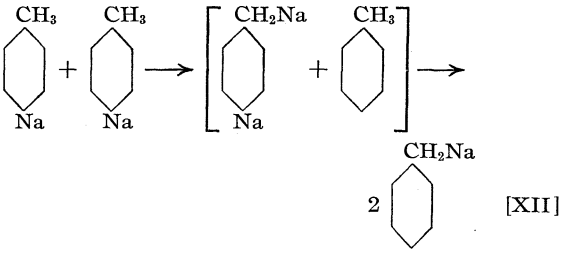
Reaction Mechanisms.—It is quite clear that there are at least two stages in the formation of benzylsodium from toluene, chlorobenzene and sodium.

$$C_6H_5Cl + 2Na \longrightarrow C_6H_5Na + NaCl \quad [X]$$

$$C_6H_5Na + C_6H_5CH_3 \longrightarrow C_6H_5CH_2Na + C_6H_6 \quad [XI]$$

The same reactions are probably the predominant ones when potassium is used in place of sodium, even though no direct evidence has been obtained as yet for the precursory formation of phenylpotassium. Reaction [XI] is apparently irreversible, for no benzoic acid has been isolated after carbonation of a reaction mixture of benzylsodium (free of toluene) and benzene which was stirred for fourteen hours at room temperature.

The migration of sodium in the transformation of *o*- and *p*-tolylsodiums to benzylsodium may be due to an allylic rearrangement of the type frequently observed with organometallic compounds. It is, however, difficult to account on such a basis for the conversion of *m*-tolylsodium to benzylsodium. Another possible mechanism that may involve all three isomeric tolylsodiums is the following



[XII]

That is, one molecule of *p*-tolylsodium may first metalate another molecule, and the resulting *p*-sodiobenzylsodium may then metalate the toluene formed in the first metalation to give benzylsodium. The apparent absence of any homoterephthalic acid, p-$HO_2CC_6H_4CH_2CO_2H$, suggests that reaction [XII] is either invalid or that *p*-sodiobenzylsodium metalates toluene with great ease.

It has been suggested that the difficulties of applying an allylic rearrangement for the tolylsodiums can be avoided by assuming the presence of traces of toluene, possibly formed by hydrolysis. This toluene would be metalated by the tolylsodium to give benzylsodium and toluene. Since the toluene is regenerated during the reaction, a small quantity would be adequate as a sort of catalyst. This sequence of reactions must be rapid because of the observed fairly prompt conversion of tolylsodium to benzylsodium.

Thermal Stabilities.—It has long been known that methylsodium, ethylsodium and methylpotassium are thermally labile, and that some decomposition occurs at room temperature,[18] particularly at initial stages.[19] Also, it appears that phenylalkali compounds are less thermally stable

(15) Gilman, Van Ess and Hayes, THIS JOURNAL, **61**, 643 (1939).

(16) (a) Some general references together with experimental work are given in the paper by Gilman and Parker, *ibid.*, **46**, 2816 (1924); (b) Gilman and Van Ess, *ibid.*, **55**, 1258 (1933); (c) Gilman and Pauvitz, *ibid.*, **62**, 1301 (1940).

than benzylalkali types. In our lateral metalations by phenylsodium no benzoic acid was isolated. This is strikingly illustrated in the metalation of β-methylnaphthalene which gave an almost analytically pure β-naphthylacetic acid. The non-isolation of benzoic acid may not have been due to thermolysis of small amounts of phenylsodium, but rather to a rapid, irreversible metalation. However, the action of heat on *m*-tolylsodium in petroleum ether illustrates a marked difference in thermal stabilities of *m*-tolylsodium and benzylsodium. When *m*-tolylsodium is prepared from *m*-chlorotoluene and sodium in petroleum ether, and with no refluxing, there results an 85% yield of *m*-toluic acid unaccompanied by any phenylacetic acid. But with only a ten-minute period of refluxing, phenylacetic acid (6.4% yield) but no *m*-toluic acid was formed. The benzylsodium formed intermediately in such reactions is relatively little affected by prolonged refluxing. The products of thermolysis other than benzylsodium have not as yet been examined.

Organolithium compounds differ markedly from other organoalkali compounds in thermal stabilities. For example, *p*-tolyllithium was found neither to decompose nor to rearrange after relatively long periods of refluxing in petroleum ether.

Experimental Part

Reaction of Sodium with Di-*p*-tolylmercury.—In a three-necked flask provided with stirrer, condenser and nitrogen inlet, was placed a mixture of 10 g. (0.43 g. atom) of sodium, 7.7 g. (0.02 mole) of di-*p*-tolylmercury, and 160 cc. of petroleum ether (b. p. 85–115°). The di-*p*-tolylmercury is not totally soluble in the solvent, but apparently reacted completely inasmuch as none was recovered at the end of the reaction. A reaction set in after the mixture was refluxed for ten minutes. The yellow-brown reaction mixture, after nineteen hours of refluxing, was cooled, carbonated by solid carbon dioxide, and then hydrolyzed. The yield of phenylacetic acid (mixed melting point) was 3.1 g. or 57%. In addition, the mother liquor yielded 0.13 g. of an oily solid which appears to be mainly phenylacetic acid.

When toluene was substituted for the petroleum ether, the yield of phenylacetic acid was 3.6 g. or 66%.

A sealed tube experiment now in progress indicates that di-*p*-tolylmercury and sodium in petroleum ether react very slowly at room temperature if there be no shaking or stirring.

Reaction of Sodium with Di-*o*-tolylmercury and Di-*m*-tolylmercury.—The di-*o*-tolylmercury and di-*m*-tolylmercury were prepared by conventional procedures using the Grignard reagents. Parallel experiments were made with each isomer, using three-necked flasks, 7.7 g. (0.02 mole) of mercurial, 10 g. (0.43 g. atom) of sodium wire and 160 cc. dry, unsaturate-free petroleum ether (b. p. 85–100°). Each mixture was stirred and refluxed for eighteen hours; and before carbonation with solid carbon dioxide, the red color characteristic of benzylsodium was evident.

The yield of phenylacetic acid from the di-*o*-tolylmercury experiment was 0.95 g. or 17.5%; and the yield from the di-*m*-tolylmercury experiment was 2.02 g. or 37.2%. No phenylmalonic acid was isolated from either carbonation product. Also, no toluic acid (*o*- or *m*-) was isolated from either reaction mixture, although the slightly lower melting point of the phenylacetic acid from the di-*o*-tolylmercury experiment may indicate the possible presence of traces of *o*-toluic acid.

The approximate times noted for inception of reaction between the mercurials and sodium were: di-*o*-tolylmercury, twenty minutes; di-*m*-tolylmercury, fifteen minutes; and di-*p*-tolylmercury, ten minutes.

Preparation of Phenylsodium in Toluene.—In a 500 cc. three-necked flask, equipped with a nitrogen inlet, condenser, mercury-sealed stirrer and thermometer, was placed a mixture of 150 cc. of toluene, 11.5 g. (0.5 g. atom) of sodium sand, and 22.5 g. (0.2 mole) of chlorobenzene. After stirring at room temperature for about forty-five minutes, the temperature started to rise. By appropriate cooling, the temperature was not allowed to exceed 40° during the entire reaction period, which was about two hours. When the temperature started to fall, the mixture was immediately poured jet-wise upon crushed solid carbon dioxide. The yield of benzoic acid (mixed melting point) was 21.2 g. or 87%.

Apropos the thermal stability of phenylsodium, two parallel preparations were made in a customary manner from 5 g. (0.014 mole) of diphenylmercury, 2 g. of sodium wire and 100 cc. of benzene. One of these was refluxed for twenty-four hours and after carbonation yielded 2.13 g. (62%) of benzoic acid. The other, stirred at room temperature for twenty-four hours, yielded 2.96 g. (86%) of benzoic acid.

Attempt to Prepare Phenylpotassium in Toluene.—To a mixture of 7.4 g. (0.19 g. atom) of potassium sand in 100 cc. of toluene, cooled to 0°, was added 11.2 g. (0.1 mole) of chlorobenzene in 45 cc. of toluene at such a rate that the temperature at no time rose above 0°. The time required for the addition in this orienting experiment was four and one-half hours. Carbonation, at the end of this time, gave 7.3 g. or a 60% yield of phenylacetic acid. On concentration of the mother liquors from the crystallization of an aliquot of the total acidic material, no benzoic acid was isolated.

Preparation of *p*-Tolylsodium.—In each of the experiments, the results of which are given in Table I, 12.7 g. (0.1 mole) of *p*-chlorotoluene, 5.5 g. (0.23 g. atom) of sodium sand and 75 cc. of solvent were used. The sodium sand should be as fine as possible, inasmuch as the reaction starts more promptly and runs a smoother course when the sand is very fine. It is also recommended that the fine sodium be freshly prepared. The conventional procedure of heating sodium in xylene was used for the preparation of the fine sodium. Reaction sets in almost immediately when the *p*-chlorotoluene is added to the sodium in the organic medium, and is accompanied by a temperature rise and the formation of black specks on the sodium. The mixture is stirred rapidly, and the temperature is

held between 35–40°. After about one and one-half hours the temperature shows no further tendency to rise. Then the cooling-bath is removed, and stirring is continued until room temperature is reached. In carbonating by solid carbon dioxide it is desirable to add 100–200 cc. of dry ether when benzene is used as the medium, in order to reduce freezing of the benzene. The excess sodium is destroyed by the cautious dropwise addition of ethanol and water.

TABLE I

PREPARATION OF *p*-TOLYLSODIUM IN SOME SOLVENTS

[0.1 Mole of *p*-Chlorotoluene]

Solvent	Yield of *p*-toluic acid G.	%
Benzene	8.9	65.5
Benzene	9.5	70.0
Cyclohexane	7.8	57.3
Cyclohexane	7.6	56.0
Pet. ether (70–80°)	10.1	74.3
Pet. ether (70–80°)	9.7	71.3
Toluene	10.9	80.1
Toluene	10.8	80.0

Preparation of Benzylsodium

A. From Chlorobenzene, Sodium and Toluene.—The preliminary operations in the following experiment were those described in the preparation of phenylsodium in toluene. After the formation of phenylsodium the suspension was refluxed for three hours. As soon as refluxing started, the black suspension assumed a brick-red color, and at the end of three hours the color was typical of benzylsodium. Carbonation, in the usual manner by solid carbon dioxide, gave 20.9 g. or a 77% yield of phenylacetic acid (mixed melting point). Carbonation after refluxing for six hours gave an 80% yield of phenylacetic acid. There was no perceptible formation of phenylmalonic acid under either of these sets of experimental conditions.

B. From *p*-Tolylsodium by Heating.—In each of the experiments, the results of which are given in Table II, the *p*-tolylsodium was prepared in accordance with directions given earlier from 0.1 mole of *p*-chlorotoluene, 0.23 g. atom of sodium sand, and 75 cc. of the solvent designated. The yields of phenylacetic acid are based on the initial 0.1 mole of *p*-chlorotoluene, and not on the % of *p*-tolylsodium obtained from the *p*-chlorotoluene.

TABLE II

PREPARATION OF BENZYLSODIUM BY HEATING *p*-TOLYLSODIUM IN SOME SOLVENTS

Solvent	Reflux period, hours	Yield of phenylacetic acid G.	%
Benzene	24	7.1	52.2
Benzene	16	6.8	50.0
Benzene	12	6.6	48.5
Toluene	4	8.5	62.0
Toluene	14	10.75	79.0
Toluene	14	10.7	79.0
Cyclohexane	18	7.3	53.7
Cyclohexane	14	7.9	58.1
Pet. ether (70–80°)	18	8.5	62.5

Rapid and Slow Carbonation of Benzylsodium.—The general conclusions drawn from the results reported recently[16e] on the rapid and slow carbonation of amylsodium were substantiated with benzylsodium. Two parallel preparations of benzylsodium were made from 11.2 g. (0.1 mole) of chlorobenzene, 5.75 g. (0.25 g. atom) of sodium sand, and 75 cc. of toluene. One of these was carbonated by pouring on solid carbon dioxide (time, five seconds); yield of phenylacetic acid 9.9 g. (72.9%); and no phenylmalonic acid isolated. The other was carbonated by gaseous carbon dioxide (time, four to five hours); yield of phenylacetic acid, 2.4 g. (17.6%); and yield of phenylmalonic acid, 3.8 g. (42.2%).

The mode of formation of benzylsodium is without essential effect, for benzylsodium from dibenzylmercury, sodium wire and toluene gave on rapid carbonation (five seconds) 3.3 g. (61%) of phenylacetic acid, and 0.03 g. or less than 1% of phenylmalonic acid; on slow carbonation (five hours, gaseous carbon dioxide), 0.46 g. (8.5%) of phenylacetic acid and 0.81 g. (22.8%) of phenylmalonic acid.

Preparation of Benzylpotassium

A. From Chlorobenzene, Potassium and Toluene.—In a 500-cc. round-bottomed flask, provided with the customary appurtenances mentioned previously, was placed a mixture of 8.5 g. (0.22 g. atom) of potassium sand and 100 cc. of toluene. A solution of 11.2 g. (0.1 mole) of chlorobenzene in 50 cc. of toluene was added very slowly, the temperature being kept between 30–35°. Since there is no induction period, the temperature starts rising with the addition of the first few drops of chlorobenzene. Occasional cooling with an ice-bath is necessary. The average time necessary for the addition of the chlorobenzene is one and one-half hours. At the conclusion of this preliminary operation, the reaction mixture was refluxed for one hour, during which time the color changed from black to a brilliant brick-red. On completion of the refluxing, the mixture was cooled and poured jet-wise upon solid carbon dioxide. The yield of pure phenylacetic acid was 11.2 g. or 82%.

B. From Phenylpotassium and Toluene.—A mixture of 5 g. (0.016 mole) of di-*n*-butylmercury, 3 g. (0.077 g. atom) of potassium and 50 cc. of benzene was stirred for sixty hours at room temperature. At the end of this time an aliquot, which was removed and carbonated and then hydrolyzed and acidified, gave no odor of valeric acid, thereby establishing the absence of *n*-butylpotassium. Subsequent to the addition of 50 cc. of toluene to the main reaction mixture, refluxing was carried out for six hours. The mixture was then cooled, and carbonated by pouring on solid carbon dioxide. Large pieces of potassium were removed by filtration, and then the carbonation mixture was hydrolyzed carefully and in sequence with butanol, ethanol and water. The yield of phenylacetic acid was 1.9 g. or 44%.

C. From Di-*p*-tolylmercury and Potassium.—A mixture of 7.7 g. (0.02 mole) of di-*p*-tolylmercury, 7.8 g. (0.2 g. atom) of potassium and 160 cc. of petroleum ether (b. p., 85–115°) was refluxed for 18.5 hours. Subsequent to cooling and carbonation, hydrolysis was effected by ethanol and then by water. The yield of phenylacetic acid was 0.9 g. or 16.5%. In addition, there was obtained 0.17 g. of a water-insoluble acid which charred at about 300°.

Reaction of Benzylpotassium with Gaseous Carbon Dioxide.—A suspension of benzylpotassium was prepared in accordance with the directions given in the preparation from potassium, chlorobenzene and toluene. At the end of the refluxing period, the mixture was cooled and then carbonated by passing carbon dioxide over the surface of the well-stirred suspension. The temperature was kept between 35–40°, and a negative color test[20] was obtained in fifteen minutes. The weight of the total acids was 10.1 g., and this mixture was separated, on the basis of solubility differences in chloroform, to give 2.1 g. or a 23% yield of phenylmalonic acid and 7.5 g. or a 55% yield of phenylacetic acid.

Reaction of Benzylpotassium with Benzophenone.—To benzylpotassium prepared from potassium (0.1 g. atom), chlorobenzene and toluene, was added 18.2 g. (0.1 mole) of benzophenone in 50 cc. of toluene over a one and one-half hour period. The brick-red color slowly disappeared and the solution assumed a deep emerald-green color, possibly due (in part) to the formation of the potassium ketyl of benzophenone. The temperature was not allowed to exceed 40°, and the mixture was stirred for one hour after the temperature ceased rising. Subsequent to hydrolysis, there was isolated 22 g. or a 59% yield of diphenylbenzylcarbinol melting at 87–88°.

Preparation of 3,5-Dimethylbenzylpotassium.—To a mixture of 8.5 g. (0.22 g. atom) of potassium sand and 100 cc. of dry mesitylene, was added slowly a solution of 11.2 g. (0.1 mole) of chlorobenzene and 39 cc. of mesitylene. The time of addition was one and one-half hours, and the temperature was kept between 30–35°. The black suspension changed slowly to the characteristic brick-red color upon refluxing for one hour. After carbonation by solid carbon dioxide and hydrolysis, there was isolated 13 g. or a 79% yield of 3,5-dimethylphenylacetic acid melting at 99.5–101°.

Under corresponding conditions, when sodium sand was used in place of the potassium sand, 3.3 g. or a 20% yield of 3,5-dimethylphenylacetic acid was obtained, in addition to some as yet unidentified tarry oil.

Slow Carbonation of 3,5-Dimethylbenzylpotassium.—In an orienting experiment, 3,5-dimethylbenzylpotassium was carbonated by the slow addition of gaseous carbon dioxide. The yield of 3,5-dimethylphenylacetic acid was 30%. In addition, there was obtained a 15% yield of 3,5-dimethylphenylmalonic acid, which softened at 149–150° and melted with decomposition at 154–155°.

Anal. Calcd. for $C_{11}H_{12}O_4$: neut. equiv., 104; C, 63.46; H, 5.77. Found: neut. equiv., 106, 107; C, 63.55, 63.57; H, 5.85, 5.81.

β-Naphthylmethylsodium.—Phenylsodium was prepared from 5.7 g. (0.25 g. atom) of sodium sand and 11.2 g. (0.1 mole) of chlorobenzene in 100 cc. of benzene. To the phenylsodium was added 28.4 g. (0.2 mole) of β-methylnaphthalene. No reaction was evident after stirring at room temperature for one hour. The mixture was refluxed for twenty-one hours, carbonated by solid carbon dioxide and then worked up in a customary manner to yield 0.8 g. or 4.3% of β-naphthylacetic acid melting at 137–139°. The yield of acid was 31% when metalation was effected by *n*-butylsodium (from di-*n*-butylmercury) in petroleum ether (b. p. 85–100°) at room temperature for twenty-six hours.

Phenylisopropylsodium (By Richard V. Young).—A mixture of 2.6 g. (0.01 mole) of diethylmercury, 0.035 g. atom of sodium and 25 cc. of cumene was stirred for twelve hours. In the course of the reaction a red precipitate formed, and this gave a positive color test. Carbonation of the reaction mixture by solid carbon dioxide gave a 41% yield of phenyldimethylacetic acid (mixed melting point). This preparation was carried out some time ago, and in view of the other results reported at this time it is quite possible that the widely used phenylisopropylpotassium might be prepared readily by metalation of cumene by benzylpotassium.

Benzyllithium from Toluene and *n*-Butyllithium.—To a filtered ether solution of *n*-butyllithium, prepared from 27.4 g. (0.2 mole) of *n*-butyl bromide,[21] was added 180 cc. of toluene. Within five minutes of the application of heat, a heavy white precipitate (probably lithium bromide) formed. After refluxing for nineteen hours, carbonation was effected by solid carbon dioxide, and the yield of phenylacetic acid was 0.06 g. or 0.22%.

Experiment on Thermal Stability

Dangers in Handling Organopotassium Compounds and Potassium.—In our experiments, we have generally used the conventional three-necked flasks provided with a mercury-sealed stirrer, condenser, and inlet tube for dry nitrogen. Inasmuch as dry organopotassium compounds, like benzylpotassium, are spontaneously inflammable on atmospheric exposure, there are occasional fire risks when the apparatus is disconnected. At times some of the benzylpotassium splashes up into parts of the apparatus attached to the flask, and is dried there by the stream of nitrogen. This risk can be decreased by stirring the solution vigorously at the end of the reaction so that some of the solvent wets any benzylpotassium and thereby prevents premature ignition.

Potassium residues should not be allowed to accumulate, and should not be added to sodium residues. There are two cases, in different laboratories, where sodium residues under kerosene have ignited and exploded. The causes of these accidents are not known, but it is possible that potassium residues in the sodium residues may be responsible. Potassium peroxide appears to form readily, and in contact with fresh potassium surfaces may give rise to violent explosions. If this is one of several possible explanations, then shaking a container of potassium residues may increase the hazard by exposing fresh surfaces.

Acknowledgment.—The authors are grateful to F. W. Moore for assistance.

Summary

The pronounced effectiveness of benzylalkali compounds in some interconversion reactions of organometallic compounds made desirable improved and convenient directions for the preparation of benzyl types. Benzylpotassium, now available for the first time in workable quantities, is readily prepared in 82% yield from toluene, chlorobenzene and potassium. Benzylsodium can be obtained in 80% yield by heating *p*-tolylsodium (from *p*-chlorotoluene and sodium in 80% yield) in petroleum ether; and in 80% yield by heating phenylsodium (from chlorobenzene and sodium in 87% yield) with toluene.

There is a lateral migration of sodium to give benzylsodium when *o*-, *m*-, or *p*-tolylsodium is heated. *p*-Tolyllithium is stable under these conditions. However, *n*-butyllithium metalates toluene laterally to give benzyllithium (0.2% yield).

In addition to other lateral metalations, an account is given of rates of carbonation, thermal stabilities, reaction mechanisms and some hazards in manipulating organopotassium compounds and potassium.

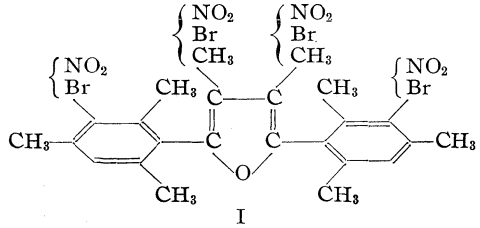
Some Substituted 2,5-Dimesitylfurans

BY ROBERT E. LUTZ AND CHARLES J. KIBLER

This investigation has been made in order to study the effect of substitution of mesityl groups on the reactions of the furan nucleus, and also to test the possibility of stereoisomerism involving restricted rotation on the inter-nuclear bonds.

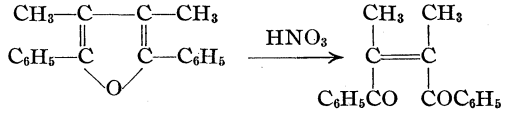


I

Five 2,5-dimesitylfurans of the type I have been prepared by methods in which the final step has completed the introduction of groups requisite for diastereoisomerism due to restricted rotation. In no case was there found any evidence of the existence of isomers. It would appear, therefore, that under the somewhat drastic preparative conditions involved in all but one case, stereoisomers are not stable enough for independent existence, as would be expected since interference effects in this type of compound should be small. It is, of course, possible that labile isomers, once formed, might be stable enough to exist under ordinary conditions; and further investigation should be made, including an attempt to resolve a suitable derivative which presumably would have the more stable *trans-dl* configuration.

In the preparation and study of the compounds mentioned above, it was found that the mesityl groups offer very little hindrance to nitration and bromination at the furan β-positions and that these β-positions are generally more reactive than the unsubstituted positions in the mesityl nuclei. The results parallel those obtained in the halogenation of 2,5-diphenylfuran.[1]

The most striking generalization arising from this investigation concerns oxidative ring fission, which is a reaction characteristic of 2,5-diarylfurans with no ortho substituents in the aryl nuclei. The *cis* unsaturated 1,4-diketone is produced whenever this stereoisomer is stable under the reaction conditions,[2] as is illustrated in the case of the oxidation of diphenyldimethylfuran (II) to the new *cis* unsaturated diketone, III. There are



II III

over 25 examples of this reaction among the 2,5-diaryl types alone, and there is now no authentic failure of the reaction when tried. Substituents in these compounds in the para position of the phenyls include chlorine and bromine, and in the furan β-positions, chlorine,[1,2] methyl,[3] chloromethyl,[3] phenyl,[1,2] and mesityl.[4] On the other

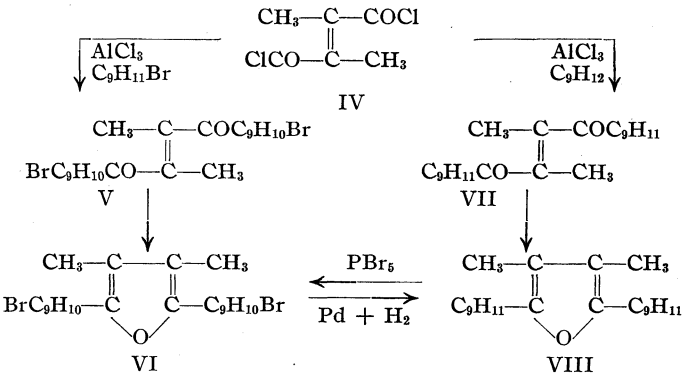
hand, 2,5-dimesitylfuran and a large number of derivatives are now known, including a number described in the experimental part of this paper. Among the substituents are bromine and nitro in the mesityl nuclei, and bromine, nitro, methyl, phenyl[5] and mesityl[6] in the furan β-positions. These compounds consistently have resisted oxidative ring fission under the usual conditions effective for the 2,5-diphenyl types. If they have reacted at all, they have undergone only nitration or decomposition; in no case was there any evidence of simple ring fission to the unsaturated 1,4-diketone.

These results are significant in connection with the mechanism of the oxidative ring fission. It has been suggested[2,7] that the reaction involves addition of nitric acid or its equivalent (an anhydride or a mixed anhydride) to the diene system of the furan, followed by break-up and loss of the equivalent of nitrous acid, the ethylene linkage being formed before the break in the oxygen bridge of the ring with the consequent production of a *cis* product whenever this isomer is stable under the conditions of the experiment. The failure consistently of 2,5-dimesitylfurans to undergo the oxidative ring fission is readily understandable if one assumes that the α-mesityl groups offer hindrance to addition at the ends of the diene system involved, and supports the hypothesis that α-substitution in general, including displacement of one group by another, involves 1,4-addition and elimination at the α-carbons. Since substitution in the β-positions is not hindered to any significant extent by α-mesityl groups, it might be supposed also that β-substitution proceeds either direct or by addition and elimination at the vinyl ether system, —C=C—O—, but without involving addition at the α-carbon.

Experimental Part

2,5 - Di - (bromomesityl) - 3,4 - dimethylfuran (VI).—The preparation of this furan, VI, was accomplished in two ways. One synthesis began with the Friedel–Crafts reaction between dimethylfumaryl chloride (IV) and bromomesitylene. The desired unsaturated diketone, di-(bromotrimethylbenzoyl)-ethylene (V), was obtained but in extremely poor yield. Zinc and acetic acid reduction of this and dehydration of the product with acetic anhydride and sulfuric acid gave di-(bromomesityl)-dimethylfuran (VI) in good yield.

The first step in the above synthesis was entirely impractical because under the necessary conditions of the Friedel–Crafts reaction bromomesitylene undergoes dismutation to mesitylene and di- and tribromomesitylene, a reaction for which there are many analogies[8] and one which proceeds more rapidly than the desired Friedel–Crafts reaction. Under the most favorable conditions a very difficultly separable mixture was obtained which contained large amounts of di-(trimethylbenzoyl)-ethylene and only a small amount of the desired di-(bromomesityl) derivative, V; laborious fractional crystallization was necessary for separation. This synthesis, however, in conjunction with the second preparation to be described below, shows the structure of the final product and the location of the bromine atoms in the mesityl nuclei. The two halogens of the furan, VI, are not removable by means of zinc dust and acetic acid but are eliminated by catalytic hydrogen.



The best preparation of di-(bromomesityl)-dimethylfuran (VI) was through direct bromination of dimesityldimethylfuran (VIII) with phosphorus pentabromide.

The Friedel–Crafts Reaction between Dimethylfumaryl Chloride and Bromomesitylene.—A series of reactions was run using aluminum chloride as catalyst and carbon

(8) α- and β-bromonaphthalenes with aluminum chloride and toluene at 100° give a mixture of bromotoluenes and naphthalene, and in carbon disulfide (refluxing) α-bromonaphthalene gives β-bromonaphthalene and 1,2-dibromonaphthalene [Roux, *Ann. chim. phys.*, [6] **12**, 345 (1887)]; bromobenzene and aluminum chloride at high temperature give benzene and dibromobenzene [Dumreicher, *Ber.*, **15**, 1867 (1882)]; and *o*-dichlorobenzene, methyl chloride, and aluminum chloride at 100° give trichloromesitylene [Friedel and Crafts, *Ann. chim. phys.*, [6] **10**, 418 (1887)].

disulfide as solvent, with variation in temperature, proportion of materials and time of reaction. The following compounds were isolated: dibromomesitylene, tribromomesitylene, di - (trimethylbenzoyl) - dimethylethylene (VII), the desired di - (bromotrimethylbenzoyl) - dimethylethylene (V), and 1 - bromomesityl - 2,3 - dimethyl - 4-mesityl-2-butenedione-1,4. The bromomesitylene used was carefully purified and had the b. p. 117° at 25 mm. and m. p. −0.1°. Three typical experiments were as follows:

(a) Bromomesitylene (69 g.) was added to 300 cc. of carbon disulfide and 136 g. of anhydrous aluminum chloride, followed quickly by 31 g. of dimethylfumaryl chloride, added dropwise with stirring, allowing the mixture to reflux gently for one hour. This gave 81 g. of a mixture of diketones. Tribromomesitylene (2.3 g.) was obtained from the residues (identified by m. p. 227–228° and analysis). The diketone mixture was fractionally crystallized from acetone, butanone, ethyl acetate, and other solvents until 10 mg. of nearly pure monobromo derivative remained, the melting point becoming constant.

(b) In another run, the temperature was held to 22°. From this all three diketones were isolated. At 0° to −5° no reaction occurred.

(c) With a large excess of bromomesitylene, the product was nearly pure di-(trimethylbenzoyl)-ethylene (yield, 78%). Steam distillation of the residues gave unchanged bromomesitylene, and then dibromomesitylene which solidified in the condenser; the yield was 68% based on disproportionation to mesitylene and dibromomesitylene. The dibromomesitylene was identified by m. p. 64° and b. p. 278–279°.

trans - **4 - Bromomesityl - 2,3 - dimethyl - 1 - mesityl-2-butenedione-1,4,** $BrC_9H_{10}COC(CH_3)=C(CH_3)COC_9H_{11}$. —This compound was obtained in only very small amounts by fractional crystallization of the mixtures of diketones, the best sample melting from 124–127° (rosets of blade-shaped plates).

Anal. Calcd. for $C_{24}H_{27}O_2Br$: C, 67.6; H, 6.4. Found: C, 65.3; H, 6.0.

trans - **1,4 - Di - (bromomesityl) - 2,3 - dimethyl - 2 - butenedione-1,4, V.**—The best sample obtained melted at 140–143°.

Anal. Calcd. for $C_{24}H_{26}O_2Br_2$: C, 56.9; H, 5.2. Found: C, 56.9; H, 5.0.

A mixture of 0.07 g. of V with 0.5 cc. of concd. acetic acid, 1 cc. of acetic anhydride and 0.5 g. of zinc dust was boiled for one minute and filtered. One drop of concd. sulfuric acid was added to the filtrate; then, when worked up in the usual way, the furan, VI, was obtained in good yield.

2,5-Dimesityl-3,4-dimethylfuran, VIII.—Attempts to oxidize the furan with concd. nitric acid in acetic or propionic acid gave only resinous products even at −10°.

2,5-Di-(bromomesityl)-3,4-dimethylfuran, VI.—A mixture of 0.2 g. of dimesityldimethylfuran, VIII, and 0.8 g. of phosphorus pentabromide (50% excess) was heated at 100° for three minutes and allowed to cool slowly (ten minutes). Decomposition in water gave an oil which solidified. Crystallization from isopropanol gave 0.28 g. of nearly pure product (rhomboids); m. p. 111.5–113°.

Anal. Calcd. for $C_{24}H_{26}OBr_2$: C, 58.8; H, 5.3. Found: C, 58.4, 58.9; H, 5.2, 5.5.

Runs on a large scale gave poorer yields ranging from 65–75%.

The furan was not appreciably affected by zinc dust and concd. acetic acid. Hydrogenation with palladium on barium sulfate catalyst proceeded with absorption of approximately two molecules of hydrogen, and 2,5-dimesityl-3,4-dimethylfuran, VIII, was isolated and identified.

3,4 - Dibromo - 2,5 - di - (bromomesityl)-furan (XVII).—This furan (XVII) was prepared in three ways. The best synthesis started with dimesitylfuran, XIV. Bromination directly[9] gives mixtures which are not easily handled, but the 3,4-dibromo derivative, XV, has actually been made in this way and isolated.[9] Using phosphorus pentabromide at 90°, the desired tetrabromo derivative, XVII, is produced in excellent yield; when an insufficient quantity of this reagent is used, a difficultly separable mixture of the tri- and tetrabromo compounds, XVIII and XVII, is obtained; but at a higher temperature with an excess of the reagent there is produced the pentabromo derivative, XVI.

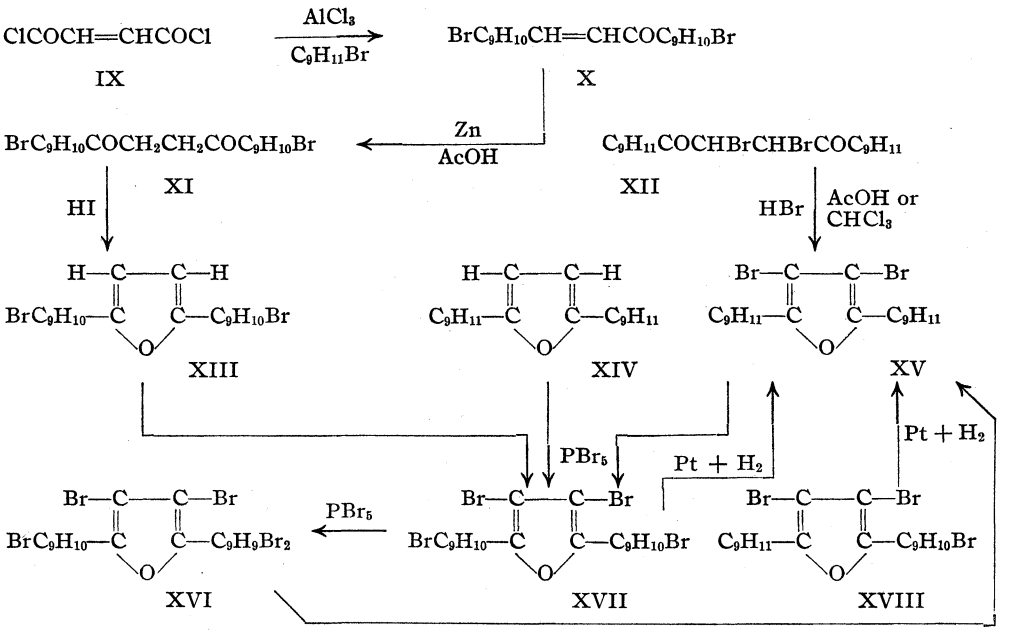
A second synthesis started with the Friedel–Crafts reaction between fumaryl chloride and bromomesitylene.[9] Here dismutation of bromomesitylene does not interfere seriously although it occurs to some extent. Reduction of the resulting unsaturated diketone to the saturated diketone, XI, was followed by dehydration to the furan, XIII, with hydriodic acid; and finally bromination with phosphorus pentabromide gave the tetrabromo derivative, XVII, in good yield.

The third synthesis utilized 3,4-dibromodimesitylfuran, XV, which was prepared by an improved method through the action of hydrogen bromide in acetic acid or chloroform on di-(trimethylbenzoyl)-dibromoethane, XII. The furan, XV, reacted with phosphorus pentabromide to give the tetrabromo derivative, XVII, in excellent yield.

Attempts to make the tetrabromo furan, XVII, by dehydration of the dibromide of di-(bromotrimethylbenzoyl)-ethylene (X) were unsuccessful.

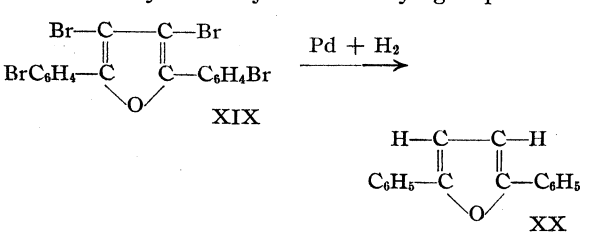
The positions of the halogens in the tetrabromo furan, XVII, are established by two of the syntheses described above involving different orders of introduction of halogens and starting from the dibromo derivatives, XI and XII, in which the location of the halogens is known, and by the reductions described below.

(9) Lutz, Johnson, and Wood, THIS JOURNAL, **60**, 716 (1938).



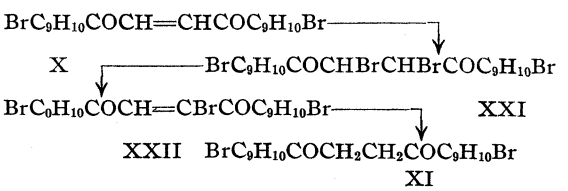
Reductive elimination of the halogens could not be brought about by means of zinc and acetic acid since no aliphatic halide groupings were involved. Hydrogenation with a palladium catalyst removed halogens from the mesityl nuclei in four compounds which were tested, namely, di-(bromomesityl)-dimethylfuran (VI), and the tri-, tetra- and pentabromo furans, XVIII, XVII and XVI. In the latter three cases the bromines in the β-positions of the furan nucleus resisted the catalytic reduction and remained untouched. Reduction, then, distinguishes between the two types of halogens, those in the mesityl nuclei being the more active and reducible.

The resistance of the halogens in the furan β-positions toward reduction was observed only in the 2,5-dimesitylfuran series, however; 3,4-dibromo-2,5-di-(bromophenyl)-furan, XIX, under comparable conditions is readily reduced by palladium and hydrogen to diphenylfuran, XX, with elimination of all four halogens including those in the furan β-positions. Probably the resistance to reduction of the β-halogens in the dimesitylfuran series is to be attributed to steric hindrance by the adjacent mesityl groups.



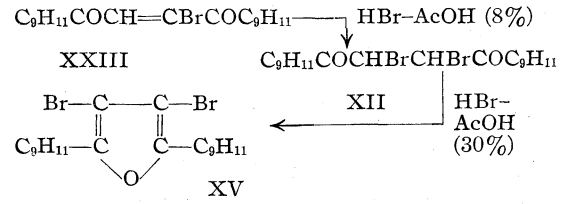
The various reactions described above show clearly that both in dimesityl- and diphenylfuran the β-positions in the furan nucleus are consistently more reactive toward bromination than the free positions in the aryl nuclei. Each mesityl or phenyl nucleus can subsequently be brominated once in each ring. The introduction finally of a second bromine into either mesityl nucleus meets with resistance, and disubstitution could be brought about in only one of the two rings under the most drastic conditions which were employed, the pentabromo derivative, XVI, being the result.

Some Halogen Derivatives of the Dimesityl 1,4-Diketones.—Incidental to this research, the following reactions were carried out. The dibromide of di-(bromotrimethylbenzoyl)-ethylene was made by direct addition of bromine to the unsaturated diketone, X. When a solution of the dibromide (XXI) in concd. acetic acid was refluxed, hydrogen bromide was quickly eliminated with formation of the bromo unsaturated diketone, XXII. The structure of this compound was proved by analysis and reduction to the saturated diketone, XI.

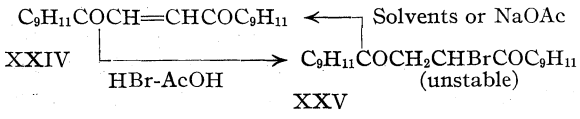


In the dimesityl series the dibromo diketone,

XII, was made by the action of 8% hydrogen bromide in concd. acetic acid on di-(trimethylbenzoyl)-bromoethylene, XXIII, the reaction proceeding quickly at room temperature. The conversion of the product by dehydration into the dibromo furan, XV, required longer standing under similar conditions with 30% hydrogen bromide in concd. acetic acid; while the yield was poor, no unchanged material was left to complicate the separation of the product.



Di-(trimethylbenzoyl)-ethylene, XXIV, itself reacts with hydrogen bromide in concd. acetic acid at 10° to give the addition compound, XXV, which was isolated and was moderately stable in the solid state. This product lost hydrogen bromide when treated with sodium acetate or upon standing in contact with solvents, particularly during crystallization, the unsaturated diketone, XXIV, being regenerated.



In connection with the relative stabilities of halides in the various saturated 1,4-diketones of the type under discussion, it is worthy of note that the chloro analog of XXV, namely, di-(trimethylbenzoyl)-chloroethane, also is unstable.[10] The dibenzoylchloro and bromoethanes require higher temperatures for decomposition, usually fusion temperature. The dihalides, both in the dimesityl and in the dibenzoyl series, decompose on melting or in boiling solvents with loss of halogen acid to give the halogeno unsaturated diketones. The dimesityl mono- and dihalogeno compounds in general, however, lose halogen acid with definitely greater ease than do the diphenyl analogs, perhaps due to the greater negativity of the mesityl groups as compared with phenyls.

Little is known about the corresponding halogeno compounds with an aryl group substituted on the ethylene linkage, but it should be pointed out that the two pairs of stereoisomers of the 1,2,4-trimesityl halogeno 1,4-diketones, $C_9H_{11}COCH(C_9H_{11})CH(X)COC_9H_{11}$, are known and are remarkably stable, resistant even to the action of sodium acetate in boiling ethanol.[6]

Meso - 1,4 - dimesityl - 2,3 - dibromobutanedione - 1,4, XII, was obtained when the unsaturated bromo diketone, XXIII, was dissolved at room temperature in 8% hydrobromic–concd. acetic acid, the dibromo diketone separating within two minutes.

1,4 - Dimesityl - 2 - bromobutanedione - 1,4 (Di-(trimethylbenzoyl)-bromoethane), XXV.—One gram of XXIV was added to 18 cc. of 13% hydrobromic acid in concd. acetic acid at 10°, the solid dissolving quickly. After standing for fifteen minutes and diluting with water, a gum was obtained which solidified. Crystallization from methanol gave a small amount of the dibromide, XII, formed by the brominating action of the bromo diketone, XXV, under these conditions.[11] The filtrate deposited 0.83 g. of the addition compound, XXV. It was difficult to purify any lost hydrogen bromide during crystallization. By careful manipulation and crystallization at moderate temperatures a sample of m. p. 81.5–82° was obtained. The analysis for bromine was low, indicating some loss of hydrogen bromide on standing, but it showed beyond question that one and only one bromine was present.

Anal. Calcd. for $C_{22}H_{25}O_2Br$: Br, 19.9. Found: Br, 18.9.

A small sample, when refluxed in ethanol for ten minutes with sodium acetate, gave di-(trimethylbenzoyl)-ethylene, XXIV, in quantitative yield.

***trans* - 1,4 - Di - (bromomesityl) - 2 - butenedione - 1,4, X,** was prepared by the Friedel–Crafts reaction[9] between fumaryl chloride and bromomesitylene. From the residues of the run, by steam distillation, dibromomesitylene of m. p. 63–64° was obtained and identified.

2,3 - Dibromo - 1,4 - di - (bromomesityl) - butanedione-1,4, XXI.—To a stirred suspension of 8 g. of X in 400 cc. of concd. acetic acid, heated to 60–65°, was added 2.68 g. of bromine in concd. acetic acid, the stirring being continued with heating for a short time after addition. The suspended solid went into solution as the bromine was added, and the difficultly soluble dibromide separated. On cooling and filtering 10 g. was obtained (82%). It crystallized from acetic acid or benzene as long flat rectangular prisms which melted with decomposition at about 250°.

Anal. Calcd. for $C_{22}H_{22}O_2Br_4$: C, 41.4; H, 3.5. Found: C, 41.2; H, 3.3.

Attempts to furanize this compound with 30% hydrobromic acid in concd. acetic acid failed, and only unchanged material was obtained after standing for five months in contact with the reagent. When refluxed with this reagent the hydrogen bromide was expelled and the bromo unsaturated diketone, XXII, was isolated. Reduction of the dibromide with zinc dust and concd. acetic acid in the usual way gave the saturated diketone, XI.

***trans* - 2 - Bromo - 1,4 - di - (bromomesityl) - 2 - butenedione-1,4, XXII.**—A suspension of the dibromide, XXI, in

(10) Lutz and Wood, THIS JOURNAL, **60**, 229 (1938).

(11) *Cf.* Lutz and Stuart, *ibid.*, **59**, 2324 (1937).

concd. acetic acid was refluxed for one hour and diluted with water. A good yield of the bromo unsaturated diketone, XXII, was obtained and crystallized from isopropanol; light yellow needles of m. p. 154–155°.

Anal. Calcd. for $C_{22}H_{21}O_2Br_3$: C, 47.4; H, 3.8. Found: C, 47.1; H, 3.8.

Reduction with zinc dust and concd. acetic acid in the usual way gave the saturated diketone, XI.

2,5-Dimesitylfuran, XIV.—Attempts to dehydrate the saturated diketone with dry hydrogen chloride in boiling concd. acetic acid (twenty-seven hours) or chloroform at room temperature (standing for six months), were not successful as preparative methods for the furan because the reactions were not complete. The hydriodic acid method was used.[9]

Oxidation with potassium permanganate in acetone, water or concd. acetic acid gave only small amounts of mesityl carboxylic acid.

2,5-Di-(bromomesityl)-furan, XIII, was made by hydroiodic acid dehydration of XI.

3,4-Dibromo-2,5-dimesitylfuran, XV, was prepared[9] by stepwise bromination of dimesitylfuran, XIV, but the yields were poor and uncertain. The dehydration of the dibromo diketone, XII, was studied in order to find effective conditions. Acetic anhydride and 30% hydrobromic acid in concd. acetic acid had no effect. With chloroform or concd. acetic acid, saturated with dry hydrogen chloride and allowed to stand, respectively, for one and six months, there were obtained impure mixtures that were difficult to purify. The following two experiments were highly successful, the latter being of advantage only when the material was needed quickly.

(a) A solution of 5 g. of the dibromo diketone, XII, in 50 cc. of dry chloroform, saturated with dry hydrogen bromide, was allowed to stand at room temperature for six months. The progress of the reaction was followed by withdrawing samples at intervals, evaporating the solvent under an air blast, and determining the melting point. The entire product was worked up in this way, 3.6 g. being obtained (m. p. 130–137°). Crystallization from ethanol gave 3.1 g. melting at 139–142°. The yield of dibromofuran (60%) does not take into account the material withdrawn for tests.

(b) A suspension of 10 g. of XII in 80 cc. of 30% hydrogen bromide–concd. acetic acid was allowed to stand at room temperature, the reaction being complete in two weeks. The resinous product obtained by diluting the mixture with water was crystallized three times from ethanol giving a 37% yield of nearly pure furan. A large amount of resinous material was formed in this reaction.

Attempts to hydrogenate the furan with platinum oxide or palladium on barium sulfate as catalysts were without result, the bulk of the furan being recovered unchanged.

3,4-Dibromo-2,5-di-(bromomesityl)-furan, XVII.—This furan was prepared by the bromination of the furans, XIV, XV, XIII and XVIII, by the same procedure described below, using phosphorus pentabromide. A large excess of reagent was necessary due to loss of bromine. With an insufficient amount a difficultly separable mixture of tri- and tetrabromo furans was obtained. The temperature was not allowed to go above 90° in order to avoid formation of the pentabromo derivative. 2,5-Dimesitylfuran was used in large scale preparations because it was the most easily obtained of the starting materials.

A mixture of 0.2 g. of dimesitylfuran and 1.5 g. of phosphorus pentabromide was ground together thoroughly and heated at 88–90° for forty-five minutes. The red melt was then hydrolyzed in water, the oily product coagulating on standing. The yield of crude but nearly pure material was 0.41 g. (m. p. 170–172.5°). It crystallized from ethanol, isopropanol, and ethyl acetate; long rectangular plates; m. p. 177°.

Anal. Calcd. for $C_{22}H_{20}OBr_4$: C, 42.6; H, 3.25; Br, 51.55. Found: C, 42.34; H, 3.6; Br, 51.2.

The furan occurs in two distinct modifications. As usually obtained it was in the form of long rectangular plates melting at 175–177°, but these were usually contaminated by traces of the second form (rhombic). The presence of the rhombic form, visible under the microscope, probably accounted for the unsharp melting point. The rhombic form was obtained free from the other modification only once, after filtration of a hot solution of the compound in isopropanol. It melted sharply at 166° and, after solidifying in the capillary tube, remelted sharply at 177°.

Reduction of 0.4 g. of XVII with hydrogen and palladium on barium sulfate as catalyst (0.5 g.) in 25 cc. of ethanol involved absorption of two molecules in nine hours and 0.29 g. of 3,4-dibromo-2,5-dimesitylfuran, XV, was isolated and identified.

2-Bromomesityl-3,4-dibromo-5-mesitylfuran, XVIII.—In the first brominations carried out under somewhat milder conditions than those described above, a mixture of this furan, XVIII, and the tetrabromo derivative, XVII, was obtained and separated by laborious fractional crystallization and by sublimation under reduced pressure.

A mixture of 4 g. of XIV and 25 g. of phosphorus pentabromide was heated for thirty minutes at 70°, giving 8 g. of product. It was repeatedly crystallized from ethyl acetate and isopropanol, giving the tetrabromo compound pure. The residues were subjected to fractional sublimation in the vacuum oven at 150°. The tribromo compound distilled first and was finally purified by crystallization from isopropanol, the sample obtained melting at 125.5–126.5° (blade-shaped scales).

Anal. Calcd. for $C_{22}H_{21}OBr_3$: Br, 44.4. Found: Br, 41.3.

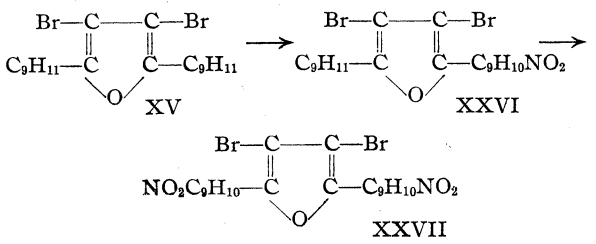
From analyses it was evident that the sample still contained some impurity, probably the dibromo derivative, but not enough material was left for further purification.

2-Bromomesityl-3,4-dibromo-5-dibromomesitylfuran,[9] XVI.—Nine grams of bromine (7 moles) in 10 cc. of carbon disulfide was added slowly to a mixture of 2 g. of dimesitylfuran, 5 cc. of carbon disulfide, and 0.5 g. of iron filings; the mixture was then refluxed gently for four hours. A quantitative yield of the pentabromo derivative was obtained; m. p. 280–282.5°.

Zinc dust and concd. acetic acid had no effect on this compound. Hydrogenation using palladium on barium sulfate gave 3,4-dibromo-2,5-dimesitylfuran (XV).

The pentabromide was prepared also by the action of phosphorus pentabromide at 100° on the tetrabromo compound, XVII.

3,4 - Dibromo - 2,5 - di - (nitromesityl) - furan (XXVII).—This furan was prepared by the action of a 1–3 mixture of concd. nitric and acetic acids at refluxing temperature on 3,4-dibromodimesitylfuran (XV). The mononitro derivative, XXVI, was obtained under similar conditions when a lower concentration of nitric acid was used.



3,4 - Dibromo - 2 - mesityl - 5 - nitromesitylfuran, XXVI.—Dimesityldibromofuran, XV, did not react with 1–10 mixture (by vol.) of concd. nitric and acetic acids at 100°. Nitration was brought about as follows: a solution of 0.38 g. of XV in 20 cc. of concd. acetic acid and 3.8 cc. of concd. nitric acid was refluxed for thirty minutes and diluted with water. Crystallization of the product from ethanol gave 0.28 g. of nearly pure mononitro derivative; needles of m. p. 121.5–122.5°.

Anal. Calcd. for $C_{22}H_{21}O_3NBr_2$: C, 52.1; H, 4.2; N, 2.75. Found: C, 52.5; H, 4.0; N, 2.3.

Nitration further with 1–4 (by vol.) concd. nitric-acetic acid mixture (refluxed) gave the dinitro derivative, XXVII.

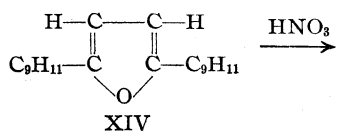
Zinc dust and concd. acetic acid (refluxed) gave a solid of m. p. 150–153° which has not been investigated further.

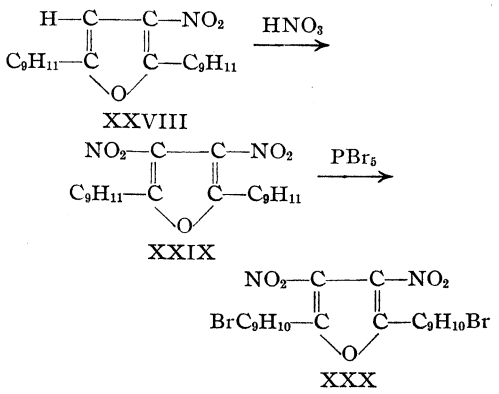
3,4 - Dibromo - 2,5 - di - (nitromesityl) - furan, XXVII.—A mixture of 0.8 g. of dibromodimesitylfuran (XV), 5 cc. of concd. nitric acid and 15 cc. of concd. acetic acid was refluxed for five minutes and diluted with water. The product was crystallized from ethanol; yield 0.57 g. It crystallized from ethanol and isopropanol as tapered needles melting at 204–205°.

Anal. Calcd. for $C_{22}H_{20}O_5N_2Br_2$: C, 47.85; H, 3.65; N, 5.1. Found: C, 47.5; H, 3.8; N, 5.2.

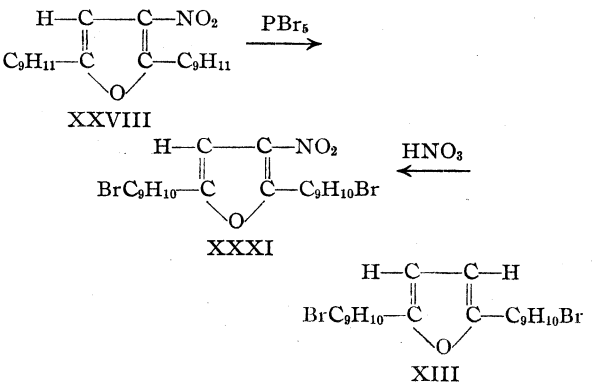
A thorough examination of the residues from this preparation failed to reveal any trace of another compound.

2,5 - Di - (bromomesityl) - 3,4 - dinitrofuran (XXX).—The logical synthesis of this furan by nitration of di-(bromomesityl)-furan (XIII) was unsuccessful because of the surprising resistance to the substitution of the second nitro group. The desired furan was prepared from dimesitylfuran (XIV) by successive substitutions of two nitro groups in the β-positions in the furan nucleus, followed by bromination with phosphorus pentabromide.





The first step in the above synthesis involved introduction of one nitro group into a β-position in the furan nucleus to give XXVIII; this is evident from the following facts. Bromination of the mononitro product, XXVIII, gave di-(bromomesityl)-nitrofuran (XXXI) which was made in a second way by nitration of di-(bromomesityl)-furan (XIII). The positions of the bromine atoms in XXXI are demonstrated conclusively by this second synthesis. The position of the nitro group of both XXVIII and XXXI in the furan β-position is evident from the following considerations: it has been shown that the nitro groups in dinitrodi-(nitromesityl)-furan (XXXII) effectively block bromination in the remaining vacant positions in the mesityl nuclei; therefore, bromination of XXVIII could not have involved both mesityl groups if one of them already carried the nitro group as a substituent; instead, bromination in only one (the unsubstituted) mesityl nucleus or/and the two β-positions in the furan ring would have occurred, whereas actually the bromines are known to have gone one to each mesityl group.



From these facts, then, it is evident that the first nitro group enters a furan β-position. The presence of this nitro group blocks substitution of

bromine in the remaining furan β-position and halogens then enter the two mesityl nuclei.

Unfortunately, further nitration of the 2,5-di-(bromomesityl)-3-nitrofuran (XXXI) could not be controlled successfully to give the desired dinitro derivative, XXX; when the reaction was forced it went too far and there was produced a compound which apparently contained five nitro groups. Thus, a simple proof of structure for XXX could not be obtained and it was necessary to be content with indirect evidence.

In nitration of dimesitylnitrofuran (XXVIII) it might be supposed that the second nitro group would not be able to enter the remaining furan β-position, but would, like bromine, enter a mesityl nucleus. However, from the fact that only one more nitro group (the second) entered, it is to be presumed that it went to the second furan β-position since, otherwise, substitution in both and not just one mesityl group would be expected. Furthermore, the formula XXIX for the dimesityldinitrofuran best explains the introduction subsequently of two bromines by the action of phosphorus pentabromide; if the alternative structure with the second nitro group in a mesityl nucleus were assumed, then bromination of the dinitro compound could have introduced only one bromine atom and this in the unsubstituted mesityl nucleus, because, as has just been shown, a nitro group in one furan β-position blocks bromination at the other β-position, and because, as will be shown below, a nitro group in a mesityl group hinders further substitution in this nucleus. Since this reasoning is involved, the evidence is not as conclusive as could be desired.

2,5-Dimesityl-3-nitrofuran, XXVIII,[9] reacts with 1–4 (by vol.) concd. nitric–acetic acid mixture (boiling for two minutes) to give the dinitro derivative, XXIX.

2,5-Dimesityl-3,4-dinitrofuran, XXIX.—A solution of 1 g. of dimesitylfuran, XIV, in 15 cc. of concd. acetic acid and 5 cc. of concd. nitric acid was refluxed for five minutes and cooled, the dinitro derivative, XXIX, crystallizing; yield 0.5 g. A crystalline impurity, visible under the microscope, was removed by repeated crystallization from isopropanol and from concd. acetic acid. The dinitrofuran crystallized as hexagonal plates of m. p. 213°. It is difficultly soluble in the alcohols.

Anal. Calcd. for $C_{22}H_{22}O_5N_2$: C, 67.0; H, 5.6; N, 7.1. Found: C, 66.7, 67.1; H, 5.4, 5.6; N, 7.0.

From the mother liquors 0.2 g. of mesityl carboxylic acid was isolated.

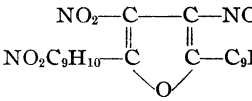
2,5-Di-(bromomesityl)-3,4-dinitrofuran, XXX.—A mixture of 0.28 g. of dimesityldinitrofuran, XXIX, and 0.7 g. of phosphorus pentabromide was heated at 90° for thirty minutes, then 0.3 g. more of the reagent was added and heating continued for fifteen minutes at the same temperature. Hydrolysis gave an oil which solidified. Washing with methanol several times on the filter left 0.36 g. (92%) of nearly pure dibromo compound, XXX. It crystallized from isopropanol or concd. acetic acid as colorless rhombic plates melting at 200.5–201.5°.

Anal. Calcd. for $C_{22}H_{20}O_5N_2Br_2$: C, 47.8; H, 3.65. Found: C, 47.7; H, 3.8.

2,5-Di-(bromomesityl)-3-nitrofuran, XXXI.—A solution of 0.1 g. of di-(bromomesityl)-furan (XIII) in a 1–3 mixture (by vol.) of concd. nitric and acetic acids was refluxed for five minutes. On cooling 0.06 g. of the nitro derivative, XXXI, separated and was purified from isopropanol; m. p. 130–130.5°.

Anal. Calcd. for $C_{22}H_{21}O_3NBr_2$: C, 52.1; H, 4.2. Found: C, 51.7, 51.6; H, 4.0, 4.2. (Carbon analyses on known compounds were running consistently 0.3% low when these were made.)

This furan, XXXI, was obtained in a second way as follows: a mixture of 0.1 g. of 2,5-dimesityl-3-nitrofuran, XXVIII, and 0.3 g. of phosphorus pentabromide was heated at 90–93° for fifteen minutes and hydrolyzed. The product was crystallized from isopropanol giving 0.05 g. of pure XXXI.



3,4-Dinitro-2,5-di-(nitromesityl)-furan, XXXII.—This tetranitro derivative was made by nitration of dimesityldinitrofuran, XXIX, using a stronger nitric–acetic acid mixture. The symmetrical structure, XXXII, has been assigned because the only alternative would be one in which at least one of the mesityl nuclei carried two nitro groups, an unlikely possibility. Further substitution of nitro groups was not accomplished, and phosphorus pentabromide at 100° was without action on the compound.

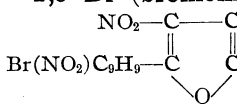
A suspension of 0.15 g. of dimesityldinitrofuran, XXIX, in 4 cc. of a 1–1 (by vol.) mixture of concd. nitric and acetic acids, was refluxed for five minutes and diluted with water, the product crystallizing. Recrystallizing from ethyl acetate gave 0.1 g. of nearly pure product; m. p. 266–267°.

Anal. Calcd. for $C_{22}H_{20}O_9N_4$: N, 11.56. Found: N, 11.8.

Nitration of 2,5-Di-(bromomesityl)-furan and the 3-Nitro Derivative.—When the furans, XIII and XXXI, were treated with a 1–1 mixture (by vol.) of fuming nitric and concd. acetic acids at 90–94° for five minutes, a product was obtained which crystallized from isopropanol or concd. acetic acid as long rectangular plates of m. p. 287–288°. It gave no mixture melting point depression with XXXIII of m. p. 251–252°. But in view of the analysis and this difference in melting point, there is little doubt of non-identity with XXXIII.

Anal. Calcd. for $C_{22}H_{17}O_{11}N_5Br_2$: C, 38.45; H, 2.5. Found: C, 38.7, 38.14; H, 3.1, 3.14.

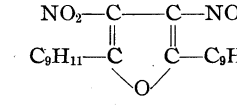
2,5-Di-(bromonitromesityl)-3,4-dinitrofuran,



XXXIII.—This furan could not be made by bromination of the tetranitro compound, XXXII; but it was obtained through a different order of introducing the groups, namely, by nitration of dinitro-di-(bromomesityl)-furan (XXX) with a 1–1 fuming nitric–concd. acetic acid mixture, as follows:

A solution of 0.3 g. of di-(bromomesityl)-dinitrofuran, XXX, in 6 cc. of a 1–1 (by vol.) mixture of fuming nitric and concd. acetic acids was allowed to stand for thirty minutes at 90°. On cooling 0.18 g. of nearly pure material separated. From the filtrate 0.23 g. of partly reacted material was obtained, which was nitrated again by the same procedure, giving 0.17 g. of product. It crystallized from concd. acetic acid as colorless rhombic plates which melted with decomposition at 245° (at 251–252° in an evacuated tube).

Anal. Calcd. for $C_{22}H_{18}O_9N_4Br_2$: C, 41.1; H, 2.8; N, 8.7. Found: C, 40.8, 40.7; H, 2.8, 2.7; N, 8.6.



Trinitro-2,5-dimesitylfuran.—A suspension of 0.3 g. of dimesitylfuran (XIV) was allowed to stand in 8 cc. of a 1–1 (by vol.) mixture of concd. nitric and acetic acids at room temperature until a thick paste formed. The mixture was then refluxed for three minutes and diluted with water. The amorphous product on standing overnight in ethanol became crystalline and was recrystallized from ethanol; tapered needles of m. p. 158–160°.

Anal. Calcd. for $C_{22}H_{21}O_7N_3$: C, 60.1; H, 4.8. Found: C, 60.3; H, 4.95.

After standing for several days the first filtrate deposited 0.03 g. of nitromesityl carboxylic acid which was identified by mixture melting point with a sample prepared by nitration of mesityl carboxylic acid.

***cis*-2,3-Dimethyl-1,4-diphenyl-2-butenedione-1,4 (*cis*-Dibenzoyldimethylethylene), III.**—A suspension of dimethyldiphenylfuran (II) in 4 cc. of propionic acid was made by dissolving the furan in the hot solvent and chilling to obtain fine crystals free from lumps; this mixture was maintained at −10° and treated with 0.2 cc. of concd. nitric acid in 0.6 cc. of propionic acid, also at −10°. The crystals dissolved quickly. On standing for fifteen minutes at −10° and diluting with water, the diketone, III, separated crystalline in practically quantitative yield. It crystallized from isopropanol or acetic acid–water mixtures as slender needles melting at 86.5–87°.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.8; H, 6.1. Found: C, 81.4; H, 5.8.

The structure of this compound was demonstrated by reduction with zinc dust and concd. acetic acid (boiling one minute) followed by treatment of the filtrate directly with acetic anhydride and a trace of concd. sulfuric acid to give the furan, II, in 90% yield.

3,4-Dibromo-2,5-di-(4-bromophenyl)-furan, XIX.—Catalytic reduction of 0.4 g. with 0.5 g. of palladium on barium sulfate in ethanol was complete in three hours, 4 molecules of hydrogen being absorbed; 0.16 g. of diphenylfuran, XX, was isolated, purified and identified.

Summary

1. In a study of five suitably substituted compounds, no evidence of diastereoisomerism due to restricted rotation on the internuclear 2,5-dimesitylfuran bonds has been found.

2. 2,5-Dimesityl groups prevent the oxidative fission of the furan nucleus by nitric and acetic acids, a reaction which is shown to be general for furans with 2,5-diaryl groups carrying no ortho substituents. The bearing of these results on the mechanism of furan reactions is considered.

3. The reactions involved in the synthesis and proof of structure of the various substituted 2,5-dimesitylfurans are described and discussed.

4. Catalytic hydrogen eliminates the bromines from the mesityl nuclei of four substituted 2,5-dimesitylfurans, but is without effect on bromines substituted in the β-positions. In the case of 2,5-di-(*p*-bromophenyl)-3,4-dibromofuran all four bromines are eliminated by catalytic reduction.

5. Some new halogeno saturated 1,4-diketones of the dimesityl series are described, and the relative ease of elimination of halogen acid is considered.

6. 3,4-Dibromo-2,5-dimesitylfuran is nitrated stepwise in the mesityl nuclei.

7. 2,5-Di-(bromomesityl)-3-nitro- and -3,4-dinitrofurans have been prepared by stepwise nitration and bromination of dimesitylfuran. Evidence for the structures is discussed.

8. Disubstitution in the 2,5-dimesityl groups was accomplished only in the nitration of 2,5-di-(bromomesityl)-3,4-dinitrofuran to the di-(bromonitromesityl) derivative.

The Dipole Moments and Structures of the Esters of Some Fatty and Some Inorganic Acids

BY GEORGE L. LEWIS AND CHARLES P. SMYTH

This paper is a report of measurements of dipole moment made some time ago upon three groups of substances, all of which were esters. The moments of the ethyl esters of three long-chain fatty acids were determined with the object of confirming the expectation that the long chain would have little effect upon the moment. The moments of three alkyl borates were measured with the object of studying the structures of their molecules, in particular, the possibility of rotation around the B–O bonds. The moments of triphenyl phosphite, phosphate and thiophosphate were determined in the hope of obtaining further evidence as to the values of the moments of the semipolar bonds, $P^+–O^-$ and $P^+–S^-$. The moments were obtained in the usual manner from measurements of the dielectric constants and densities of solutions in benzene or heptane. The dielectric constants were measured at a frequency of 520 kilocycles with a crystal-controlled heterodyne beat apparatus previously described,[1] and the densities were determined with an Ostwald–Sprengel pycnometer in a manner described elsewhere.[2]

Purification of Materials

Benzene and heptane were purified as in previous work.[3] The ethyl undecylate, palmitate, and stearate were portions of the materials which had been carefully purified by Dr. W. O. Baker in this Laboratory for use in studying the dielectric constants in the solid state.[4]

The three alkyl borates were prepared by Dr. Allen Scattergood by fractionating a mixture of two moles of boric acid and nine moles of the corresponding alcohol according to the method given in "Organic Syntheses."[5] The liquids had the following values of the boiling point, the density d, the refractive index for the sodium D line n_D, and the dielectric constant ϵ at 25°: *n*-propyl borate, b. p. 177–178°, d 0.85448, n_D 1.39227, ϵ 2.239; *i*-butyl borate, b. p. 208.0–208.5°, d 0.84033, n_D 1.40101, ϵ 2.213; *s*-butyl borate, b. p. 193–194°, d 0.82902, n_D 1.39444, ϵ 2.194.

Triphenyl Phosphite.—Material from the Eastman Kodak Company was washed with dilute sodium carbonate solution and then with water, dried over calcium chloride, filtered, and vacuum distilled at 200° and 6 mm.; $n^{25}D$ 1.58801.

Triphenyl Phosphate.—Material from the Eastman Kodak Company was recrystallized from distilled ether three times; m. p. 46°.

Triphenyl Thiophosphate.—Material from the Eastman Kodak Company was recrystallized from distilled ether three times; m. p. 53°.

Experimental Results

The dielectric constants, ϵ, and the densities, d, of benzene or heptane solutions containing mole fraction c_2 of solute are given in Table I, the polarizations P_2 being listed in the last column. The polarization of the pure solvent is given as P_1. Table II lists in the second column the values of MR_D, the molar refraction for the D sodium line, obtained directly from the experimental data for the long chain esters and the borates, and calculated for the phosphite, phosphate and thiophosphate from the refractions of the corresponding alkyl compounds,[6] the refraction of benzene, and atomic refractions given in Landolt–Börnstein. The third column gives the polarizations P_2 for the pure liquids at 25°, the fourth column the polarizations P_∞ obtained by extrapolation to $c_2 = 0$ of the values of P_2 in Table I, and the fifth column gives the dipole moments calculated in the usual manner.

Discussion of Results

For the long-chain esters of the fatty acids in Table II the difference between the polarization of the pure liquid and that of the substance at infinite dilution decreases with increasing length of the carbon chain, the difference being 25.0 for ethyl undecylate, 17.8 for ethyl palmitate, and 15 for the stearate, for which the difference is obtained by a rough extrapolation of the polarization of the pure liquid down to 25°. Increase in the length of the chain effectively dilutes the dipoles and thereby reduces the intermolecular action, which is responsible for the difference between P_2 and P_∞. This difference is very small in the three alkyl borates as it is in ethyl ether[7] and for the same reason. The three ethyl groups form a shield around the three C–O moments, while, as will be seen presently, the three B–O dipoles radiating from the center of the molecule presumably cancel one another. The variation of P_2 with concentration for triphenyl phosphite in Table I is much less than that in the cases of the

phosphate and thiophosphate, which indicates that the P–O and C–O moments are well screened by the phenyl groups in the former, while the large $P^+–O^-$ and $P^+–S^-$ dipoles in the latter two give rise to strong intermolecular action.

The moments of ethyl undecylate, palmitate and stearate in Table II may be regarded as identical. They are also identical with the value 1.86 found in this Laboratory for ethyl acetate in benzene solution[8] but lower than the value 1.98 for ethyl acetate in heptane.[9] In general, the moments of a large number of esters in the literature show an increase in value from the methyl to the ethyl, presumably because of induction, with little change produced by further lengthening of this part of the molecule. On the other side of the molecule, addition of carbon to go from formate to acetate to propionate lowers the moment slightly as it lowers the dissociation constant, the latter to a much greater extent. The moments of these three long-chain ethyl esters are only 0.05 higher than the values for ethyl propionate[8,10] and butyrate[10] in benzene solution, a difference to be expected from the difference in solvent effect. It may, therefore, be concluded that the long chains in these molecules do not affect the dipole moment of the molecule or hinder its free orientation in externally applied electric fields of frequencies up to those employed in the present measurements.

The moment of propyl borate in Table II fits well into the series of values 0.75, 0.77 and 0.79 previously found for ethyl borate,[11] butyl borate,[12] and amyl borate,[12] respectively. The branching of the carbon chain seems to raise the moment slightly, the isobutyl and *s*-butyl borate moments in Table II being 0.85. In view of the zero mo-

ment found for boron trichloride[7] and the symmetrical, triangular planar structures found by electron diffraction for the boron halides and boron trimethyl[13] and the analogous symmetrical structure found by X-ray analysis for the BO_3 group in crystalline boric acid and metallic metaborates[14] it seems almost certain that, in these alkyl borates, the boron lies at the center of an equilateral triangle with the oxygens at the three apices. As the resultant of the three B–O moments would thus be zero, any moment of the molecule as a whole must be due to the H–C and C–O bond moments. The total R–O moment may be taken as approximately 1.2 acting in the C–O direction.[15] If all positions of rotation around the B–O bonds were equally probable and if the oxygen valence angle were 110°, the resultant moment of the trialkyl borates should be[16] $1.2\sqrt{3}\sin 110° = 1.95$. However, the borates should have structures which through resonance are mainly the resultant of contributions from three structures such as  . Consequently, the B–O should have approximately one-third double-bond character, which would tend to make the three carbons attached to the three oxygens coplanar with the boron and the oxygens and give oxygen valence angles of about 120°. If steric repulsion between the alkyl groups were negligible, there would be eight possible coplanar arrangements of the three alkyl groups, six of them equivalent to one another and having a moment 2.1 and the remaining two being equivalent to one another and having zero moment. The resultant observed moment should then be $2.1\sqrt{6/8} = 1.8$. Increase of the oxygen valence angles to a rather probable value of 125° would decrease this calculated value by 0.1. The observed values in Table II are less than half of these calculated values.

Examination of the bond and kinetic theory radii of the atoms in these molecules shows that neglect of steric repulsion in calculating moments for the molecules is quite unjustifiable. In the hypothetical structure in which free rotation is supposed, the positions in which the alkyl groups turn on to the same side of the molecule, thereby giving the maximum resultant moment, are rendered much less probable by repulsion between the groups. The resulting tendency to occupy positions giving lower resultant moment could account for the difference between the low observed and the high calculated moment values. In the more probable structure in which partial double-bond character hinders or prevents rotation around the B–O bonds, steric repulsion renders the six equivalent, unsymmetrical, planar structures impossible or highly improbable without distortion. The distortion and greatly decreased probability of these structures of large moment and the greatly increased probability of the two symmetrical structures of zero moment, in which steric repulsion is small or negligible, can easily account for the smallness of the observed moments.

The conclusion that steric repulsion is the cause of the low moments of the alkyl borates is borne out by examination of the moment values, 1.85 and 1.90, found by Otto[12] for butylboric and amylboric acids, respectively. If the H–O moment is taken[15] as 1.5, the moment calculated as before for the hypothetical structure having freedom of rotation around the B–O bonds is 2.35 and the value calculated for the planar structure without rotation around the B–O bonds is about 2.1. As there is only one alkyl group in these molecules, steric repulsion should be very much less than that in the trialkyl borates. Indeed, of the eight possible arrangements in the planar structure, the two equivalent ones having largest moment should have almost as little steric repulsion as the two with smallest moment, only the dipole–dipole interactions reducing somewhat the probabilities of the former two. The observed value 1.9 is thus reduced but slightly below the roughly calculated value 2.1. The observed moments of the trialkyl borates and the monoalkyl boric acids are evidently consistent with the planar structure in which the three B–O bonds making angles of 120° with one another have sufficient double-bond character to prevent rotation around the bonds, although, in the so-called unsymmetrical planar structure, steric effects would tend to twist the carbons attached to the oxygens out of the plane of the boron and the oxygens. The moment values alone do not, however, preclude the possibility of rotation around the B–O bonds.

The triphenyl phosphite molecule looks some-

what analogous to those of the alkyl borates, but the moment observed for it is more than twice as large. If all positions of rotation around the C–O and P–O moments were equally probable, its mean square moment could be written[16] $\mu_1^2 = 3m_1^2(1 + 2\cos^2\theta\cos\varphi) + (3m_2^2 + 6m_1m_2\cos\theta)(1 + 2\cos\varphi)$, in which m_1 is the sum of the H–C and C–O bond moments, m_2 is the P–O bond moment, θ is the oxygen valence angle, and φ is the phosphorus valence angle. The same equation was used to calculate the moment of the alkyl borates, for which the fact that φ was 120° caused all the terms containing m_2, the B–O moment, to drop out. m_1 is calculated[15] from the moment of diphenyl ether 1.14 as 1.0, and m_2 is calculated as the difference 1.2 between the H–O and H–P bond moments.[15] The oxygen valence angle θ is taken as 110° as in the borates. The phosphorus valence angle is 100° in trimethylphosphine and varies from 98° to 104° in the phosphorus trihalides.[17] If it is taken as 100° in triphenyl phosphite, the moment calculated by the above equation is 2.0, in exact agreement with the observed value in Table II. Increase of the angle φ to 110° reduces the calculated value to 1.8 and further increase to 120° reduces it to 1.6. In spite of the excellent agreement between the observed and calculated moment values, examination of the atomic dimensions shows that certain positions of rotation around the P–O bonds are impossible because of interference of the benzene rings with one another. There is, however, no general exclusion of the positions of highest moment like that which lowers the moment so much in the case of the borates. A sufficiently wide variety of positions appears to be possible to permit of a distribution of moment values close to the random one given by the equation. If, instead of using the estimated value 1.2 for the single P–O bond moment to calculate the resultant moment of the triphenyl phosphite molecule, the observed moment of the molecule is used to calculate the P–O moment, the value obtained is 1.2, which may therefore be regarded as an approximate experimental value for the normal P–O bond.

The moments of the phosphate and thiophosphate molecules are changed from that of the phosphite by the presence of the semipolar bond $P^+–O^-$ or $P^+–S^-$ and the calculated mean square moment should be

$$\mu_2^2 = \mu_1^2 + m_3^2 + 6m_2m_3\cos\chi + 6m_1m_3\cos\theta\cos\chi$$

where μ_1 is the moment of the phosphite as given by the previous equation for it, m_2 is the semipolar bond moment, χ is the angle which the semipolar bond makes with the three P–O bonds, and the other quantities are the same as those used in the previous equation. In the case of the phosphite, the most probable value of the O–P–O angle, $\varphi = 100°$, gives exact agreement between the observed and calculated moments. If $\varphi = 100°$ in the phosphate and thiophosphate, then the $O–P^+–O^-$ angle χ may be calculated as 118°, since the $P^+–O^-$ or $P^+–S^-$ bond should lie symmetrically with respect to the three P–O bonds. When μ_2 is set equal to the observed moment for the phosphate or thiophosphate in Table II and μ_1 is taken as the observed phosphite moment, which agrees with the calculated value, the moment m_3 of the semipolar $P^+–O^-$ bond is given by the equation as 3.5 and that of the $P^+–S^-$ bond as 3.2. If all the phosphorus valence angles were identical so that $\chi = \varphi = 110°$, μ_1 would have the calculated value 1.83, and the values of m_3 calculated would be 3.2 for the $P^+–O^-$ bond and 2.9 for the $P^+–S^-$ bond. As the first structure, in which $\varphi = 100°$ and $\chi = 118°$, seems to be the most probable approximation, the values 3.5 for $P^+–O^-$ and 3.2 for $P^+–S^-$ should be most nearly correct. It should be borne in mind, however, that, as in the previously considered[18] case of the same bonds in $POCl_3$ and $PSCl_3$, neither bond is a pure semipolar structure, as other resonating forms, particularly double-bonded structures, contribute to the structures of the molecules. The values must, in any event, be regarded as approximate because of possible errors in the assumed bond moments and valence angles. The $P^+–O^-$ moment value 3.5 is identical with that found for this bond in $POCl_3$, while the value 3.2 for the $P^+–S^-$ bond is considerably higher than the apparent value 2.5 found for it in $PSCl_3$, which was thought to be too low because of the inductive action of the P–Cl dipoles. The small difference 0.3 here found between the $P^+–O^-$ and $P^+–S^-$ moments justifies the conclusion previously reached[18] that the two moments are not very different from one another, the two lying in the neighborhood of 3.5, where most of the more or less hybrid semipolar bonds seem to lie. It would appear that the $P^+–S^-$ is actually some-

(17) See ref. 13, p. 80.

(18) Smyth, Lewis, Grossman and Jennings, THIS JOURNAL, **62**, 1219 (1940).

what lower than the P^+-O^- moment in contrast to the fact that the C=S moment is 0.3 higher than the C=O, which latter bonds contain large contributions from semipolar forms.[19]

Summary

The dielectric constants and densities of solutions of ethyl undecylate, palmitate and stearate in heptane, of *n*-propyl, *i*-butyl and *s*-butyl borate in benzene, and of triphenyl phosphite, phosphate and thiophosphate in benzene have been measured at 25° and used to calculate the dipole moments of the molecules of the solutes.

The small variation of polarization with concentration shows the intermolecular action to be very small in the three trialkyl borates and in triphenyl phosphite and to decrease with increasing molecular size in the long-chain fatty acid esters. The small intermolecular action is due to effective screening of the dipoles from one another by the hydrocarbon groups, while the large intermolecular action in the phosphate and thiophosphate is due to the presence of an imperfectly screened semipolar bond.

Ethyl undecylate, palmitate and stearate have dipole moments indistinguishable from one another and from those of ethyl propionate and butyrate, which shows that the long chains in these molecules do not affect the dipole moment of the molecule or hinder its free orientation at 25° in an alternating electric field of frequency as high as 520 kc. Equations are derived for the calculation of the resultant moments of the trialkyl borates and of triphenyl phosphite, phosphate and thiophosphate on the assumption of equal probabilities of all the positions of rotation around the B–O and P–O bonds. Strong steric repulsion between the alkyl groups in the borates lowers their moments to less than half of the values calculated on the basis of free rotation as well as on that of B–O bonds stiffened by double-bond character. Excellent agreement is obtained between the observed and the calculated values for triphenyl phosphite, where steric hindrance plays a minor role. The equations are used to calculate approximate moment values for three bonds as follows: P–O, 1.2; P^+-O^-, 3.5; P^+-S^-, 3.2.

A Redetermination of the Parameters in Ammonium Bifluoride

BY M. T. ROGERS AND L. HELMHOLZ

Introduction

The structure of ammonium bifluoride has been determined by Pauling,[1] who gave approximate values of the parameters obtained with the use of the data of Hassel and Luzanski.[2] He found a hydrogen-bonded structure with each nitrogen atom surrounded by four fluorine atoms at tetrahedral corners, the mean N–F distance being 2.76 ± 0.06 Å. and the F–F distance 2.37 ± 0.10 Å. The value we have found[3] for the F–F distance in KHF_2, 2.26 ± 0.01 Å., is equal to Pauling's value of the distance in NH_4HF_2 to within its limits of error, so it is not possible to say whether or not the distance has been increased by the formation of two additional hydrogen bonds in NH_4HF_2. For this reason a more accurate determination of this distance has been made.

(1) L. Pauling, *Z. Krist.*, (A) **85**, 380 (1933).
(2) O. Hassel and N. Luzanski, *Z. Krist.*, **83**, 448 (1932).
(3) L. Helmholz and M. T. Rogers, THIS JOURNAL, **61**, 2590 (1939).

The unit translations found by Hassel and Luzanski[2] and the parameters given by Pauling[1] have been revised and the limits of error reduced. From these new values the F–F and N–F distances have been calculated to be F–F = 2.32 ± 0.03 Å. and N–F = 2.82 ± 0.03 Å. The weakening of the F–F bond in the formation of two hydrogen bonds in passing from KHF_2 to NH_4HF_2 is thus shown to exist; the increase in bond length amounts to 0.06 ± 0.04 Å. The space group D_{2h}^7 used by Pauling has been confirmed by the absence of reflections of the type $(h0l)$, h odd, observed by Hassel and Luzanski.

Experimental Method and Results

Oscillation photographs about the c and a axes were taken of crystals of orthorhombic NH_4HF_2 prepared by evaporation of solutions of NH_4HF_2 in glacial acetic acid.

The space group was shown to be D_{2h}^7 by the

absence of reflections of type $(h0l)$, h odd, and $(hk0)$, h and k odd. The reflection (102) reported by Hassel and Luzanski, which would eliminate this group, was sought but not observed on any photographs. This justifies the choice made by Pauling. The unit cell contains four molecules and the dimensions of the unit were found to be

$a_0 = 8.426 \pm 0.020$ Å.; $b_0 = 8.180 \pm 0.020$ Å.; $c_0 = 3.69 \pm 0.05$ Å.

The first two are from oscillation photographs, the third from layer line measurements. Data giving a_0 and b_0 are shown in Table I. These correspond to axial ratios $1:0.971:0.438 = a_0:b_0:c_0$ compared by goniometric values $1:0.977:0.444 = a_0:b_0:c_0$ (Groth).

TABLE I

EQUATORIAL MEASUREMENTS

(hkl)	$d_{obsd.}$ Å.	a_0 obsd. Å.
400	2.105	8.421
600	1.405	8.434
800	1.053	8.424
1000	0.0842	8.423
	Average a_0	8.426
020	4.097	8.195
040	2.045	8.180
060	1.362	8.172
080	1.022	8.177
	Average b_0	8.180

The relative intensities of all observed reflections were estimated visually using a calibrated scale.

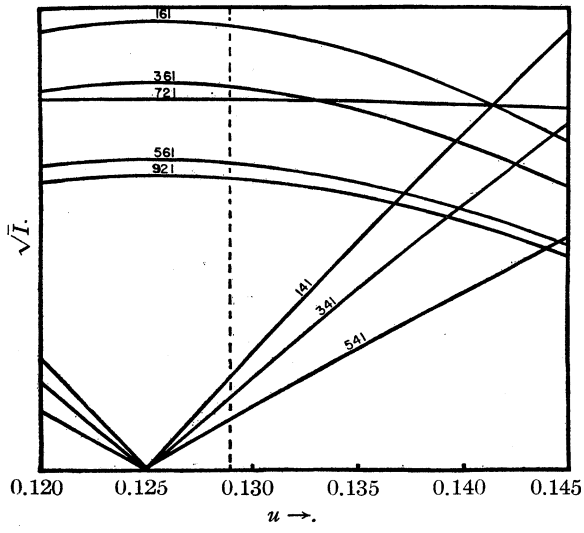

Fig. 1

Theoretical values for the relative intensities were calculated using the formula

$$I = C \frac{1 + \cos^2 2\theta}{\sin 2\theta} F^2 \exp -3.0 \left(\frac{\sin\theta}{\lambda}\right)^2$$

where F is the structure factor and $\exp -3.0 \left(\frac{\lambda}{\sin\theta}\right)^2$ the temperature factor. The structure factors for the four classes of planes are

I $F = 4f_F \sin 2\pi ku \sin 2\pi lv$ for h odd, k even

II $F = 4f_{NH_4} \cos 2\pi \left(\frac{h+k}{4} + lz\right) - 4f_F \sin 2\pi ku \sin 2\pi lv$ for h even, k odd

III $F = 4f_F(\cos 2\pi hw - \cos 2\pi ku \cos 2\pi lv)$ for h odd, k odd

IV $F = 4f_{NH_4} \cos 2\pi \left(\frac{h+k}{4} + lz\right) + 4f_F(\cos 2\pi kw + \cos 2\pi ku \cos 2\pi lv)$ for h even, k even

The f values used were those of Pauling and Sherman.[4] The intensities of reflections $(h00)$ depend only on parameter w, and of reflections $(0k0)$ only on parameter u, and a rough determination of these parameters might have been made using the observed $(h00)$ and $(0k0)$ intensities. The intensities of these reflections, however, are so sensitive to the choice of f values for F^- and NH_4^+ that little confidence was felt in the determination carried out from this starting point, and, indeed, the parameters thus obtained led to marked discrepancies between calculated and observed intensities for planes of different types.

To overcome this difficulty the determination was carried out in the following manner. The parameter u was determined first using observed intensities for planes of class I with $l = 1$. The factor $\sin v$ is known closely enough from Pauling's determination of $v = 0.135 \pm 0.01$ since it enters only as a common factor. The calculated intensities are plotted as functions of u in Fig. 1. The value $u = 0.131 \pm 0.002$ is found.

Accepting this value of u it is now possible to choose the f values for NH_4^+ which will account for the observed intensities of $(0k0)$ planes. The appropriate f_{NH_4} values were found to be close to the values used by Pauling.[1] Experimental values of f_{NH_4} have been obtained by Wyckoff and Armstrong[5]; a comparison of these values with those we have used is shown in Table II.

TABLE II

Sin θ/λ	0.1	0.2	0.3	0.4	0.5	0.6	0.7
f_{NH_4} (Pauling)	8.11	6.01	3.96	2.65	1.99	1.68	1.55
f_{NH_4} (Hartree)	6.7	4.4	3.1	2.50	2.0	1.65	1.65
f_{NH_4} (used)	7.7	5.64	3.70	2.43	2.00	1.68	1.55
f_{NH_4} (Wyckoff)	8.8	5.5	3.1	1.8	1.2		

We next obtained an approximate value of w, 0.137 ± 0.004, from reflections $(h00)$. The value of v was obtained by comparing intensities of

(4) L. Pauling and J. Sherman, *Z. Krist.*, **81**, 1 (1932).
(5) Wyckoff and Armstrong, *ibid.*, **72**, 319 (1930).

planes of Class I with varying values of l, using the value found for u. The calculated intensities plotted as functions of v are shown in Fig. 2. Planes with $k = 2, 6, 10$ were used since these vary negligibly with u in the allowed range for that parameter.

The value $v = 0.131 \pm 0.003$ was obtained in this way. A more accurate value of w was then found using intensities of reflections of type III with $l = 0$, which depend only on u and w. Plots were made of the calculated intensities as functions of both u and w for these planes and values of these parameters giving the best agreement with observed intensities were taken. To account for the observed intensity ratios of 910:930:350:530 it was found necessary to use the lower limit for u ($u = 0.129$). The value of w chosen was $w = 0.137 \pm 0.002$. This choice was confirmed by plotting calculated intensities for reflections of type III with $l = 1$ as functions of w using previously obtained values of u and v.

The reflections of type II, h even and k even, with different values of l were used to obtain a value of z. Intensities which were very sensitive to u, v, or w were not used. As before, calculated intensities were plotted as a function of z and the best value chosen; $z = 0.540 \pm 0.005$ was found.

Comparison of calculated and observed intensities for reflections of type II (Table III) served as a check on all these parameters. The calculated and observed intensities for all reflections observed are listed in Tables III to VI. Intensities of reflections observed by Hassel and Luzanski[2] and not by us are designated by letters rather than numbers.

Conclusions.—The values of the F–F distance calculated using these parameters are

$$F_1\text{–}F_1 = 2.31 \pm 0.035 \text{ Å.}$$
$$F_2\text{–}F_2 = 2.320 \begin{matrix} +0.03 \\ -0.02 \end{matrix} \text{ Å.}$$

The lower limit is less in the latter case since the value chosen for u was the lower limit (0.129) given it in the determination above; probably u cannot be less than 0.129.

Comparing these values with the value F–F 2.26 ± 0.01 Å. for KHF_2 it is seen that there is a slight increase in the distance in NH_4HF_2, amounting to between 0.03 and 0.08 Å., due to the weakening of the bond by the two extra hydrogen bonds formed in NH_4HF_2.

The N–F distances found are $N\text{–}F_1 = 2.80 \pm 0.02$ Å., and $N\text{–}F_2 = 2.80 \pm 0.03$ Å. This value is larger than the average found by Pauling (2.76 Å.) and is 8% larger than the value N–F = 2.63 Å. for NH_4F. We thus confirm the observation of Pauling that the hydrogen bond in NH_4HF_2 is weaker than that in NH_4F. The longer ammonium ion to fluorine contacts are: $N\text{–}F_I = 3.02$ Å. and $N\text{–}F_{II} = 3.40$ Å.

Summary

The unit translations for the orthorhombic crystal NH_4HF_2 have been revised to $a_0 = 8.426$ Å., $b_0 = 8.180$ Å., $c_0 = 3.69$ Å. The space group and structure given by Pauling have been confirmed and the parameters redetermined:

$$z = 0.540 \pm 0.005 \text{ Å.} \qquad u = 0.129 \begin{matrix} +0.003 \\ -0.001 \end{matrix} \text{ Å.}$$
$$w = 0.137 \pm 0.002 \text{ Å.} \qquad v = 0.131 \pm 0.003 \text{ Å.}$$

The four smallest N–F distances are all equal to 2.80 ± 0.025 Å. and the F–F distances in the two non-equivalent HF_2^- ions are found to be 2.32 ± 0.03 Å.

The Crystal Structure of Potassium Fluoroiodate, KIO_2F_2

BY LINDSAY HELMHOLZ AND M. T. ROGERS

Introduction

A complete knowledge of the crystal structure of potassium fluoroiodate should afford considerable evidence concerning the steric effect of unshared electron pairs in molecules and ions and concerning the influence of relative electronegativity on the interatomic distances. The structure determination has been carried out to investigate these questions. Unfortunately it has turned out that the number of parameters to be determined is so great that, although the general characteristics of the structure are certain, the accuracy of the determination permits us to make only qualitative remarks about the effects mentioned above.

It has been found that the $IO_2F_2^-$ group approximates an octahedral group with two of the positions unoccupied. A tetrahedral configuration for the ion, which might have been anticipated from the similarity of the unit dimensions of this crystal and those of KIO_4, is clearly impossible.

A distinction between oxygen and fluorine atoms or ions in the structure is suggested by the intensities and the interatomic distances, but it is impossible for us to insist on our assignment and so to give any detailed discussion of the influence of electronegativity on bond distance.

The observation that potassium iodate, formed by the hydrolysis of the compound in moist air, is oriented to a considerable extent on the surface of the fluoroiodate suggests (as is borne out by the structure) that the crystal resembles KIO_3 much more than KIO_4.

Procedure.—Potassium fluoroiodate was prepared by dissolving potassium iodate in concentrated hydrofluoric acid and allowing the resulting solution to stand until, after a few days, tabular crystals were precipitated. Some smaller crystals were formed for which the principal direction of growth was normal to the plate. Goniometric measurements showed the crystals to be identical with those described by Groth.[1] In order to prevent reaction of the crystals with atmospheric moisture they were coated with a layer of lacquer.

(1) Groth, "Chemische Krystallographie," Teil II, Leipzig, 1908, p. 94.

Oscillation photographs were taken with CuK_α and MoK_α radiations and Laue photographs with continuous radiation ($\lambda_{min.} = 0.24$ Å.) from a tungsten target. Intensities were estimated visually using a calibrated scale and photographs of different exposure times. For the CuK_α pictures the influence of absorption was considered; for the Mo pictures the crystals were small enough so that the absorption correction was shown to be negligibly small.

Space Group and Unit Cell.—Laue photographs taken with the X-ray beam normal to the plates showed the Laue symmetry D_{2h}. The regular absences $h0l$, $h \neq 2n$ and $0kl$, $l \neq 2n$ were observed giving C_{2v}^5 and D_{2h}^{11} as possible space groups. A pyroelectric experiment which gave a positive result eliminated D_{2h} and established $C_{2v}^5 - Pca$ as the correct space group for the crystal.

The dimensions of the unit cell were found, from oscillation photographs, to be $a_0 = 8.38 \pm 0.02$ Å.; $b_0 = 5.97 \pm 0.02$ Å.; $c_0 = 8.41 \pm 0.02$ Å. The data from which these values were obtained are listed in Table I. The X-ray data give the axial ratios $a:b:c = 0.996:0.7098:1$ to be compared with the crystallographic axial ratios $a:b:c = 0.9925:2 \times 0.7074:1$ given by Groth.[1]

Assuming the density of the fluoroiodate to have a value close to the densities of potassium iodate (3.89 g./cm.^{3}) and periodate (3.61 g./cm.^{3}) the number of molecules in the orthorhombic unit was found to be four. The density calculated for four molecules per unit cell is 3.71 g./cm.^{3} Numerous Laue photographs of long exposure time showed no reflections requiring a large unit.

Determination of the Structure.—For the space group $C_{2v}^5 - Pca$ there exists only one set of positions, the general four-fold positions $4a$):[2] x, y, z; $\bar{x}, \bar{y}, \frac{1}{2} + z$; $\frac{1}{2} - x, y, \frac{1}{2} + z$; $\frac{1}{2} + x, \bar{y}, z$.

There are then three parameters to be determined for iodine and three for potassium. The eight fluorine atoms in the unit are to be placed in two sets of positions $4a$, and the eight oxygen atoms also in two sets of the four-fold positions.

The first step in the structure analysis was the determination of the iodine parameters. For this

purpose a Patterson projection on the x–z plane was made using $h0l$ data. This projection (Fig. 1) shows strong peaks, corresponding to iodine–iodine interactions, at $x = \frac{1}{2}$, $z = 0$; $x = 0$, $z = \frac{1}{2}$; and $x = z = \frac{1}{2}$. This distribution can be accounted for only if the iodine parameters $x_1 = z_1 = 0$, or an arrangement equivalent to this. This assignment of parameters may be checked by a qualitative consideration of the intensities. The intensities of reflection from planes (hkl), with $h + l \neq 2n$ were observed to be very much weaker than the reflections with $h + l = 2n$ even for large values of h, k and l. For the iodine parameters $x_1 = z_1 = 0$ the iodine contribution to the intensities of the type of planes first mentioned is zero.

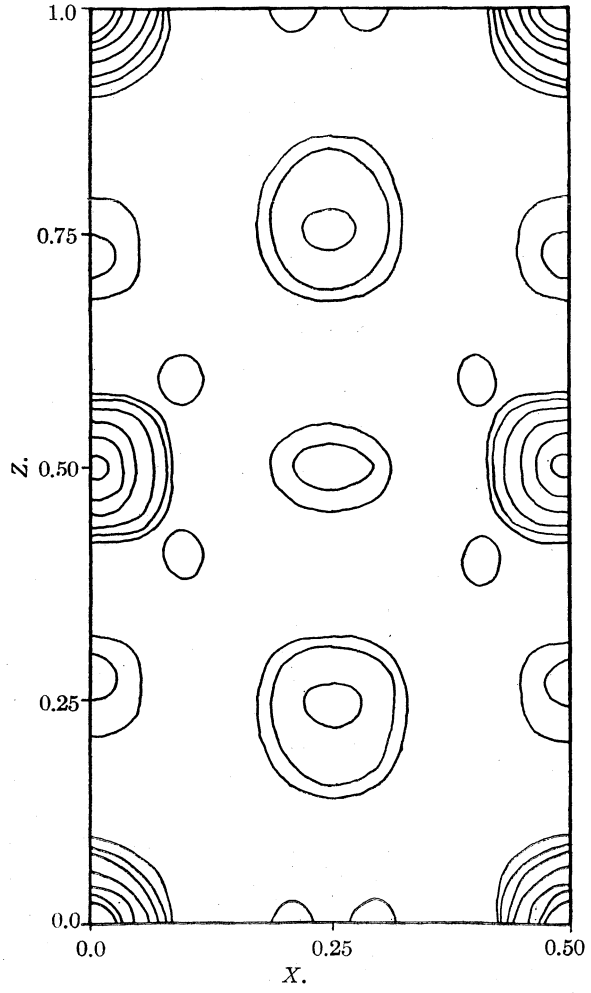

Fig. 1.—Patterson projection, $P(x,z)$, on x–z plane.

A Harker projection, $H(xy\frac{1}{2})$, making use of the two-fold screw axis parallel to z, was calculated as the next step in the determination. This gave a value for the y-parameter for iodine, $2y = 0.135$. Complete data were not used in preparing this projection but the final structure indicates that the 200 important reflections which were used gave a very reliable value for the parameter. No other use was made of the projection.

Since the projection of the scattering matter in the cell on the x–y plane contains a center of symmetry it was profitable next to make a Fourier projection on this plane using the (hk0) data. The signs of the F's for all strong reflections are unambiguously determined by the iodine contribution, so that, starting with these reflections, a complete Fourier projection could be made by a process of successive approximations. From the first of these the potassium ions were found to have $x \approx 0.25$, $y \approx 0.50$.

As long as only reflections to which iodine contributes were used, a plane of symmetry, not present in the crystal, persists along a line $x = 0$. The strongest F to which iodine does not contribute, F_{310}, was next introduced arbitrarily with positive sign. The introduction of this single F_{310} destroys the plane of symmetry and permits the assignment of approximate x and y parameters for potassium ions, fluorine and oxygen atoms. The final projection, shown in Fig. 2, was obtained by including all the $F_{(hk0)}$'s in the Fourier series. The letters refer to the atoms with parameter z, the primed letters to equivalent atoms at $z + \frac{1}{2}$. The c-glide planes are indicated by dotted lines, the a-glide plane by the dashed line. Contour lines have been drawn at 20, 30, 40, 50, 100, 150, 250, and 350 on an arbitrary scale.

Figure 2 shows clearly the iodine atoms at I and

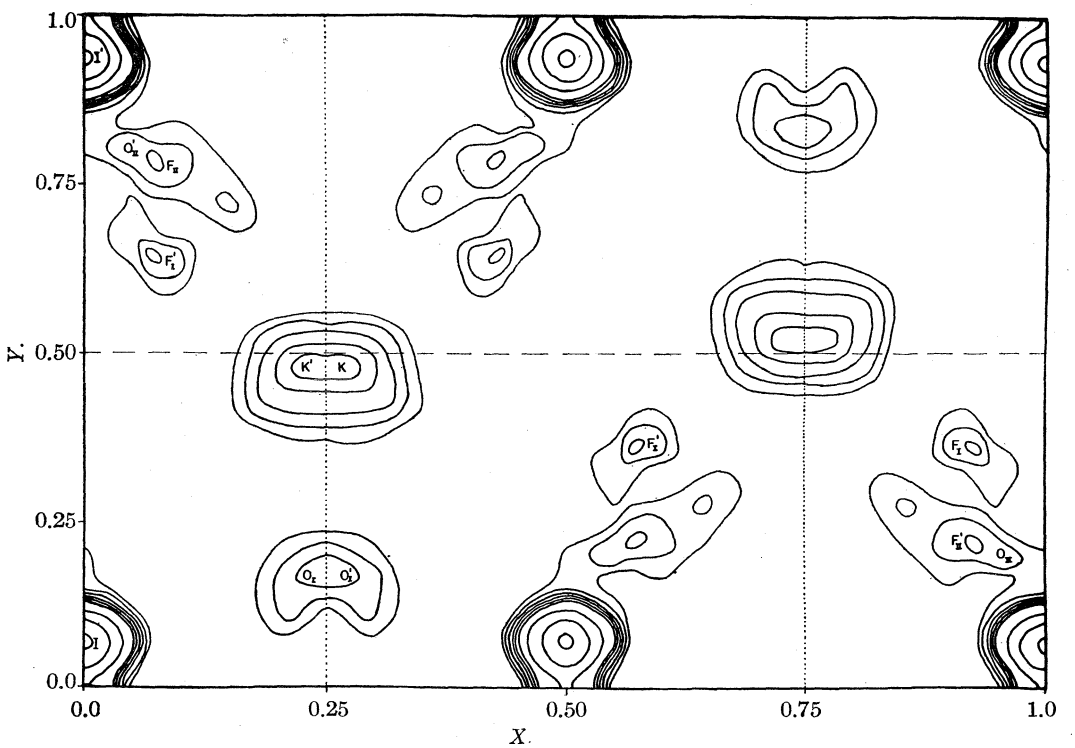

Fig. 2.—Fourier projection of scattering matter on (001) face.

I′. The peak K (and K′) is unresolved and due to equivalent potassium ions at xyz and $\frac{1}{2} - x, y, z + \frac{1}{2}$. The differentiation of oxygen and fluorine atoms cannot be made on the basis of the projection, and evidence for the distinction finally made is not entirely conclusive but the discussion will be continued on the basis of the final assignment and it will be borne in mind that an exchange of oxygen atoms for fluorine in the structure is possible within the limits of error of the X-ray data. The unresolved peak at O_I (O_I') is due to oxygen atoms and the clearly defined maximum at F_I can be identified as a fluorine atom. The remaining somewhat diffuse maximum in the neighborhood of F_{II} and O_{II} is believed to be due to the superposition of two maxima.

The atoms were given x- and y-parameters as indicated by the lettering of the maxima and as seem reasonably definite from the size of the maxima for all cases except that of O_{II}. Two possible positions for this atom are compatible with the projection; (1) the maximum corresponding to O_{II} lies so close to I that it is not observed, or (2) the maximum for O_{II} is part of the O_{II}–F_{II} maximum which is unresolved. A decision in favor of the second alternative was made with reasonable certainty on the basis of the intensities of reflection which are independent of the iodine atoms.

The evaluation of the z parameter was carried out by making use of the general characteristics of the X-ray spectra, the Patterson projection, and structural arguments as outlined below. It is seen (most clearly on Laue photographs) that, for all pairs of reflections (hkl) and (lkh) having the same type of structure factor, the intensities are very nearly equal for all values of h and l. This fact together with the evidence of the Patterson projection indicates that a projection of the scattering matter on the x–z plane has approximately tetragonal symmetry.

If F_I is associated with any iodine atom it must be bonded to I and not to I′ since the projection of the distance I′ − F_I on the x–y plane (see Fig. 2) is greater than could correspond to an iodine–oxygen bond. The projection places another fluorine atom at F_{II}, which might be bonded to I′ as far as the projection is concerned. If this were the case and if I − F_I were equal to I′ − F_{II} then the projection of the interatomic distance on the x–z plane should show up on the Patterson projection where no maximum is observed. Since F_{II} is the same distance from I as F_I and lies on a straight line through I and F_I (in the projection)

it is suggested that these two atoms form opposed bonds with iodine and by referring to the argument in the previous paragraph the values of x_{FI} and x_{FII} will be approximately ± 0.08. This assignment of parameters is made more probable by the small maximum at $z = 0.40$, $x = 0.10$ on the Patterson projection.

The oxygen atom O_I may be assigned fairly definite parameters, the Patterson projection indicating that z_{O_I} cannot be very large. From the projection x has two possible values $\approx 0.25 \pm 0.025$. This choice must be made on the basis of structural arguments and intensities of *hkl* planes. If $IO_2F_2^-$ groups are postulated then certainly x must be less than 0.25. The possibility that x is larger than 0.25 is not altogether unreasonable and was considered seriously but no fit between experimental and calculated intensities could be obtained on this basis. With F_I, F_{II} and O_I placed the choice of parameters for O_{II} was made by concluding from the Patterson projection that it must have a position relative to the z-axis similar to that of O_I relative to the x-axis. In trying to find the proper parameters the iodine to fluorine distances were considered to be equal, as were the iodine to oxygen distances.

The potassium parameters were determined roughly from the projections and then refined by comparison of observed and calculated intensities. The parameters were varied subject to the condition that distances from potassium to oxygen and fluorine be larger than 2.60 Å.

The atomic positions fixed by the means described in the previous paragraphs were finally varied by small amounts (0.005 to 0.01) to obtain the best fit between experimental and observed intensities. The resulting parameters are given below:

	x	y	z
I	0.00	0.067 ± 0.001	0.00
K	.215 ± 0.005	.465 ± .005	.29 ± 0.005
F_I	− .08 ± .01	.355 ± .01	.09 ± .01
F_{II}	.08 ± .01	− .22 ± .01	− .09 ± .01
O_I	.215 ± .01	.175 ± .01	.035 ± .01
O_{II}	− .02 ± .01	.19 ± .01	.210 ± .01

The atoms occupying the positions F_I and F_{II} it was felt must be the same, either oxygen or fluorine. The position of these atoms is fairly well fixed and it is found that the agreement is considerably better for some of the weak reflections if fluorine atoms are placed in positions F_I and F_{II}. The fact that the I–O distance for this assignment is so closely equal to the same interatomic distance in $(NH_4)_2H_3IO_6$ also lends support to this arrangement.

Tables II and III give the calculated and observed F_{hkl}'s. Pauling–Sherman f-values were used in calculating the F's.

As an additional check on the parameters the ratio of intensities I_{hkl}/I_{lkh} were compared with the calculated intensity ratio. Since the inter-

planar distances d_{hkl} and d_{lkh} are so nearly equal quantitative use could be made of the Laue intensities for such pairs of reflections. Reflections with $n\lambda$ in the neighborhood of the critical absorption limit for iodine were not used in these comparisons. The intensities were estimated visually with the use of a calibrated scale. Table IV gives the results.

TABLE IV

	hkl	I_{hkl}/I_{lkh} obsd.	I_{hkl}/I_{lkh} calcd.
1	(415)	15.0	13.10
2	(611)	5.5	4.22
3	(613)	2.4	2.02
4	(614)	1.0	0.98
5	(615)	7.5	6.30
6	(617)	7.5	10.8
7	(811)	4.5	4.5
8	(813)	3.5	4.9
9	837	2.0	30.0[a]
10	429	8.0	6.2

[a] The calculated F's for both reflections are so small for this case 5.7 and 1.0 that a very small error in parameters makes a very large error in the calculated intensities.

Discussion of the Structure.—The crystal structure derived from the above parameters is shown in Fig. 3. The fluoroiodate ion, as shown in the figure, consists of a central iodine atom forming bonds to two fluorine and two oxygen atoms. The fluorine atoms lie on a straight line through the iodine atom and may be thought of as forming opposed bonds. The oxygen atoms lie in a plane perpendicular to the I–F bonds and form bonds with the iodine atom at about 100°. This arrangement gives the group as a whole the appearance of an octahedron with two of the corners removed. It may perhaps better be thought of as a trigonal bipyramid in which one of the three equivalent orbitals is occupied by an unshared pair and the angle between the remaining two decreased from 120 to approximately 100°. The interatomic distances are: $I–O_I = 1.93 \pm 0.05$ Å.; $I–O_{II} = 1.92 \pm 0.05$ Å.; $I–F_I = 2.00 \pm 0.05$ Å.; $I–F_{II} = 1.99 \pm 0.05$ Å.; $O_I–O_{II} = 2.85 \pm 0.10$ Å.; and the angle $O_I–I–O_{II} = 100 \pm 7°$. The fluorine–oxygen contacts are the same within the limits of error and equal to 2.75 ± 0.10 Å.

This configuration of the $IO_2F_2^-$ group is the same, within the limits of error, as that reported by Stevenson and Schomaker[3] for $TeCl_4$ in which the unshared pair of electrons has apparently the same steric effect as in the $IO_2F_2^-$ ion.

(3) D. P. Stevenson and Verner Schomaker, THIS JOURNAL, **62**, 1267 (1940).

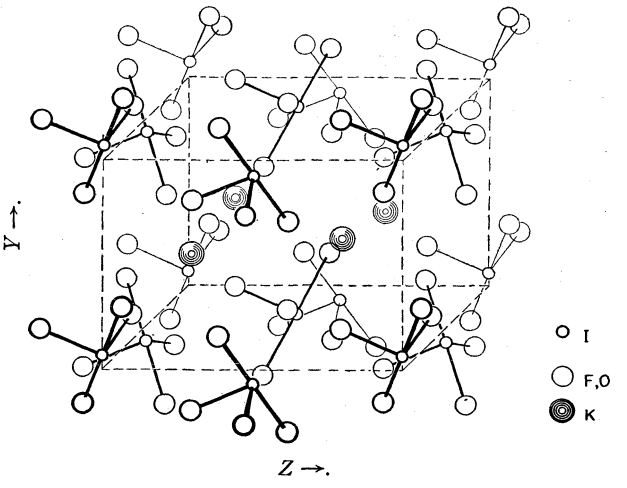

Fig. 3.—Structure of potassium fluoroiodate.

The effect of the unshared pair of electrons on the bond distances may be discussed by comparing the effective iodine radius in this compound with the iodine radii in other related compounds. The data for a number of these compounds are shown in Table V. The table shows that a considerable decrease in the effective iodine radius can be correlated with an increase in formal charge. Since the unshared pair in $IO_2F_2^-$ contributes the same number to the formal charge of iodine as the two additional electron pair bonds in IO_6^{5-} the I–O distances in the two ions might be expected to be nearly the same. The iodine radii for the cases of the iodates and of IF_5 seem to be much too large to be accounted for on the assumption that the radius is a simple function of the formal charge. It is true, however, that the determinations of these two distances are not completely reliable, and satisfactory answer has not yet been given to the question of the existence of discrete IO_3^- ions in iodate crystals.

TABLE V

Compd.	I – X, Å.	Configuration	Formal charge	I-radius
KIO_4[a]	2.23	Octahedral	+3	1.18
$(NH_4)_2H_3IO_6$[b]	1.93	Octahedral	+1	1.27

If the iodine–oxygen and iodine–fluorine dis-

tances in potassium iodate and iodine pentafluoride are assumed to be even approximately correct then it would seem evident that two cases must be distinguished. If a vacant orbital exists in the coördination polyhedron, the unshared pair may occupy that orbital and its effect on the iodine radius will be small and may be correlated with the formal charge on the central atom. If no such vacant orbital exists, then the extra electrons become an "inert pair" having no steric effect, but causing a relatively large increase in the iodine radius.

The Structure.—The coördination of oxygen and fluorine atoms about potassium is irregular but it is probable that the packing of the $IO_2F_2^-$ groups is the determining factor in the structure. The K–O and K–F contacts are: O_I-K = 2.75, 2.76 Å.; $O_{II}-K$ = 2.63, 3.03 Å.; F_I-K = 2.64, 3.06 Å.; $F_{II}-K$ = 2.74, 3.04 Å.

The interatomic distances which are less than 3.50 Å. between oxygen and fluorine atoms of different anion groups are: F_I-F_{II} = 2.77, 3.23 Å.; F_I-O_{II} = 3.40 Å.; $F_{II}-O_I$ = 3.24 Å.

There are, in addition, two distances between iodine atoms and oxygen atoms in different $IO_2F_2^-$ groups that are shorter than three Ångströms: $I-O_I$ = 2.82 Å.; $I-O_{II}$ = 2.88 Å.

The similarity between this structure and that reported for potassium iodate may be seen if one considers an altered KIO_2F_2 in which the I–O contacts just mentioned are made real bonds so that each oxygen atom is shared between two iodine atoms. If, then, the iodine atoms and bonds to oxygen atoms are placed in the x–z plane, then this plane will be identical with a plane $z = 0$ for the potassium iodate structure. In this altered structure the I–F bonds will be in a vertical position along the lines $x = z = 0$, etc. If now one atom of oxygen is substituted for two atoms of fluorine and this atom shared between two iodine atoms the structure would become the cubic structure attributed to potassium iodate. It is suggested that the similarity, although not very great, is sufficient to cause the orientation effects observed on photographs of KIO_2F_2 in which some of the salt had hydrolyzed. The powder lines had quite definite maxima at positions corresponding to the equator and layer lines for potassium iodate oriented with the cube edges parallel to the orthorhombic axes of KIO_2F_2.

Summary

From a determination of the crystal structure of KIO_2F_2 it has been found that the $IO_2F_2^-$ group is composed of an iodine atom forming bonds at approximately 100° with two oxygen atoms, and perpendicular to the plane of these three atoms, two opposed bonds at 180° to fluorine. The configuration may perhaps best be thought of as that of a trigonal bipyramid in which one of the three equivalent orbitals is occupied by an unshared electron pair. The interatomic distances in the ion were found to be: I — O = 1.93 ± 0.05 Å.; I — F = 2.00 Å. ± 0.05 Å. The O–I–O bond angle = 100 ± 10°. The influence of the unshared pair on the bond distance is discussed.

The Redistribution Reaction. VIII. The Relative Affinity of Mercury and Lead for Methyl and Ethyl Radicals

BY GEORGE CALINGAERT, HAROLD SOROOS AND GEORGE W. THOMSON

Previous papers[1,2] of this series have described the redistribution reaction for the interchange of alkyl radicals in alkyl compounds of lead, tin, silicon, or mercury. Redistribution of alkyl groups is not confined to systems containing a single metal, but under suitable conditions can take place between compounds of more than one metal. This was illustrated in the first paper[1] of this series by an analytical distillation[3] curve for the reaction product of tetramethyltin with tetraethyllead, which indicated the presence of all ten possible R_4M compounds.

The fact that the equilibrium composition of a redistributed mixture corresponds to a random distribution of all the organic radicals present indicates that the relative affinity of a given radical for a given metal is independent of the

(1) Calingaert and Beatty, THIS JOURNAL, **61**, 2748 (1939).

(2) Calingaert, Beatty and Soroos, *ibid.*, **62**, 1099 (1940); Calingaert, Soroos and Hnizda, *ibid.*, **62**, 1107 (1940).

(3) Calingaert, Beatty and Neal, *ibid.*, **61**, 2755 (1939).

nature of the other radicals attached to the metal. When two metals, for example mercury and lead, are present in the system, the same should still hold true for each metal separately, but it does not follow that the different radicals, for example methyl and ethyl, should be divided equally between the two metals. If the affinity of the methyl radicals, relative to that of the ethyl radicals, is greater for mercury than for lead, then the R_2Hg compounds will contain a greater proportion of methyl than the R_4Pb compounds. Based on the law of mass action, this difference in relative affinity can be expressed by a "relative affinity constant," K, whose value is given by $K = [Me\text{-}Hg][Et\text{-}Pb]/[Et\text{-}Hg][Me\text{-}Pb]$, where the brackets denote the proportions of the four different R-M bonds in the total product.

The above example is particularly suitable for experimental study, first, since it includes two dissimilar metals of different valence, for each of which alone the redistribution reaction is known[2] to occur readily, giving random equilibrium mixtures, and, second, since its reaction product is of such nature as to facilitate an accurate analysis.[3] Accordingly, two tests were made, one with a mixture of tetramethyllead and diethylmercury, the other with tetraethyllead and dimethylmercury, each mixture containing equal proportions of methyl and ethyl radicals, and equivalent amounts of mercury and lead. Both mixtures, with aluminum chloride as the catalyst, underwent redistribution at 80° in five hours. The results are given in Tables I–III, and the distillation curves for the reaction products are shown in Fig. 1.

The data show that: (1) the recovery of each metal was quantitative, exclusive of handling losses resulting from filtration and transfer of

material, and there was no appreciable decomposition. Also, the over-all per cent. methyl in the product equalled that of the input, within experimental error. (2) The over-all equilibrium was completely attained, since the same product was obtained starting with either pair of metal alkyls. (3) Each metal yielded a random equilibrium mixture. (4) The per cent. methyl (67.2 ± 0.7) in the mercury alkyls was about twice that in the lead alkyls, corresponding to a marked difference in relative affinity of mercury and lead for methyl with respect to ethyl radicals. (5) The numerical values of K (as defined above) of 4.2 and 4.9 are in excellent agreement, in view of the sensitivity of the constant to slight differences in the composition of the product.

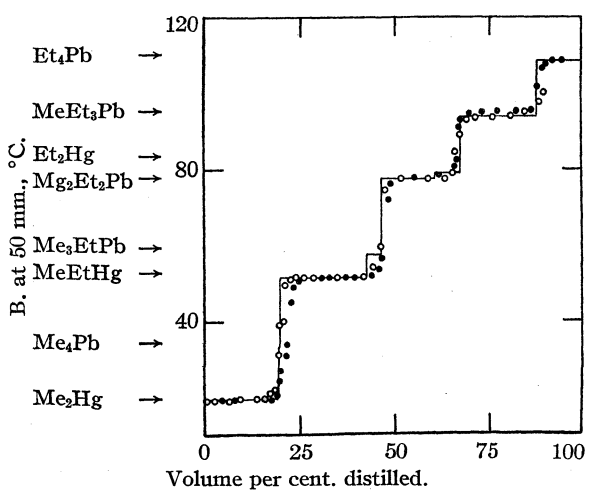

Fig. 1.—Distillation of reaction product from: ○—Me_4Pb + Et_2Hg; ●—Et_4Pb + Me_2Hg. Solid line calculated for random equilibrium mixtures, with 50.0% R-Hg and 50.0% R-Pb bonds, and with a total of 49.3% Me radicals, 33.3% Me-Hg and 16.0% Me-Pb.

Investigations of this kind obviously can be extended to other systems containing two or more metals or other central atoms or groups which, individually, are known to undergo redistribution under the conditions used. The reaction was shown to occur between the methyl and ethyl compounds of lead and tin,[1] and quantitative experiments are in progress to determine the value of K.

A few related observations of the interchange of radicals between different RM compounds have been reported, although the existence of equilibria has nowhere been recognized. Schlenk and Holtz[4] prepared methyllithium and phenyllithium by treating ethyllithium with methylmercury and phenylmercury, respectively. Challenger and Ridgway[5] isolated di-α-naphthylmercury, diphenyl-α-naphthylbismuth, and triphenylbismuth from the reaction product obtained by heating a mixture of tri-α-naphthylbismuth and diphenylmercury at 200° for two hours. Evidence has been reported[6] indicating similar reactions between diphenylselenium and *n*-butyllithium, diphenylmercury and *n*-butylsodium, and between triarylbismuth compounds and *n*-butyllithium or *n*-butylsodium.

Accordingly, it appears that redistribution reactions like the one described in the present study may be expected to occur, under suitable experimental conditions, in a variety of other analogous systems. It is evident that the analysis of such equilibria as these furnishes a useful method for the determination of relative bond energies, in which the comparison is obtained from a single reaction process, under strict equilibrium conditions, and is uncomplicated by side or consecutive reactions. Investigation of the temperature coefficient of these energies is also facilitated, inasmuch as the equilibria for each metal taken alone are not affected by temperature, so far as has been observed.

Experimental

Tetramethyllead and Diethylmercury.—To 1.83 g. (0.014 mole) of aluminum chloride contained in a small 3-

(4) Schlenk and Holtz, *Ber.*, **50**, 262 (1917).

neck flask fitted with a dropping funnel, reflux condenser, and thermometer, was added a mixture of 134.9 g. (0.502 mole) of tetramethyllead and 253.7 g. (0.973 mole) of diethylmercury, while cooling the flask in ice water. An atmosphere of nitrogen was maintained within the system during the addition and for the duration of the experiment. The mixture was kept at 78–83° for four hours, after which it was cooled and allowed to stand at room temperature overnight. The catalyst was extracted by shaking with water; the oily layer was separated and shaken twice with concentrated ammonia solution and finally with distilled water. After filtration through paper to remove traces of water, the product was fractionated[3] through a column packed with glass helices. The metal alkyls distilled readily and without decomposition. The various fractions were analyzed for lead and mercury. Figure 1 shows the distillation curve, Table I the analyses, and Table III the composition of the product.

Tetraethyllead and Dimethylmercury.—The above experiment was repeated, starting with 2.0 g. (0.015 mole) aluminum chloride, 233 g. (1.006 mole) dimethylmercury (which contained 0.001 mole tetramethyllead), and 162 g. (0.498 mole) tetraethyllead. The reaction time was five hours at 80°, and the product stood at room temperature over two nights. Subsequent handling was the same as above. The distillation curve, analyses, and composition of the product are given in Fig. 1 and Tables II and III, respectively.

Summary

Mixtures of diethylmercury with tetramethyllead, and of dimethylmercury with tetraethyllead, containing equal proportions of methyl and ethyl radicals and equivalent amounts of mercury and lead, undergo redistribution and yield the same random equilibrium mixture, in which the mercury shows a greater relative affinity than lead for methyl with respect to ethyl radicals.

The Redistribution Reaction. IX. Redistribution of Halides and of Esters[1]

BY GEORGE CALINGAERT, HAROLD SOROOS, VINCENT HNIZDA AND HYMIN SHAPIRO

As stated in the first paper of this series,[2] the redistribution reaction is not confined to organometallic compounds, but also has been found to take place in two distinctly different fields, namely, aliphatic halides and esters. So far, the work in these and other fields has been merely exploratory, designed to furnish only a roughly quantitative measure of the occurrence or non-occurrence of redistribution. No attempt has been made to study the influence of the different reaction variables, such as the temperature and amount of catalyst, and no accurate material balances or measurements of the amount of side reaction with the catalyst have been obtained. Further experiments are in progress but, pending future publication of their results, the present paper completes the presentation of the experimental data previously cited.[2]

In the halides, redistribution was found to occur between ethylene dichloride and dibromide, between ethyl chloride and ethylene dibromide, and between ethyl bromide and ethylene dichloride, in each case using 1.5–3 mole per cent. aluminum chloride as the catalyst.

As shown in Fig. 1 and Table I, in the first of these reactions, between the two ethylene dihalides, the composition of the product corresponded within experimental error to a random distribution of the halogen atoms. In this one case, we found later that our result has been fully antici-

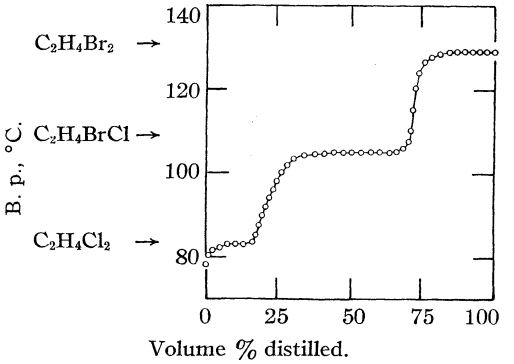

Fig. 1.—Distillation of the reaction product from $C_2H_4Br_2$ + $C_2H_4Cl_2$.

TABLE I

PRODUCTS FROM THE REDISTRIBUTION OF ETHYLENE DICHLORIDE WITH ETHYLENE DIBROMIDE

	Composition, mole per cent. Found	Calcd.[2] for r^a = 0.467
$C_2H_4Cl_2$	23.0	21.8
C_2H_4ClBr	47.4	49.8
$C_2H_4Br_2$	29.6	28.4

[a] r is the atomic fraction of chloride found in the product.

(1) For paper VIII, see Calingaert, Soroos and Thomson, THIS JOURNAL, **62**, 1542 (1940).

(2) Calingaert and Beatty, *ibid.*, **61**, 2748 (1939).

pated by Dougherty,[3] who stated that the reaction was reversible and that its product corresponded to "the laws of chance." The significance and generality of this statement apparently was not appreciated by either this author or his readers, since no subsequent reports on the subject appear in the literature.

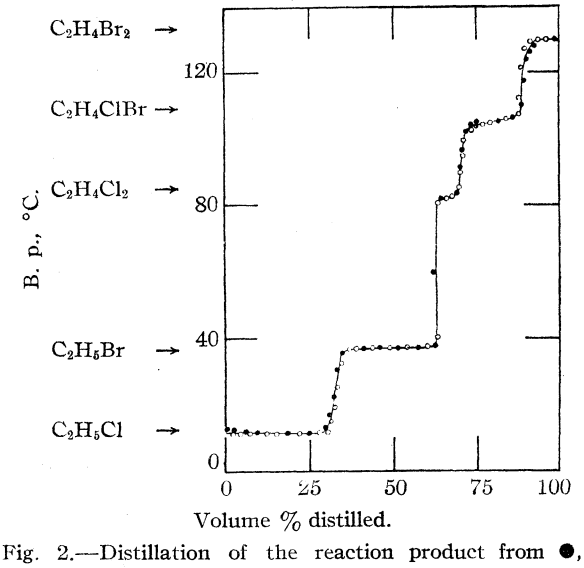

Fig. 2.—Distillation of the reaction product from ●, $C_2H_4Cl_2 + C_2H_5Br$; ○, $C_2H_4Br_2 + C_2H_5Cl$.

In the other two of these reactions, the products, which contained each of the expected five ethyl and ethylene halides, were identical, showing that equilibrium was attained from both sides. The analytical data are shown in Fig. 2 and Table II.

TABLE II

PRODUCTS FROM THE REDISTRIBUTION OF (1) ETHYL CHLORIDE WITH ETHYLENE DIBROMIDE AND (2) ETHYL BROMIDE WITH ETHYLENE DICHLORIDE

	Composition found, mole per cent. (1)	(2)
C_2H_5Cl	35	34
C_2H_5Br	30	29
$C_2H_4Cl_2$	7	9
C_2H_4ClBr	17	18
$C_2H_4Br_2$	11	10

In this case, the composition of the product is not fixed solely by the laws of probability, since it depends on the relative affinities of the two halogens for the ethyl and ethylene radicals, as was shown in paper VIII of this series[1] for the distribution of methyl and ethyl radicals between mercury and lead. Inspection of the data in Table II shows that the relative affinity factor departs slightly from unity, in the direction of a preponderance of ethyl chloride and of ethylene dibromide and chlorobromide. At the same time, the three ethylene dihalides as a group within themselves are, as before, present in proportions corresponding to a random equilibrium mixture.

In the ester field, redistribution of the alkoxy radicals was found between dimethyl and dibutyl oxalates, between methyl acetate and ethyl butyrate, and between furfuryl acetate and ethyl furoate, in each case using 3–5 mole per cent. aluminum ethylate as the catalyst and a heating time of five hours at about 100°. Blank experiments showed that, in the absence of the catalyst, no redistribution took place.

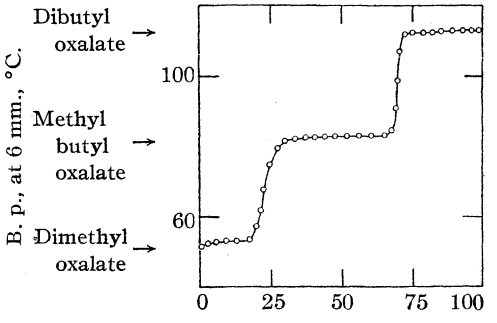

Fig. 3.—Distillation of the reaction product from dimethyl oxalate + dibutyl oxalate.

The first of these three systems, as seen from Fig. 3 and Table III, gave the expected three compounds in just the proportions of a random equilibrium mixture. Here, the accuracy of the analysis was facilitated by the relatively wide spread in the boiling points of the components.

TABLE III

PRODUCTS FROM THE REDISTRIBUTION OF DIMETHYL WITH DIBUTYL OXALATE

	Composition, mole per cent. Found	Calcd. for $r^a = 0.52$
$(COOMe)_2$	28	27
MeOOCCOOBu	48	50
$(COOBu)_2$	24	23

[a] r is the fraction of methoxyl radicals found in the product.

For the second of these ester systems, the composition of the product again is determined by relative affinities, in this case of the two alkoxy radicals for the two acyl radicals. Inspection of the results, given in Fig. 4 and Table IV, indicates that equilibrium was reached, and that the relative affinity factor in this case is close to unity, giving a symmetrical distribution of the radicals.

The third ester system—furfuryl acetate and ethyl furoate—gave quite similar results (Fig. 5

(3) Dougherty, THIS JOURNAL, **51**, 576 (1929).

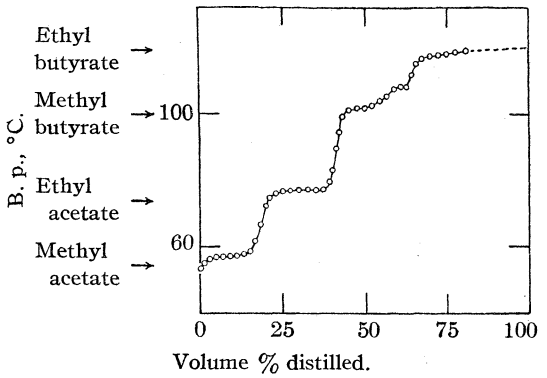

Fig. 4.—Distillation of the reaction product from ethyl acetate + methyl butyrate.

TABLE IV

PRODUCTS FROM THE REDISTRIBUTION OF ETHYL ACETATE WITH METHYL BUTYRATE

	Composition, mole per cent. Found	Calcd.[1] for $K = 1$, $[CH_3CO] = 0.50$ and $[OMe] = 0.45$[a]
CH_3COOMe	25.4	22.5
CH_3COOEt	23.4	27.5
C_3H_7COOMe	22.7	22.5
C_3H_7COOEt	28.5	27.5

[a] Concentrations are those taken in the reactants; the [OEt] was augmented by the $Al(OEt)_3$ used as catalyst.

and Table V), but the data suggest that either equilibrium was not completely attained or else there is a relative affinity factor greater than unity, in favor of the two original compounds.

TABLE V

PRODUCTS FROM THE REDISTRIBUTION OF FURFURYL ACETATE AND ETHYL FUROATE

	Composition found, mole per cent.
Ethyl acetate	23
Furfuryl acetate	24
Ethyl furoate	33
Furfuryl furoate	20

Altogether, it is evident that accurate determinations of equilibria such as these can furnish definite and specific information regarding some of the relative bond strengths in the compounds involved.

Experimental Part

Redistribution of Halides.—A mixture of 49.5 g. (0.5 mole) of ethylene dichloride, 98 g. (0.52 mole) of ethylene dibromide, and 2 g. (0.015 mole) of aluminum chloride was heated to refluxing for two hours. There was some decomposition and liberation of halogen acid. The reaction mixture, after cooling and extracting the catalyst with water, was analyzed by fractional distillation,[4] using a glass spiral packing in the column.

(4) Calingaert, Beatty and Neal, THIS JOURNAL, **61**, 2755 (1939).

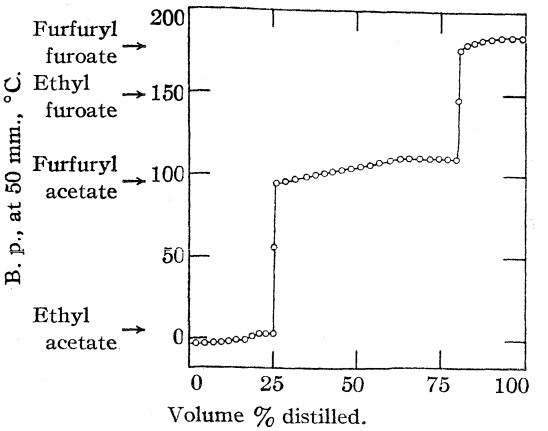

Fig. 5.—Distillation of the reaction product from furfuryl acetate and ethyl furoate.

The redistribution of a 2:1 mixture of ethyl chloride and ethylene dibromide, and of the corresponding mixture of ethyl bromide and ethylene dichloride, was carried out in steel bombs using about three mole per cent. aluminum chloride as catalyst. The mixtures were heated, respectively, to 25° for fourteen days and to 115° for twenty hours. After decomposing the catalyst with water, the products were distilled from the bomb and fractionated.

Redistribution of Esters.—A mixture of 47.2 g. (0.4 mole) of dimethyl oxalate, 80.8 g. (0.4 mole) of di-*n*-butyl oxalate and 5 g. (0.03 mole) of aluminum ethylate[5] was heated in a small flask to refluxing for five hours. The aluminum ethylate dissolved partially and later a voluminous flocculent white precipitate formed. After cooling in ice water, the reaction mixture was shaken twice with dilute hydrochloride acid. The ester layer was separated, washed with dilute sodium bicarbonate solution, and dried over anhydrous sodium sulfate. The aqueous layer and washings were extracted with several portions of ether, the extracts being combined and dried over sodium sulfate. The main product and ether extracts were subsequently fractionated.

The other ester systems were redistributed in essentially the same manner. The product from the redistribution of methyl butyrate with ethyl acetate was distilled directly from the catalyst, the distillate being subsequently fractionated.

Summary

Experimental data are presented for the redistribution reaction in the following six halide or ester systems: ethylene dibromide and ethylene dichloride, ethyl chloride and ethylene dibromide, ethyl bromide and ethylene dichloride, dimethyl oxalate and dibutyl oxalate, ethyl acetate and methyl butyrate, furfuryl acetate and ethyl furoate.

DETROIT, MICHIGAN RECEIVED DECEMBER 9, 1939

(5) The aluminum ethylate was prepared according to the method described in "Organic Syntheses," XV, 82.

Acetoacetyl Chloride

BY CHARLES D. HURD AND CHARLES D. KELSO

Since acetylketene, in conjunction with its resonance isomer β-crotonolactone, is the structure[1] of the dimer of ketene it seemed reasonable to think that acetoacetyl chloride could be synthesized from it by reaction with hydrogen chloride. Such proved to be the case.

$$CH_3COCH{=}CO + HCl \longrightarrow CH_3COCH_2COCl$$

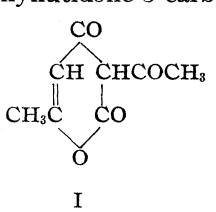
In the present synthesis low temperatures were found to be necessary because of the instability of acetoacetyl chloride at temperatures above −20°. A slight excess of hydrogen chloride was used in the synthesis and this excess remained in solution at the low temperature used. It was possible to remove this hydrogen chloride by vacuum treatment.

When acetoacetyl chloride was warmed to room temperature dehydroacetic acid (I) was formed

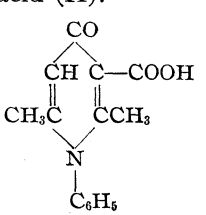
$$2CH_3COCH_2COCl \longrightarrow C_8H_8O_4 + 2HCl$$

Half of the hydrogen chloride was eliminated in three hours.

Low temperature (−60°) reactions of the acid chloride with alcohol or aniline gave rise to ethyl acetoacetate, $CH_3COCH_2COOC_2H_5$, and acetoacetanilide, $CH_3COCH_2CONHC_6H_5$, respectively. When acetoacetyl chloride was treated at room temperature with aniline there was formed 1-phenyllutidone-3-carboxylic acid (II).



I



II

Another reaction investigated was that of acetoacetyl chloride and benzene in the presence of aluminum chloride. Benzoylacetone was produced.

$$C_6H_6 + CH_3COCH_2COCl \xrightarrow{AlCl_3} C_6H_5COCH_2COCH_3 + HCl$$

Acetylketene also formed benzoylacetone in a similar type of reaction but the yield was smaller.

$$C_6H_6 + CH_3COCH{=}CO \xrightarrow{AlCl_3} C_6H_5COCH_2COCH_3$$

(1) Hurd and Williams, THIS JOURNAL, **58**, 964 (1936); Hurd and Abernethy, *ibid.*, **62**, 1147 (1940).

The behavior of acetoacetyl chloride toward the Grignard reagent was studied also. A fair yield of benzoylacetone was formed with phenylmagnesium bromide at −50°.

$$C_6H_5MgBr + CH_3COCH_2COCl \longrightarrow C_6H_5COCH_2COCH_3 + MgBrCl$$

Several other β-diketones were synthesized to test the generality of this reaction. These included 2,4-octanedione from butylmagnesium bromide, 2,4-undecanedione from heptylmagnesium bromide, 2,4-dodecanedione from octylmagnesium bromide, and 5-methyl-2,4-undecanedione from 2-octylmagnesium bromide. This work will be reported in a subsequent article.

Experimental Part

Acetylketene, or "diketene," was generously donated for this study by the Carbide and Carbon Chemicals Corporation. We are very grateful for this assistance. This material was always redistilled before use: b. p. 42° (30 mm.).

Preparation of Acetoacetyl Chloride.—Dry hydrogen chloride was passed into 5 g. of cold acetylketene. At the outset the temperature was held near the freezing point of the acetylketene (−7°) but the temperature was changed to −50° or below as rapidly as the ability to withstand crystallization would permit. Usually this was only a few minutes. The cooling bath was solid carbon dioxide and acetone. When hydrogen chloride escaped through the outlet tube the reaction was stopped. The reaction mixture solidified on prolonged standing at −78°.

Analysis showed the presence of 107–109% of the theoretical amount of halogen, hence the product was contaminated with hydrogen chloride. It was kept at −70°, subjected to a vacuum of 20 mm. for five minutes and reanalyzed. The Cl-content was 104% of the theoretical. Another vacuum treatment for four minutes at −70° resulted in a solid which analyzed correctly (99.67, 99.20%) for halogen. This material was not stored but was used promptly for each experiment.

Method on Analysis.—A small dewar flask (7 cm. long by 1 cm. inside diameter) served as a weighing bottle. It was chilled to about −75° by rinsing it with butyl ether at −78°. Then 0.5 cc. of the cold butyl ether was added. The flask was stoppered and weighed, after which a 0.4-g. portion of the acetoacetyl chloride was introduced. The flask was reweighed and lowered carefully into a 500-cc. Erlenmeyer flask containing an excess of dilute base. Analysis for chloride ion followed the usual Volhard method.

Melting Point.—A three-junction copper–constantan thermocouple was calibrated at the melting points of ice, mercury and carbon tetrachloride. The acetoacetyl chloride, prepared as described above, analyzed for 99.3% of the theoretical amount of chlorine. This material melted sharply between −50 and −51°.

Behavior on Warming.—A 7-g. sample of acetoacetyl chloride which contained the equivalent of 1.9 g. of hydrogen chloride was allowed to come slowly to room temperature. The hydrogen chloride which was evolved was collected in standard alkali. At the end of three hours, 1.0 g. of hydrogen chloride was evolved. Only 0.15 g. was lost after another forty hours. Dehydroacetic acid crystals were deposited.

To this reaction product was added a slight excess of aniline. The reaction proceeded without warming, and much heat was evolved. Dehydroacetic acid reacts with aniline but heat is necessary to make the reaction take place. The product was treated with dilute hydrochloric acid to remove aniline and aniline hydrochloride. The solid was filtered off and recrystallized twice from alcohol. The melting point was 260–265° with decomposition. The neutral equivalent was found to be 235, which indicates that the product was 1-phenyllutidone-3-carboxylic acid.[2]

Reaction with Aniline at −60°.—Acetoacetyl chloride, prepared from 2.5 g. of acetylketene, was dissolved in 10 cc. of dry ether. Six grams of aniline in 20 cc. of dry ether was cooled to −60°. The acid chloride solution was poured into the aniline solution in small portions, both solutions being kept at −60° or below. This mixture was allowed to stand at −60° for three hours. The mixture was treated with water. The white solid dissolved completely. The layers were separated. The ether layer was dried and evaporated. The residue was a gummy mass which would not recrystallize from alcohol or ligroin. The residue was dissolved in ether and treated with 6 cc. of concentrated hydrochloric acid diluted with 20 cc. of water. This treatment removed the excess of aniline and removal of the ether yielded 2.3 g. of a solid which, when recrystallized from ligroin, melted at 84–85°, the melting point of acetoacetanilide. The yield was 44%.

Evaporation of the original aqueous layer yielded 3.8 g. of solid, presumably aniline hydrochloride, the theoretical amount being 3.85 g.

Reaction with Alcohol at −60°.—The reaction was run in the same manner as the previous reaction, using 2.5 g. of acetoacetyl chloride in 10 cc. of ether and 1.6 g. of absolute alcohol in the same volume of ether. The oil obtained from the aqueous layer yielded 1.6 g. (27% yield) of ethyl acetoacetate, b. p. 98° (65 mm.); semicarbazone, m. p. 120°.

Friedel–Crafts Reaction.—Thirty-six grams of benzene and 10.8 g. of acetoacetyl chloride, made by passing an excess of dry hydrogen chloride into 7.6 g. of acetylketene and then evacuating to 20 mm. at −70° until the weight of the product checked the calculated weight to 0.1 g., were placed in a flask and cooled to −50°. Twelve grams of aluminum chloride was added in portions with stirring over a period of two hours. Between additions the reaction mixture was allowed to warm up until the reaction appeared to be proceeding too vigorously. The dry-ice and acetone bath was then used to freeze out the reactants. This means of controlling the reaction was used until all the aluminum chloride was added. The mixture was allowed to warm up slowly. A sirupy layer settled to the bottom. The benzene was decanted and the sirupy layer was hydrolyzed with dilute hydrochloric acid. A semi-solid mass was obtained. On steam distillation of it, a little liquid was noted, then 3.6 g. (27% yield) of solid benzoylacetone was collected separately. It melted[3] at 59–60°. There was a non-volatile residue which was not characterized.

Friedel–Crafts Reaction with Acetylketene.—Thirty-nine grams of benzene and 8.4 g. of acetylketene were placed in a flask and cooled to −5°. Twenty-nine grams of aluminum chloride was added in portions as before and the reaction was controlled as above. The product was isolated by the same technique as above. The steam distillation yielded 1.7 g. of benzoylacetone melting at 59–60°. The yield is 10.5%.

In this reaction, 2.2 moles of aluminum chloride per mole of acetylketene was used, while in the preceding reaction, 1.1 moles of catalyst per mole of acid chloride was used.

Reactions of Acetoacetyl Chloride and Phenylmagnesium Bromide.—Phenylmagnesium bromide (0.2 mole in 250 cc. of ether) was prepared in the usual manner in an atmosphere of nitrogen. The reagent was filtered and transferred to a separatory funnel and dropped into 0.1 mole (12 g.) of acetoacetyl chloride in 150 cc. of dry ether at −60°, over a period of one and one-half hours in an atmosphere of nitrogen. The reaction mixture was allowed to stand overnight. The mixture was hydrolyzed with water and acetic acid after removal of most of the ether. The oil was removed from the aqueous layer by ether extraction. The extract was dried over sodium sulfate, the ether removed and the oil distilled at 20 mm. pressure. Two grams of an oil which partially soldified on standing was obtained in the boiling range 128–130° at 20 mm. The residue would not distil at a bath temperature of 250°. Recrystallization from ligroin gave a solid melting at 58–59°. This material and the products from the Friedel-Crafts reaction gave semicarbazones melting at 242–247° with decomposition. This is the melting point recorded for the disemicarbazone of benzoylacetone.[3]

The yield of benzoylacetone from this reaction is 12%.

Summary

Acetoacetyl chloride has been prepared from acetylketene and hydrogen chloride. It is unstable above −20°. Decomposition at room temperature yields dehydroacetic acid. Reactions with aniline, alcohol, and phenylmagnesium bromide are described.

Both acetoacetyl chloride and acetylketene undergo the Friedel–Crafts reaction with benzene and aluminum chloride.

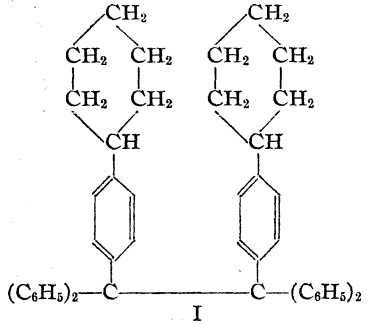
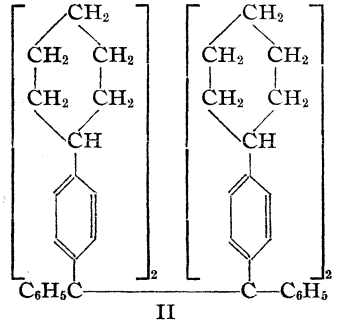
Hexa-*p*-alkylphenylethanes. X.[1] *p*-Cyclohexyl Derivatives of Hexaphenylethane

BY C. S. MARVEL AND CHESTER M. HIMEL

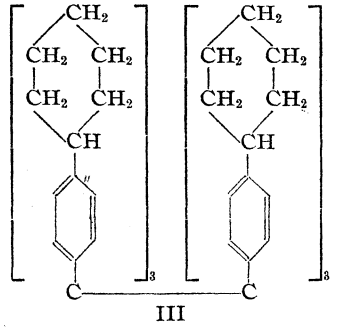
In connection with the study of the effect of alkyl groups on the dissociation of substituted hexaphenylethanes, di- (I), tetra- (II) and hexa- (III) -*p*-cyclohexylphenylethanes have been prepared and their dissociation measured by the magnetic susceptibility method.[2]



I



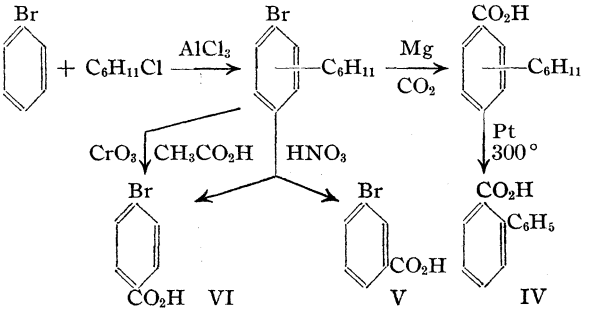
II



III

Zugrăvescu and Zugrăvescu[3] already have reported the preparation of di-*p*-cyclohexylphenyltetraphenylethane (I), and Brown and Marvel[4] have described a hexacyclohexylphenylethane which was believed to be the *para*-isomer (III). However, that product was prepared from a bromocyclohexylbenzene obtained by the action of cyclohexyl chloride on bromobenzene in the presence of aluminum chloride[5] and has been shown to be a mixture of isomers.

The bromocyclohexylbenzene obtained from the Friedel–Crafts reaction[4,5] has a fairly constant boiling point and its refractive index is very close to that of the product prepared by diazotization of *p*-aminocyclohexylbenzene and replacement of the diazonium group with bromine.[5] The product of the Friedel–Crafts reaction, however, contains the ortho-, meta- and para-isomers. The presence of the ortho-isomer has been demonstrated by carbonation of the Grignard reagent from the bromocyclohexylbenzene to give a mixture of acids which on dehydrogenation gave *o*-phenylbenzoic acid (IV). Meta- and para-isomers have been shown to be present by oxidation with nitric



acid to yield a mixture of bromobenzoic acids from which pure *m*-bromobenzoic acid (V) and pure *p*-bromobenzoic acid (VI) have been separated. The presence of the para-isomer also has been established by the oxidation of the bromocyclohexylbenzene in acetic acid solution by chromic acid to give pure *p*-bromobenzoic acid.

Bodroux and Thomassin[6] have described the bromination of cyclohexylbenzene to give *p*-bromocyclohexylbenzene. This reaction takes place readily and apparently yields the pure para-isomer since oxidation has given only *p*-bromobenzoic acid and conversion to the Grignard reagent followed by carbonation has produced *p*-cyclohexylbenzoic acid (VII) in yields of 80% of

VII

the theoretical amount. As a further check on the purity of the *p*-bromocyclohexylbenzene obtained by this process, a sample has been made from *p*-aminocyclohexylbenzene and one of the carbinols described below has been made from each sample of the bromo compound. No difference in the properties of the carbinols thus obtained has been detected.

The three triarylcarbinols corresponding to the desired ethanes (I, II and III) have been prepared by treating the Grignard reagent from *p*-bromocyclohexylbenzene with benzophenone, ethyl benzoate and diethyl carbonate, respectively. All three carbinols thus prepared were obtained in crystalline form. The tri-*p*-cyclohexylphenylcarbinol melted at 180–181°, or twelve degrees higher than has been reported by Neunhoeffer.[7] It seems probable that Neunhoeffer may have had some ethyl ether of the carbinol mixed with the carbinol. We found that unless unusual care was taken to use alcohol-free ether in handling the carbinol, some ether formed and a low-melting product resulted. Our mono-*p*-cyclohexylphenyldiphenylchloromethane melted at 126–127°. Zugrăvescu and Zugrăvescu[3] report the melting point to be 123°. Our sample of the corresponding hexaarylethane peroxide melted at 158–159° whereas it has been reported[3] to melt at 164°.

The tri-*p*-cyclohexylphenylcarbinol, the corresponding chloromethane and peroxide obtained in this work did not have properties which agreed with those previously reported by Brown and Marvel.[4] It seems obvious that the products reported earlier as para-isomers are really mixtures of unknown composition.

The ethanes (I, II and III) were prepared from the carbinols by the usual procedures. The ethanes were not isolated but were characterized by conversion to the corresponding peroxides. Magnetic susceptibility measurements on benzene solutions of the ethanes showed that di-*p*-cyclohexylphenyltetraphenylethane (I) was dissociated to the extent of 9 ± 1% at 0.1 molar concentration and 25°. Its solution was an orange-yellow. This ethane, like other mono-*p*-alkylphenylethanes, decomposed very slowly. The tetra-*p*-cyclohexylphenyldiphenylethane gave a cherry-red solution and was dissociated to the extent of 10 ± 1% at 0.1 molar concentration and 25°. This ethane decomposed extensively in thirty-six hours. Hexa-*p*-cyclohexylphenylethane was quite insoluble and very unstable so that magnetic susceptibiliy measurements were not very satisfactory. The freshly prepared solutions had a Burgundy-red color and measurements at 0.01 molar and 25° indicated a dissociation of 50 ± 7%. Assuming that the mass law holds, this would indicate a dissociation of about 22% at 0.08 molar concentration. This value is very close to those found for other hexa-*p*-alkylphenylethanes.[1] The most remarkable fact concerning these dissociation measurements is that the disubstituted ethane is dissociated to almost the same extent as the tetra-substituted compound.

Experimental

***p*-Bromocyclohexylbenzene.**—**(a) Bromination of Cyclohexylbenzene.**—The method described by Bodroux and Thomassin[6] was used with the modification that iron was added as a bromination catalyst and the reaction mixture was stirred. The yield of bromo compound was 85%; b. p. 106–108° (1.5 mm.); $n^{20}D$ 1.5588; d^{25}_4 1.275.

(b) From *p*-Aminocyclohexylbenzene.—*p*-Nitrocyclohexylbenzene was prepared according to the method of Neunhoeffer[8] and reduced over Raney nickel to give a 97% yield of the amine. The amine hydrobromide was suspended in 40% hydrobromic acid and diazotized at 5°. The insoluble diazonium salt was decomposed with copper bronze powder. The material which separated from solution was a mixture of the phenol and the bromo compound. The phenol was removed with some difficulty by extraction with 10% potassium hydroxide solution. The yield of bromo compound was about 35%; b. p. 110° (1.5–2 mm.); $n^{20}D$ 1.5594; d^{25}_4 1.265.

(c) From Bromobenzene, Cyclohexyl Chloride and Aluminum Chloride.—This procedure previously described[4,5] gave a product of b. p. 93–95° (1 mm.); $n^{20}D$ 1.5605; d^{20}_4 1.300.

The ether solution of the Grignard reagent from 24 g. of this bromo compound was poured on solid carbon dioxide and the organic acids thus formed were isolated. The yield was 14.2 g. (70%) of product melting at 103–106°. A 0.3-g. sample of this acid was dehydrogenated by heating with a platinum on charcoal catalyst[9] at 300° for two hours. This treatment gave 0.02 g. of *o*-phenylbenzoic acid, m. p. 113°. This acid when mixed with an

(7) Neunhoeffer, *Ann.*, **526**, 61 (1936).

(8) Neunhoeffer, *J. prakt. Chem.*, **241**, 95 (1932).

(9) Linstead, Millidge, Thomas and Walpole, *J. Chem. Soc.*, 1146 (1937).

authentic specimen of *o*-phenylbenzoic acid (m. p. 114°) did not depress its melting point.

Oxidation of 9.5 g. of this bromocyclohexylbenzene in 100 cc. of boiling 50% acetic acid with 20 g. of chromic acid for twenty-four hours gave 0.3–0.5 g. of *p*-bromobenzoic acid, m. p. 252°.

By refluxing 2 g. of the bromo compound with 150 cc. of dilute nitric acid (sp. gr. 1.04) for four days, then adding 10 cc. of concentrated nitric acid (sp. gr. 1.42) and continuing the heating for three more days, some oxidation was obtained. The yield of acidic products was 0.6 g. The portion least soluble in hot water melted at 252° and was considered to be *p*-bromobenzoic acid. *m*-Bromobenzoic acid, m. p. 152–154°, was obtained from the remainder. This material did not depress the melting point of an authentic specimen of *m*-bromobenzoic acid whereas a mixture of it with *o*-bromobenzoic acid melted at 137–142°.

p-Cyclohexyl Derivatives of Triphenylcarbinol.—The Grignard reagent of *p*-bromocyclohexylbenzene (prepared by method (a)) was obtained in ether solution using a little ethylmagnesium bromide as a catalyst to start the reaction. Most of the ether was distilled from the reaction mixture and replaced by dry benzene. Then about 70% of the calculated amount of benzophenone, ethyl benzoate or diethyl carbonate, depending on the carbinol desired, was added. The reactions were carried out and the products isolated in the usual manner. The carbinols crystallized readily. Alcohol-free ether was used to avoid formation of some ether of the carbinol. Unless this precaution was taken the carbinols melted low.

From 86 g. of *p*-bromocyclohexylbenzene, 75 g. (65%) of *p*-cyclohexylphenyldiphenylcarbinol was obtained. The product was purified by recrystallization from petroleum ether (b. p. 90–100°) and then melted at 95–96°.

Anal.[10] Calcd. for $C_{25}H_{26}O$: C, 87.72; H, 7.60. Found: C, 87.55; H, 7.62.

From 239 g. of bromo compound, 65 g. (30%) of phenyldicyclohexylphenylcarbinol was obtained. This product first separated as an oil. A sample dissolved in low-boiling petroleum ether and held at the temperature of solid carbon dioxide for three days deposited a few crystals. When these were added to the main oil it crystallized completely. Recrystallization from petroleum ether (b. p. 90–100°) gave a product melting at 102–103°.

Anal. Calcd. for $C_{31}H_{36}O$: C, 87.73; H, 8.49. Found: C, 88.26; H, 8.66.

From 358 g. of the bromo compound, 80 g. (35%) of tri-*p*-cyclohexylphenylcarbinol was obtained. The first crop of crystals amounted to 65 g. The residual oil was distilled with steam and then washed with low-boiling petroleum ether to give an additional 15 g. of crystals. This second lot of crystals was recrystallized from reagent acetone. The first crop of crystals weighing 3–4 g. was *p,p'*-dicyclohexylbiphenyl.[7] The second crop of crystals was added to the 65 g. of crude product first obtained and all of this carbinol recrystallized from acetone. The pure carbinol thus obtained melted at 180–181°.

Anal. Calcd. for $C_{37}H_{46}O$: C, 87.75; H, 9.09. Found: C, 87.71; H, 9.18.

(10) The analyses reported in this paper are microanalyses and were done by Messrs. L. G. Fauble and W. H. Taylor.

From the acetone mother liquors 2–3 g. of *p,p'*-dicyclohexylbenzophenone, m. p. 136°,[7] was isolated.

A 3.58-g. sample of *p*-bromocyclohexylbenzene prepared by method (b) was converted to the Grignard reagent and treated with diethyl carbonate. The product was isolated as above. The carbinol thus prepared also melted at 180–181° and a mixture of this sample with a sample of carbinol prepared from *p*-bromocyclohexylbenzene obtained by method (a) also melted at 180–181°.

p-Cyclohexyl Derivatives of Triphenylchloromethane.—The carbinols were dissolved in dry benzene and acetyl chloride and heated for several hours at reflux temperature. The solutions were concentrated and cooled and then an excess of petroleum ether (b. p. 30–60°) was added. The chlorides thus precipitated were recrystallized from absolute ethyl acetate.

p-Cyclohexylphenyldiphenylchloromethane, m. p. 125–126°.

Anal. Calcd. for $C_{25}H_{25}Cl$: Cl, 9.83. Found: Cl, 9.70, 10.19.

Phenyldi-*p*-cyclohexylphenylchloromethane, m. p. 155–156°.

Anal. Calcd. for $C_{31}H_{35}Cl$: Cl, 8.01. Found: Cl, 7.95.

Tri-*p*-cyclohexylphenylchloromethane, m. p. 169–170°.

Anal. Calcd. for $C_{37}H_{45}Cl$: Cl, 6.76. Found: Cl, 6.73.

p-Cyclohexyl Derivatives of Triphenylmethyl Peroxide.—Solutions of the cyclohexylphenylethanes for use in the magnetic susceptibility measurements were prepared by treating solutions of the chloromethanes in benzene with silver and filtering the solutions. After the measurements were made the solutions were exposed to the air and evaporated to dryness. The solid residue thus obtained was dissolved in hot benzene, filtered and diluted with six to ten volumes of absolute alcohol. The peroxides crystallized from this mixture.

p-Cyclohexylphenyldiphenylmethyl peroxide, m. p. 158–159°, was obtained in 65–75% yields.

Anal. Calcd. for $C_{50}H_{50}O_2$: C, 87.98; H, 7.33. Found: C, 88.57; H, 7.47.

Phenyldi-*p*-cyclohexylphenylmethyl peroxide, m. p. 120–121°, was obtained in 55–60% yields.

Anal. Calcd. for $C_{62}H_{70}O_2$: C, 87.94; H, 8.27. Found: C, 88.47; H, 8.39.

Tri-*p*-cyclohexylphenylmethyl peroxide, m. p. 178–179°, was obtained by shaking a benzene solution of the chloromethane with silver in the air and recrystallizing as outlined above. The ethane decomposed so rapidly that by the time the magnetic susceptibility measurements were completed there were too many products in solution to give a peroxide which could be purified.

Anal. Calcd. for $C_{74}H_{90}O_2$: C, 87.92; H, 8.91. Found: C, 87.66; H, 9.26.

p-Cyclohexyl Derivatives of Triphenylcarbinol Ethyl Ether.—The respective carbinols were dissolved in ethyl alcohol, a drop of concentrated hydrochloric acid added, and the solutions boiled for a few minutes. On cooling the ethers crystallized.

p-Cyclohexylphenyldiphenylmethylcarbinol ethyl ether, m. p. 106–107°.

Phenyldi-*p*-cyclohexylphenylmethylcarbinol ethyl ether, m. p. 152–153°.

Anal. Calcd. for $C_{33}H_{40}O$: C, 87.61; H, 8.85. Found: C, 88.12; H, 8.94.

Tri-*p*-cyclohexylphenylmethylcarbinol ethyl ether, m. p. 189–190°.

Anal. Calcd. for $C_{39}H_{50}O$: C, 87.64; H, 9.36. Found: C, 87.97; H, 9.40.

Magnetic Susceptibility Measurements.—The magnetic susceptibility measurements were made as previously described.[2] Some difficulty was encountered due to the insolubility of the ethanes and for that reason it is necessary to report some of the details of the preparation of the ethane solutions which were used.

When a 0.2 molar solution of *p*-cyclohexylphenyldiphenylchloromethane (1.802 g. of chloride in 25 cc. of benzene) was shaken with silver, a heavy precipitate formed. This was obviously the ethane since on opening the tube to the air a 60–70% yield of peroxide was obtained and the orange-yellow color of the solution did not fade until the precipitate had completely disappeared. Similar results followed the first attempts to prepare 0.05 molar solutions of the ethane. It was then discovered that traces of undissolved chloromethane in the apparatus seemed to cause the rapid crystallization of ethane. A supersaturated solution of the ethane which could be used in the magnetic susceptibility measurements was obtained by putting 0.08 to 0.1 mole of the chloromethane in the apparatus with benzene, evacuating and sealing the outfit and then gently boiling the benzene until the vapor had condensed over the walls to remove stray crystals. After cooling, the silver was added and the mixture was shaken and filtered. Ethane began to crystallize from the solution in about three to six hours but the measurements could be completed before that happened. The values for dissociation of the ethane obtained on these supersaturated solutions checked well with those calculated from measurements made with a 0.025 molar solution of the ethane. After each measurement the apparatus was opened to the air and the peroxide which formed was isolated. The yields were usually about 70%, showing that the ethane had not undergone complete disproportionation.

No difficulties were encountered in preparing the solutions of the tetra-*p*-cyclohexyldiphenylethane. Measurements were made on both 0.1 and 0.05 molar benzene solutions. These solutions were cherry-red. Magnetic susceptibility measurements showed that this ethane had undergone extensive decomposition after thirty-six hours.

The ethane from tri-*p*-cyclohexylphenylchloromethane was very insoluble. By dissolving 0.305 g. of the chloride in 25 cc. of benzene, shaking with silver for fifteen minutes and filtering, a clear Burgundy-red solution of ethane was obtained. The magnetic susceptibility measurements were made at intervals until no free radical remained in solution. The values for $\chi_{sol.}$ obtained in these measurements were plotted and extrapolated to zero time[1] and this value used to calculate the degree of dissociation. The errors involved in this measurement may be large as no information is available as to the amount of ethane or radical held by the silver. Since the measured dissociation is 50% the exact concentration of ethane or radical is more important than it is in measurements of solutions which contain less radical. The calculations here are based on the assumption that the ethane in solution is 80% of the theoretical amount at zero time. The uncertainty in the value of 50% for the dissociation is thus about ±7%. The table gives the data on magnetic susceptibility.

MAGNETIC SUSCEPTIBILITY AND DEGREE OF DISSOCIATION OF *p*-CYCLOHEXYL DERIVATIVES OF HEXAPHENYLETHANE

Hexaphenylethane	*t*, °C.	% Ethane in benzene	$-\chi \times 10^6$ solution	α %	Molarity	$K \times 10^3$	α at 0.1 *M* %
Di-*p*-cyclohexyl (I)	27	3.0	0.6924	13.5	0.04	3.36	8.5
	26	3.0	.6931	13.0	.04	3.08	8.0

Hexa-*p*-cyclohexyl (III)	26	1.1	.6938	50	.01		

Summary

The dissociation of di-*p*-cyclohexylphenyltetraphenylethane, tetra-*p*-cyclohexylphenyldiphenylethane and hexa-*p*-cyclohexylphenylethane into free radicals has been measured by the magnetic susceptibility method. The dissociation in benzene at 26–28° is 9 ± 1% in 0.1 *M* solution, 10 ± 1% in 0.1 *M* solution and 50 ± 7% in 0.01 *M* solution, respectively.

The Elimination of Hydrogen Bromide from Stigmasterol 22,23-Dibromide

BY ERHARD FERNHOLZ, WILLIAM L. RUIGH AND HOMER E. STAVELY

Under certain conditions the tetrabromides of stigmasteryl acetate[1] and brassicasteryl acetate[2] can be converted into dibromides containing the halogen in the side-chain on carbon atoms 22 and 23. In view of the fact that sterols with more than one double bond in the side-chain are not known, it seemed of interest to prepare such compounds from the new dibromides by the elimination of hydrogen bromide. The bromine atoms in the 22,23-dibromides of stigmasterol and brassicasterol are firmly bound and resist boiling methyl alcoholic alkali for several hours. While short boiling of stigmasteryl acetate 22,23-dibromide with 20% alcoholic potassium hydroxide removed only the acetyl group, prolonged boiling resulted in the formation of a mixture of halogen-free sterols from which only stigmasterol could be obtained in sufficiently pure form to assure its identity. This reducing action of alcoholic potassium hydroxide on the dibromide is somewhat analogous to its action on neopentyl iodide.[3]

Somewhat to our surprise the only product isolated in pure form from the action of boiling pyridine (116°) or quinoline (234°) on the dibromide was stigmasteryl acetate.

When the dibromide was refluxed in 2-ethylhexanol (b. p. 183°) in the presence of an excess of anhydrous potassium acetate the sole reaction product isolated was the acetate of a triene, m. p. 128–129°, which on hydrolysis yielded the triene alcohol, m. p. 125–126°. The new compound reacted with 3 moles of hydrogen yielding a saturated sterol which was identical with stigmastanol in melting point and rotation and gave an acetate and *m*-dinitrobenzoate with correct constants. This indicates that no rearrangement has occurred in the carbon skeleton of the side-chain.

The presence of a conjugated system of double bonds is indicated by the characteristic ultraviolet absorption spectrum[4] with a λ max. = 237.5 mμ, illustrated in Fig. 1. The shifting of the absorption maxima toward the longer wave length with the increase in the number of alkyl substituents, especially on the 1 and 4 position of a conjugated system, is illustrated by this compound. Butadiene has a λ max. = 217 mμ and, 2,3-dimethylbutadiene (see Fig. 1) has λ max. = 225.[5] The compound reacted with maleic anhydride, but resisted hydrogenation with sodium and alcohol.

In order to obtain information regarding the location of the two double bonds the substance was ozonized, and the volatile carbonyl compounds thus obtained transformed into *p*-nitrophenylhydrazones. By means of chromatographic adsorption the hydrazone of acetaldehyde was obtained in pure form, indicating that the ethyl group of the side-chain carries one of the double bonds.

Having fixed the position of one of the double bonds in the conjugated system the other must occupy the position between 22 and 23 or 25 and 26. The latter position seems most improbable since it would involve a shift of double bonds along four carbon atoms. Further, it is unlikely

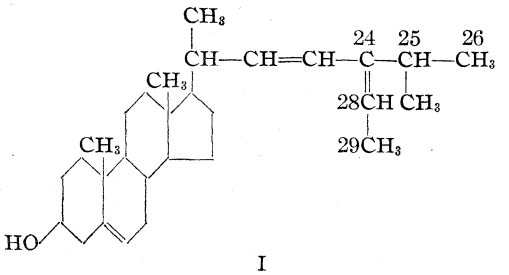
that formaldehyde *p*-nitrophenylhydrazone would remain undetected in the products from ozonolysis. The new stigmastatrienol is thus Δ-5,22,24:28-stigmastatrienol-(3) shown in formula I.



I

The compound autoxidized very readily, and showed peroxide reactions after short exposure to air. A sample took up 14% of a mole of oxygen within eighteen hours. The substance was definitely more sensitive to oxygen than ergosterol which has a conjugation in the ring system.

Experimental

Reactions of Stigmasteryl Acetate 22,23-Dibromide

(a) **Alcoholic Potassium Hydroxide.**—One gram of the acetoxydibromide was refluxed with 50 cc. of 20% ethyl alcoholic potassium hydroxide for twenty-one hours. Water was added and the mixture extracted with ether. The ether residue was crystallized from alcohol. A yield of 0.6 g. of material was obtained melting at 140–148°. Repeated crystallizations raised the melting point to 162°. This material was acetylated by means of acetic anhydride in the presence of pyridine at room temperature. The product melted at 139° and gave no depression with stigmasteryl acetate (141°). Also the rotation $[\alpha]_D$ −56° agreed with that of stigmasteryl acetate, and on bromination a tetrabromide of m. p. 205° was obtained. *Anal.* Calcd. for $C_{31}H_{50}O_2$: C, 81.88; H, 11.09. Found: C, 81.95; H, 10.93.

(b) **Pyridine.**—Three grams of stigmasteryl acetate 22,23-dibromide were refluxed with 20 cc. of dry pyridine for seven hours. After addition of water the mixture was extracted with ether, the ether washed with dilute acid, then with water, dried, and evaporated. The residue was recrystallized repeatedly from ethanol, and 1.5 g. of stigmasteryl acetate (m. p. 139°, $[\alpha]_D$ −54° in chloroform) was obtained; 1.0 g. of this acetate was dissolved in 15 cc. of ether and 25 cc. of 5% bromine in acetic acid was added. After two hours the precipitate was filtered and washed with ether; 1.2 g. of the characteristic stigmasteryl acetate tetrabromide of m. p. 205° was thus obtained.

A similar experiment in boiling quinoline (b. p. 234°) also yielded stigmasteryl acetate although in lower yield.

Preparation of the Acetate of Stigmastatrienol.—Fifty grams of fused potassium acetate was added to 550 cc. of 2-ethylhexanol, and 50 cc. of the alcohol was distilled off to remove traces of water; to the hot solution was rapidly added 50 g. of stigmasteryl acetate 22,23-dibromide and one gram of hydroquinone as anti-oxidant. The mixture was refluxed for one hour while a stream of dry carbon dioxide was passed in through a tube reaching the bottom of the flask. After cooling, water was added and the octyl alcohol layer washed several times with water. The solvent was then removed on the steam-bath in a stream of carbon dioxide in a good vacuum. The oily residue was dissolved in 75 cc. of hot *n*-butyl alcohol containing 0.1 g. of hydroquinone and the solution allowed to crystallize in the icebox. The solid was filtered off and washed with cold alcohol and recrystallized from a mixture of 50 cc. of butanol and 25 cc. of ethanol; yield 13.8 g., m. p. 123–125°. This material still contained traces of unchanged dibromide. This could be removed by sublimation in a high vacuum. The pure material forms shining leaflets from 95% alcohol, m. p. 128–129° (sealed capillary under CO_2), $[\alpha]^{24}_D$ −47° (26.0 mg. in 2 cc. chloroform solution, 1-dm. tube, α_D −0.61°).

Anal. Calcd. for $C_{31}H_{48}O_2$: C, 82.24; H, 10.69. Found: C, 81.74; H, 10.58. The carbon values are low because of rapid autoxidation.

Bromination of the Triene Acetate.—To a solution of 0.5 g. of the crude acetate m. p. 123–125° in 5 cc. of ether, 14 cc. of a 5% bromine solution in acetic acid was added. A small precipitate of stigmasteryl acetate tetrabromide (25 mg.) was obtained, largely due to the presence of some stigmasteryl acetate dibromide in the starting material. The acetate of the trienol does not form an insoluble bromide.

Reaction with Maleic Anhydride.—One gram of the acetate was refluxed with 0.5 g. of maleic anhydride in 10 cc. of dry toluene for ninety minutes. The solution was then evaporated to dryness, hydrolyzed with methyl alcoholic potassium hydroxide on the steam-bath, diluted with water and extracted with ether. Only 172 mg. of a neutral material was obtained probably from the oxidation of the substance before reaction with maleic anhydride. No attempt was made to purify the addition product.

Saponification.—To 0.618 g. of the triene acetate was added 15 cc. of 0.5 *N* KOH in 95% alcohol and this solution, as well as a blank, refluxed for one hour. The solutions were then titrated to determine the consumption of alkali. Calcd. for 1 acetyl: 1.35 cc. *N* KOH; found: 1.34 cc. The sterol was isolated by means of ether, crystallized from alcohol, and obtained in the form of leaflets, m. p. 125–126° (sealed capillary under CO_2).

Anal. Calcd. for $C_{29}H_{46}O$: C, 84.81; H, 11.29. Found: C, 84.33; H, 11.62.

Reduction with Sodium and Alcohol.—The trienol (3.5 g.) was dissolved in absolute alcohol (350 cc.) and heated with a flame. In the course of two hours 35 g. of sodium was added in portions. The hot solution was then poured into water and the sterol extracted with ether. It consisted largely of starting material of which 80% could be recovered. An examination of the mother liquors failed to disclose the presence of a dihydro derivative, particularly stigmasterol.

Catalytic Hydrogenation.—The acetate of stigmastatrienol (2.08 g.) was suspended in acetic acid (50 cc.) and hydrogenated with platinum oxide catalyst. An amount of hydrogen corresponding to three moles was taken up within a few hours. Shaking was continued for twenty-four hours and the hydrogenation product isolated. It

gave a faint Liebermann reaction and was therefore dissolved in 50 cc. of chloroform, 40 cc. of acetic anhydride, cooled and treated with 15 cc. of concentrated sulfuric acid. The acetate was then recrystallized from alcohol and melted at 130–131°, $[\alpha]^{24}D$ +17°. These are also the constants for stigmastyl acetate. The acetate was saponified and converted into the 3,5-dinitrobenzoate, m. p. 213–214°, $[\alpha]^{24}D$ +15°. This derivative yielded after saponification stigmastanol, m. p. 135–136°, $[\alpha]^{24}D$ +24°.

Ozonization.—Two grams of the acetate of stigmastatrienol suspended in 20 cc. of acetic acid was ozonized for one hour; 100 cc. of water was then added and the mixture distilled through a column. The receiver contained *p*-nitrophenylhydrazine in 50% acetic acid. The distillation was discontinued when about 20 cc. had come over. The yield of crude hydrazone was 341 mg. On digestion with benzene it left undissolved 81 mg. of an unknown orange-yellow compound, m. p. 204°. The benzene soluble fraction was chromatographed on aluminum oxide and developed with benzene. The lower, orange layer was eluted with ether, giving a crude hydrazone of m. p. 118–123°. This was recrystallized from hot water and also from benzene–petroleum ether and melted then at 128–129°. Its identity with acetaldehyde *p*-nitrophenylhydrazone was shown by a nitrogen determination and mixed melting point determination. *Anal.* Calcd. for $C_8H_9O_2N_3$: N, 23.47. Found: N, 23.65.

Summary

Stigmasteryl acetate 22,23-dibromide yields stigmasterol or its acetate when treated with alcoholic potassium hydroxide, pyridine or quinoline. With potassium acetate in a high boiling alcohol a new stigmastatrienol acetate is obtained. Observations are reported indicating that the new compound is Δ-5,23,24:28-stigmastatrienol.

The Saponification of Ethyl Esters of Aliphatic Acids

BY H. S. LEVENSON AND HILTON A. SMITH

In a previous paper it was demonstrated that the effect of chain length on the velocity of acid catalyzed esterification of normal acids was quite similar to its effect on the velocity of saponification of the ethyl esters of the same acids.[1] The purpose of the present paper is to supplement the work on the saponification of aliphatic esters which is already available in the literature[2] so that a complete comparison of the effect of an aliphatic radical on the velocity of saponification of ethyl esters may be made with the recently published material on the catalyzed esterification of their corresponding acids.[3]

Experimental

Ethyl laurate was obtained from Eastman Kodak Co. The ester was fractionated under reduced pressure in a 5 ft. (1.5 meter) Vigreux column, and constant-distilling fractions were used.

Ethyl β-methylvalerate and ethyl isocaproate were prepared by esterification of the corresponding acids[4] with ethanol using sulfuric acid as a catalyst. The preparation of these acids has already been described.[3,5] The esters were purified by fractionation in a small 2-foot (0.6 meter) Vigreux column.

The ethyl esters of diethylacetic acid, dipropylacetic acid, dibutylacetic acid and di-isobutylacetic acid were prepared by esterification of the acids. Diethylacetic acid was obtained from Eastman Kodak Co. and the other acids were prepared by malonic ester syntheses.[3] The diethyl and di-isobutylacetic acid esters were purified by fractionation in a 5 foot (1.5 meter) Vigreux column, while the 2-foot column was used for purification of the other two.

Each ester was analyzed by complete saponification of weighed samples with excess alkali, and back titration with standard acid. All of the esters gave analyses between 99.5 and 100.5%, the precision of this method being about 0.5%.

The velocity determinations were carried out in 85% aqueous ethanol, this medium being prepared in the manner already described.[1] The method of making velocity determinations was similar to that previously employed.

Experimental Calculations and Results

In general, the rate constants were calculated using the second order reaction rate equation

$$k = x/t(a - x)a \qquad (1)$$

where a is the initial concentration of each reactant, and x represents the concentration of each reactant at the time t. The results of a typical run are given in Table I.

The runs with the esters of diethyl, dipropyl, and dibutyl acetic acids were so slow that, at higher temperatures, the action of alcoholic sodium hydroxide on the Pyrex glass reaction flasks was appreciable. This was indicated by an

TABLE I

SAPONIFICATION OF ETHYL LAURATE AT 55°
a = (ester) = (NaOH) = 0.0500 mole/liter

t, min.	x	10^3k (liters mole^{-1} sec.$^{-1}$)
3.08	0.00713	18.4
6	.01279	19.1
9	.01633	18.0
15	.02281	18.6
25	.02917	18.7
42	.03513	18.7
80	.04079	18.5
115	.04334	18.9

increase in the values of the velocity constant toward the latter portion of each run. An approximate correction was applied as follows.

The relation between the total amount of sodium hydroxide (x) reacting with ester plus glass to that (y) reacting with the ester only is given by the equation

$$x = y + 2.303 \frac{k_g}{k_s} \log \frac{a}{a - y} \qquad (2)$$

where a is the initial concentration of ester and alkali, k_s is the reaction velocity constant for the saponification reaction and k_g is the unimolecular reaction rate constant representing the action of the alkali on the glass bottle. The values of k_g at 45 and 55° were 1.4×10^{-7} and 9.6×10^{-7} sec.$^{-1}$, respectively. The corrected k values were found by determining y for each experimental x, using for k_s the uncorrected figure, and substituting in equation I. These corrections were applied for runs at temperatures of 45 and 55°. Table II gives a sample of such calculations.

TABLE II

SAPONIFICATION OF ETHYL DIPROPYLACETATE AT 55°
a = (ester) = (NaOH) = 0.05 mole/liter

t, min.	x	y	10^3k (liters mole^{-1} sec.$^{-1}$) Uncor.	Cor.
460	0.01028	0.0096	0.188	0.172
1230	.02052	.0184	.189	.157
1860	.02610	.0232	.196	.155
2820	.03237	.0282	.217	.153
4290	.03859	.0331	.263	.152

The values of k for each ester are given in Table III. These were calculated by averaging the individual rate constants over 20 to 80% reaction except where corrections were made for glass reaction. For these only, figures for 20–60% reaction were averaged since the corrections are approximate, and become relatively large after 60% reaction.

TABLE III

Average	.0100	.0255	.0635	.153

[a] The figures for the butyrate are given for comparison purposes, and are interpolated from the data of Smith and Levenson.[1]

The plot of log k against $1/T$ is shown in Fig. 1.

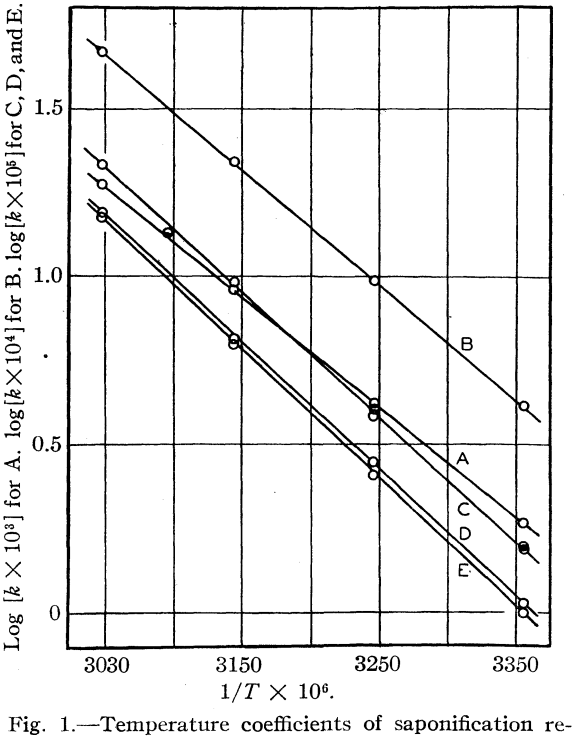

Fig. 1.—Temperature coefficients of saponification reactions: A, ethyl laurate and ethyl isocaproate; B, ethyl β-methylvalerate; C, ethyl diethylacetate; D, ethyl dipropylacetate; E, ethyl dibutylacetate; ○, points from data of Levenson and Smith; ◒, points for ethyl diethylacetate from data of Evans, Gordon and Watson.[2]

The saponification of ethyl diethylacetate in 85% ethanol was also studied by Evans, Gordon and Watson.[2] Figure 1 shows reasonable agreement with their data. The activation energies for these reactions are given in Table IV. They were calculated from the slopes of the lines in Fig. 1, and were checked by the method of least squares.

TABLE IV

ACTIVATION ENERGIES FOR THE SAPONIFICATION OF ALKYL SUBSTITUTED ALIPHATIC ETHYL ESTERS

Ethyl ester	E, cal./mole
Butyrate[a]	15,100
Laurate	15,100
Isocaproate	15,000
β-Methylvalerate	15,700
Diethylacetate	17,200 (17,400)[b]
Dipropylacetate	17,200
Dibutylacetate	17,700

[a] From the data of Smith and Levenson (ref. 1).
[b] The value obtained by Evans, Gordon, and Watson (ref. 2).

Discussion

The rate constants for ethyl laurate when compared with those for ethyl butyrate give additional confirmation to the fact that an increase of the chain length of an alkyl chain beyond four carbon atoms has no measurable effect on the velocity of saponification of esters under the conditions of the experiments here reported.

The results for β-methylvalerate and isocaproate combined with the earlier work of Smith and Levenson[1] and of Evans, Gordon and Watson[2] show the same effect for methyl substitution as was found for acid-catalyzed esterification in methanol.[5] The effect of substitution of a methyl group in the α, β, or γ position is the same in each process, as is shown in Table V.

TABLE V

EFFECT OF METHYL SUBSTITUTION ON REACTION VELOCITY

Position in which substitution takes place	Esterification	% Change saponification
α, (propionic ⟶ isobutyric)	62	78
β, (butyric ⟶ isovaleric)	76	77
γ, (valeric ⟶ isocaproic)	0	0

It is thus evident that in saponification as well as in esterification, only when substitution of a methyl group for a H atom in a normal alkyl chain takes place in the α or β position is the reaction velocity affected.

The effect of the simultaneous lengthening of two normal alkyl chains is shown in Table VI.

Just as in esterification, there is a much larger decrease in k when the chains are lengthened from the isobutyrate to the diethylacetate than was caused by the change from acetate to isobutyrate. Further lengthening of the carbon chain results in relatively smaller changes in saponification velocity. The changes in the activation energy also parallel those found for esterification.

TABLE VI

EFFECT OF CHAIN LENGTH OF ETHYL ESTERS OF DI-SUBSTITUTED ACETIC ACIDS ON THEIR VELOCITY OF SAPONIFICATION

Ethyl ester	$10^3 \times k_{25°}$	E
Acetate[a]	6.92	14,700
Isobutyrate[b]	0.801	15,000
Diethylacetate	.0154	17,200
Dipropylacetate	.0106	17,200
Dibutylacetate	.0100	17,700

[a] $k_{25°}$ and E for ethyl acetate are from the data of Smith and Levenson.[1] [b] $k_{25°}$ for ethyl isobutyrate was taken from the data of Evans, Gordon, and Watson, and E is a value recalculated from their data.[6]

The k values for the saponification of ethyl di-isobutylacetate are not included in Table III. This compound saponifies so slowly that the glass reaction correction becomes quite large. All that can be said with certainty is that this ester saponifies about one-third as fast as does dibutylacetic acid ester. ($k_{25°}$ for the di-isobutyl substituted ester is approximately 0.0031×10^{-3}.) A similar result was found in esterification studies.

The effect of increased methyl substitution in the α position also parallels that found for esterification, as is shown by the data of Evans and co-workers[2] for the saponification of esters of isobutyric and trimethylacetic acids.

In short, the processes of the acid catalyzed esterification of aliphatic acids and of the saponification of their ethyl esters are completely similar at least as far as the effect of the character of the alkyl chain upon reaction velocity is concerned.

Summary

The kinetics of the saponification in 85% ethanol of the following esters has been studied: ethyl laurate, ethyl isocaproate, ethyl β-methylvalerate, ethyl diethylacetate, ethyl dipropylacetate, ethyl dibutylacetate, and ethyl di-isobutyl acetate.

It is demonstrated that the effect of the character of the alkyl chain on reaction velocity is the same for the processes of acid-catalyzed esterification and saponification.

Kinetics of the Esterification of Substituted Benzoic Acids

BY R. J. HARTMAN AND A. G. GASSMANN[1]

The esterification of substituted benzoic acids has been studied by Hartman and Borders,[2] and by Hartman, Storms and Gassmann,[3] and others.[4,5] These investigations showed that in hydrion catalyzed esterifications, the reaction is facilitated by recession of electrons from the seat of the reaction and is therefore, according to Williams,[6] a Class B reaction. Both E and P of the Arrhenius equation

$$k = PZe^{-E/RT}$$

have been found to affect the reaction velocity. The effect of a meta or para substituent on the benzene nucleus on the reaction velocity is expressed by the equation[7]

$$\log k = \log k_0 + \rho\sigma$$

where k is the velocity constant of the substituted reactant, k_0 is the velocity constant of the unsubstituted reactant; ρ is a constant depending on the reaction, medium and temperature, and σ is a constant depending upon the substituent. Good agreement between observed and calculated values was found for the acids studied.

The object of this investigation was to determine the velocity constants of esterification of each of the three monosubstituted iodo-, fluoro-, methoxy-, and ethoxybenzoic acids with methyl alcohol and catalyzed by hydrions. Because *p*-iodobenzoic acid is only slightly soluble in methyl alcohol, its reaction rate was not studied. Using the data thus obtained, the energies of activation were determined in order to analyze the results in the light of the Arrhenius equation.

Experimental

Materials.—Absolute methanol was purified by the method of Bjerrum and Lund.[8] Water, aldehyde and ketone tests were negative. The acids were obtained either from Eastman Kodak Company or from Professor C. S. Marvel of the University of Illinois. The melting points of the purified acids agreed with those recorded in the literature. The acids were dried over phosphorus pentoxide, preceded in certain instances by drying in an oven at 105–110°.

Procedure.—The procedure followed was similar to that of Hartman and Borders.[2] The total acid concentration was determined at the beginning and at intervals throughout the course of the reaction by titrating 5-ml. samples against barium hydroxide solution using phenolphthalein as indicator. Correction was made for the expansion of solvent. The thermostats were maintained at 25.00, 40.00, 50.00 and 60.00 ± 0.02°.

Results and Discussions

The value of the velocity constant which accounts for the retardation of the reaction due to the water formed is given by the equation[9]

$$k = \frac{(r + a)\ln\left[\frac{a}{a - x}\right] - x}{crt}$$

where r is a constant which compensates for the water formed, a is the initial organic acid concentration, x is the quantity of acid esterified in time t, c is the concentration of the hydrion catalyst, and k is the velocity constant in g. moles/liter/sec. The values of r used were[2,10]

Temp., °C.	25	40	50	60
r	0.22	0.36	0.50	0.65

Table I shows a typical esterification reaction. The individual figures for $(a - x)$ and for k represent averages of several runs.

TABLE I

ESTERIFICATION OF m-FC_6H_4COOH AND CH_3OH AT 25°
$a = 0.1034$, $c = 0.0197$

Time, min.	$a - x$	$10^4 k$
1560	0.0820	1.32
2940	.0675	1.33
4320	.0572	1.29
5760	.0471	1.32
7200	.0410	1.28

No values of k were used which represent less than 20% or more than 80% reaction. This eliminates anomalies that might result from experimental errors and hydrolysis effect at the beginning and end of a reaction. Table II gives the velocity constants and energy of activation for benzoic acid and the eleven substituted benzoic acids studied in this investigation.

TABLE II

VELOCITY CONSTANTS AND ENERGIES OF ACTIVATION FOR HYDRION CATALYZED ESTERIFICATION OF AROMATIC ACIDS WITH METHYL ALCOHOL

Acid	$10^4 k$ 25°	40°	50°	60°	Energy of activation E
o-Iodobenzoic	0.331	1.13	2.27	4.21	14,300
p-Fluorobenzoic	.756	2.45	5.04	9.02	14,400
p-Methoxybenzoic	1.04	3.34	6.73	13.07	14,300
p-Ethoxybenzoic	1.13	3.22	6.52	14.25	13,400
m-Fluorobenzoic	1.31	3.90	8.63	16.51	14,300
m-Iodobenzoic	1.37	3.89	8.62	16.65	14,400
m-Methoxybenzoic	1.91	5.68	13.03	25.32	14,600
Benzoic	1.94	6.57	15.24	28.69	15,500
o-Fluorobenzoic	1.99	5.62	12.54	23.84	14,000
m-Ethoxybenzoic	2.11	6.50	13.61	26.55	14,300
o-Ethoxybenzoic	6.61	24.88	38.28	74.58	13,700
o-Methoxybenzoic	8.30	25.76	51.96	89.15	13,900

The values of E were obtained graphically from the slope of the line obtained by plotting log k against the reciprocal of the absolute temperatures. The energy of activation of benzoic acid was found to be 15,500 cal. The same value was reported by Hartman and Borders.[2] Hinshelwood and Legard[11] report 15,700 calories.

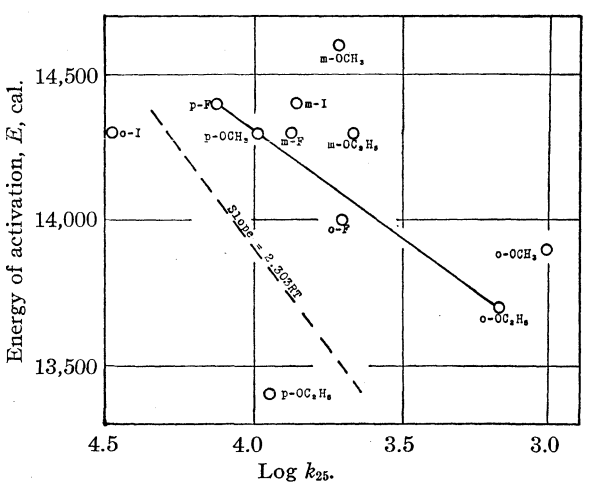

Fig. 1.—Relationship between speed of reaction and activation energy.

Table III gives the observed values of log k_{25} for meta and para substituted acids and the corresponding values as calculated from Hammett's equation.[7] The value of ρ was -0.54[2] and the values of σ were taken from Hammett.[7] The average error of log k is greater than the mean value of probable error by Hammett.[7] It is noticed in Table III that the error is greater for the *p*-methoxy-, *p*-ethoxy-, and *p*-fluorobenzoic acids than for the corresponding meta substituted acids. The average error of log k for the meta substituted acids is 0.056, which compares very favorably with that of Hartman and Borders[2] and Hammett.[7]

TABLE III

COMPARISON OF LOG k_{25} OBSERVED WITH LOG k CALCULATED FROM THE EQUATION: LOG $k = -3.712 + \sigma(-0.54)$

Acid	Log k, obsd.	Log k, calcd.	Error
m-Ethoxybenzoic	−3.676	−3.793	0.117
m-Methoxybenzoic	−3.719	−3.774	.055
m-Iodobenzoic	−3.863	−3.902	.039
m-Fluorobenzoic	−3.883	−3.894	.011
p-Ethoxybenzoic	−3.947	−3.577	.370
p-Methoxybenzoic	−3.983	−3.568	.415
p-Fluorobenzoic	−4.121	−3.745	.376
		Av.	.198

Because of the lack of close agreement between the observed and calculated values of log k for the *p*-methoxy-, *p*-ethoxy-, and *p*-fluorobenzoic acids, it appears that the Hammett equation fails in these instances.

To determine whether changes in velocity are due to changes in E or to changes in P of the equation $k = PZe^{-E/RT}$, log k was plotted against the measured value of E. Changes of E would be responsible alone if the resulting slope of the line were 2.303 RT. Figure 1 shows such a plot where the broken line represents the theoretical line having a slope of 2.303 RT and the solid line represents an approximate graphical average obtained from the data of this investigation. It is apparent that the two lines do not have the same slope and it may therefore be concluded that changes in E are not alone responsible for changes in reaction velocities. That the P term changes has been found to be true in the investigations of Hartman and Borders[2] and those of Hinshelwood and Legard.[11]

Summary

1. The study of the effect of polar groups has shown that the velocity of hydrion-catalyzed esterification of substituted benzoic acids is increased by displacement of electrons toward the carboxyl groups.

2. Comparison of experimental log k with that calculated from the Hammett equation shows good agreement for the meta substituted acids. Good agreement was not found, however, for the *p*-ethoxy-, *p*-methoxy-, and the *p*-fluorobenzoic acids.

3. Both the P factor and energy of activation have an effect on the velocity of esterification.

Molecular Size Distribution in Ethylene Oxide Polymers

BY PAUL J. FLORY

Little progress has been made toward the elucidation of the composition of high polymers by the two known experimental methods, fractionation[1] and ultracentrifugal analysis,[2] both of which yield at best only approximate results. In certain cases, however, it is possible to deduce theoretical relationships by means of which accurate size distributions can be calculated. Such relationships have been presented previously for linear condensation polymers.[3] In this paper size distribution equations will be derived for polymers formed by successive addition of *monomers* to a fixed number of chains. The bearing of the results on the interpretation of polymer viscosities will be discussed.

It has been known for a long time[4] that ethylene oxide reacts with ethylene glycol to form diethylene glycol and higher glycols by successive additions of ethylene oxide as follows

$$HOCH_2CH_2OH \xrightarrow{+CH_2CH_2O} HO[CH_2CH_2O]_2H \xrightarrow{+CH_2CH_2O} \text{etc.}$$

Ethylene oxide has been found to react similarly with alcohols, amines,[5] mercaptans, and acids, yielding, under proper conditions, polymers of considerable length.[6] In the patent literature there are described many technical processes in which polyoxyethylene glycol chains are built up through the reaction of ethylene oxide with a substance containing an appropriate functional group such as NH_2, NH, OH, SH or COOH. The available evidence indicates that these processes proceed exclusively by the reaction of monomer (ethylene oxide) with molecules possessing the propagating functional group (*e. g.*, OH); *reaction of polymer with polymer does not occur.* The process can be represented by

$$m_1 \xrightarrow{+m} m_2 \xrightarrow{+m} m_3, \text{ etc.}$$

where m_1 is the initial species which bears the propagating functional group, m represents ethylene oxide, and m_x is the product formed from m_1 plus $x - 1$ ethylene oxides.[7]

There are other types of polymers which, under certain conditions, may be formed by analogous mechanisms. It has been suggested that formaldehyde polymerization[8] initiated by traces of moisture proceeds as follows

$$HOCH_2OH \xrightarrow{+CH_2O} H[OCH_2]_2OH \xrightarrow{+CH_2O} \text{etc.}$$

Similar mechanisms may account for the conversion of cyclic anhydrides,[9] cyclic esters[10] (lactones) and cyclic acetals[11] to the corresponding linear polymers. Some of these reactions are sufficiently reversible to allow interchange to occur, and, as will be shown in another paper, interchange reactions may modify the molecular size distribution.[12]

The distribution of species obtained by the above mechanism of polymerization and the distribution resulting from condensation polymerization are strikingly different. Condensation polymerizations, *e. g.*, the polymerization of a hydroxy acid, proceed by the occurrence of reactions of the type

$$m_x + m_y = m_{x+y}$$

where m_x and m_y represent molecules composed of x and y units, respectively, x and y being integers from 1 to ∞. Not only do the polymer molecules react with monomers, but polymers of all sizes react with other polymers. In all of these reactions the same chemical process is involved, and it has been demonstrated in the case of polyesterification that all of them proceed with equal ease.[13]

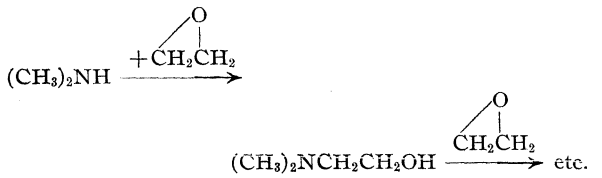
(13) P. J. Flory, *ibid.*, **61**, 3334 (1939).

The treatment presented below is applicable to polymerization processes which fulfill the following two conditions: (i) the total number of molecules possessing propagating functional groups (*e. g.*, the total number of glycol molecules) must remain constant throughout the reaction; (ii) the chains must be built up by a sequence of kinetically identical additions of monomer (ethylene oxide). In cases where the initial propagating molecules are neither glycols nor alcohols, *e. g.*, in the process[6]



condition (ii) will not be entirely satisfied. The rate of the first step will in general differ from the rates of subsequent steps, although the rates of the latter should not differ appreciably from one another. If the reaction is carried out under conditions such that reaction of the initial propagating molecules (*e. g.*, $(CH_3)_2NH$ above) with ethylene oxide is substantially complete before more than a small fraction of the ethylene oxide has been consumed, then the following treatment will serve as a satisfactory approximation. The first addition product ($(CH_3)_2NCH_2CH_2OH$, above) must then be considered the initial chain propagator. In cases where the initial step is extremely slow, the treatment of Dostal and Mark[14] may be approximately applicable.

The fundamental equations may be derived as follows. Letting N_1, N_2, N_3, etc., be the numbers of the species m_1, m_2, m_3, etc., which possess zero, one, two, etc., added ethylene oxides

$$dN_1/dt = -fN_1 \qquad (1)$$

where f is some function dependent upon the kinetics of the process and the manner in which it is carried out. Presumably, f (which includes the velocity constant) will be a function of the ethylene oxide concentration, but it may be a function of other variables also, such as t and the number of propagating molecules N^0. The solution of the present problem depends in no way upon the nature of f, so long as it is consistent with the above conditions. In view of condition (ii), the rate at which m_2 is converted into m_3 must be, similarly, fN_2. Hence

$$\begin{aligned} dN_2/dt &= fN_1 - fN_2 \\ dN_x/dt &= fN_{x-1} - fN_x \end{aligned} \qquad (2)$$

(14) H. Dostal and H. Mark, *Z. physik. Chem.*, **B29**, 299 (1935).

The rate of disappearance of ethylene oxide is

$$-dm/dt = fN^0 \qquad (3)$$

The ratio at time t of ethylene oxide consumed to N^0 is given by

$$\nu = \Delta m/N^0 = \int_0^t f\,dt \qquad (4)$$

Also

$$d\nu = f\,dt \qquad (4')$$

Substituting (4') in (1) and (2)

$$dN_1 = -N_1 d\nu \qquad (5)$$

$$dN_x = (N_{x-1} - N_x)d\nu \qquad (6)$$

Integrating (5)

$$N_1 = N^0 e^{-\nu}$$

Substituting this equation in (6) when $x = 2$ and integrating the resulting differential equation

$$N_2 = N^0 \nu e^{-\nu}$$

Substituting this equation in (6) with $x = 3$ and integrating

$$N_3 = N^0(\nu^2/2)e^{-\nu}$$

It is evident that continuation of this process yields

$$N_x/N^0 = e^{-\nu}\nu^{x-1}/(x-1)! \qquad (7)$$

This general expression (7) for the mole fraction of x-mer in the polymer (exclusive of unreacted ethylene oxide) is Poisson's distribution formula. From the nature of the problem dealt with here, it is obvious, without the above derivation, that the numbers of molecules of various sizes must be represented by Poisson's distribution.[15] A brief kinetic derivation has been included in order to point out the scope of applicability of (7) to size distribution problems.

The weight fraction distribution is usually of more interest than the mole fraction distribution. Since the molecular weight of the x-mer species is given by

$$M_x = xM + (M^0 - M)$$

where M is the molecular weight of one unit (ethylene oxide) and M^0 is the molecular weight of the initial molecule (*e. g.*, ethylene glycol) from which growth proceeded, the weight fraction of x-mer is

$$w_x = \frac{M_x N_x}{(\nu M + M^0)N^0} = \left[\frac{x + (M^0 - M)/M}{\nu + M^0/M}\right] e^{-\nu}\nu^{x-1}/(x-1)! \qquad (8)$$

The subsequent discussion will deal with the case in which $M^0 = M$. Hence

$$w_x = [\nu/(\nu+1)]e^{-\nu}x\nu^{x-2}/(x-1)! \qquad (9)$$

(15) See T. C. Fry, "Probability and its Engineering Applications," D. Van Nostrand Co., New York, N. Y., 1928.

Even when $M^0 \neq M$, (9) may be used for high polymers without significant error.

The number average molecular weight,[16] which equals the total weight of polymer in molecular weight units divided by the number of molecules, is given by

$$M_n = \nu M + M^0 \qquad (10)$$

or, when $M^0 = M$

$$M_n = M(\nu + 1) \qquad (10')$$

The degree of polymerization, *i. e.*, the *number average* value of x, is given by

$$DP = \nu + 1 \qquad (11)$$

For condensation polymers the weight fraction distribution is given by[17]

$$w_x = (1 - p)^2 x p^{x-1} \qquad (12)$$

where p is the fraction of the functional groups which have undergone condensation. Their degree of polymerization is given by

$$DP = 1/(1 - p) \qquad (13)$$

The solid curves in Figs. 1 and 2 represent weight fraction distributions, calculated from (9), for polyethylene oxides (or other polymers formed by reactions conforming with (i) and (ii)). The values of ν are included with each curve. For comparison, portions of two condensation polymer distributions have been included also (broken curves). The one shown in Fig. 1 has been calculated from (12) when $p = 0.9091$.

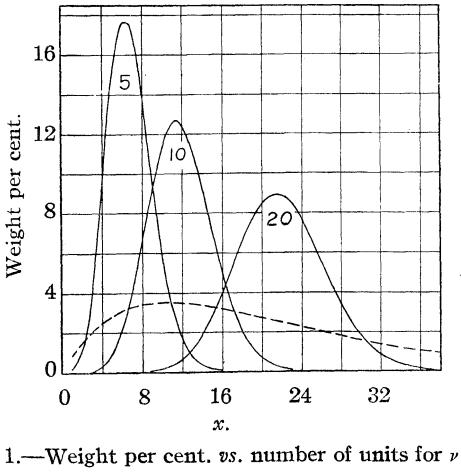


Fig. 1.—Weight per cent. *vs.* number of units for $\nu = 5$, 10 and 20. The broken curve represents a $DP = 11$ condensation polymer.

(16) The terms *number average* and *weight average* and their definitions were introduced by E. O. Kraemer and W. D. Lansing, *J. Phys. Chem.*, **39**, 153 (1935). The number average molecular weight, defined by $M_n = (1/N^0)\Sigma N_x M_x$, is the average obtained by end-group, osmotic, ebullioscopic or cryoscopic methods. The weight average is defined by equation (14), *cf. seq.*

(17) The symbol w_x is used here in place of the Π_x of an earlier paper, ref. (3).

This curve and the $\nu = 10$ polyethylene oxide curve possess the same number average, *i. e.*, $DP = 11$ for each. Both the $\nu = 100$ curve and the broken curve in Fig. 2 represent $DP = 101$.

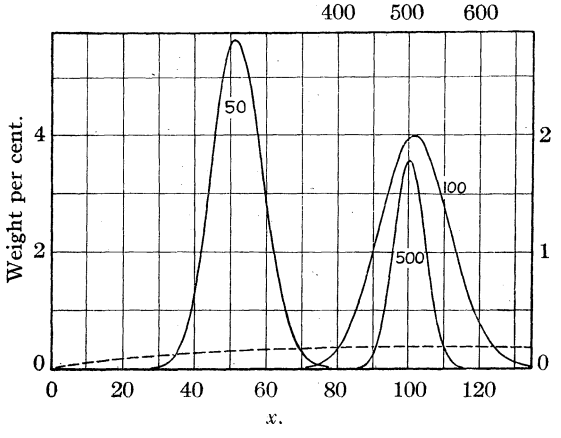

Fig. 2.—Weight per cent. *vs.* number of units for $\nu = 50$, 100 and 500. The broken curve represents a $DP = 101$ condensation polymer. The $\nu = 500$ curve is drawn to the scales along the upper and right margins; scales for the other curves are given along the lower and left margins.

The much greater homogeneity of the polyethylene oxide distribution compared with the condensation polymer distribution is apparent in these graphs. For example, in the range $x =$ 8–16, inclusive, there is included 79.6% of the $DP = 11$ ($\nu = 10$) polyethylene oxide; only 27.3% of the $DP = 11$ condensation polymer lies in the same range of sizes. The weight percentages of monomer in these two polymers are 0.041 (exclusive of unreacted ethylene oxide) and 0.826, respectively. At $DP = 101$ (Fig. 2) the difference is even more pronounced: in the range 90–112, inclusive, one finds 74.8% of the polyethylene oxide, but only 8.35% of the condensation polymer; the calculated weight percentages of monomer are 4×10^{-42} and 10^{-2}, respectively.

The other feature of the polyethylene oxide distribution which should be mentioned is the dependence of the heterogeneity on ν. Suppose the breadth of the curve midway between the maximum and the x-axis be adopted as the measure of heterogeneity. The number of species included in such a range increases as ν increases. However, the ratio of this breadth to $\nu + 1$, the distance of the maximum from the ordinate axis, decreases as ν increases. From this point of view the *relative* heterogeneity decreases as ν increases. Comparison of the $\nu = 100$ and 500 curves in Fig. 2 demonstrates this feature.

Kraemer and Lansing[16] have called attention to the necessity of using the weight average molecular weight M_w, defined by

$$M_w = \Sigma w_x M_x \qquad (14)$$

in the Staudinger relationship between the viscosity of a dilute solution of a polymer and its molecular weight. Recently the author[18] has found that the weight average molecular weight of linear polyesters can be expressed as a simple function of their viscosity in the liquid state. Whereas molecular weight determinations by cryoscopic, osmotic, and end-group methods yield number averages, viscosity methods yield weight averages when applied to heterogeneous polymers. It is important, therefore, to know the relationship between these two averages for a given distribution.

Substituting (9) in (14) and placing $M_x = xM$

$$M_w = M\left(\frac{\nu e^{-\nu}}{\nu + 1}\right)\sum_1^\infty \frac{x^2\nu^{x-2}}{(x-1)!} \qquad (15)$$

The summation rearranges to

$$\sum_2^\infty \frac{(x^2-1)\nu^{x-2}}{(x-1)!} + \sum_1^\infty \frac{\nu^{x-2}}{(x-1)!}$$

$$= \sum_3^\infty \frac{\nu^{x-2}}{(x-3)!} + 3\sum_2^\infty \frac{\nu^{x-2}}{(x-2)!} + \sum_1^\infty \frac{\nu^{x-2}}{(x-1)!}$$

$$= (\nu + 3 + 1/\nu)\sum_0^\infty \nu^x/x!$$

$$= (\nu + 3 + 1/\nu)e^\nu$$

Substituting this expression for the summation in (15)

$$M_w = M(\nu^2 + 3\nu + 1)/(\nu + 1) \qquad (16)$$

Dividing (16) by (10′)

$$M_w/M_n = 1 + \nu/(\nu + 1)^2 \qquad (17)$$

This ratio of weight average to number average is plotted as a function of DP in Fig. 3 (lower curve). The ratio approaches unity asymptotically as ν increases. For condensation polymers this ratio, which has been shown[3] to be equal to $1 + p$, approaches two as a limit with increasing DP (upper curve in Fig. 3).

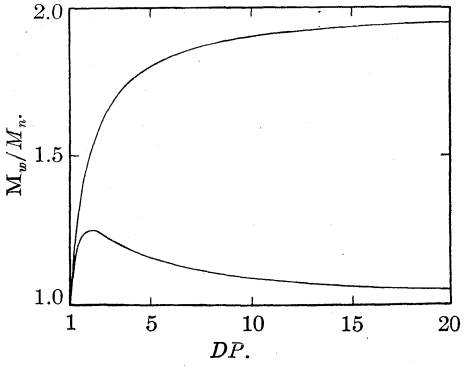

Fig. 3.—Ratio of weight average to number average as a function of DP. Upper curve, condensation polymers; lower curve, polyethylene oxides.

(18) P. J. Flory, THIS JOURNAL, **62**, 1057 (1940).

The ratio M_w/M_n may be regarded as a measure of the non-uniformity of the size distribution,[2] a value of unity representing complete homogeneity. On this basis polyethylene oxide heterogeneity must disappear as the average molecular weight becomes infinite. This does not mean that an extremely high molecular weight polymer would be composed essentially of a single species. Rather, it is the *relative* heterogeneity discussed above which disappears as the molecular weight becomes indefinitely large. However, when a high molecular weight polyethylene oxide is subjected to the types of experiments frequently applied to polymeric substances, *e. g.*, to viscosity measurements, ultracentrifugal analysis, and diffusion experiments, it may be expected to behave essentially as if it were a single species. This is in sharp contrast to condensation polymers which approach a constant degree of non-uniformity (M_w/M_n) as the average molecular weight approaches infinity.

Hibbert and co-workers[19] have prepared polyoxyethylene glycols by the reaction of the dihalide of a lower polyoxyethylene glycol with the mono-sodium alcoholate of another polyoxyethylene glycol. The polymers so prepared have been shown to be structurally identical[20] with polyethylene oxides. It should be possible to prepare heterogeneous polyoxyethylene glycols by the reaction

$$ClCH_2CH_2Cl + NaOCH_2CH_2ONa \longrightarrow Cl[CH_2CH_2OCH_2CH_2O]_xNa + x\,NaCl$$

which, being a condensation polymerization, should yield the typical condensation polymer distribution. After conversion of the end-groups to OH, the polymer should be identical, except in size distribution, with a polymer prepared from ethylene oxide and a small amount of ethylene glycol under conditions such that (i) and (ii) above are fulfilled. Comparison of their number average and weight average molecular weights, the latter determined viscometrically, would provide an experimental test of the size distribution equations.

(20) W. Barnes and S. Ross, *ibid.*, **58**, 1129 (1936).

Summary

It has been shown that in a polymer formed exclusively by the addition of monomers to a fixed number of polymer molecules, the numbers of species of various sizes are represented by Poisson's distribution law. Equations representing weight fraction distributions have been derived, and the calculated weight per cents. of various species in several polymers having average sizes of 6 to 500 units are shown graphically.

The distribution for these polymers, typified by the polyethylene oxides, has been contrasted with the distribution in condensation polymers. The former are much more homogeneous. Whereas the ratio of weight average to the number average molecular weight of condensation polymers approaches two as the degree of polymerization increases, for the polyethylene oxide distribution this ratio approaches unity.

CINCINNATI, OHIO RECEIVED MARCH 18, 1940

The Nature of the Thiocyanate Complex of Molybdenum

BY C. F. HISKEY* AND V. W. MELOCHE

In the determination of small amounts of molybdenum, the molybdenum as molybdate is reduced with stannous chloride in the presence of an alkali thiocyanate. The red coloration which is formed under these circumstances, is used in a wide variety of colorimetric procedures.[1] The earliest observations of this reaction were made concurrently by Braun and by Skey.[2] About forty years later, Chilesotti[3] electrolyzed acid solutions of molybdates from which he presumably obtained trivalent molybdenum. He reported that when these solutions were treated with potassium chloride or potassium thiocyanate, red salts were formed with a composition of $K_3Mo(SCN)_6 \cdot 4H_2O$ and K_3MoCl_6. Somewhat later Sand[4] and Rosenheim[5] carried out detailed investigations of the complexes which molybdenum formed in the trivalent and pentavalent states. They performed their reductions electrolytically, treating the solutions with an alkali thiocyanate and then extracting the red colored forms with ether. From the ethereal extracts complexes were precipitated with pyridine or quinoline, and, from an analysis of the complexes, these workers attempted to deduce its structure. The complex was variously reported at that time as $MoO(SCN)_3$, $Mo(OH)_2(SCN)_3$ and as $R_2MoO(SCN)_5$ where the R was an alkali atom. In addition to these structures they also were successful in isolating other series of thiocyanate complexes which were formed under nearly identical conditions. In some of these structures the molybdenum was trivalent and the complexes possessed different degrees of hydration. Other compounds differed only in the amount of alkali chloride bound into this complex. In view of the wide variety of structures observed, it becomes extremely difficult to decide which of these formulas should be assigned to the compound under question. Barbieri considered the thiocyanate complex to be $MoO(SCN)_3 \cdot H_2O$. In 1926, Krauskopf and Schwartz[6] reported $Mo(SCN)_3$ on the basis of a simple analysis of the ether extract. However, Wm. Wardlaw and his students[7] reinvestigated the problem of the thiocyanate complex formation and, as a result of a number of experiments decided that the structure of the complex could be either ($H_2MoO_2(SCN)_3$) or $H_2(MoO(SCN)_5)$ although he also isolated a large number of different salts series of the type $H_2(Mo_2O_3(SCN)_6)$. Thus, again no positive identification of the desired structure could be made.

In considering these variously proposed structures, it seemed somewhat doubtful to us that one could assume that the compounds isolated from the dark colored oily mixtures which these workers obtained were identical with the red thiocyanate used in the analytical determination of molybdenum. In view of the more drastic conditions

which these workers used, it seemed desirable to us to conduct a study in order to establish some of the limiting conditions governing proposals for structure of the complex. To that end, an investigation was begun to determine (1) whether the complex formed in the usual analytical procedure was identical with that formed between quinquevalent molybdenum and thiocyanate and whether it was at all possible for the trivalent molybdenum to form a red colored thiocyanate, (2) whether an equilibrium study of the reaction between the quinquevalent molybdenum and the thiocyanate ion would give some evidence as to the structure of the complex and (3) whether the pronounced color changes, which have been observed in quinquevalent molybdenum solutions, could be correlated with a previous observation of Hurd and Hiskey[8] that varying the acid concentrations resulted in a bleaching effect on the molybdenum thiocyanate complex.

1. The Valence State of the Molybdenum in the Complex.—It is recalled that when a molybdate solution, 2 *N* with hydrochloric acid is reduced with such reducing agents as stannous chloride,[9] the silver reductor,[10] or metallic mercury[11] quinquevalent molybdenum is formed. With all three of these agents the procedures have been made quantitative.

The solution of quinquevalent molybdenum, 2 *N* in hydrochloric acid, is amber-red in color. When the solution is in 8 *N* hydrochloric acid, it is emerald-green. These two colored forms of the molybdenum exist in equilibrium with each other. This equilibrium can be shifted from one form to the other simply by varying the hydrochloric acid concentration.

When the amber-colored form of the quinquevalent molybdenum is treated with an alkali thiocyanate solution, an interaction will begin proceeding at an appreciable speed to form a red complex which in appearance and properties seems to be identical with that formed when molybdenum is reduced with stannous chloride in the presence of thiocyanate. If the green colored form is treated with an alkali thiocyanate, no such reaction is observed. On the other hand, if the molybdenum is reduced under more drastic conditions, it can be brought to the trivalent state. Thus, when molybdenum is reduced in the Jones reductor (Zn) in 1–2 *N* sulfuric acid, it forms a green colored trivalent molybdenum compound. If the trivalent compound is treated with an alkali thiocyanate, meanwhile protecting the solution from atmospheric oxidation by blanketing with carbon dioxide or nitrogen, no red colored thiocyanate complex will be formed with the molybdenum even after a half-hour interval. Nor is it possible under these same conditions to extract any red colored complex from this solution with ether or butyl acetate. However, if some oxidant like hydrogen peroxide is added in such amounts as to bring the molybdenum to the five-valent state, the red compound will then be observed.

It is felt that evidence such as this definitely implies that there is no red trivalent complex of molybdenum but that the molybdenum in this complex must be approximately five-valent. In a more striking way, it can be shown that this is so, simply by taking an acid solution of molybdate and alkali thiocyanate and passing it through the Jones reductor. At first, as the solution comes in contact with the zinc, the red molybdenum thiocyanate complex appears but, as it moves down the tube, the solution loses its red color and when reduction is complete it has the blue-green color characteristic of trivalent molybdenum in dilute acid solutions.

The significance of these observations seems to be that as the molybdate passes down the reductor, the action of the zinc brings the molybdenum first to the five-valent state. At this point it reacts with the thiocyanate ion present to form the characteristic red color but, as the reducing action of the zinc is prolonged, the molybdenum is reduced to the trivalent state with the destruction of the red complex.

Besides the green trivalent form of molybdenum there is also a pink form of the trivalent state. It was thought that perhaps this substance reacted with the thiocyanate ion to give red trivalent complex and so it also was studied. This pink modification can be formed in a variety of ways. The essential element of the methods is that the molybdate must be reduced in fairly high concentrations of hydrochloric acid. Foerster[12] formed this pink trivalent molybdenum by electrolytic reduction while in a recent paper Hiskey, Springer and Meloche[13] show that this compound

can be formed by reduction in the silver reductor in hydrochloric acid concentrations above 4 *N*. Despite a wide variety of attempts to combine this substance with thiocyanate to form an ether soluble extract, our results were uniformly negative. Consequently it seems reasonable to conclude that trivalent molybdenum does not form any red colored thiocyanate complex.

In an attempt to establish more definitely that molybdenum in the thiocyanate complex is quinquevalent in character, it was decided to obtain the light absorption curves of this complex formed in two different ways. In one case, the complex was formed by reducing molybdate in the presence of an alkali thiocyanate with stannous chloride solution. In the other, the thiocyanate complex was formed by permitting an equivalent amount of a pure quinquevalent molybdenum solution to react with the thiocyanate ion until equilibrium was attained and then to determine its light absorption characteristics. In these experiments the concentration of the molybdenum and the thiocyanate ion in the final solution which were compared were exactly the same. The comparisons were made with the aid of special spectrophotometric equipment. A description has been given by James and Birge.[14]

The absorption curves for the two solutions are plotted in Fig. 1. For the purpose of comparison one of the curves is lowered in relationship to the other, but, on examination, it is apparent that they are practically identical. In addition to studying the absorption characteristics of the aqueous solutions of the thiocyanate complex formed in these two ways, similar studies were made of the butyl acetate extracts of these two solutions. By extracting the two solutions studied in Fig. 1 with butyl acetate, extracts containing approximately the same concentration of molybdenum and thiocyanic acid were obtained. The absorption spectra of these two extracts is given in Fig. 2. From this evidence it seems clear that the color characteristics are the same whether the complex is formed in the conventional manner or by the interaction of thiocyanate and quinquevalent molybdenum.

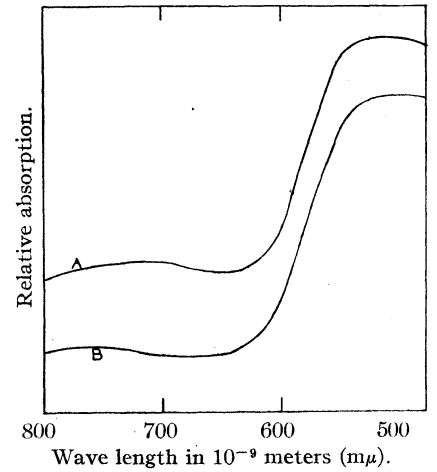

Fig. 1.—A = Mo^{+6} + SCN^- + $SnCl_2$; B = Mo^{+5} + SCN^-.

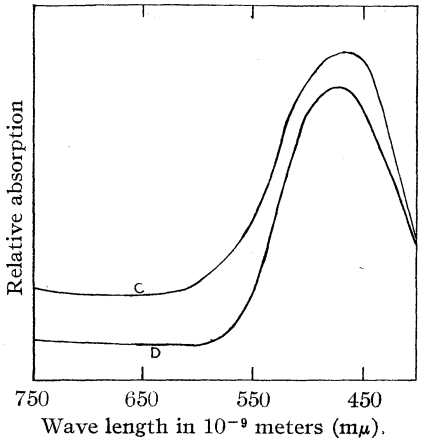

Fig. 2.—Butyl acetate extracts: C, extract of A; D, extract of B.

Therefore, it seems reasonable to conclude that trivalent formulas can be completely eliminated and that one of the limiting conditions concerning the structure of the thiocyanate complex of molybdenum must be a quinquevalent character for the molybdenum.

2. The Reaction between Quinquevalent Molybdenum and the Thiocyanate Ion. General Discussion.—At the outset of these studies it was recognized that the reaction between the thiocyanate ion and quinquevalent molybdenum did not lend itself to the most exact thermodynamical studies because certain difficulties are regularly encountered in the exact measurement of the molybdenum thiocyanate formed. Among those difficulties may be listed the interference due to the pink complex formation of the thiocyanate ion, as well as a fading effect of the molybdenum complex once it has formed.

A characteristic phenomenon of the acidified thiocyanate solutions is the tendency to form a pink colored substance. This pink colored substance is formed under conditions nearly the same

(14) James and Birge, *Trans. Wisconsin. Acad. Sci.*, **31**, 1 (1938).

as those which might be expected to prevail during the study of the reaction. It has often been observed in this Laboratory that it can be formed by placing a few drops of hydrochloric acid in a 20% solution of potassium thiocyanate. Once formed it can be extracted with any of the usual solvents employed in the molybdenum extraction. Many workers have thought that this pink compound is the ferric thiocyanate, but, even though it does possess a great similarity, it should be emphasized that it can also be formed in carefully distilled thiocyanic acid solutions where no iron could be present. In our particular studies we observed that invariably on mixing hydrochloric acid with a thiocyanate solution, followed by addition of quinquevalent molybdenum, the slow formation of a pure pink color would first be observed. After this color had developed for about ten minutes, the amber tint of the molybdenum complex would appear and reach a maximum while the pink color slowly would fade out. In an approximate fashion the course of these reactions might be represented graphically by the series in Fig. 3.

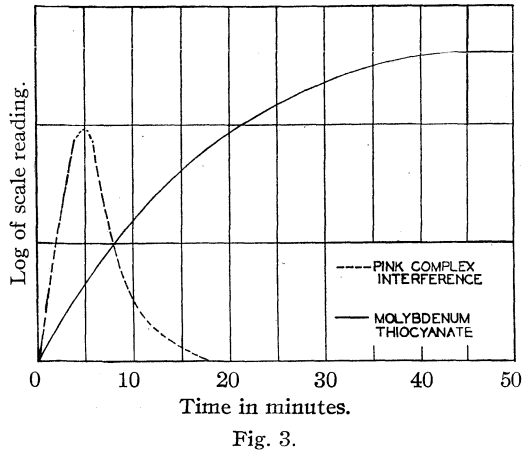

Fig. 3.

A second difficulty encountered in the study of this reaction is one due to an erratic and seemingly unpredictable fading which often occurs during these studies. When solutions of thiocyanate and quinquevalent molybdenum are mixed together and the concentrations are about 0.08 molar and 4.01×10^{-5} molar, respectively, the readings obtained from the colorimeter often will show that the color in some of the tubes has faded almost completely while others give perfectly reproducible values. Attempts to find out whether such phenomena were due to the catalyzing influence of traces of impurities seemed to give a negative answer. It did seem, however, that this type of phenomenon occurred with greater frequency in solutions of high hydrochloric acid concentration. Thus, in the four hydrochloric acid concentrations studied, 1.0, 1.5, 2.0, 2.5 *N*, the frequency of this type of fading was greatest in the 2.5 *N* and least in the 1.0 *N* solutions It also was observed that small amounts of stannous chloride solutions hastened the fading of all the solutions to which it was added.

Apart from these erratic fadings, all solutions of the complex showed a very slow fading after the maximum was attained. Thus a typical time *vs.* intensity curve when the hydrochloric acid concentration in the system was about 2.0 *N* appears in Fig. 4. At higher concentrations, the fading was more rapid and at lower concentrations it was much slower.

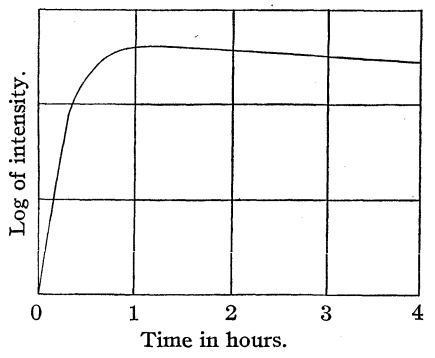

Fig. 4.—Molybdenum thiocyanate intensity as a function of time.

Despite this consecutive fading effect, we felt that we could profitably study the thiocyanate–molybdenum reaction because fading was generally extremely slow and the slight drift was scarcely detectable in the regions where data were of most significance.

Preparation of Materials

A. Approximately 1 Molar Thiocyanic Acid Solution.—This solution was prepared by taking 1 molar alkali thiocyanate, adding 30 ml. of concentrated sulfuric acid per liter and distilling the solution formed in an all glass distilling apparatus. The distillation was carried out at 20 mm. of mercury pressure. Whenever the thiocyanic acid came into contact with certain kinds of organic matter such as the skin, filter paper, cloth, stopcock grease, etc., a pink coloration would be induced. Apparently traces of organic matter or dust would also produce this color effect. In order to obtain a colorless thiocyanic acid solution and keep it so, all apparatus with which it came into contact had to be washed with a small amount of it until a pink coloration no longer formed. Standardization was effected by titration with alkali using phenolphthalein as in-

dicator. This was followed by a Volhard titration as an additional check on the purity of the solution. All of the thiocyanic acid prepared was used within twelve hours or less because, by that time, traces of its decomposition products could already be detected.

B. Quinquevalent Molybdenum Solutions.—This solution was prepared by taking 20.10 ml. of a 0.02495 molar molybdate solution, diluting with an equal amount of 4 *M* hydrochloric acid, heating to 80° and reducing in a silver reductor according to the method of Birnbaum and Walden.[10] The reduced solution was then diluted to one liter with additional 2 *M* acid. The solution was thus 5.01×10^{-4} molar with respect to the molybdenum and 2 *M* with hydrochloric acid. It was always prepared just before an experiment was to be performed.

C.—All other reagents used such as the thiocyanate salts and chlorides of lithium, sodium and potassium were C. P. analyzed and were used without further purification.

Experiments and Results

(1) The Reversible Character of the Reaction.—In this study the attempt was made to demonstrate whether or not the reaction was truly a reversible one. In most cases the usual procedure would be to demonstrate that from whatever side the reaction was begun, the final concentrations of the various components would be the same. But in this instance such an experiment could not be made directly because it was not possible to get pure molybdenum thiocyanate. Therefore, it became necessary to prepare molybdenum thiocyanate solutions of higher concentrations, and then, by proper dilution, to cause the molybdenum thiocyanate to decompose until equilibrium was attained. Then comparing these solutions to others which contained the same total concentration of quinquevalent molybdenum and thiocyanate acid but in which the formation of the molybdenum thiocyanate was performed directly, it became possible to see whether the equilibrium position was the same for the forward and the reverse reaction. In testing this reaction experimentally, two series of solutions were prepared. In one series, which we may designate as the A series, the solutions were prepared in the following manner.

To a 100-ml. volumetric flask, 8 ml. of 5.015×10^{-4} molar solution of quinquevalent molybdenum 2 molar with hydrochloric acid is added followed by 16 ml. of concentrated C. P. hydrochloric acid and varying amounts of water and thiocyanate solution to make up the remaining 100 ml. The solutions were then thoroughly shaken and set aside.

The other series, B was prepared by mixing the same amounts of quinquevalent molybdenum and hydrochloric acid plus 26 ml. of distilled water. To those solutions various amounts of the potassium thiocyanate solution were added and, after mixing, the solutions were permitted to stand until the color density was more than twice that of the corresponding solution in the series A. Then the appropriate amount of distilled water was added to bring the volumes of the solutions to 100 ml. and thus to bring the gross concentration of molybdenum and the thiocyanic acid to the same value as that in the A series. The solutions were permitted to stand while the molybdenum thiocyanate complex slowly decomposed until equilibrium was obtained. The amount of the complex was then determined by measurements in the Evelyn colorimeter using the no. 420 filter manufactured by the Rubicon Company. The results obtained as well as all of the data pertinent to this determination are listed in Table I.

TABLE I

0.9355 *M* KSCN soln., ml.	H_2O[a] added, ml.	Final concn. of KSCN in both series	Log galvanometer deflection Series A	Series B

26	24	.2172	.581	.581
24	22	.2339	.581	.585

[a] This was the water withheld in series B.

A comparison of the results for the two solutions reveals that there is little difference in the equilibrium concentrations obtained under a given set of conditions even though the reaction is carried out in widely different manners and from opposite sides of the equation. This is a true test of reversibility and consequently established such a character for the reaction under discussion.

(2) Effect of Electrolyte Concentration on Equilibrium of the Reaction.—During the course of these investigations, it was observed that apparently the equilibrium of the reaction was affected by the character of the cations present. For example, it was observed in several instances that when a given concentration of thiocyanate solutions reacted with a fixed amount of quinquevalent molybdenum, apparently the density of the molybdenum thiocyanate color was greater when the sodium salt of thiocyanic acid was used instead of the potassium salt. Although such effects were known especially from the work of LaMer and others, it was thought worth while to investigate this effect more fully. Besides, any attempt to make equilibrium studies with the end in view of attempting to evaluate the thiocyanate–molybdenum ratio necessitated some knowl-

edge of the degree of these effects so that they could be accounted for properly in any later work.

With this objective in view, another series of solutions was prepared in which the concentration of the molybdenum, as well as the concentration of the free thiocyanate acid, was fixed. To these solutions variable amounts of four different electrolytes were added. These electrolytes were hydrochloric acid and the chlorides of lithium, sodium and potassium. The equilibria for these various systems were established at a temperature of 24.5°, and were attained after two hours. Stock solutions of hydrochloric acid and salts were 2 *M*. Suitable amounts of them were made up with water to a volume of 62 ml. and to this was added 38 ml. of quinquevalent molybdenum and thiocyanic acid mixtures so that their final molarities and that of the hydrochloric acid were 8.018×10^{-5}, 0.305 and 0.167 *M*, respectively. The data obtained are plotted in Fig. 5.

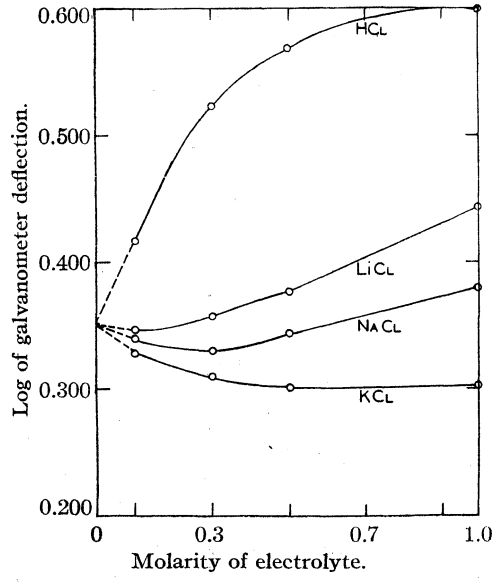

Fig. 5.—Effect of electrolyte concentration on equilibrium.

It is obvious from these data that not only does the ionic concentration of the system have a pronounced effect on the equilibrium of the reaction but that the degree of this effect is specific for the different cations used. It is also apparent that when the concentration of the added electrolytes is at zero (excepting the 0.167 *M* hydrochloric acid in all solutions), the color density indicates that little more than one-half of the quinquevalent molybdenum has reacted with the thiocyanate. The addition of more hydrochloric acid is sufficient to shift the equilibrium of the reaction to completion when its concentration is one molar. With the salts, however, the effect on the equilibrium is much less striking. It is apparent that in order to demonstrate this effect to best advantage it is necessary to choose such a concentration of the thiocyanate that the limiting color density is reached not because of a high thiocyanic acid concentration but rather because of the effect of the added electrolytes. Thus, it would be possible, if more than enough thiocyanate were added to drive the reaction to completion, to observe no effect from small amounts of added electrolytes.

The interpretation of this evidence leads one to believe that the structure of the complex in aqueous solution is not closely related to these salt effects but rather that what is being observed is some change of the apparent activities of the various components of this system due to salting-out or salting-in effects. However, more work would have to be done before any good explanation could be advanced.

Evaluation of the Thiocyanate–Molybdenum Ratio for the Complex.—Throughout this paper it has been postulated that the reaction between quinquevalent molybdenum and the thiocyanate can, in the most general way, be represented by the reaction

$$[Mo^{5+}R]^{n+} + n(SCN^-) \longleftrightarrow [Mo^{5+}R]^{n+}(SCN^-)n \quad (1)$$

It was generally apparent that the most likely value for n in this reaction was three, although as had been pointed out in the earlier discussion it had not been established conclusively by any of the previous investigators. In view of this fact, it seemed desirable to attempt an estimation of this ratio from a consideration of the effect which varying concentrations of the thiocyanate would have on the equilibrium of the reaction. Since these studies were to be made by means of colorimetric measurements, certain special details had to be considered. These details were largely associated with the need for exact measurements of all the substances participating in the reaction. Some of these difficulties were resolved by the mathematical treatment which was made of this problem. If we consider the reaction listed by equation 1, it is clear that this formulation does not consider the very pronounced effect of the hydrochloric acid observed in the preceding experiment. It seems better to represent the equation in a modified form such as equation 2.

$$[Mo^{5+}R]^{n+} + n(SCN^-) \longleftrightarrow [Mo^{5+}R](SCN)_n + X(OH^-) \quad (2)$$

The equilibrium constant of this reaction would then be

$$K' = \frac{C[Mo^{5+}R](SCN)_n C^x(OH)}{C[Mo^{5+}R]^{n+} C^n(SCN)} \quad (3)$$

Since the concentrations involved in these studies were to be low, one need not express K' in terms of activities. If the hydrochloric acid concentration is held constant for a series of studies, it then becomes possible to incorporate it in some new constant K and obtain

$$K = \frac{C[Mo^{5+}R](SCN)_n}{C[Mo^{5+}R]^{n+} C^n(SCN)} \text{ where } K = \frac{K'}{C^x(OH)} \quad (4)$$

Now let A = concentration of complex formed, B = total concentration of quinquevalent molybdenum, and C = total concentration of thiocyanate. Then the equilibrium constant can be expressed

$$K = \frac{A}{(B - A)(C - nA)^n} \quad (5)$$

Since A is small in comparison with C, it may be omitted from $(C - nA)^n$ term. Then

$$K = \frac{A}{(B - A)C^n} \quad (6)$$

Rearranging, $A = KBC^n - KAC^n$, $A + AKC^n = KBC^n$

$$\frac{A}{B} = \frac{KC^n}{(1 + KC^n)} \quad (7)$$

Setting $A/B = {}^1/_2$ and writing that value of C where $A/B = {}^1/_2$ as $C_{1/2}$, we have $KC_{1/2}^n = 1$ and $K = (1/C_{1/2})^n$. Substituting this value of K into equation 7, and rearranging we have

$$A = B\left(\frac{\left(\frac{C}{C_{1/2}}\right)^n}{1 + \left(\frac{C}{C_{1/2}}\right)^n}\right) \quad (8)$$

It is this equation which is used in the evaluation of the thiocyanate molybdenum ratio. By setting up a table in which the values for the term

$$\left(\frac{C}{C_{1/2}}\right)^n \Big/ 1 + \left(\frac{C}{C_{1/2}}\right)^n$$

are expressed as a function of the ratio $C/C_{1/2}$, it becomes extremely easy to calculate the value of A for any value of n and for any value of B. In using equation 8 for the experimental determination of the thiocyanate–molybdenum ratio, the theoretical curves for a plot of the log galvanometer deflection as a function of the thiocyanate concentration were calculated for various values of n. This could be done quite easily given the term for any particular value of B. In order to illustrate the use of the equation, a discussion of the method employed in evaluating the various terms is given.

(a) **Evaluation of A.**—Since A represents the amount of the complex which has formed under a given set of conditions, it can be determined by measuring the density of its color. In the usual colorimetric process, one simply calibrates the galvanometer deflection for these solutions. When monochromatic light is used and when Beer's law holds for the particular system under study, it will be found that the logarithm of the galvanometer deflection equals (kC), the product of the concentration and some constant.

In the process under discussion, this calibration was effected by taking a known amount of quinquevalent molybdenum and adding such an excess of thiocyanate that the reaction was driven to completion. Consequently the concentration of the complex becomes identical with that of quinquevalent molybdenum taken. It was in this way that the calibration curve illustrated in Fig. 6 was obtained.

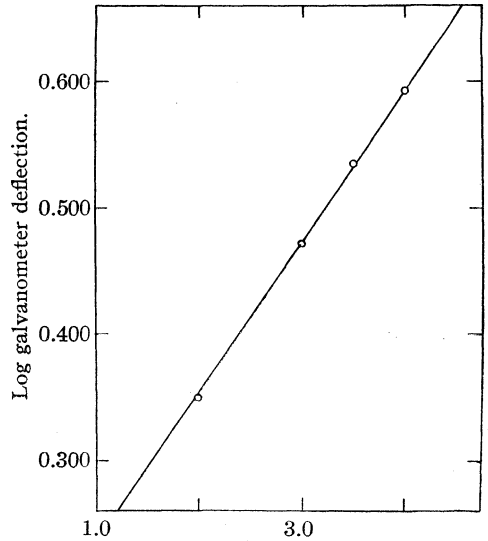

Fig. 6.

(b) **Evaluation of B.**—B was known because the solutions of quinquevalent molybdenum were prepared by quantitative reduction of analyzed molybdate solutions.

(c) **Evaluation of $C_{1/2}$.**—This concentration is determined by plotting the color density of a series of solutions as a function of the thiocyanate concentration. For any fixed amount of quinquevalent molybdenum, this plot will approach a limiting value of the color density. The concentration of the thiocyanate at the half-way point is the $C_{1/2}$ term wanted. In the actual determina-

tion of the thiocyanate–molybdenum ratio, a large number of series of solutions were prepared and their color densities determined. In each series the hydrochloric acid concentration and the quinquevalent molybdenum concentration were held constant while the concentration of the thiocyanate was varied. In Figs. 7, 8, and 9 some of the data are plotted.

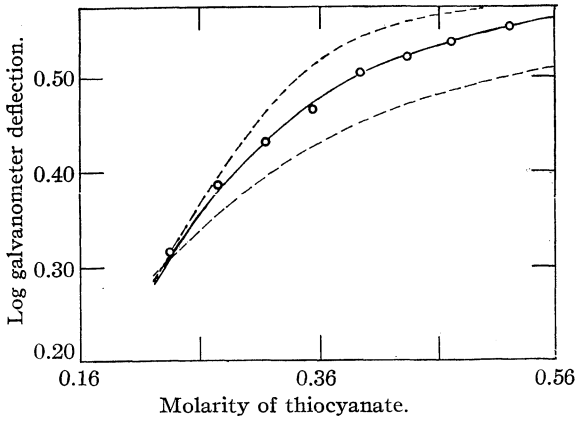

Fig. 7.—Theoretical curves: - - - - $N = 2$ and 4; ——— $N = 3$; ○, experimental points; 1.0 molar HCl concentration.

It should be remembered that in the mathematical treatment the hydrochloric acid concentration was incorporated into the special equilibrium constant K; therefore, at any given hydrochloric acid concentration, the $C_{1/2}$ term must be evaluated from the data. After $C_{1/2}$ is evaluated, it then becomes possible to calculate the theoretical curves observed in the figures.

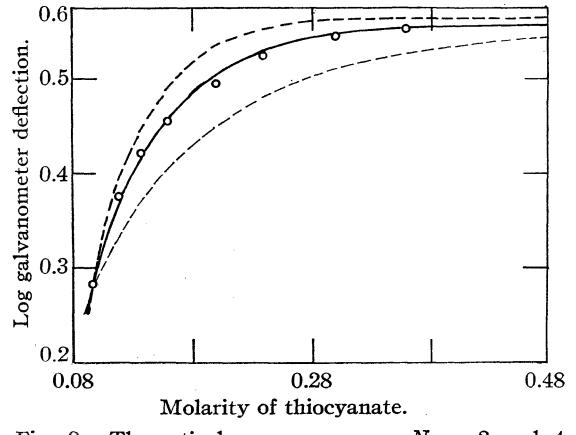

Fig. 8.—Theoretical curves: - - - - $N = 2$ and 4; ——— $N = 3$; ○, experimental points; 1.5 molar HCl concentration.

In the above figures only the experimental points are listed. All of the lines drawn represent

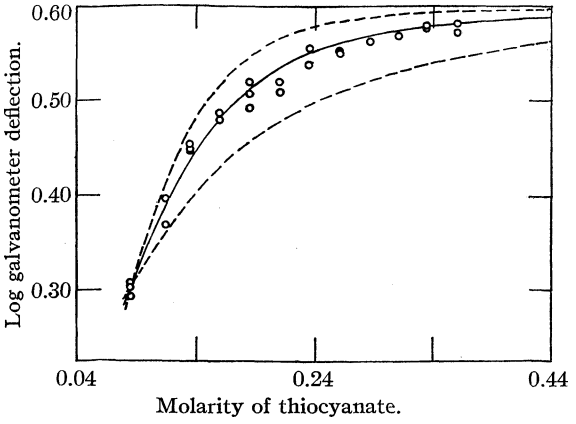

Fig. 9.—Theoretical curves: - - - - $N = 2$ and 4; ——— $N = 3$; ○, experimental points; 2.0 molar HCl concentration.

theoretical lines calculated with aid of equation 8. Experiments were also run in hydrochloric acid concentrations above 2.5 N but, since it became virtually impossible to get any semblance of reproducibility at this concentration, those experiments were discontinued. In fact, it can be observed that the results obtained at 2.0 M leave something to be desired. Examination of the data and the plots of these data reveals a close similarity between the theoretical values calculated for a thiocyanate ratio of three and the experimental points observed. It seemed reasonable to conclude that such a close agreement clearly establishes this ratio in a not too ambiguous manner. While one must admit that this ratio has not been established with stoichiometrical exactness from the data presented herein, nevertheless it is important to recognize that no matter how strict the interpretation of the results, a possible deviation greater than 6 or 7% from the value of 3 is not permitted.

If one attempts to solve equation 8 directly for the value of n, a much too rigorous testing of data is obtained. This is due to the fact that we obtain such a term as

$$n = \frac{\log \frac{A}{B - A}}{\log \frac{C}{C_{1/2}}}$$

As A approaches B the value of the $\log A/(B - A)$ term becomes extremely uncertain because a small variation in the value of the $(B - A)$ term causes large variations in $\log A/(B - A)$. As A approaches $B/2$ the expression becomes indeterminate and for values of A greater than $B/2$ it becomes impossible to obtain suitable experimental data.

Despite these general limitations, however, one thing remains clear; these experiments establish this ratio of 3 as a property of the colored substances in solution and not as a property of some dry compound isolated from tarry mixtures of many different substances.

Along with these general observations several other points may be made concerning the character of the reaction. Of these, perhaps the most important is the fact that from the slowness with which equilibrium is attained, one may conclude that this is not an ionic reaction. Additional evidence that the molybdenum complex is not ionic may be surmised from its extreme solubility in a large number of organic solvents. Consequently a representation of the reaction which involves only an exchange of the thiocyanate ion with the chloride ions of quinquevalent molybdenyl chloride must be considered as an over simplification.

3. Fading Effect Induced by Hydrochloric and Sulfuric Acids.—The next problem considered in this study was one associated with the very pronounced fading of the molybdenum thiocyanate observed in high acid concentrations. This effect was used to bleach the molybdenum thiocyanate color and thus prevent the molybdenum from interfering in the colorimetric determination of the rhenium. In view of similar striking color changes observed in pure quinquevalent molybdenum solutions, it was thought desirable to make a study of these two processes in order to determine whether any analogy existed between them.

Experimental

A. Quinquevalent Molybdenum Color Transition.—On taking a solution of quinquevalent molybdenum whose hydrochloric acid concentration is slowly increased, one may observe the series of color changes listed in Table II. This color transition may also be observed by starting with 8 *N* hydrochloric acid and progressively diluting with water whereby the same colors will appear in reverse order.

TABLE II

Molarity HCl	Color of solution	Molarity HCl	Color of solution
0.0–0.5	Faint amber	6.3–7.3	Brown changes to dark olive color
0.5–5.5	Amber color becomes more intense	7.7	Light olive
3.5–5.5	Amber changing to dark brown	8.0	Chrome-green
5.5–6.3	Brown color darkens appreciably	8.0	Above color becomes a pure emerald-green

For the purpose of this discussion, it will only be necessary to consider the color effects at the lower acid concentrations for which the color densities were measured. The measurements were made in the Evelyn colorimeter using the no. 420 filter.

The stock quinquevalent molybdenum solution used was 0.0107 and 2 molar with hydrochloric acid. Solutions of hydrochloric acid prepared by mixing various amounts of water with 5 molar hydrochloric acid had a total volume of 20 ml. To these solutions 5 ml. of the quinquevalent molybdenum solution was added, and the resulting solutions thoroughly mixed. The solutions were transferred to the colorimeter and the galvanometer deflection observed. Data obtained in this manner are plotted in Fig. 10.

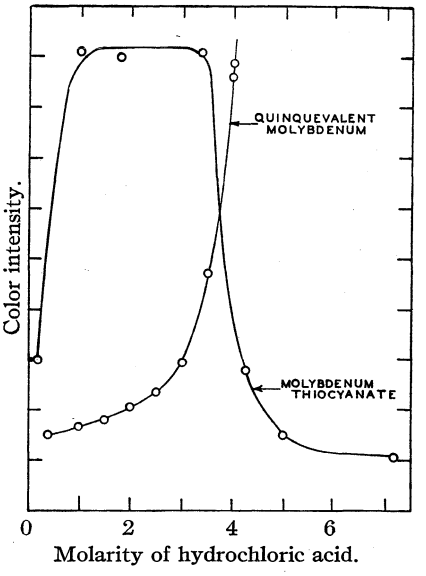

Fig. 10.

In studying the transition caused by the sulfuric acid, small amounts of hydrochloric acid added as a constituent of the stock solution of quinquevalent molybdenum exerted a profound effect upon the action of the sulfuric acid. In order to make the experiments comparable, it was neces-

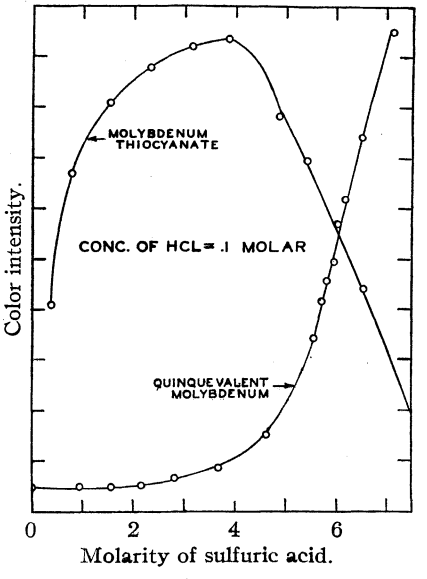

Fig. 11.

sary to adjust the hydrochloric acid concentration in the final solution to 0.1 molar. In these experiments our stock molybdenum solution was 0.015 molar with respect to molybdenum and 1.0 molar with hydrochloric acid. Five ml. of the stock solution was diluted to 50 ml. with a solution whose sulfuric acid concentration was known. After thoroughly mixing the readings of the color density were taken. These data are plotted in Fig. 11.

B. Fading Effect of the Thiocyanate Complex of Molybdenum.—The determination of the fading effect of these acids upon the molybdenum thiocyanate complex was done about five years ago, and for those experiments an Eastman Universal colorimeter was used. The principle of the instrument was based on a comparison of the color density of a solution with a standard glass wedge whose color density changed regularly from one end to the other. While the results obtained using such an instrument are not particularly quantitative, they still are sufficiently so to indicate the qualitative aspects of the process we are discussing. In those series, the molybdenum thiocyanate complex was formed by the reduction of alkali molybdate solution with stannous chloride in the presence of potassium thiocyanate while the concentrations of the hydrochloric and sulfuric acids were varied.

The solution, whose color density was to be studied, was prepared by taking 60.5 ml. of an acid solution whose concentration was known and adding to it 2 ml. of the molybdate solution (200 micrograms per ml.) and 2.5 ml. of a 10% potassium thiocyanate solution. Then, 7.5 ml. of 10% stannous chloride was added. The readings were taken after the solution had reached an equilibrium condition showing only a very slight fading effect as a function of time. They are plotted in Figs. 10 and 11.

In plotting these two sets of data, it was necessary to adjust the ordinates in order to properly compare the two curves. When this is done it will be observed how nearly identical the threshold acid concentrations are for these two effects.

It seems clear, therefore, that these two reactions are related to each other in no indirect manner. We feel, therefore, that a possible interpretation of these results is that the two effects are due to similar reactions: that in the case of the quinquevalent molybdenum, a colorless form, which we call "W," is progressively transformed into the amber colored form which we shall refer to as "X." In the case of the molybdenum thiocyanate complex, there is a red colored form W′ corresponding to the W form of the quinquevalent molybdenum and a colorless form of the thiocyanate complex X′ corresponding to the X form of the quinquevalent molybdenum.

If this interpretation is correct, then it is quite logical to agree that whatever the formula for the thiocyanate complex, it must contain within itself the possibility of explaining the fading effect observed.

With the information available from this research it is not possible for us to make any thoroughgoing prediction of what it should be like. Whether the color transitions observed are due to complex formation or to hydration cannot be adequately treated now but the correlation of these two phenomena make it seem likely that a study of the simpler system (*i. e.*, quinquevalent molybdenum without thiocyanate) will give information which has a direct bearing on the structure of the thiocyanate complex.

Acknowledgment.—The authors would like to express their indebtedness to the generous financial support of the Works Projects Administration and to the Brittingham Foundation for the use of the special spectrometer provided by their funds. They would also like to express their appreciation to Messrs. Warren Olson, V. F. Springer and Max Wolfe for their aid in the execution of some of the laboratory work.

Conclusions

An examination of the literature reveals that there is no clear formulation for the structure of the thiocyanate complex of molybdenum. In this research, evidence has been advanced to show that whatever the structure of the molybdenum thiocyanate complex, the formula of it must: (1) indicate quinquevalency for the molybdenum in the complex, (2) show a thiocyanate–molybdenum ratio of three and (3) offer an explanation of the color transitions observed.

The Chlorinates. III. Temperature–Concentration Equilibria in the Systems Methylene Chloride–Chlorine and Methyl Chloride–Chlorine. The Perchlorides of Methylene and of Methyl[1,2]

BY J. ALLEN WHEAT, II, AND A. W. BROWNE

In determining temperature–concentration equilibria in the system methylene chloride–chlorine the experimental procedure was identical with that followed in the earlier work with chloroform and chlorine.[2] The data obtained are presented in Table I and are plotted in Fig. 1.

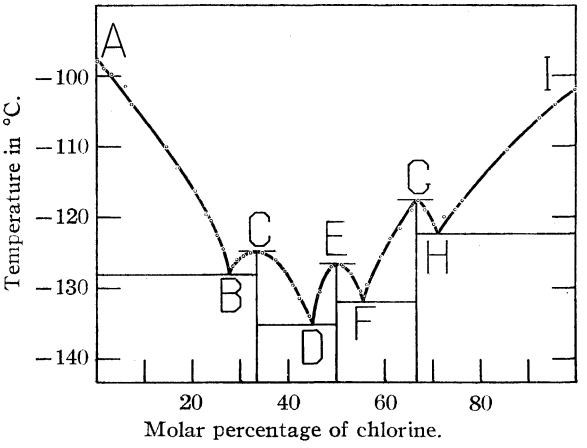

Fig. 1.—Freezing point *vs.* composition for system of methylene chloride–chlorine.

For the investigation of the system methyl chloride–chlorine, in which both components are vapors at ordinary temperatures, a special apparatus, shown in Fig. 3, was used. This consisted essentially of a closed reaction cell immersed in a pentane bath, the temperature of which could readily be controlled between −150° and +20° by means of liquid air. Accessory devices facilitated the introduction of measured amounts of either component into the cell. For

each concentration studied, the system was cooled well below the freezing point, with constant agitation, until solidification occurred. The bath was then allowed to warm slowly, with constant stirring, and the temperature of the bath at which the last trace of the solid phase disappeared, was taken as the freezing point. Possible error due to temperature lag between bath and cell was elimi-

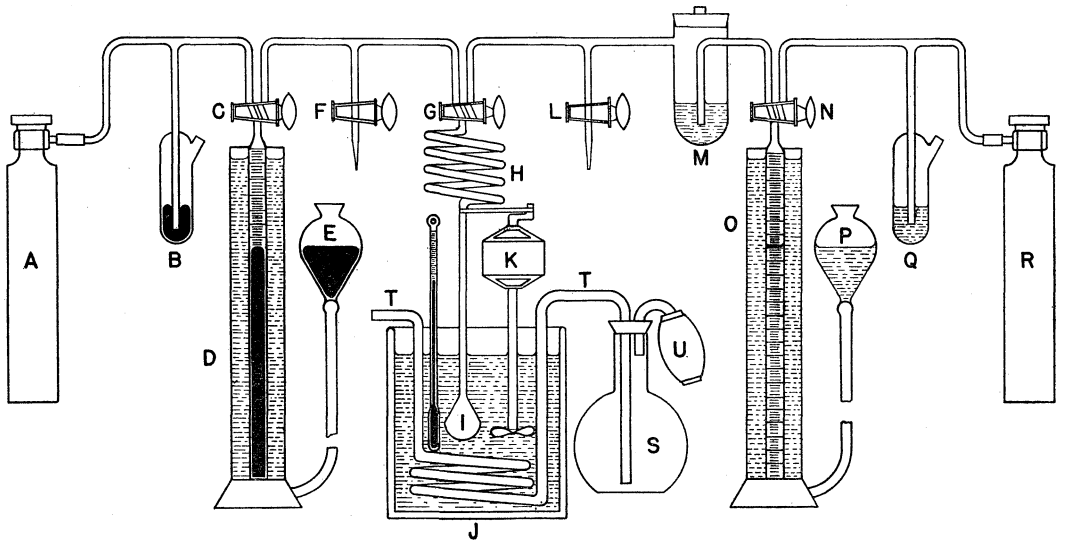

Fig. 3.—A, Cylinder of CH_3Cl; B, gas trap (mercury); C, double stopcock; D, E, water-jacketed gas buret and leveling bulb (mercury); F, exhaust stopcock; G, double stopcock; H, glass spiral; I, reaction cell; J, pentane-bath; K, electric motor; L, exhaust stopcock; M, gas drying bottle (concentrated sulfuric acid); N, double stopcock; O, P, water-jacketed gas buret and leveling bulb (saturated NaCl in water); Q, gas trap (saturated aqueous solution of sodium chloride); R, cylinder of chlorine; S, liquid air supply; T, copper tubing; U, aspirator pump.

nated by special calibration of the pentane thermometer with the aid of several pure gases whose (known) melting points were determined in the same way. The data are submitted in Table II, and are plotted in Fig. 2.

The data in the foregoing tables clearly indicate the formation of three chlorinates of methylene chloride, and two chlorinates of methyl chloride, all with congruent melting points, as follows

(1) methylene chloride hemichlorinate, $(CH_2Cl_2)_2 \cdot Cl_2$, −124.5°
(2) methylene chloride monochlorinate, $CH_2Cl_2 \cdot Cl_2$, −126.5°
(3) methylene chloride dichlorinate, $CH_2Cl_2 \cdot 2Cl_2$, −117.5°
(4) methyl chloride hemichlorinate, $(CH_3Cl)_2 \cdot Cl_2$, −120°
(5) methyl chloride monochlorinate, $CH_3Cl \cdot Cl_2$, −122°

While no evidence concerning the structure of these compounds has been obtained as yet, it is possible to write their formulas in the manner tentatively suggested for the chlorinates of chloroform and of carbon tetrachloride in the earlier articles of the current series. The fact that the maximum number of chlorine molecules held in combination by any of the chloromethanes is equal to the number of chlorine atoms in the chloromethane molecule tends, in the opinion of the authors, to confirm the idea that the solvates under investigation are coördination compounds.

In conformity with the definition of perchlorides proposed in the second article of this series, the three chlorinates of methylene chloride and the two of methyl chloride may be regarded as perchlorides of methylene, and of methyl, respectively. Their empirical composition could therefore be expressed by the formulas $(CH_2)_2Cl_6$, CH_2Cl_4, CH_2Cl_6, $(CH_3)_2Cl_4$ and CH_3Cl_3.

Summary

Two chlorinates of methyl chloride, or perchlorides of methyl, and three chlorinates of methylene chloride, or perchlorides of methylene, have been identified and their congruent melting points determined.

(1) This article is based upon the thesis presented to the Faculty of the Graduate School of Cornell University by J. Allen Wheat, II, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(2) For the preceding articles in the current series, see Wheat and Browne, THIS JOURNAL, **58**, 2410 (1936); **60**, 371 (1938); **62**, 1575 (1940).

that chlorine attached to carbon will denote a pair of electrons to free chlorine. The purpose of the current investigation was to determine whether or not chlorides, in which the chlorine was attached to a more electropositive element than carbon, would also form solvates with free chlorine.

In the present investigation of the freezing point *vs.* concentration equilibria in the system of hydrogen chloride–chlorine, the experimental procedure was substantially identical with that employed in the study of the system of methyl chloride–chlorine.[2] The data obtained are presented in Table I and are plotted in Fig. 1.

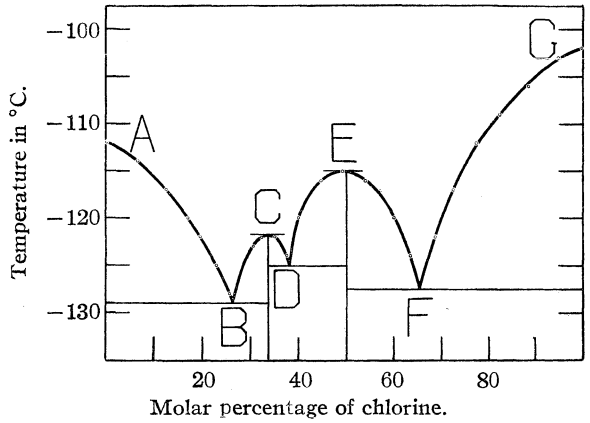

Fig. 1.—Freezing point *vs.* composition in system of hydrogen chloride–chlorine.

From the foregoing data it may be concluded that chlorine forms two solvates (chlorinates) with hydrogen chloride, whose empirical formulas and congruent melting points are as follows: (1) hydrogen chloride hemichlorinate, $(HCl)_2:Cl_2$, −121°; (2) hydrogen chloride monochlorinate, $HCl:Cl_2$, −115°.

Nothing concerning the structure of these compounds can be deduced from these data, but the authors venture the statement that it seems probable that hydrogen chloride should be combined with free chlorine by a coördinate covalent link. Since the hydrogen–chlorine link in hydrogen chloride is more polar than the chlorine–chlorine link in the free chlorine, the chlorine attached to hydrogen probably donates a pair of electrons which is accepted by the free chlorine. The structural formulas would therefore be

(1) H—Cl ⟶ Cl—Cl ⟵ Cl—H
(2) H—Cl ⟶ Cl—Cl

In conformity with the definition of perchlorides proposed in the second article of the current series,[2] the compounds identified during this investigation may be considered as perchlorides of hydrogen whose empirical formulas are H_2Cl_4 and HCl_3.

Summary

Two chlorinates of hydrogen chloride or perchlorides of hydrogen, have been identified and their congruent melting points determined.

The Chlorides of Gallium

BY A. W. LAUBENGAYER AND F. B. SCHIRMER

The formation of compounds by gallium has been shown to present numerous interesting problems, both of valence state and of molecular configuration. While trivalency, which is to be expected for this atom, is well established, the molecular species and configuration of the compounds in this state have not been well understood. Gallium also has been reported[1] to show divalence, a condition which cannot be reconciled with its atomic structure, and univalence, which should be possible due to the use of only the $4p$ electron for bonding purposes. Very little work is available about these lower valence states.

(1) L. de Boisbaudran, *Compt. rend.*, **93**, 294 (1881).

The system gallium–chlorine is a favorable one to study because gallium–chlorine bonds are strong enough to ensure reasonably stable molecules and the volatility of the chlorides makes it possible to investigate them in the vapor phase.

Gallium trichloride has been shown[1] to resemble aluminum chloride closely, being associated at lower temperatures. While a recent vapor pressure and density investigation[2] of this compound has given considerable data, this work does not agree on a number of points with the reports of earlier investigators, the temperature range cov-

(2) Fischer and Jubermann, *Z. anorg. allgem. Chem.*, **227**, 227 (1936).

ered is not extensive enough to afford all the desired information, and the interpretation of the data is incomplete.

Gallium dichloride was prepared by de Boisbaudran[1] and other workers[3] by the reduction of gallium trichloride with hot gallium, but the conditions for preparation have not been well established, the purity of the product seems to have been considerably in doubt, and its properties have not been completely surveyed.

No reduction of gallium dichloride to a monochloride has been demonstrated, although Nilson and Pettersson suggested that a brownish colored film which remained on the walls of the glass reaction tube after reduction of the trichloride with excess gallium might have been the monochloride.

In the present investigation vapor phase studies of gallium trichloride over an extended temperature range have been undertaken. Pure gallium dichloride has been prepared and its properties, especially its behavior in the vapor phase, have been investigated. The possibility of obtaining gallium monochloride has been examined.

Apparatus and Procedure for Vapor Studies.—Because the system gallium–chlorine is very reactive, especially toward water and oxygen, the apparatus shown in Fig. 1, constructed completely of Pyrex glass, was used for vapor pressure and density measurements. This apparatus employed the vapor pressure cell A which had a glass manometer of the "sickle" type,[4] similar to a Bourdon gage. The cell could be connected by means of an interchangeable ground glass joint to the chain equipped with a mercury manometer, a McLeod gage, a vacuum pump, and drying tubes through which air could be admitted. The volume of the cell was determined by weighing it empty and then filled with water to the points on tubes B and C where they later would be sealed off. Corrections for change of volume with temperature were calculated.

The glass ampule containing the sample was scratched with a file, weighed, and introduced into the cell through tube B, which then was sealed off. The cell was attached to the chain, C was connected to D by glass and rubber tubing, and the cell was completely evacuated simultaneously on both sides of the sickle. C was sealed off and the zero positions of the pointers E and F were noted by means of a telescope. S_1 was closed, the cell was taken from the chain and shaken to break the sample tube, and then was reattached, and the chain beyond S_1 was evacuated. The temperature of the sample was controlled by immersing the cell to its side arm in a suitable thermostat. As the pressure in the cell rose the pointers were balanced approximately by admitting air through S_5 and S_1. When equilibrium at a given temperature was attained the pointers E and F were brought to their zero positions by manipulating the pressure of air, and this pressure was then read on the mercury manometer and corrected to give the pressure of the sample. To be sure that equilibrium was realized, the pressures corresponding to given temperatures were determined, both as the temperature was progressively raised and as it was lowered. By varying the size of the cell and the weights of sample used, accurate vapor pressure and density data could be secured over a wide temperature range. The apparatus and method were shown to be satisfactory by making measurements on pure aluminum chloride.

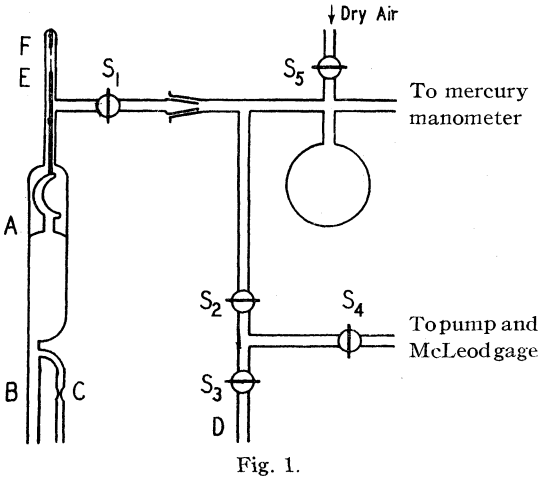

Fig. 1.

Study of Gallium Trichloride

Preparation and Analysis.—Gallium trichloride was prepared by the action of chlorine diluted with nitrogen on hot gallium. The product was distilled in a stream of nitrogen to remove the excess chlorine and further purified by sublimation *in vacuo*. It was analyzed by putting it into solution in 1% nitric acid and determining the gallium as the oxide and the chlorine as silver chloride.[5]

Anal. Calcd. for $GaCl_3$: Ga, 39.59; Cl, 60.41. Found: Ga, 39.55; Cl, 60.35.

Vapor Pressure of Gallium Trichloride.—Measurements were made in the temperature range 50 to 200°. The data for duplicate runs agree satisfactorily and are summarized in Table I. They check those reported by Fischer and Jubermann[2] but also cover a lower temperature range and thus give more information about the solid–vapor equilibrium.

The values of log p plotted against $1/T$ give solid–vapor and liquid–vapor lines which intersect at 77°, the melting point. The points for the liquid–vapor equilibria give a smooth slightly curved line, indicating a small change in the heat of vaporization with temperature. The thermal data for gallium trichloride calculated on the basis of these measurements are summarized in Table II and are compared with the values previously reported.

Vapor Density of Gallium Trichloride.—To determine the maximum association possible in

the vapor phase, measurements were made between 117 and 177°, as low a temperature range as was practical to use. No evidence was obtained for association beyond the dimer, Ga_2Cl_6.

To follow the dissociation of the dimeric molecule, further vapor density measurements were made between 177 and 498°, the highest temperature to which the glass sickle could be heated without undergoing permanent distortion. Establishment of equilibrium and absence of any decomposition of the sample was proved by rechecking the data as the cell cooled. The results for a sample weighing 0.5763 g., measured in a cell of 223.4 cc. capacity, are given in Table III. The apparent molecular weight, the fraction α of the dimeric molecules dissociated according to the equation $Ga_2Cl_6 \rightleftarrows 2\,GaCl_3$, and the logarithm of the equilibrium constant K_p are tabulated for each temperature.

Log K_p plotted against $1/T \times 10^3$ gives a very smooth curve which is not a straight line, the slight curvature being real and indicating a difference in the heat capacity of the two molecular species present. The heat of dissociation, calculated from the slope of the line at 365° where the dissociation is about 50%, is about 20 kilocalories. The dissociation of the saturated gallium trichloride vapor at its b. p., 200°, is only 1.5%. A second run on a sample of 0.7365 g. in the same cell gave temperature–log K_p values which check very closely with those listed in Table III. The data agree well with the results reported by Fischer and Jubermann[2] for the range above 258°. They reported a heat of dissociation of 21 kilocalories calculated from a straight line representing log K_p plotted against $1/T \times 10^3$, but when their data are replotted clear evidence for the slight curvature noted in the present investigation is apparent.

Electron diffraction studies of gallium trichloride vapor in the temperature range in which it has been shown to be at least 98% dimeric are in progress to determine the configuration of the molecule, Ga_2Cl_6.

Study of Gallium Dichloride

Preparation and Analysis.—Gallium trichloride was held during a period of one hour at 175° with an excess of gallium in an evacuated Pyrex reaction tube. The dichloride which formed was heated to 225° and distilled away from the non-volatile impurities. During the distillation some decomposition occurred, gallium trichloride condensing with the dichloride in the cooler portions of the tube and gallium remaining behind. This decomposition, however, was not very serious and a good yield of dichloride was obtained. The section of the tube containing the chlorides was sealed off and placed in an-

other glass tube which was evacuated and sealed. The tube containing the mixed chlorides was broken and the dichloride was purified by holding it at 160° and distilling off the more volatile trichloride. When most of the trichloride had been removed, the tube was cooled and the dichloride, which cracks away from the glass on cooling when fairly pure, was powdered by shaking. This powder was heated to 160° and the last traces of trichloride were driven to the cool end of the tube and sealed off. The pure gallium dichloride remaining was transferred and subdivided *in vacuo*, either by pouring the loose powder or by carefully melting it and allowing the liquid to flow. If the temperature was not raised much above the melting point, 170°, no appreciable decomposition occurred.

For analysis a weighed tube containing gallium dichloride was broken under 2% nitric acid. When the sample reacted with the nitric acid a small amount of gallium always formed. The solution was filtered and the gallium and fragments of glass were collected. The gallium and chlorine in the filtrate were determined as in the analysis of gallium trichloride. The metallic gallium was dissolved in aqua regia and precipitated as the hydroxide, which was added to that obtained from the main precipitation. The weight of the glass was determined and the weight of sample used was obtained by difference.

Anal. Calcd. for $GaCl_2$: Ga, 49.58; Cl, 50.42. Found: Ga, 49.42; Cl, 50.41.

The analytical results show that a chloride having a gallium–chlorine atomic ratio of 1 to 2 is secured by reduction of gallium trichloride under the conditions outlined, and that this compound can be freed completely of contaminating trichloride. No evidence of the formation of a monochloride in the presence of a large excess of gallium was observed.

Properties of Gallium Dichloride.—Gallium dichloride forms colorless crystals which were found to melt at 170.5 ± 0.5°, considerably higher than the value 164° reported by de Boisbaudran.[1] It is very probable that he did not have the pure substance. Liquid gallium dichloride does not wet glass readily but forms small droplets in the tube. The density of the liquid is greater than that of Pyrex glass, since fragments of the sample tubes were observed to float on the melt. The transparent colorless crystals which formed when gallium dichloride froze became opaque on further cooling and, in some cases, the movement through the solid of what appeared to be a crystalline boundary was observed. Single transparent crystals, grown by sublimation just below the melting point, were chilled quickly and were observed under the microscope to slowly become opaque. The evidence indicates that the solid is dimorphic and that the inversion is reversible, but attempts to determine the transition point were not conclusive. This transition is, however, not at all the same phenomenon as that reported by de Boisbaudran[1] as evidence of dimorphism of gallium dichloride. As will be pointed out later, the formation of a colored product when the dichloride is heated, which he mentioned, is satisfactorily explained by the formation of tiny droplets of gallium due to thermal decomposition.

Gallium dichloride deliquesces to give a thick sirupy colorless solution when exposed to the air. If it is placed in water a dark chocolate-brown solid precipitates. This solid slowly reacts with the water to give a gas, probably hydrogen, and the solid turns white, presumably forming gallic hydroxide. The liberation of a gas with an offensive odor, reported by de Boisbaudran and thought by him to be gallium hydride, was not observed in this investigation.

Gallium dichloride was found to dissolve readily in benzene with no apparent chemical interaction. It reacted with carbon tetrachloride and a black solid formed. This solid was insoluble in water, hydrochloric acid, and aqua regia and appeared to be carbon. Gallium dichloride is a powerful reducing agent.

In order to study the thermal stability of gallium dichloride, a sample in one end of an evacuated tube was heated and the other end of the tube was kept cool. Heating at 180° for three hours caused no change in the sample. At 200° a few small crystals of gallium trichloride collected in the cool end of the tube during one hour and, when the dichloride was cooled, a slight grayish color due to the formation of gallium was apparent in the solid. At still higher temperatures the decomposition to gallium and gallium trichloride was more rapid and globules of gallium were observed to form. When the dichloride was heated in Pyrex glass for some time at 500° the surface of the glass very slowly turned brown. The brown film could not be removed by aqua regia nor a mixture of nitric and chromic acids. These reagents would have reacted with the film had it been gallium monochloride. It is probable that the brown film was produced by a slight reaction of hot gallium or gallium dichloride with the glass.

Vapor Pressure and Apparent Molecular Weight of Gallium Dichloride.—In order to gain information concerning the molecular state of gallium dichloride and the equilibrium between the dichloride, gallium, and the trichloride, samples of the dichloride were heated in glass cells and vapor pressure and density determinations were made. The data for four runs, in

which the weight of sample per cc. of cell volume was varied, are given in Table IV. In each run the pressures for several temperatures were remeasured as the cell cooled. Good checks were obtained, proving that equilibrium had been satisfactorily established. The curves obtained by plotting temperature against pressure are shown in Fig. 2. In the first two runs the liquid phase was present for all the measurements and the curves are for saturated vapor pressures. Curves 3 and 4 flatten out beyond the point where the chlorides were completely vaporized. The equilibrium vapor pressures were found to decrease with decrease in weight of sample per cc. of cell volume. The data prove that the pressure of the vapor at equilibrium with the liquid is not a function of the temperature alone, but also is dependent upon the total weight of sample per unit volume of cell, and the system is divariant.

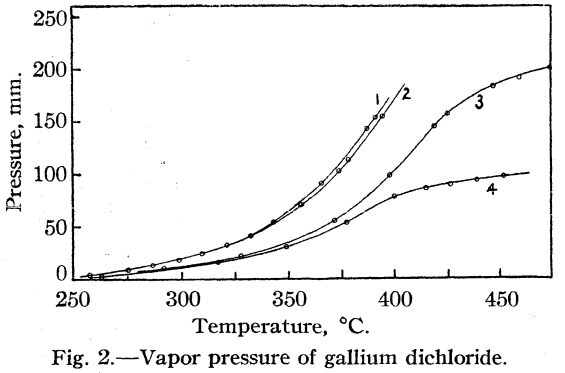

Fig. 2.—Vapor pressure of gallium dichloride.

Since the pressures were shown conclusively to be equilibrium values and the changes are easily reversible, the principle of the phase rule may be applied to the system. Experience with the dichloride has shown that above 200° it decomposes reversibly to gallium trichloride and gallium. Gallium trichloride in this temperature range has been shown to involve an equilibrium between the dimer and the monomer. Due to its high volatility the trichloride is probably completely in the vapor phase. Gallium is not volatile at the temperatures used and liquid gallium has been observed to exist as a separate phase in contact with liquid dichloride with no evidence of being soluble in the dichloride. Hence, in this system, when equilibrium prevails, there should be two liquid phases and one vapor phase. The system has two components and should be univariant. The authors are unable to suggest a satisfactory explanation of the observed divariancy. No reason for increasing the number of components or decreasing the number of phases can be suggested.

TABLE IV

VAPOR PRESSURE AND APPARENT MOLECULAR WEIGHT OF GALLIUM DICHLORIDE

Run	Cell volume, cc.	Sample, g.	Sample per cc. cell volume, g.	Temp., °C. (±0.5)	Pressure, mm. (±0.2)	Apparent mol. wt.

Molecular weights, calculated for the temperature ranges in Runs 3 and 4 where the chlorides were completely vaporized, are given in the last column in Table IV. These have been calculated on the assumption that the total weight of sample was in the vapor phase. Since some liquid gallium

undoubtedly was present, the actual average molecular weights for the vapor must be somewhat lower. The theoretical molecular weights for the molecules Ga_2Cl_6, $GaCl_3$, Ga_2Cl_4, and $GaCl_2$ are 352.2, 176.1, 281.2, and 140.6, respectively. The molecular weights in Table IV can be accounted for by postulating that the vapor was a mixture of molecules of $GaCl_2$ with heavier molecules, undoubtedly Ga_2Cl_6 and $GaCl_3$ and perhaps Ga_2Cl_4.

Klemm and Tilk found that solid gallium dichloride is diamagnetic and concluded that the solid is composed of Ga_2Cl_4 molecules and not $GaCl_2$. The present investigation indicates that considerable quantities of $GaCl_2$ molecules exist in the vapor above 400° under the conditions of the experiments. There seems to be no chance of determining the configuration of the gallium dichloride molecules by an electron diffraction study of its vapor because of the complex mixture of molecules present.

Summary

1. The equilibrium vapor pressures of gallium trichloride have been studied from 50 to 200° and its thermal properties have been determined. Vapor density studies from 117 to 498° give no evidence for association beyond the dimer. The saturated vapor is more than 98.5% dimeric up to 200°, and above this temperature reversible dissociation to the monomer becomes marked, the vapor being 88% dissociated at 498°.

2. Gallium dichloride has been prepared and a method for purifying it has been devised. The properties of the pure compound have been examined. Decomposition to gallium trichloride and gallium becomes appreciable at 200°. Vapor pressure measurements from 219 to 459° indicate that the system is divariant, although it apparently involves three phases and two components. Vapor density measurements in the range 400 to 470° indicate that the vapor contains some $GaCl_2$ molecules, in which gallium must show the anomalous valence of two.

3. No evidence for the existence of gallium monochloride was observed.

A Theory of Chromatography

BY J. NORTON WILSON

The so-called chromatographic adsorption method of analysis was originated by the Russian botanist M. Tswett.[1] He discovered that if a solution containing a mixture of colored solutes is allowed to run through a vertical glass tube filled with a suitable powdered adsorbing material, the material adsorbed in the column appears as a series of colored bands, indicating that a partial separation of the components of the solution has taken place. This series of colored bands is known as a chromatogram. The separation can be completed by a procedure known as development of the chromatogram: there is poured through the column a suitable solvent which washes the colored bands down the tube at different rates, the lowest-lying band moving the fastest. If this process is carried out in a sufficiently long tube with the use of a sufficiently large volume of solvent it is possible to effect complete separation of the original components of the solution into a series of discrete bands separated by clear spaces of adsorbent.

The technique just outlined has become in recent years an important method for the separation, purification and identification of small amounts of complex naturally-occurring organic compounds; these developments have been described at length by Zechmeister and Cholnoky.[2] The method also has been applied to some extent in inorganic chemistry[3]; the most spectacular application in this field has been to the separation of lithium isotopes.[4]

Although the nature of the phenomenon seems to be roughly understood,[2] there has appeared so

far in the literature no quantitative treatment by means of which even an approximate prediction can be made of the width or rate of development of the bands to be expected in a given chromatogram. There is presented here a theoretical treatment which is based on the assumption of instantaneous equilibrium between the solution and the adsorbed material. The chromatography of a solution containing a single solute will be discussed first; it is evident that this simple problem must be solved before the more complicated problem of the chromatography of mixtures can be attacked successfully.

The Chromatography of a Solution Containing One Solute.—Let us consider a long column which contains M grams of adsorbent per centimeter of its length; we wish to calculate the distribution of adsorbed material in the column after a volume v of a solution containing solute at an initial concentration c_0 has passed through it. We shall assume that equilibrium between adsorbed material and the solution in contact with it is always maintained and that the volume of the interstices between the particles of adsorbent per unit length of the column is negligible. Let the isotherm which represents the adsorption of the given solute on the adsorbent be

$$q/m = f(c) \qquad (1)$$

where q is the number of millimoles of solute adsorbed on m grams of adsorbent in equilibrium with a solution whose concentration is c moles per liter. Then under equilibrium conditions at any point in the column where the concentration of solute is c there will be adsorbed Q millimoles of solute per centimeter length of the column, where

$$Q = Mf(c) \qquad (2)$$

Let the distance from the top of the column to any lower point in the column be x, and consider the changes in Q and c which occur at x when an element of volume dv of solution, whose concentration at x is c, passes through a thin cross-sectional layer of the column, of thickness dx, on which is adsorbed initially an amount $Q dx$ of solute. The number of millimoles of solute adsorbed on this layer will change by an amount $(\partial Q/\partial v)_x\, dv\, dx$, and the concentration of the solution will change by $(\partial c/\partial x)_v dx$. The number of millimoles of solute contained in the volume dv of solution will therefore change by an amount $(\partial c/\partial x)_v\, dx\, dv$. But since the total amount of solute is unchanged, we have

$$\left(\frac{\partial Q}{\partial v}\right)_x dv\, dx + \left(\frac{\partial c}{\partial x}\right)_v dv\, dx = 0 \qquad (3)$$

Substituting for Q from equation 2 we obtain as the differential equation for the chromatography of a single solute

$$\left[\frac{\partial}{\partial v}(Mf(c))\right]_x + \left(\frac{\partial c}{\partial x}\right)_v = 0 \qquad (4)$$

The general solution of this equation is

$$c = \varphi\{v - Mxf'(c)\} \qquad (5)$$

where φ is an arbitrary function and $f'(c)$ is the first derivative of $f(c)$. This equation will apply either to the process of formation of the chromatogram or the process of development. Different boundary conditions will apply to the two cases.

Let the chromatogram be formed by pouring a volume v of a solution whose initial concentration is c_0 through the column. The appropriate boundary conditions are:

$$\left.\begin{array}{ll} (1)\ \text{When } v = 0, & f(c) = 0 \text{ for } x \geqslant 0 \\ (2) \qquad v > 0, & f(c) = f(c_0) \text{ at } x = 0 \\ (3) \qquad vc_0 = \int_0^\infty Q dx = \int_0^\infty Mf(c) dx & \end{array}\right\} \qquad (6)$$

The last is a conservation condition.

It has been found that the first two boundary conditions are satisfied only by a discontinuous solution: $\varphi = const. = c_0$ up to a certain value of x; $\varphi = 0$ beyond that value. Application of conditions (2) and (3) leads to the solution:

$$\left.\begin{array}{l} \text{For } 0 \leqslant x < \frac{vc_0}{Mf(c_0)},\ Q = Mf(c_0) \\ \text{For } x > \frac{vc_0}{Mf(c_0)},\ Q = 0 \end{array}\right\} \qquad (7)$$

The discontinuous nature of the solution 7 accounts in a satisfactory way for the sharpness of the bands observed in chromatographic experiments; the result is also in accordance with the experimental observation that the intensity of color is approximately uniform throughout the band ($Q = Mf(c_0) = \text{const.}$).

We may now consider the case in which a band already formed is developed by passage through the column of a volume V of some solvent not necessarily the same as the solvent used in forming the band. Let the adsorption isotherm for the solute in the developing solvent be

$$q/m = F(c) \qquad (8)$$

We assume that the band was formed in accordance with equations 7, *i. e.*, that up to some point $x = x_1$, $Q = Q_0 = \text{const.}$; beyond x_1, $Q = 0$. We may also write

$$Q_0 = Mf(c_0) = MF(c_0') \qquad (9)$$

where c_0' is the concentration of solute which would be in equilibrium with Q_0 in the new solvent, and is not necessarily equal to c_0. The boundary conditions to be applied are

$$\left.\begin{array}{l}(1)\ \text{When } V = 0,\ 0 \leqslant x \leqslant x_1,\ Q = Q_0 = MF(c_0') = const. \\ (2)\ \text{When } V > 0,\ \text{at } x = 0,\ Q = MF(c) = 0 \\ (3)\ \text{For all values of } V,\ \int_0^\infty MF(c)dx = \int_0^\infty Q_0 dx = const.\end{array}\right\} \quad (10)$$

The solution of equation 4 for these conditions is

$$\left.\begin{array}{l}Q = 0 \text{ for } 0 \leqslant x < \frac{Vc_0'}{MF(c_0')} \text{ and for } x > x_1 + \frac{Vc_0'}{MF(c_0')} \\ Q = Q_0 \text{ for } \frac{Vc_0'}{MF(c_0)} < x < x_1 + \frac{Vc_0'}{MF(c_0')}\end{array}\right\} \quad (11)$$

The conclusion is thus reached that the band should remain sharp during the process of development and that its width should remain constant as it moves down the column. Experimentally these conclusions are found to hold only approximately.

The solutions 7 and 11 have been verified for the special case of the isotherm $f(c) = Kc$, where K is a constant, by an independent method in which the column was considered as being divided up into a large number of thin layers perpendicular to the wall of the tube. The process of formation or development of the chromatogram was treated as a succession of steps; in each step a small element of volume of solution was allowed to pass through the column layer by layer, coming into equilibrium with each layer in turn. The over-all effect was obtained by summing the effects of the individual steps in the process; a limiting value was then found for the summation by letting the thickness of the layers and the magnitude of the elements of volume become infinitesimal. The calculation will not be presented here in detail since it is tedious and treats only a special case. The method just outlined does, however, have the advantage of making clear the physical reason for the discontinuous nature of the bands: as an infinitesimal element of volume of solution passes over an infinitesimal element of length of the column just beyond the leading edge of the band, it deposits an infinitesimal amount of solute. The concentration of solute in the element of volume decreases in this process however by a *finite* amount, so that the concentration of the solution becomes zero in a small number of infinitesimal steps, *i. e.*, within an infinitesimal distance from the leading edge of the band.

In the development of equations 7 and 11 it has been assumed that the volume of the interstitial space between the particles of adsorbent is negligible, and that the volume v of solution or V of developing solvent is passed completely through the column before the measurement of the width and position of the band is made. In actual practice the interstitial volume is not negligible, and the developing solvent is added as soon as all of the original solution has entered the column, and is added continuously until the development has been carried to a convenient stage. If these facts are taken into account, the treatment of the problem is little altered.

Let the volume of interstitial space per centimeter length of the column be α cc. Then it is seen readily that the initial width of the band when a volume v of solution has entered the column is $vc^0/(\alpha c^0 + Mf(c^0))$. The edges of the band are sharp, as before, and the amount of solute per centimeter length of the band has the uniform value $\alpha c^0 + Mf(c^0)$ millimoles.

Let us now consider in detail the development of this band, assuming that the same solvent as was used in forming the band is added as soon as the solution has all entered the column. When a small volume ΔV of solvent enters the column, the liquid within the column will be displaced a distance $\Delta V/\alpha$. A volume ΔV of solution whose concentration is c^0 will leave the lower edge of the band and will form an extension to the band of width $\Delta Vc^0/(\alpha c^0 + Mf(c^0))$. Suppose the upper edge of the band meanwhile has migrated a distance Δx. Since the liquid between this point and the point $x = 0$ has not passed through any part of the band, the volume of solvent which has been used to dissolve the solute formerly adsorbed between $x = 0$ and $x = \Delta x$ is $\Delta V - \alpha\Delta x$. If the concentration of solute in this volume of solvent has reached the value c^0, then

$$(\Delta V - \alpha\Delta x)c^0 = Mf(c^0)\Delta x$$

Whence

$$\Delta x = \frac{\Delta Vc^0}{\alpha c^0 + Mf(c^0)}$$

We conclude that the band should maintain the constant width $vc^0/(\alpha c^0 + Mf(c^0))$, and should migrate at a rate $c^0/(\alpha c^0 + Mf(c^0))$ cm. per cc. of developing solvent added to the column, provided the same solvent is used in developing the band as was used in forming it. A similar analysis

may be used to discuss the case in which a new solvent is used for development, whose adsorption isotherm is $q/m = F(c)$. As in the previous treatment (equation 9) let $f(c^0) = F(c^{0\prime})$. Then it is shown readily that the width of the band will change to $vc^0/(\alpha c^{0\prime} + Mf(c^0))$; after it has reached this value the width will remain constant and the band will migrate at a rate $c^{0\prime}/(\alpha c^{0\prime} + Mf(c^0))$ cm. per cc. of developing solvent added to the column. In practice the width of the bands varies widely with changes in the nature of the developing solvent. A discussion will now be given of the formation and development of chromatograms formed from solutions containing several solutes. In this discussion the volume of the interstitial space between the particles of adsorbent will for convenience be neglected. The treatment can easily be extended to take the interstitial volume into account.

The Chromatography of Mixtures.—The treatment of the formation and development of a chromatogram containing a mixture of solutes is very simple if the solutes are independently adsorbed, *i. e.*, if the adsorption isotherm of each solute is a function of the concentration of that solute alone. In that case each of the solutes will form a uniform band of width $vc_i^0/Mf_i(c_i^0)$, where v is the initial volume of the solution, c_i^0 is the initial concentration of the i'th solute, and $f_i(c_i)$ is the corresponding adsorption isotherm. These bands, each of which has its origin at $x = 0$, will overlap; if the solutes are colored, the resulting chromatogram will appear as a series of contiguous color zones, throughout each of which the color is constant. On development with the original solvent, each of the bands will move independently of the others at a rate equal to $c_i^0(Mf(c_i^0)$ cm. per cc. of developing solvent drawn through the column. In general these rates will be different; after sufficient development the bands will be completely separated, and will have, according to the present treatment, their original width and intensity.

In most actual cases, however, the adsorption of one solute is affected by all other solutes present, so that the adsorption isotherm of the i'th solute in a solution containing n solutes is a function of the concentrations of all the solutes. We thus write for the i'th solute

$$q_i/m = f_i(c_1, c_2, c_3, \ldots c_n) \qquad (12)$$

There appear to exist no general rules for predicting the form of the functions f_i in terms of the adsorption isotherms which apply to pure solutions of the individual solutes.[5] It is usually true that the adsorption of one solute from a solution of given concentration is less when a second solute is present than when only the first solute is present, and that the decrease in the adsorption of the first solute is greater, the greater the adsorption tendency of the second solute. It is well known, however, that the reverse effect, co-precipitation, sometimes occurs, and that in other cases two solutes may adsorb independently of each other. The difficulty of finding an explicit expression for the f_i's will not affect our general considerations, however, and we shall see that the results obtained from the treatment of the chromatography of mixtures, with the interdependence of the adsorption isotherms taken into account, are qualitatively similar to the results for the case in which all solutes adsorb independently of one another.

The Formation of a Mixed Chromatogram.—Let a chromatogram be formed from a volume v of a solution containing n solutes whose initial concentrations are $c_1^0, c_2^0, \ldots c_n^0$. Let the adsorption isotherms be defined by equation 12. For the i'th solute the differential equation, its general solution, and the boundary conditions governing the formation of the chromatograms are, in analogy with equations 4, 5 and 6:

$$\left.\begin{aligned} &\left[\frac{\partial}{\partial v}\{Mf_i(c_1, c_2, \ldots c_n)\}\right]_x + \left[\frac{\partial c_i}{\partial x}\right]_v = 0 \\ &c_i = \varphi\left[v - xM\frac{\partial f_i(c_1, c_2, \ldots, c_n)}{\partial c_i}\right] \end{aligned}\right\} \quad (13)$$

Boundary conditions

$$\left.\begin{aligned} &(1)\ \text{When } v = 0,\ x \geqslant 0: f_i(c_1, c_2, \ldots, c_n) = 0 \\ &(2)\qquad v > 0,\ x = 0: f_i(c_1, c_2, \ldots, c_n) = f_i(c_1^0, c_2^0, \ldots, c_n^0) \\ &(3)\quad vc_i^0 = \int_0^\infty Qi\,dx = \int_0^\infty Mf_i(c_1, c_2, \ldots, c_n)dx \end{aligned}\right\} \quad (14)$$

The solution for a given value of v is similarly $Q_i = Mf_i(c_1^0, c_2^0, \ldots, c_n^0)$ between $x = 0$ and $x = x_j$ at which point one of the solutes, say the j'th solute, has become exhausted. At this point there will be a discontinuity. Evidently

$$x_j = \frac{vc_j^0}{Mf_j(c_1^0, c_2^0, \ldots, c_n^0)} \qquad (15)$$

The solute which is exhausted at the first discontinuity is thus the one for which the quantity on the right side of equation 15 is lower than that for any other component in the solution. It should be noted that each of the solutes is adsorbed to

(5) Freundlich, "Colloid and Capillary Chemistry," Methuen, London, 1926, p. 200 ff.

some extent between $x = 0$ and the first discontinuity at $x = x_j$.

The amount of the i'th solute adsorbed between 0 and x_j is

$$Mf_i(c_1^0, c_2^0, \ldots, c_n^0)x_j = \frac{f_i(c_1^0, c_2^0, \ldots, c_n^0)}{f_j(c_1^0, c_2^0, \ldots, c_n^0)} vc_j^0 \quad (16)$$

The amount of the i'th solute originally present in the solution was vc_i^0. Hence the concentration of the i'th constituent in the solution which traverses the column beyond the first discontinuity is

$$c_i' = c_i^0 - \frac{f_i(c_1^0, \ldots, c_n^0)}{f_j(c_1^0, \ldots, c_n^0)} c_j^0 \quad (17)$$

The concentrations of all constituents change in this way at the first discontinuity; beyond this point the adsorption of the i'th solute is given by the equation

$$Q_i = Mf_i(c_1', c_2', \ldots, c_n'); c_j = 0 \quad (18)$$

This solution will hold between x_j and the point x_k where the k'th constituent is exhausted and the next discontinuity occurs. The changes in concentration at this discontinuity can be calculated in a similar way, and the process continued until all the solutes are exhausted. The equations representing the formation of a chromatogram from a volume v of a solution containing a mixture of solutes may then be summarized thus:

$$\begin{aligned}
&\text{For } 0 \leq x < x_j, \quad Q_i = Mf_i(c_1^0, c_2^0, c_3^0, \ldots)\\
&\qquad x_j = \frac{vc_j^0}{Mf_j(c_1^0, c_2^0, \ldots)}\\
&\text{For } x_j < x < x_k, \quad Q_i = Mf_i(c_1', c_2', c_3', \ldots)\\
&\qquad c_i' = c_i^0 - \frac{f_i(c_1^0, c_2^0, c_3^0, \ldots)\, c_j^0}{f_j(c_1^0, c_2^0, c_3^0, \ldots)} \quad (19)\\
&\qquad x_k = x_j + \frac{vc_k'}{Mf_k(c_1', c_2', c_3', \ldots)}\\
&\qquad Q_j = 0\\

In Fig. 1A is shown a graphical representation of the results obtained from the application of these equations to the hypothetical case of a chromatogram formed from 10 cc. of a solution containing three solutes, each at an initial concentration of 0.02 mole per liter. It has been assumed that the adsorption isotherms are of the type proposed by Langmuir[6] to account for the sorption of dilute gases on solid surfaces:

$$q_i/m = A \frac{a_i c_i}{1 + \sum_j a_j c_j} \quad (20)$$

where A is a constant characteristic of the adsorbent and a_i is a constant characteristic of the i'th solute. The summation is taken over all solutes. This isotherm was chosen because it affords a convenient representation of the effect of one solute in lowering the adsorption of another. For convenience A and M have been taken equal to unity. The value $a_1 = 40$ has been assigned to solute number 1, with $a_2 = 20$ and $a_3 = 5$. For comparison in Fig. 1B, 1C and 1D are shown the chromatograms which would be formed from 10 cc. of a solution containing only one of these solutes at a concentration of 0.02 mole per liter. In connection with Fig. 1A it should be noted that whether the adsorption of a given solute increases or not after passing a discontinuity in the chromatogram depends on the total amount of the given solute which has been adsorbed up to that point, as well as on the solute which is exhausted at the discontinuity.

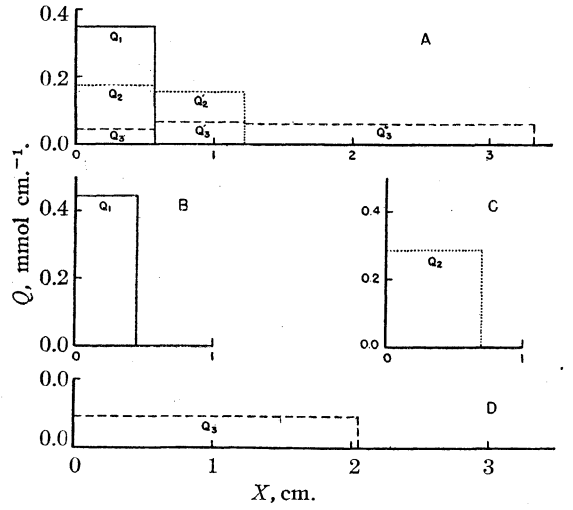

Fig. 1.—A: Chromatogram formed from a solution containing three solutes. B, C, D: Chromatograms formed from the same volume of solution containing only one solute (Solutes 1, 2 and 3, respectively). X is the vertical distance measured from the top of the column.

The Development of Mixed Chromatograms.—Since the discussion of the development of a mixed chromatogram becomes very complicated in the general case, the present treatment will be

(6) I. Langmuir, *Phys. Rev.*, **2**, 331 (1913); **6**, 79 (1915); THIS JOURNAL, **38**, 2221 (1916).

limited to the case of a chromatogram formed from a solution containing two solutes. Let the chromatogram formed from a volume v of a solution of initial concentrations c_1^0, c_2^0, be represented as follows:

$$\left.\begin{aligned} 0 < x < x_1\text{:}\quad & Q_1 = Mf_1(c_1^0, c_2^0);\ Q_2 = Mf_2(c_1^0, c_2^0) \\ & x_1 = \frac{vc_1^0}{Mf_1(c_1^0, c_2^0)} \end{aligned}\right\}\ \text{Band 1}$$

$$\left.\begin{aligned} x_1 < x < x_2\text{:}\quad & Q_1 = 0;\ Q_2 = Mf_2(c_2') \\ & x_2 = x_1 + \frac{vc'}{Mf_2(c_2')} \\ & c_2' = c_2^0 - \frac{f_2(c_1^0, c_2^0)\, c_1^0}{f_1(c_1^0, c_2^0)} \end{aligned}\right\}\ \text{Band 2} \qquad (21)$$

If this chromatogram is developed with a small volume V of the same solvent as was used in forming the chromatogram, the two solutes will migrate at different rates. The origin of the adsorbed solute 2 will migrate to a point $x_{20} = Vc_2^0/Mf_2(c_1^0, c_2^0)$. The solution as it reaches the point x_1 will have acquired the concentrations c_1^0, c_2^0; as it passes this point solute 1 will be completely, and solute 2 partially adsorbed. The discontinuity at x_1 will therefore migrate to a point $(v + V)c_1^0/Mf_1(c_1^0, c_2^0) = x_1' = (v + V)x_1/v$. The amount of solute 2 adsorbed between this point and $x = 0$ is then

$$\left\{\frac{(v + V)c_1^0}{Mf_1(c_1^0, c_2^0)} - \frac{Vc_2^0}{Mf_2(c_1^0, c_2^0)}\right\} Mf_2(c_1^0, c_2^0) = (v + V)c_1^0 \frac{f_2(c_1^0, c_2^0)}{f_1(c_1^0, c_2^0)} - Vc_2^0$$

The concentration c_2'' of solute 2 which passed the point x_1' is then given by the expression

$$Vc_2'' = vc_1^0 \frac{Mf_2(c_1^0, c_2^0)}{Mf_1(c_1^0, c_2^0)} - (v + V)c_1 \frac{f_2(c_1^0, c_2^0)}{f_1(c_1^0, c_2^0)} + Vc_2^0$$

Whence

$$c_2'' = c_2^0 - c_1^0 \frac{f_2(c_1^0, c_2^0)}{f_1(c_1^0, c_2^0)} = c_2' \qquad (22)$$

Thus the concentration of solute 2 in the solution traversing band 2 during this development is the same as went into the formation of the second band. The lower end of band 2 will therefore migrate to the point

$$x_2' = x_1' + \frac{(v + V)c_2'}{Mf(c_2')} = \frac{V + v}{v} x_2$$

The development will proceed in this way until the point x_{20}, the origin of solute 2, overtakes the point x_1', the discontinuity between bands 1 and 2. This will occur at a volume

$$V = v \left\{\frac{c_2^0 f_1(c_1, c_2^0)}{c_1^0 f_2(c_1^0, c_2^0)} - 1\right\}^{-1}$$

When V exceeds this value, the bands will separate. The solute 2 will all be contained in the second band which on further development will migrate at the rate $c_2'/Mf_2(c_2')$, and will maintain the constant width

$$\frac{vc'}{Mf_2(c_2')} \left\{\frac{c_2^0 f_1(c_1^0, c_2^0)}{c_2^0 f_1(c_1^0, c_2^0) - c_1^0 f_2(c_1^0, c_2^0)}\right\}$$

It should be noted that the volume V required for separation of the bands is infinite if the ratio $c_2^0 f_1(c_1^0, c_2^0)/c_1^0 f_2(c_1^0, c_2^0)$ is equal to unity. The departure of this ratio from unity is thus a measure of the ease of separation of two substances by chromatography on a given adsorbent. If the ratio is equal to unity the separation is impossible unless a different adsorbent is used or the value of the ratio is changed by altering the concentration of the initial solution.

The development of solute 1 is somewhat more complicated. As the origin of solute 2 moves through the first band, it will be accompanied by a discontinuity in the adsorption of solute 1. Suppose the adsorption of solute 1 between the beginning of the first band and the origin of solute 2 in the first band is given by $Q_1 = Mf_1(c_1')$. When the volume V of developing solvent has passed through the system, the origin of solute 1 will have moved to $x_{10} = Vc_1'/Mf_1(c_1')$. Between x_{20} and x_1' the adsorption of solute 1 is given by $Q_1 = Mf_1(c_1^0, c_2^0)$. Application of the conservation condition gives

$$vc_1^0 = Mf_1(c_1')(x_{20} - x_{10}) + Mf_1(c_1^0, c_2^0)\,(x_1' - x_{20}) \qquad (23)$$

Substituting the expressions previously derived for x_{20}, x_{10} and x_1', we obtain

$$c_2^0\{f_1(c_1') - f_1(c_1^0, c_2^0)\} = f_2(c_1^0, c_2^0)\{c_1' - c_1^0\} \qquad (24)$$

This equation can be solved for c_1' if the initial concentrations and the adsorption isotherms are known. When the two bands have separated, the solute 1 will be all contained within the first band, whose rate of migration will then be $c_1'/Mf_1(c_1')$, and whose width will maintain the constant value $vc_1^0/Mf_1(c_1')$. In Fig. 2 there is shown a graphical representation of several stages in the development of a hypothetical chromatogram which is assumed to have been formed from 10 cc. of a solution in which $c_1^0 = c_2^0 = 0.02$ mole liter^{-1}. The adsorption isotherms have been assumed to be of the Langmuir type, with

$$Q_1 = MA \frac{a_1 c_1}{1 + a_1 c_1 + a_2 c_2};\quad Q_2 = MA \frac{a_2 c_2}{1 + a_1 c_1 + a_2 c_2}$$

For convenience M and A have been given the value unity, and the values $a_1 = 40$, $a_2 = 10$ have

been assumed. Q_1, Q_2 are in units of millimoles per centimeter.

The treatment evidently can be extended to more complex situations involving a greater number of solutes, but the computations become much more involved. The development of such a complex chromatogram may take place in any one of a number of ways depending on the initial concentrations and the adsorption isotherms. The initial development will lead to broadening of the bands. At some point in the development the initial band system of contiguous bands will split into two sub-systems, each of which may later split again. This process will continue until each of the solutes initially present occupies a separate band, provided that the condition for separability of the solutes is fulfilled.

Discussion of the Theory

The theory presented here is in essence a very simple one. Since the processes of diffusion, adsorption and desorption proceed at finite rates, however, the present theory, in which it is assumed that the effects of diffusion can be neglected and that equilibrium between solute and adsorbed material is instantaneously reached, can provide only an approximate description of the phenomena of chromatography. The theory does account for the qualitative features of chromatography in a satisfactory way and provides a convenient basis from which a more precise theory may be developed.

The theory predicts that a chromatogram formed from a solution containing only one solute should form a single sharp band, and that if this chromatogram is developed with the same solvent as was used in its formation, the band should maintain a constant width and sharply defined edges. Experimentally none of these predictions is quantitatively verified. Solutes which adsorb strongly do in many cases form surprisingly sharp bands whose width does not vary rapidly on development and whose edges become diffuse only slowly. On the other hand, a solute which is not strongly adsorbed often forms a band whose lower edge is somewhat diffuse when the chromatogram is formed. The width of such a band and the diffuseness of its edges may increase quite rapidly as development proceeds. These observations are readily explained when the factors which have been neglected in the present treatment are taken into account. The width of a band may increase

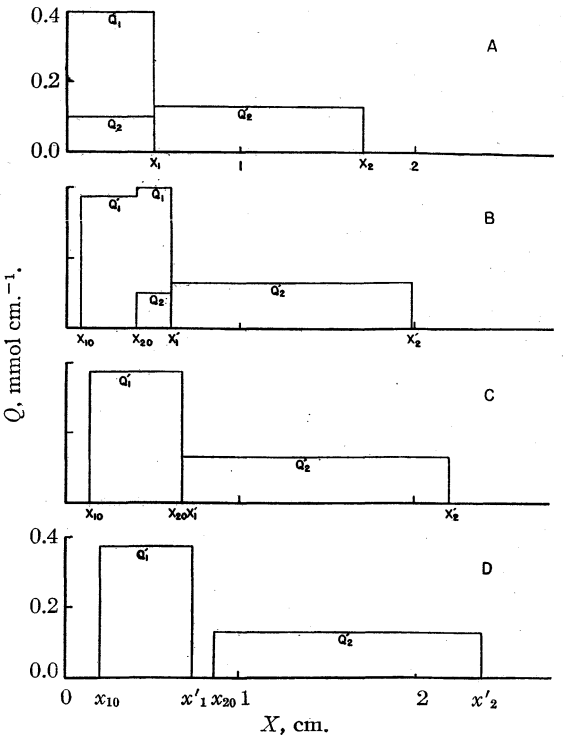

Fig. 2.—Stages in the development of a two-solute chromatogram, after various volumes V of developing solvent have passed through the column: A, $V = 0$; B, $V = 2.00$ cc.; C, $V = 3.33$ cc.; D, $V = 5.00$ cc. X is the vertical distance measured from the top of the column.

because of diffusion, or because the leading edge of the band migrates too rapidly on account of a low rate of adsorption, or because the trailing edge of the band migrates too slowly on account of a low rate of desorption. All these effects will lead the edges of the band to become diffuse. The process of diffusion is probably the least important of the factors leading to broadening of the bands since its effects are automatically corrected to a considerable extent as development proceeds. It is likely that in many cases a solute which is adsorbed but slightly will also have a low rate of adsorption, so that the leading edge of its chromatogram should migrate too rapidly and become more and more diffuse. The effects arising from low rates of adsorption and desorption can be diminished by decreasing the rate at which liquid flows through the column, but as the rate of flow decreases the importance of diffusion effects increases.

A further complication is introduced by the fact that the flow of liquid through the column is not uniform. The liquid usually flows more slowly at

the center of the column than near the walls of the tube. It is difficult to eliminate this effect completely, though its importance can be reduced somewhat by careful packing of the column. As a result of the varying rate of flow the development of a chromatogram proceeds more rapidly near the wall of the tube than at the center, so that an initially uniform and approximately horizontal band becomes dome-shaped (concave downward). Diffusion can then occur in a radial direction in the column, and the effect of this diffusion is not corrected for in the process of development. As a consequence the colored band as it is observed through the wall of tube appears to become wider and both edges to become diffuse. When the column is removed from the tube and carefully sliced it is often found that the band is narrower and more sharply defined near the center of the column than near the periphery.

Some preliminary experiments have shown that the band widths and rates of development predicted by means of the theory from adsorption measurements are correct as to order of magnitude. In these experiments all adsorption data used were determined directly with the same adsorbent as was used in the chromatographic experiments. The value of α, the volume of voids per centimeter length of the column, was determined by measuring the length of the packed column filled by a measured volume of liquid. The experiments will not be described in detail because of the wide variation in adsorbent properties among samples of a given adsorbent obtained from different sources. The experiments were moreover of only an exploratory nature; a systematic study of the extent to which the predictions of the theory approximate the results of experiment has yet to be made.

The following results were obtained. The initial width of a band formed on alumina from a solution of picric acid in benzene was 10% greater than the width predicted from adsorption measurements; on the other hand, a band formed on alumina from an aqueous solution of methylene blue had a width three times the predicted value. In a test of the relation between the width of the band and its rate of migration on development, the observed rate of development was found to be about 80% of the predicted rate. In this experiment a solution of lycopene in a mixture of benzene and petroleum ether was used; the adsorbent was calcium carbonate. The width of the lycopene band did not remain constant, but increased from 2 mm. to 4 mm. while the band was migrating 15 mm.

The theory presented here differs qualitatively from earlier ideas about the subject in one important respect. The belief has been expressed by some authors that the first color zone of a mixed chromatogram contains, before development occurs, essentially only the most strongly adsorbed solute. According to the present treatment, on the other hand, the first color zone should contain some of each solute initially present, in proportions determined by the initial concentrations and the adsorption isotherms. That the latter conclusion is correct was verified by the following experiment. A chromatogram was prepared by pouring a large volume of an extract of dried grass in a mixture of petroleum ether and benzene into a large column packed with powdered sugar. Seven bands of various widths and colors were formed; the first was quite wide. The liquid was forced completely through the column, which was then dried and removed from the tube. The first color zone was cut from the column and repacked on top of a second narrower column freshly packed with powdered sugar. When the same solvent as was used in preparing the first chromatogram was poured through this new column, the same sequence of six color zones appeared below the top band as occurred below the top band in the original chromatogram; the intensities of color and the relative widths of the bands were moreover roughly the same as in the original band system, in accordance with the present theory.

The present theory is also applicable to capillary analysis. In capillary analysis the lower end of a vertical strip of porous paper is allowed to dip into a solution of colored solutes. The solution rises in the paper strip because of capillarity; if the solutes are adsorbed by the paper a chromatogram is formed at the lower end of the paper in accordance with equations 19. This chromatogram may then be developed by dipping the lower end of the strip of paper into pure solvent and allowing solvent to rise in the paper through the initial chromatogram.[7]

The present treatment also may be applied to the chromatographic technique developed by W. G. Brown.[8] In this technique the chromatogram is formed on a sheet of blotting paper pressed be-

(7) Schwab and Jockers, *Angew. Chem.*, **50**, 546 (1937).
(8) W. G. Brown, *Nature*, **143**, 377 (1939).

tween glass plates, the upper one of which has a small hole bored through the center. The solution is allowed to run into the blotting paper from a glass tube whose fine capillary tip passes through the hole in the upper plate and presses against the paper. The chromatogram spreads radially from the point of contact as center. If M' is the mass of blotting paper per square centimeter, Q' the number of millimoles adsorbed per square centimeter, and r the radius measured from the point of contact, the equations analogous to equation 7 and 11 become, for formation of the chromatogram

$$\left.\begin{aligned} 0 \leqslant r_2 < \frac{vc^0}{\pi M'f(c^0)} \quad & Q' = M'f(c^0) \\ r^2 > \frac{vc^0}{\pi M'f(c^0)} \quad & Q' = 0 \end{aligned}\right\} \qquad (25)$$

and for development of the chromatogram with a volume V of the same solvent

$$\left.\begin{aligned} 0 < r^2 < \frac{Vc^0}{\pi M'f(c^0)}, \quad & Q' = 0 \\ \frac{Vc^0}{\pi M'f(c^0)} < r^2 < \frac{(V+v)c^0}{\pi M'f(c^0)}, \quad & Q' = M'f(c^0) \\ r^2 > \frac{(V+v)c^0}{\pi M'f(c^0)}, \quad & Q' = 0 \end{aligned}\right\} \qquad (26)$$

Thus it is predicted that the area of the ring will remain constant, and that the band will become narrower as development proceeds. This prediction is usually not verified experimentally because of diffusion and the finite rates of adsorption and desorption. The equations 25 and 26 may be readily corrected to take into account the interstitial volume between the fibers of the paper, or extended to the case of a mixed chromatogram. If the interstitial volume is taken into account it readily can be shown that the area of the band should remain constant if the same solvent is used for development as was used in forming the chromatogram, but should change if a different solvent is used for development.

It remains to discuss the possibility of using the present theory to predict on the basis of known sorption isotherms whether or not a given adsorbent may be used for the chromatographic separation of a given set of solutes. In view of the approximation involved in the neglect of diffusion and of rates of adsorption and desorption, it is evident that only an approximate prediction can be made; the complete application of the theory requires moreover a knowledge of the dependence of the sorption isotherms on the concentrations of all solutes present. In most cases it is more difficult and tedious to acquire this knowledge than to determine empirically which adsorbents are useful for the separation. In case adsorption isotherms for solutions containing only single solutes are available, a rough prediction can be made by assuming that the solutes are independently adsorbed; the separations actually obtained will in general be better than those predicted on the basis of this assumption. A better approximation may be made by fitting the adsorption isotherm for each solute, using measurements made on solutions containing that solute alone, to a curve of the Langmuir type: $q_i/m = Ka_ic_i/(1 + a_ic_i)$. It is usually possible to fit adsorption data to such a curve over small ranges of concentration, especially at low concentrations, say from 0 to 0.01 mole per liter. A very rough approximation to the adsorption isotherms which apply to a solution containing a mixture of solutes may then be obtained by using the a_i's obtained in this way, assuming that in mixed solutions $q_i/m = Ka_ic_i/(1 + \Sigma_i a_ic_i)$. Calculations made in this way, in spite of their approximate nature, might be useful for instance in deciding on a suitable adsorbent with which to attempt the separation of amino acids resulting from protein hydrolysis.

Summary

A theory of chromatographic analysis has been developed on the basis of the assumption that equilibrium between solution and adsorbent is instantaneously established and that the effects of diffusion can be neglected. The theory accounts qualitatively for the separations effected in chromatographic analysis, for the uniformity of color in the adsorption bands, and for the sharpness of the edges of the bands. Some experimental evidence is presented to show that the theory provides a semi-quantitative description of chromatographic adsorption. A brief discussion is given of the factors which make quantitative agreement between the theory and experiment unlikely.

The Kinetic Decomposition of Ethyl Chlorocarbonate II. Foreign Gas Effects

BY A. R. CHOPPIN AND G. F. KIRBY, JR.

A study of the kinetics of decomposition of pure ethyl chlorocarbonate was published recently and the present report constitutes the second in this series. The effects of foreign materials on the rate constant have been considered in specific relation to their normal decomposition described in the previous report. The techniques employed were chosen to coincide as nearly as possible with those of the original investigation, thus minimizing errors of comparison.

The thermoregulation and reaction system were essentially as described in the previous article.[1] The reaction was investigated by a static method in an all-glass system. A glass diaphragm and an automatic pressure regulating device were used in following the rate of reaction.

Experimental

Before the first run with any gas each reaction cell was thoroughly cleaned and flamed. A small bulb containing ethyl chlorocarbonate was first sealed into the cell and the foreign gas supply attached to the cell through a small side arm. The cell was then alternately evacuated and rinsed with the gas to displace adsorbed molecules of air and water vapor. The gas was next admitted to the desired pressure and the reaction vessel sealed. The vessel was finally brought to the temperature of the bath and the reactant bulb broken with the glass enclosed hammer.

When liquids of high vapor pressure were used as foreign materials a similar procedure was followed. However, when the vapor pressure was too low for the effective utilization of this method solutions of the liquid in ethyl chlorocarbonate were prepared. These solutions were chosen by composition to give approximately the desired partial pressure of each component, introduced into bulbs, and discharged in the cell in the usual way. The substances were tested thoroughly for chemical interaction before this procedure was employed.

In some cases the foreign substance was admitted at room temperature and the gas laws used to predict its partial pressure at reaction temperature. In other cases the foreign gas was allowed to come to temperature equilibrium before breaking the reactant bulb. Checks between the two methods showed the error to be negligible.

Oxygen, carbon dioxide, hydrogen and nitrogen were purified in conventional washing procedures for certain runs. They were not refractionated, however. Commercial carbon tetrachloride, hexane and benzene were subjected to careful fractionation. Nitric oxide was prepared according to the method of Johnston and Giauque[2] and stored in a five-liter container. Because of the difficulty of separating nitric oxide from certain other oxides of nitrogen, particularly nitrous oxide, the effect of the latter compound on the reaction was investigated. For this purpose a cylinder of the commercial product was used without further purification.

Experimental Results

As previously reported[1] the temperature 175° is approximately in the middle of the measurable range and gives rate constants of a convenient magnitude. This temperature was used for the greater number of runs on foreign gas effects. The effects of foreign materials on the rate were catalogued by comparison with the values for the specific rate constant k obtained in the previous research, and checked by controls during the present investigation. Where low pressure runs were made this effect was taken into account in tabulating the effect of foreign materials.

Runs were first made in the presence of an excess of carbon dioxide for the purpose of testing the reaction for reversibility. No measurable equilibrium effect could be detected. However, the carbon dioxide molecules seemed quite effective in maintaining the rate. No appreciable decrease in the value of k was detected as long as the total initial pressure remained above 175 mm.

Nitrogen and oxygen were also quite effective in maintaining the high pressure energy distribution. Curves showing typical rates of decomposition in the presence of these gases are shown in Fig. 1. Curves also have been included to show the effects of benzene, carbon tetrachloride and hexane. As may be seen from Table I, hexane increases the rate slightly while benzene and carbon tetrachloride show slight depressions. The effect is so slight that they may be regarded as relatively inert.

For many reactions hydrogen has been found quite effective in maintaining the rate at low pressures of reactant. In the case of ethyl chlorocarbonate, however, hydrogen fails to fulfill this function. It is less effective than any of the previously mentioned gases.

Chlorine exhibits a positive catalytic effect which does not seem to be directly proportional to the amount of chlorine present. Analyses of the products indicated no change in the nature of

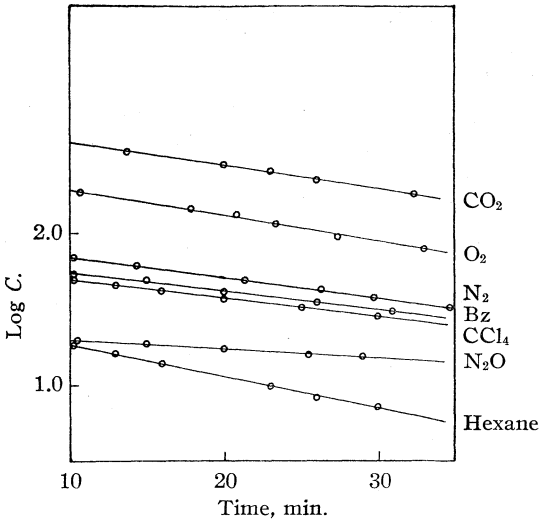

Fig. 1.

the reaction. It will be noted from Table I that the specific rate constant is more than doubled. The reaction definitely does not follow a first order rate over the first ten minutes. During this period the rate was more nearly second order with respect to the reactant. However, no good agreement for either was obtained over appreciable periods of time. Since the degree of catalysis does not seem to vary with the partial pressure of chlorine, one might conclude that the action takes place at the walls with adsorbed chlorine atoms acting as active centers. Thus a condition of saturated adsorption might govern the extent of catalytic action.

Ethyl chlorocarbonate is known to undergo both ammonolysis and hydrolysis. In the liquid state these reactions take place at the phase boundary, the reaction with aqueous ammonia proceeding quite rapidly and that with water at a much slower rate. At 175° the hydrolysis proceeds quite rapidly and the products slightly catalyze the thermal decomposition of any ethyl chlorocarbonate in excess. The presence of simultaneous reactions is apparent, and the initial stages can be described by neither a first nor second order rate. In view of the difficulty of separating these reactions the calculations of rate give at best a qualitative picture of the process, indicating principally the final effect of the bimolecular products upon the unimolecular reaction.

Inhibition by nitric oxide has been widely used as a test for one type of chain mechanism. Hinshelwood[3] has found low partial pressures quite

(3) Staveley and Hinshelwood, *J. Chem. Soc.*, 1568 (1937).

effective in suppressing the rates of a number of reactions proceeding through aliphatic free radical mechanisms. Pressures of nitric oxide of the order of 1 or 2 mm., suggested as being sufficient to seriously alter the reaction rate, were found to have no effect in the present case. As the partial pressure of nitric oxide was increased, however, a period of induction was observed. The length of the induction period varied with the partial pressure of nitric oxide (Fig. 2). At the end of the initial inhibition the reaction proceeded with a velocity greater than normal. Rate constants obtained for this region showed a consistent increase over normal values. Considering the high partial pressures of nitric oxide which caused this effect and the general unfavorable conditions for radical production, the indicated mechanism is some transient chemical interaction between the gas and the reactant. A catalytic effect of large partial pressures of nitric oxide has been observed in the decomposition of a number of compounds.[4,5,6]

In view of the difficulty of obtaining nitric oxide free from traces of nitrous oxide several runs were made with nitrous oxide to determine its effect on the reaction. Smooth curves were the result, with rates slightly depressed.

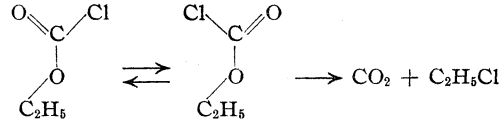
Discussion of Results

The observations cited above indicate a mechanism of extreme simplicity. This conclusion was first strongly implied by the quantitative decomposition of ethyl chlorocarbonate to carbon dioxide and ethyl chloride. Chemical analyses of these products have been further supported by spectrographic investigations.[7] No evidence of chlorine or phosgene could be obtained. Furthermore, ethyl chlorocarbonate does not absorb in the visible and the first appreciable ultraviolet absorption occurs with a continuum beginning in the region of 2500 Å.

The temperature at which decomposition takes place and the low energy requirement seems to preclude the possibility of an initial disruption into unstable fragments since the activation energy is lower by at least 40,000 cal. than any of the minimum bonding energies that might be involved. In addition to this the wall effects are negligible, the reaction proceeds smoothly over a wide range of pressures and in most cases there is no marked inert gas effect.

These facts seem to point to a mechanism involving an internal rearrangement with the elimination of carbon dioxide. The structure of ethyl chlorocarbonate as established by dipole measurements is in accord with such a mechanism.[8,9] The following resonating structures have been proposed by earlier investigators:



The work being carried on in this Laboratory, it is hoped, will be of value in establishing the significance of any structural changes insofar as they affect the decomposition.

Summary

The decomposition of ethyl chlorocarbonate has been investigated with regard to foreign materials. The products of the decomposition and a number of chemically inert gases are effective in maintaining the high pressure rate. The reaction is catalyzed by chlorine and, after a slight period of induction, by nitric oxide.

The kinetic results indicate a decomposition mechanism of a simple nature, probably involving an internal rearrangement with the elimination of carbon dioxide.

Dialkylacetyl Biurets

BY ARTHUR J. HILL AND WILLIAM M. DEGNAN[1]

In spite of the considerable success of the hypnotics of the acetamide, acyl urea, and barbituric acid types, a need still exists for less toxic compounds with hypnotic properties. The structural features which appear to account for the pharmacological action of the above-mentioned compounds are two: one or more -CONH- groups, and branched-chain alkyl groups whose function is apparently to confer high lipoid-solubility on the molecules of which they are a part. Biuret, $NH_2CONHCONH_2$, has the significant -CONH- group repeated within its structure, and furthermore has been demonstrated to have a very low toxicity. It was to be expected, therefore, that acyl biurets containing branched-chain alkyl groups might combine high hypnotic effectiveness with low toxicity. Accordingly a number of dialkylacetyl biurets were prepared with a view to the study of their pharmacological properties. The dialkylacetyl groups were chosen for their demonstrated value in the acetamide and acyl urea series.

A survey of the literature shows that two approaches to the acyl biurets have been most extensively employed. Acetyl, benzoyl, and phenacetyl biurets have been prepared by the direct acylation of biuret with the acid chlorides[2,3,4,5] and benzoyl biuret has been prepared by the treatment of urea with benzoyl chloride in the presence of pyridine.[4,6] However, attempts to reproduce these results, and to extend the method to the preparation of dialkylacetyl biurets, were disappointing, the yields being very low. Attention was therefore directed to the development of a new synthesis of acyl biurets.

The work of Billeter[7] on the preparation of acyl isocyanates, and the reaction of these compounds with amines and alcohols, together with a number of patents[8,9,10,11] on the preparation of acyl ureas and acyl urethans by these reactions, suggested the possibility of carrying out the reaction

$$RCONCO + R'NHCONH_2 \longrightarrow RCONHCONHCONHR'$$

Accordingly, a series of dialkylacetyl isocyanates was prepared by the modification of Billeter's method patented by Baeyer and Co.,[12] and these isocyanates were allowed to react with urea, substituted ureas, and thiourea, in ether or benzene suspension, and the desired biurets were obtained in yields as high as 83% of the theoretical.

Experimental

Dialkylacetyl Chlorides.—The dialkylacetic acids used were prepared by the method of Levene and Cretcher,[13] with the exception of phenylethylacetic acid, which was prepared by the saponification and subsequent decarboxylation of phenylethylmalonic ester. The acids were converted to the corresponding acid chlorides by allowing them to stand with a 100% excess of thionyl chloride for twelve hours, then refluxing to complete the reaction. The acid chlorides were purified by distillation through a packed column under vacuum.

Dialkylacetyl Isocyanates.—The appropriate acid chloride was dissolved in five volumes of carefully dried diethyl ether and added slowly during stirring to a slight excess of freshly prepared silver cyanate suspended in dry ether. A round-bottomed flask fitted with a sealed stirrer and a reflux condenser carrying a calcium chloride tube was found to be convenient as a reaction vessel. In every case reaction commenced spontaneously and was completed by refluxing the reaction mixture gently for one to three hours. The suspension was then quickly filtered through a Büchner funnel to remove the silver chloride, and the ether was removed from the filtrate in the usual manner. The resi-

TABLE I[a]

Acyl isocyanate	B. p., °C.	Yield, %

due was then distilled under vacuum. The isocyanates must be carefully protected from moisture throughout the course of preparation and purification, as they react vigorously with water to give the corresponding acetamides and carbon dioxide. The yields in this preparation ranged from 40–90%. Table I lists the acyl isocyanates prepared.

Substituted Ureas.—Monoethyl and diethyl urea were prepared by the nitrourea dearrangement method of Davis and Blanchard.[14] Other ureas were prepared by the conventional treatment of the amine hydrochlorides with potassium cyanate.

Dialkylacetyl Biurets.—These compounds were prepared by the reaction of the appropriate isocyanate with urea or a substituted urea in diethyl ether or petroleum ether. The general technique employed was as follows: the urea was suspended (or dissolved where soluble) in dry ether or petroleum ether in an Erlenmeyer flask. Slightly less than one equivalent of the acyl isocyanate dissolved in dry ether was then added quickly. A reflux condenser carrying a calcium chloride tube was attached to the flask and the suspension (or solution) was refluxed gently until the characteristic odor of the isocyanate had disappeared. The heating time varied from three to forty-eight hours. When reaction was complete the suspension (or solution) was cooled and filtered if the product appeared only slightly soluble in cold ether, or the ether was removed by distillation if the product appeared appreciably soluble. The residue was then crystallized from hot water, hot alcohol, or hot dilute alcohol. Two recrystallizations usually sufficed.

Dialkylacetyl Thiobiurets.—It was found that the dialkylacetyl isocyanates reacted slowly or not at all with thiourea at the temperature of boiling ether, so reactions in this series were carried out in boiling benzene. Thiourea was suspended in dry benzene and exactly one equivalent of the isocyanate was added. The suspension was heated for twelve hours, during which time the thiourea disappeared and a clear yellow solution with a characteristic unpleasant odor was formed. This was cooled in an ice-bath to precipitate a jelly-like material which was filtered off with some difficulty. Attempts to crystallize this crude product from water, alcohol, dilute alcohol, benzene, and dilute acetone failed, amorphous solids being obtained in each case. The acyl thiobiurets were purified by dissolution in cold alcohol, followed by precipitation by the addition of an equal volume of cold water. Several repetitions of this operation gave products which melted sharply. The acyl thiobiurets were obtained as slightly yellow amorphous powders with marked pyroelectric properties. Yields in this series were low, due primarily to handling losses during purification.

Table II lists the acyl biurets prepared. Benzoyl biuret and phenacetyl biuret are not new, having been prepared primarily for comparison with the products reported by Ostrogovich and his co-workers.[3,5] Benzoyl biuret prepared from the isocyanate was shown by mixed melting point to be identical with a sample prepared by the direct benzoylation of biuret with benzoyl chloride.

[a] Previously reported. [b] Crystallized from glacial acetic acid.

Pharmacological Results

Preliminary pharmacological tests[15] indicate that these compounds compare favorably with sodium barbital in hypnotic effectiveness. They do not show any anesthetic (depressor) action. The toxicities of these compounds, with the exception of those of the thiobiurets, are remarkably low; doses as high as 500 mg./kg. have no permanent ill effects on the test animals. The presence of branched chains in the acyl radical increases effectiveness. Alkylation in the 5-position of the biuret chain also increases effectiveness, 1-diethylacetyl-5,5-cyclopentamethylene biuret being the most active of the compounds tested.

Summary and Conclusions

1. A series of acyl biurets, including dialkylacetyl biurets, 1-dialkylacetyl-5-alkyl biurets, alkylarylacetyl biurets, and 1-dialkylacetyl-4-thiobiurets, has been synthesized by the reactions of appropriate acyl isocyanates upon urea, substituted ureas, and thiourea.

2. Preliminary pharmacological investigation indicates that these compounds possess a moderate hypnotic activity, accompanied by extremely low toxicity. The high margin of safety afforded would indicate that members of this series should be valuable sedatives.

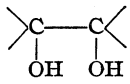
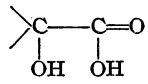
Oxidative Cleavage of α-Keto Acids and α-Keto Alcohols by Means of Lead Tetraacetate

BY ERICH BAER

In 1930 and 1931 Criegee[1] reported the possibility of splitting glycols into aldehydes and ketones by oxidation with lead tetraacetate in absolutely dry solvents. The usefulness of this reaction has been considerably increased by the recent observation of Baer, *et al.*,[2] that, where the rate of reaction between glycol and oxidizing agent is sufficiently rapid, the same operation may be carried out successfully in water, or in organic solvents containing water. Nevertheless, the method was still confined to compounds which *already contained* a pair of adjacent hydroxyl groups as exemplified by glycols (I) or α-hydroxycarboxylic acids (II).



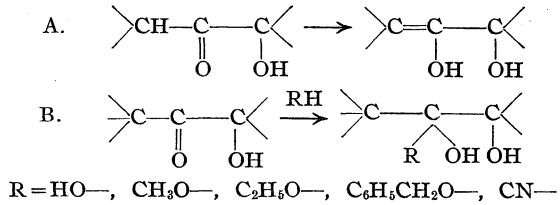
(I)



(II)

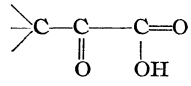
Very little has been published[3] however, concerning the extension of this technique to compounds which were not glycols, but whose structure would permit the formation of adjacent hydroxyl groups. Examples of such a type could be expected among compounds containing vicinal keto-hydroxyl groups which might be able to form the necessary hydroxyls either by enolization (reaction A) or, by addition to the keto group of water, alcohols (*e. g.*, methyl alcohol, ethyl alcohol, benzyl alcohol) or hydrocyanic acid, etc. (reaction B).

An indication of the possibility of such oxidative cleavage is to be found in two papers by Baeyer[4] in which are described the conversion of

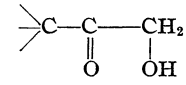


keto-isocamphoronic acid into dimethyl tricarballylic acid, pinoyl-formic acid into pinic acid and homoterpenoyl-formic acid into homoterpenylic acid by oxidation with lead peroxide in the presence of acetic or sulfuric acid. These reactions are probably to be interpreted as oxidative cleavages induced by the intermediary formation of lead tetraacetate or plumbic disulfate.

From the great variety of compounds which could conceivably form two adjacent hydroxyl groups according to reaction A or B, a few representatives of the α-ketocarboxylic acids (III) and the α-keto alcohols (IV) (with aliphatic and aromatic substituents) have been chosen as experimental material.



(III)



(IV)

The substances examined were pyruvic acid, phenylpyruvic acid, trimethylpyruvic acid, and phenylglyoxylic acid; acetyl-methylcarbinol, benzoylcarbinol, benzoin and anisoin. Their ability to enter into cleavage reactions with lead tetraacetate has been studied, and the results of the investigation constitute the subject matter of this paper.

After it had been established that under certain conditions all these substances are split by lead tetraacetate, an attempt was made to obtain a more detailed understanding of the reaction. The main point at issue was whether a pair of adjacent hydroxyl groups is actually necessary for cleavage. Secondly, if so, which of the above-mentioned possibilities (A or B) describes their formation? Finally, does the cleavage of the resulting "pseudoglycol" follow the same mechanism which Criegee postulated for the splitting of α-glycols?

(1) Criegee, *Ann.*, **481**, 275 (1930); *Ber.*, **64**, 260 (1931); *Angew. Chem.*, **50**, 153 (1937).

(2) E. Baer, J. Grosheintz and H. O. L. Fischer, THIS JOURNAL, **61**, 2607 (1939).

(3) The present investigation of the cleavage of α-keto alcohols was completed and nearly ready for publication when a paper entitled "Über durch Pervanadinsäure katalysierte Oxydationen" was published by W. Treibs (*Ber.*, **72**, 1194 (1939)) in which he mentioned, in support of his theory on the oxidation and cleavage of saturated cyclic ketones by H_2O_2, that he had succeeded in splitting an α-keto alcohol (benzoin) by lead tetraacetate into benzoic acid and benzaldehyde. However, he gave no experimental data in the above-mentioned paper. Apparently Treibs did not recognize the mechanism involved in the cleavage of α-keto alcohols and α-keto acids with lead tetraacetate, *viz.*, the necessity of forming a pair of new adjacent OH groups as the initial step in this reaction, when he asserts that α-keto acids are not cleavable by lead tetraacetate. Since considerable time has now elapsed and Treibs' experimental data have not yet appeared, it has been decided to publish the paper which was written at that time.

(4) A. Baeyer, *ibid.*, **29**, 1916, 1919, 2792 (1896).

The elucidation of the first two questions is closely connected and they have been investigated together. It is well-known that α-keto acids and α-keto alcohols may form enols or addition compounds, and therefore it seemed equally possible that the cleavage could occur through the enol forms or through the addition products of the keto forms.

To distinguish between these two possible reaction courses we were guided by the following considerations. If it can be shown that oxidative cleavage does not take place when conditions allow the formation of enol forms, but does occur as soon as substances capable of forming pseudoglycols by addition are supplied, the probability of the first alternative being correct may be considered very slight. The second alternative will be further supported if α-keto compounds which are unable to form enols because of their lack of an enolizable hydrogen atom adjacent to the keto group (*e. g.*, trimethylpyruvic acid, phenylglyoxylic acid) undergo an oxidative cleavage in the presence of glycol-forming substances, but not in their absence.

The experiments, therefore, were carried out so that in each case the α-keto acid or α-keto alcohol was dissolved in an indifferent solvent and brought into contact with lead tetraacetate in the absence of water or any other glycol-forming substance. If no significant amount of cleavage (*e. g.*, enol cleavage) or consumption of oxidizing agent had been detected after a definite time interval, then water, an alcohol, or hydrocyanic acid was added. The products of cleavage of the addition compound so formed were determined quantitatively where practicable or in other cases isolated as completely as possible and identified.

The investigation of the action of lead tetraacetate upon keto acids was particularly simple by reason of the ease with which one of the products of the reaction, carbon dioxide, could be determined quantitatively. For this operation, the keto acids were dissolved in glacial acetic acid, lead tetraacetate was added, and the carbon dioxide evolved was measured gravimetrically or volumetrically. All four of the keto acids examined yielded, with lead tetraacetate alone, only a trivial amount of carbon dioxide. The evolution of gas always came quickly to a complete standstill, and never amounted to more than 5–10% of the theoretical. It was probably caused by unavoidable traces of moisture in the solvents or the reagents, or adsorbed on the walls of the reaction vessel (see blank values in experiments II (1a, 2a, 3a); III (1a, 2a, 3a); IV (1a, 2a); V (1a). After a considerable time only a small amount of the keto acid and lead tetraacetate were used up. The addition of water, methanol, ethanol, benzyl alcohol, or hydrocyanic acid to the same mixture caused an almost instantaneous and complete cleavage of the α-keto acids. The cleavage reaction yielded 1 mole of carbon dioxide (Expt. II (1a, 2a, 3a); III (1a, 2a); IV (1a, 2a); V (1a)) for each mole of keto acid consumed and required 1 mole of lead tetraacetate (Expt. II (1c); III (1c); IV (1c); V (1c); VI (1b); VIII (1c); IX (1c)).

The compounds other than carbon dioxide resulting from the cleavage of the α-keto acids were determined by repeating the experiments as before, but using larger quantities so that the products could be isolated. According to the nature of the glycol-forming substance supplied the oxidative cleavage yielded either the free acid (Expt. III (1b); IV (1b); V (1b), its ester (Expt. II (3b); III (3); IV (2b)), or the nitrile of the original keto acid (Expt. IV (3)). These were in most cases easily isolated in good yield. However, the figures given in the experimental part obviously represent the lower limits of the actual quantities formed, because of some unavoidable losses in the isolation processes.

The presence of acetic acid arising from lead tetraacetate during the reaction made it difficult to detect the acetic acid or trimethylacetic acid expected as cleavage products of pyruvic acid and trimethylpyruvic acid, respectively. In these two cases the oxidative cleavage was carried out in benzene and in the presence of benzyl alcohol, so that instead of the free acids, their benzyl esters, which are easily isolated, resulted. These compounds as well as the silver salts, obtained by treatment of their saponification products with silver nitrate, served to identify the cleavage products as acetic or trimethylacetic acid, respectively.

The only exception to the normal course of the keto acid cleavage so far observed occurred in the case of phenylpyruvic acid. The cleavage product of this compound, to be analogous to those of the other keto acids, should have been phenylacetic acid. However, the cleavage required 2 moles of lead tetraacetate, and no crystal-

line product could be isolated. Since saponification gave mandelic acid, the original cleavage product was probably acetylmandelic acid. To explain its formation we may assume that the lead tetraacetate simultaneously effected the oxidative cleavage and an acetylation of the —CH_2— group, situated as it is between two strongly negative substituents. Similar acetylations caused by lead tetraacetate are already known, *e. g.*, that of acetoacetic ester.[5] Phenylpyruvic acid was the only keto acid of this type investigated. However, it may be expected that the cleavage of other acids of the same type will also yield derivatives of hydroxy acids. Since the hydroxy acids which would be obtained by saponification can easily be converted into aldehydes by a further oxidative reaction with lead tetraacetate, it is possible to obtain from this type of α-keto acids, aldehydes with two carbon atoms less (Equation C).

$$\text{(C)}\quad RCH_2COCOOH \xrightarrow[+\ \text{saponification}]{2Pb(OAc)_4} RCHOHCOOH \xrightarrow{Pb(OAc)_4} RCHO$$

The investigation of the α-keto alcohols was carried out as outlined above. Here, as before, the effect of lead tetraacetate on the keto compounds was first examined in dry solvents and in the absence of any glycol-forming substances. Contrary to the experience with keto acids, a slow consumption of oxidizing agent was observed. After the lead tetraacetate had completely disappeared, attempts to recognize the product of the reaction led to the isolation of the direct oxidation products of the keto alcohols—their diketones—which were obtained in good yields, but no more than traces of cleavage could be detected (see Expt. X (a, b, c)).

However, when the experiments were conducted so that the lead tetraacetate was added to the solutions of the α-keto alcohols in the presence of hydroxyl-forming substances (*e. g.*, water or alcohol) then the oxidative cleavage occurred at once and the two cleavage products, 1 mole of acid or its ester and 1 mole of aldehyde or ketone, could be isolated either as such or in the form of derivatives (see Expts. VI, VII, VIII, IX).

In the case of α-keto alcohols the oxidative cleavage and the direct oxidation tend to occur simultaneously. In the presence of glycol-forming substances the cleavage reaction predominates; in the absence of such substances the direct oxidation becomes the main reaction but proceeds far more slowly than does the above cleavage reaction.

The results of the experiments may be summarized thus. In the *absence* of hydroxyl-forming substances α-keto acids are not attacked by lead tetraacetate, while α-keto alcohols are oxidized slowly to their corresponding diketones. In the *presence* of hydroxyl-forming substances α-keto acids and α-keto alcohols undergo rapid oxidative cleavage.

These observations can probably be best interpreted as follows.

For the occurrence of oxidative cleavage of α-keto acids and α-keto alcohols the initial formation of a pair of adjacent hydroxyl groups is necessary. These glycols (or pseudoglycols) are formed by the addition of water, alcohols, or hydrocyanic acid to the keto group according to reaction B.

The oxidative cleavage of the keto compounds takes place, therefore, through their pseudoglycol forms and not, or only to an insignificant extent, through their enol form.

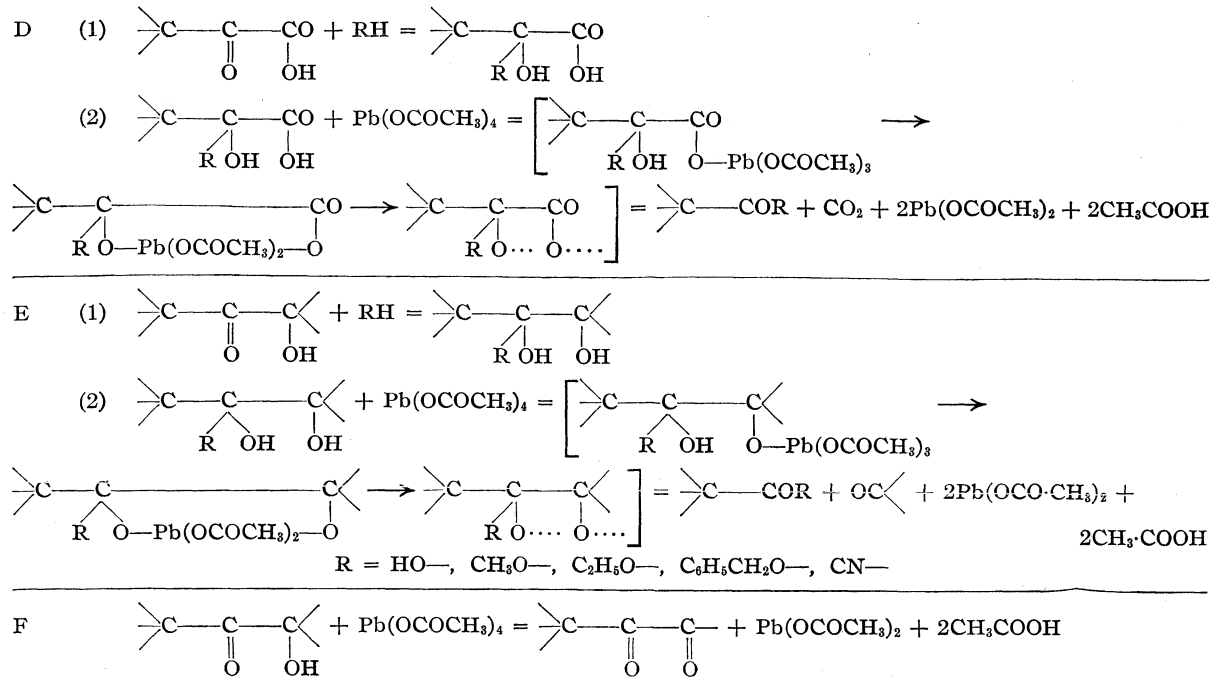
Further support for this view is the fact that trimethylpyruvic acid and phenylglyoxylic acid, which, by reason of their lack of enolizable hydrogen atoms cannot form an enol, are split by lead tetraacetate only in the presence of glycol-forming substances.

From the fact that the oxidative cleavage of α-keto acids and α-keto alcohols takes place only after the formation of a glycol, and from the nature of the resulting products, it may be assumed that the actual cleavage reaction is brought about by the same mechanism as the typical glycol cleavage produced by the action of lead tetraacetate. The fact that the cleavage products of pseudoglycols are in part different from those of true glycols does not invalidate the assumption as to the parallelism of the two reaction mechanisms, but is a natural consequence of the varying degrees of oxidation of the starting materials.

If one attempts to apply Criegee, Kraft, and Rank's[6] proposed reaction mechanism to formulate the course of the cleavage reaction following the initial formation of the two adjacent hydroxyl groups (D, 2; E, 2), a combination of the pseudoglycols with tetravalent lead must be assumed. According to Criegee these lead compounds induce the formation of biradicals which then

(5) O. Dimroth and R. Schweizer, *Ber.*, **56**, 1380 (1923).

(6) R. Criegee, L. Kraft and B. Rank, *Ann.*, **507**, 159 (1933).



decompose spontaneously into the end-products. The lead compounds assumed as intermediate stages are probably short-lived and have not yet been isolated. Their detection not only would have constituted a support for Criegee's scheme, but would have demonstrated also the close relationship between the two reactions. A substance which precipitated when lead tetraacetate was added to a solution of phenylglyoxylic acid in dry acetic acid, and which at first was suspected of being such an intermediate compound, was found later to be the plumbous salt of the starting material (Expt. IV (1)).

Even though the proof is lacking that the oxidative cleavage of pseudoglycols by lead tetraacetate proceeds through intermediate compounds similar to those postulated by Criegee for the cleavage of true glycols, the equations D and E include the assumed intermediary compounds which are placed in brackets.

The possible application of the use of lead tetraacetate to split α-keto acids and α-keto alcohols may simplify the solution of a number of problems concerning chemical constitution or tautomerism just as Criegee's glycol cleavage has proved very valuable for solving similar problems. An example of such an application where the use of lead tetraacetate would constitute a considerable simplification, is that of the tau- reactions of 1,2-ketols investigated by v. Auwers, Ludewig, Müller, Pötz and Noll.[7] In this case, the presence of substance I or II even in a mixture should be easy to detect and to determine on the basis of the cleavage products obtained by oxidation with lead tetraacetate in the presence of water as shown in equations G and H.

(G) $C_6H_5COCH(OH)CH_3$ (I) $\xrightarrow{Pb(OCOCH_3)_4,\ H_2O}$ $C_6H_5COOH + CH_3CHO$

(H) $C_6H_5CH(OH)COCH_3$ (II) $\xrightarrow{Pb(OCOCH_3)_4,\ H_2O}$ $C_6H_5CHO + CH_3COOH$

Another use of this reaction with lead tetraacetate is the detection of compounds which it is seldom possible to isolate. For example, the formation of addition products of water or alcohols with the keto group of α-keto alcohols and α-keto acids, which can be considered as hydrates or semiacetals, is often problematical. However if a mixture containing such components be subjected to an oxidative cleavage, the nature of the decomposition products will show whether or not formation of addition products has occurred.

A further practical application is the quantitative determination of α-keto acids by measurement of the carbon dioxide evolved during oxidative cleavage with lead tetraacetate.

The same reaction may be used to differentiate α-keto acids qualitatively from β-, γ-, etc., keto

(7) Von Auwers, H. Ludewig and A. Müller, *Ann.*, **526**, 143 (1936); v. Auwers, H. Pötz and W. Noll, *ibid.*, **535**, 219 (1938).

acids since in such an analogous series only the alpha-keto acids evolve carbon dioxide. To carry out this operation the acid is dissolved in as little water, or water-containing acetic acid, as possible and lead tetraacetate added. The evolution of carbon dioxide indicates the presence of an alpha-keto acid.

The investigation is being extended to other classes of compounds which should be capable of cleavage by application of the same principle.

Experimental

α-Keto Acids

I. Methods of Following Oxidative Cleavage

The cleavage reactions to be described give rise to carbonic acid and an organic acid or an acid derivative. The reactions may, therefore, be followed quantitatively by determining the carbon dioxide evolved, and qualitatively by identifying the second acid (or its derivative). The procedures used are described in detail below.

(1). Quantitative Determination of Carbon Dioxide (Gravimetric).[8]—The quantitative determination of carbon dioxide evolved during the oxidative cleavage was carried out by passing a slow current of dry, carbon dioxide-free air through the reaction flask to sweep the evolved gas into an absorption vessel. By means of gentle suction, air was drawn through a train assembled as follows: (1) a potassium hydroxide solution and calcium chloride tube; (2) the reaction vessel (a 125-cc. Erlenmeyer flask, with 3-holed rubber stopper, carrying a dropping funnel and the inlet and outlet tubes); (3) a U-tube filled with calcium chloride and kept at −10°; (4) a weighed absorption vessel for the quantitative determination of carbon dioxide. A weighed amount of the substance was placed in the dry reaction flask and absolutely water-free acetic acid and lead tetraacetate were added through the dropping funnel. The mixture was warmed to 50° while a slow stream of air was drawn through the apparatus. Since, for the establishing of the pseudoglycol theory, it was just as essential to prove the non-evolution of carbon dioxide in the absence of hydroxyl-forming substances as it was to determine the quantity of carbon dioxide produced in their presence, such a blank experiment always preceded the actual test run. The increase in weight of the carbon dioxide absorption vessel was measured after thirty minutes. The amount of carbon dioxide found in the absence of hydroxyl-forming substances was in all cases only a small per cent. of the total and was probably due to unremovable minute traces of moisture in the apparatus, in the substance, or in the solvent. After the apparatus was reassembled, water (or anhydrous hydroxyl-forming substances under investigation) was allowed to flow into the decomposition flask which was warmed to 50° while air was drawn through the apparatus until the weight of the carbon dioxide absorber remained fairly constant (forty to sixty minutes).

(2) Identification of the Second Acid.—It is impossible to describe a general procedure for the isolation and identification of the second product of the oxidative cleavage reactions. These will be dealt with under the individual headings which follow.

II. The Oxidative Cleavage of Pyruvic Acid in the Presence of Hydroxyl-forming Compounds

(1) Water as the Hydroxyl-forming Component.—**(a) Quantitative determination of carbon dioxide:** 0.3517 gram of water-free pyruvic acid (distilled several times) dissolved in 10 cc. absolutely dry acetic acid yielded, after addition of 2.8 g. of finely pulverized dry lead tetraacetate 11.8 mg. of carbon dioxide. Upon adding 10 cc. of water, oxidative cleavage occurred immediately as indicated by the visible evolution of carbon dioxide. The reaction was completed in a few minutes. After thirty minutes the increase in weight of the carbon dioxide apparatus was 169.8 mg. Calcd. amount carbon dioxide: 175.8 mg. Found: 181.6 mg., 103.2%.

(b) The second cleavage product, according to theory, would be acetic acid, which naturally cannot be detected in the presence of the large amount of acetic acid present as solvent.

(c) Determination of Lead Tetraacetate Required for the Cleavage of 1 Mole of Pyruvic Acid.—A mixture of 10 cc. of 0.1 *M* pyruvic acid (in glacial acetic acid), 30 cc. of 0.05 *M* lead tetraacetate (in glacial acetic acid) and 5 cc. of water or 5 cc. of methyl alcohol was kept at 50° for one hour. The decrease of lead tetraacetate was determined by back-titrating the excess of oxidizing agent with 0.1 *N* thiosulfate after addition of 75 cc. of a solution of potassium iodide and sodium acetate (20 g. of potassium iodide and 500 g. of sodium acetate made up to 1 liter); 21.5 cc. of 0.05 *M* lead tetraacetate solution was used up in the presence of water and 20.5 cc. in the presence of methyl alcohol, which is equivalent to 1.07 mole and 1.02 mole of lead tetraacetate, respectively, per 1 mole of keto acid oxidized.

(2) Methyl Alcohol as the Hydroxyl-forming Component.—(a) The oxidative cleavage of pyruvic acid in the presence of methyl alcohol was carried out in the same way as described in (II, 1a). 0.3651 gram of keto acid yielded 9.9 mg. of carbon dioxide; after addition of 10 cc. of water-free methyl alcohol a further 175.4 mg. of carbon dioxide was produced; total carbon dioxide, 185.3 mg. (101.5% of the theoretical).

(b) The isolation of the second product, methyl acetate, from a large excess of free acetic acid and methyl alcohol was not tried because of the obvious experimental difficulties.

(3) Benzyl Alcohol as the Hydroxyl-forming Component.—(a) The same method was used for the cleavage of pyruvic acid in the presence of benzyl alcohol: 0.3268 g. of pyruvic acid yielded 14.2 mg. of carbon dioxide. After addition of 0.8 g. of absolutely dry benzyl alcohol, a further 143.2 mg. of carbon dioxide was liberated in one hour; total, 157.4 mg. of carbon dioxide (96% of the theoretical).

(b) The isolation of the second product, benzyl acetate, was possible because of its high boiling point. By using

(8) If a Warburg apparatus is available the reaction may be followed by a volumetric measurement of the evolved carbon dioxide. The gas is liberated almost instantly. This volumetric procedure has the advantage that only very small quantities (about 0.5 mg.) of reactants are required; moreover, the time necessary for the determination is only a small fraction of that necessary for the gravimetric procedure.

anhydrous benzene as the solvent, it was possible to prove that the acid required by theory (acetic acid) is indeed the acid obtained by the oxidative cleavage of pyruvic acid.

To a solution of 1.76 g. (1/50 mole) of absolutely dry pyruvic acid[9] and 2.16 g. (1/50 mole) of absolutely dry benzyl alcohol in 50 cc. of water-free benzene[10] was added 9.3 g. (1/50 mole + 5%) of lead tetraacetate. The temperature of the solution rose from 24 to 40°, carbon dioxide was evolved and lead acetate precipitated. After one hour the lead tetraacetate was almost used up, carbon dioxide evolution had stopped and the mixture had returned to its initial temperature. After standing overnight the solution was decanted from the lead salt; the salt was washed with benzene and the combined benzene solutions were concentrated. The concentrate was diluted with ether, allowed to stand for a while, then filtered and concentrated again. The residue was fractionally distilled first *in vacuo* and then under normal pressure. The last distillation yielded two fractions: (1) b. p., 170–179°, *ca.* 0.3 g; (2) b. p., 202–212°, *ca.* 1.4 g., $n^{21}D$ 1.5150. Fraction (1) was identified as benzaldehyde by its b. p., odor and the m. p. of the *p*-nitrophenylhydrazone (192°). Fraction (2) judging by its b. p., refractive index and saponification number was fairly pure benzyl acetate. The corrected yield (1.2 g.) of benzyl acetate corresponds to 40% of the theoretical. Final proof of the identity of the acid formed from pyruvic acid in the oxidation was obtained by saponifying the benzyl ester (fraction 2) with aqueous alcoholic potassium hydroxide solution. After evaporation of the solvent the residue was acidified with sulfuric acid and the volatile acid was distilled over with the water. Water was added to the residue and the distillation was repeated until the distillate was no longer acid. The combined distillates were neutralized with barium hydroxide, concentrated *in vacuo* to a small volume and by addition of a concentrated silver nitrate solution, the silver salt of the acid was precipitated. The silver salt, recrystallized from water and dried in high vacuum, was found to contain 64.3% silver; calculated for silver acetate 64.6% silver. From 1.40 g. of fraction (2) was obtained 1.24 g. of silver acetate. In order to ascertain that the benzyl acetate (fraction 2) obtained in experiment II 3(b) was actually the product of the reaction between pyruvic acid, benzyl alcohol and lead tetraacetate, and not formed by the action of lead tetraacetate on benzyl alcohol, the experiment was repeated without pyruvic acid. After standing for forty-eight hours at room temperature, the mixture was worked up as described previously. After concentration of the solution by distilling off the ether and benzene, the residue obtained was separated into three fractions by distillation *in vacuo:* (1) b. p. (7 mm.) 62–64°, 0.45 g. (chiefly benzaldehyde, identified as *p*-nitrophenylhydrazone, m. p. 192–193°; (2) b. p. (7 mm.) 85–100°, 0.65 g. (chiefly unchanged benzyl alcohol containing a small amount of a benzyl ester); (3) a higher boiling residue which was not examined further.

The crude silver salt obtained from fraction 2 weighed 0.18 g., (which would correspond to 0.16 g. of benzyl acetate, *ca.* 5% of the theoretical). The silver content of this salt revealed it to be slightly impure silver acetate. The above blank showed, therefore, that in twice the time allowed in the experiment with pyruvic acid, the benzyl alcohol and lead tetraacetate did not yield at most more than 5% of benzyl acetate.

Therefore, in the main experiment the benzyl acetate obtained can only be a product of the reaction between pyruvic acid, benzyl alcohol and lead tetraacetate, thus proving that the reaction product of oxidative cleavage of pyruvic acid is acetic acid.

III. Oxidative Cleavage of Trimethylpyruvic Acid

(1) Oxidation in the Presence of Water. (a) Quantitative Determination of Carbon Dioxide.—The determination was carried out in the same way as described for pyruvic acid: 530.0 mg. of keto acid yielded 5.6 mg. of carbon dioxide in water-free medium (room temperature); addition of 10 cc. of water gave a further 168.9 mg. of carbon dioxide (temperature of reaction flask 40–45°). The total amount of carbon dioxide obtained was 174.5 mg. (97.5% of the theoretical).

(b) Isolation and Identification of the Second Cleavage Product.—1.30 grams (0.01 mole) of trimethylpyruvic acid was dissolved in 35 cc. of distilled water at 40° and 4.43 g. (0.01 mole) of finely pulverized lead tetraacetate was added in three portions with shaking. The oxidation took place immediately and was accompanied by a strong evolution of carbon dioxide. After thirty minutes 5 cc. of 5 *N* sulfuric acid was added and the solution extracted with ether in a continuous extractor for twenty-four hours. The ether extract, dried with sodium sulfate, was concentrated and the residue separated by fractional distillation under normal pressure into three fractions: (1) boiling up to 100°, (2) from 100–120° (1.89 g., mainly acetic acid), and (3) 120–160° (1.5 g.). Fraction 3 was separated again by fractional distillation into three fractions with b. p. ranges 118–125°, 126–148°, 148–165°. The last two fractions were only slightly soluble in water and possessed an odor similar to that of butyric acid. For the further purification and identification of the acid, an aqueous solution of the combined last two fractions, neutralized with barium hydroxide and concentrated to a small volume, was mixed with a concentrated aqueous solution of silver nitrate and the precipitated mixture of silver salts (acetate and silver trimethylacetate) separated by recrystallization from hot water. The silver trimethylacetate thus obtained was almost pure. Silver determination: calcd., for silver salt of trimethylacetic acid, Ag, 51.6. Calcd. for silver salt of acetic acid, Ag, 64.6. Found: Ag, 53.7.

(c) Lead Tetraacetate Required for Cleavage.—The determination was carried out as described in II (1c): 10 cc. of 0.1 *M* trimethylacetic acid required 19.2 cc. of 0.05 *M* lead tetraacetate in the presence of water and 20.1 cc. in the presence of methyl alcohol which is equivalent to 0.96 and 1.00 mole of lead tetraacetate, respectively, for the cleavage of 1 mole of trimethylacetic acid.

(2) Oxidation in the Presence of Methyl Alcohol.—(a) Quantitative Determination of Carbon Dioxide: 496.7 mg. of keto acid yielded 5.9 mg. of carbon dioxide in dry acetic acid; addition of 10 cc. of absolutely dry methyl alcohol gave a further 174.10 mg. of carbon dioxide (tem-

(9) Dehydrated by shaking for a long time with Drierite and centrifuged just before using.

(10) Dried with metallic sodium.

perature of reaction flask, 45–50°); total amount of carbon dioxide obtained, 180.0 mg. (107% of the theoretical.)

(3) Isolation and Identification of the Cleavage Product of Trimethylpyruvic Acid in the Presence of Benzyl Alcohol. (Benzyl Trimethylacetate as Intermediate Compound.)—To a solution of 1.30 g. (0.01 mole) of keto acid and 1.08 g. (0.01 mole) of absolutely dry benzyl alcohol in 20 cc. water-free benzene was added 4.43 g. (0.01 mole) of lead tetraacetate. The temperature of the solution rose in a short time from 24 to 37° with strong evolution of carbon dioxide. After the solution had cooled to its initial temperature and the evolution of carbon dioxide had stopped, the lead diacetate was centrifuged off, washed several times with benzene and ether and the wash solutions added to the supernatant. By carefully distilling off the ether and benzene and distillation of the residue *in vacuo*, 1.26 g. of a clear liquid boiling from 84–91° (at 7 mm.) was obtained. According to the saponification data, it contained 56% of benzyl trimethylacetate (0.374 g. of esterified trimethylacetic acid, 37% of the theoretical). The remainder apparently consisted of unesterified benzyl alcohol. The preparation of the silver salt of trimethylacetic acid from benzyl trimethylacetate was carried out as described for the preparation of silver acetate from benzyl acetate. The silver salt (crude product) obtained by this method contained 52.7% silver. Calculated for silver salt of trimethyl acetic acid, 51.6% of silver.

IV. Oxidative Cleavage of Phenylglyoxylic Acid

(1) Oxidation in the Presence of Water.—(a) Quantitative Determination of Carbon Dioxide.—0.4667 gram of absolutely dry phenylglyoxylic acid was dissolved in 10 cc. of absolutely dry acetic acid and a suspension of 4 g. of finely pulverized lead tetraacetate in 15 cc. of acetic acid was added. A bulky white, crystalline precipitate formed.[11] During the blank run the carbon dioxide liberated equalled 9.2 mg. After the addition of 15 cc. of water the precipitate dissolved again and an additional 120.8 mg. of carbon dioxide was obtained: total, 130.0 mg. (95% of the theoretical).

(b) Identification of the Second Cleavage Product.—To a solution of 1.5 g. of phenylglyoxylic acid in 50 cc. of 30% acetic acid was added a suspension of 4.48 g. of finely pulverized lead tetraacetate in 40 cc. of glacial acetic acid. The oxidative cleavage proceeded quickly and with slight warming. After the lead tetraacetate was used up the lead was precipitated by addition of the calculated amount of sulfuric acid. Concentration of the solution *in vacuo*, extraction of the residue with boiling ether and evaporation of the extract yielded 1.18 g. (96.7% of the theoretical) of pure benzoic acid, m. p. 122.5° (recrystallized from water); mixed m. p. with pure benzoic acid, 122.5°.

(c) Lead Tetraacetate Required for Cleavage.—The determination was carried out as described in II (1c). Ten cc. of 0.1 *M* phenylglyoxylic acid required 19.7 cc. of 0.05 *M* lead tetraacetate in the presence of water and 19.0 cc. in the presence of methyl alcohol, which is equivalent to 0.99 and 0.95 mole of lead tetraacetate, respectively, per mole of keto acid oxidized.

(11) The lead content of this precipitate (41%) agrees with that of plumbous phenylglyoxylate.

(2) Oxidation in the Presence of Ethyl Alcohol.—(a) Quantitative Determination of Carbon Dioxide.—0.5448 gram of phenylglyoxylic acid dissolved in 10 cc. of acetic acid yielded 7.8 mg. of carbon dioxide during the blank run. Addition of 5 cc. of ethyl alcohol liberated an additional 146.4 mg. of carbon dioxide; total, 154.2 mg. of carbon dioxide (96.5% of the theoretical).

(b) Isolation of Ethyl Benzoate from Cleavage in the Presence of Ethyl Alcohol.—To a solution of 1.5 g. of phenylglyoxylic acid and 10 cc. of absolutely dry ethyl alcohol in 30 cc. of absolutely dry benzene was added a solution of 4.43 g. of lead tetraacetate in 60 cc. of benzene and the mixture was kept at 45°[12] (carbon dioxide evolution). After one hour the lead acetate precipitate was centrifuged off and washed with ether. The combined benzene and ether solutions were extracted with 10% sodium bicarbonate solution to remove acetic acid, dried with solid potassium carbonate and concentrated. The residue, distilled *in vacuo*, yielded 1.2 g. (80% of the theoretical) of benzoic acid ethyl ester b. p. (756 mm.) 211–212°, $n^{26}D$ 1.5038.

(3) Isolation of the Cleavage Product in the Presence of Hydrogen Cyanide.—To a solution of 1.5 g. of phenylglyoxylic acid in 25 cc. of absolutely dry benzene was added a suspension of 4.43 g. of lead tetraacetate in 40 cc. of dry benzene and the mixture kept at 40–45°. The bright orange color which appeared immediately disappeared in a few minutes and the lead salt of the α-keto acid began to precipitate from the colorless solution. After forty-five minutes the solution was cooled in ice water, and about 5 cc. of anhydrous hydrogen cyanide was added, whereupon the lead salt of the α-keto acid redissolved quickly with simultaneous evolution of carbon dioxide and precipitation of lead acetate. The clear benzene solution was decanted and concentrated, using a fractionating column. In order to remove traces of lead salt the residue was dissolved in dry ether, filtered and again concentrated. The concentrate was distilled *in vacuo* and yielded 0.65 g. of phenylglyoxylic *nitrile* (50% of the theoretical), b. p. (9 mm.) 82°; b. p. (758 mm.) 208–210°; $n^{26}D$ 1.5303.

V. Oxidative Cleavage of Phenylpyruvic Acid

(1) Oxidation in the Presence of Water. (a) Quantitative Determination of Carbon Dioxide.[13]—0.492 gram of dry phenylpyruvic acid dissolved in 10 cc. of absolutely dry acetic acid yielded, after addition of 2.8 g. of finely pulverized lead tetraacetate, 13.2 mg. of carbon dioxide in the blank run. After addition of 10 cc. of water, a further 112.8 mg. of carbon dioxide was produced; total, 126.0 mg. of carbon dioxide (95% of the theoretical).

(b) The Identification of the Second Cleavage Product.—To 1.64 g. (0.01 mole) of phenylpyruvic acid dissolved in 30 cc. of glacial acetic acid was added 50 cc. of water and immediately afterward 9.3 g. (0.021 mole) of finely pulverized lead tetraacetate. The temperature of the solution rose very quickly from 27 to 39°. After ten minutes an additional 40 cc. of water was added and the mixture kept at room temperature for one hour. The lead

(12) The yield of benzoic acid ester does not differ when one adds the lead tetraacetate to the phenylglyoxylic acid in benzene first and the ethyl alcohol after thirty minutes.

(13) The experiment was carried out at room temperature except at the end when the reaction flask was warmed to 50°.

was removed by addition of 21 cc. of 2 *N* sulfuric acid and the precipitate extracted several times with alcohol and ether. The supernatant liquid combined with the alcohol and ether washings was evaporated to dryness *in vacuo*. Since attempts to isolate phenylacetic acid failed, it was obvious that secondary reactions had occurred (see theoretical part). The residue was dissolved in a mixture of 25 cc. of alcohol and 25 cc. of 2 *N* sodium hydroxide and warmed for one hour on the water-bath. After addition of 25 cc. of 2 *N* sulfuric acid the solution was evaporated again to dryness and the residue (I) exhaustively extracted with boiling ether. From the ether extract was obtained 500 mg. of fairly pure mandelic acid. Dissolving of residue (I) in a few cc. of dilute hydrochloric acid, evaporation to dryness and extraction with ether yielded a further 220 mg. of crude mandelic acid: total yield 0.77 g. of mandelic acid (50.6% of the theoretical); m. p. 118.5° after recrystallizing twice from chloroform. A mixed m. p. with mandelic acid showed no depression. The acid was readily soluble in water, gave an intense yellow color with ferric chloride and was oxidized to benzaldehyde by lead tetraacetate. The synthetically obtained mandelic acid by acetylation with acetic anhydride yielded acetylmandelic acid with the correct m. p., 54°.

(c) Lead Tetraacetate Required for Cleavage.—The determination was carried out as described in II (1c). Ten cc. of 0.1 *M* phenylpyruvic acid required 39.0 cc. of 0.05 *M* lead tetraacetate in the presence of water and 37.8 cc. in the presence of methyl alcohol which is equivalent to 1.95 and 1.90 moles of lead tetraacetate, respectively, for the cleavage of 1 mole of keto acid. The second mole of lead tetraacetate probably was used in the acetylation of the $-CH_2-$ group.

α-Keto Alcohols

Oxidative Cleavage of α-Keto Alcohols by Lead Tetraacetate in the Presence of Hydroxyl-forming Compounds.—The oxidative cleavage of α-keto alcohols by lead tetraacetate in the presence of hydroxyl-forming compounds leads to the formation of two products, one an acid, the other an aldehyde (or ketone, if the carbinol is tertiary in type). Both products of the cleavage of four α-keto alcohols have been identified (with one exception) as described below. The exception was in the case of acetylmethylcarbinol where the acid expected is acetic acid.

VI. Oxidative Cleavage of Acetylmethylcarbinol in the Presence of Water

(a) Identification of Acetaldehyde.—To 0.88 g. (0.1 mole) of freshly distilled acetylmethylcarbinol (b. p. 143.5–145°) dissolved in 20 cc. of 90% acetic acid was added 4.45 g. of lead tetraacetate. The solution became slightly warm. In order to avoid loss of acetaldehyde the process of oxidation was carried out in a closed vessel which was cooled occasionally. After twenty minutes the solution was cooled in ice and 50 cc. of water and 0.54 cc. of concentrated sulfuric acid were added. The lead sulfate was removed by centrifuging and the supernatant liquid added to a solution of lukewarm dilute hydrochloric acid containing 2.1 g. of 2,4-dinitrophenylhydrazine. The preparation was kept in ice for thirty minutes to ensure complete precipitation. After filtering with suction, the precipitate was washed with dilute hydrochloric acid and dried *in vacuo* over phosphorus pentoxide and potassium hydroxide; 2.13 g. (95% of the theoretical) of acetaldehyde 2,4-dinitrophenylhydrazone was obtained which melted at 162° after recrystallization from alcohol.

(b) Lead Tetraacetate Required for Cleavage.—The equivalent was determined as described in II (1c). The oxidative cleavage of 1 mole acetylmethylcarbinol required 1 mole of lead tetraacetate in the presence of water.

VII. Oxidative Cleavage of Benzoylcarbinol with Lead Tetraacetate

(1) In the Presence of Water. (a) Isolation of Benzoic Acid.—1.36 g. (0.01 mole) of benzoylcarbinol was dissolved in 25 cc. of 90% acetic acid and 4.84 g. (0.011 mole) of finely powdered lead tetraacetate added. The mixture was kept for twenty minutes at 50–55° with frequent shaking. After the cleavage was completed, the lead was precipitated as lead sulfate by addition of the calculated amount of concentrated sulfuric acid and removed by centrifuging. The acetic acid solution, evaporated *in vacuo*, yielded a residue out of which the benzoic acid was extracted with ether. On evaporation of the ether 0.96 g. (78.6% of the theoretical) of almost pure benzoic acid remained; m. p. after recrystallization from water was 122°. The mixed m. p. with benzoic acid showed no depression.

(b) The cleavage of the carbinol and isolation of aldehyde was carried out by procedures similar to those described for acetyl-methyl-carbinol. 1.36 g. (0.01 mole) of benzoylcarbinol yielded 1.75 g. (83% of the theoretical) of formaldehyde 2,4-dinitrophenylhydrazone which when purified by recrystallization from alcohol or petroleum ether had m. p. 154.5°.

(2) In the Presence of Ethyl Alcohol. Isolation of Ethyl Benzoate.—To a solution of 1.36 g. (0.01 mole) of absolutely dry benzoylcarbinol in a mixture of 25 cc. of absolute glacial acetic acid[14] and 5 cc. absolute ethyl alcohol 4.84 g. (0.011 mole) of finely powdered lead tetraacetate was added. The solution was heated to 50–55° and kept at this temperature for thirty minutes with frequent shaking. The preparation was diluted with 60 cc. of distilled water and the ethyl benzoate formed was extracted with ether under reflux. The ether extract was shaken with saturated sodium bicarbonate solution to remove free acid and was carefully concentrated. Distillation of the residue yielded 0.90 g. (60% of the theoretical) of benzoic acid ethyl ester, b. p. (747 mm.) 211–212°.

VIII. Oxidative Cleavage of Benzoin with Lead Tetraacetate

(1) In the Presence of Water. (a) Isolation of Benzoic Acid.—The cleavage of benzoin and isolation of the cleavage product, benzoic acid, were carried through in the same way as described for the cleavage of benzoylcarbinol (VII, 1a). However, before evaporation, the ether extract was shaken with saturated sodium sulfite solution for three hours to remove the benzaldehyde. From 2.12 g. (0.01 mole) of benzoin 0.9 g. (74% of the theoretical) of pure benzoic acid of m. p. 122.5° was obtained.

(b) Identification of Benzaldehyde as *p*-Nitrophenylhydrazone.—2.12 g. (0.01 mole) of benzoin was oxidized

(14) Glacial acetic acid and ethyl alcohol were dried by shaking for several days with Drierite and centrifuged before using.

with 4.5 g. of lead tetraacetate in 25 cc. of glacial acetic acid (VII, 1a). After removal of lead as sulfate, 2 g. of *p*-nitrophenylhydrazine was added and the solution warmed to 50°. After thirty minutes the preparation was diluted with a four-fold volume of water and kept at 0° for an hour. The crude hydrazone after recrystallization from ethyl alcohol yielded 1.8 g. (75% of the theoretical) of benzaldehyde-*p*-nitrophenylhydrazone with m. p. 192°.

(c) Lead Tetraacetate Required for Cleavage.—The equivalent was determined as described in II (1c) except that, due to the insolubility of benzoin in acetic acid, a 0.05 *M* solution was used. The mixture was kept at 50° for two and one-half hours. The oxidative cleavage of 1 mole of benzoin required 1.01 mole of lead tetraacetate in the presence of water and 1.01 mole in the presence of methyl alcohol.

(2) In the Presence of Ethyl Alcohol. Isolation of Ethyl Benzoate.—The cleavage of benzoin with lead tetraacetate in the presence of ethyl alcohol was carried out as described for benzoylcarbinol. After dilution with water the mixture was extracted with ether. The ether layer was shaken with saturated sodium bicarbonate solution to remove acids and with concentrated sodium bisulfite to remove benzaldehyde. After evaporation of the ether, the residue was distilled *in vacuo* and redistilled at atmospheric pressure.

From 2.12 g. (0.01 mole) of benzoin 1.26 g. (84% of the theoretical) of benzoic acid ethyl ester was obtained, b. p. (756 mm.) 212°. Hydrolysis of the ethyl ester yielded benzoic acid, m. p. 122.5°.

IX. Oxidative Cleavage of Anisoin by Lead Tetraacetate

(1) In the Presence of Water. (a) Isolation of Anisic Acid.—The cleavage of anisoin with lead tetraacetate was carried out by the same procedure as described for benzoylcarbinol. However, in this case, the anisic acid was separated from the ether extract by shaking with an aqueous solution of sodium bicarbonate. Acidification of the bicarbonate extract yielded anisic acid. From 2.72 g. (0.01 mole) of anisoin, 1.1 g. (76.8% of the theoretical) of anisic acid, m. p. 185° (recrystallized from water), was obtained.

(b) Isolation of Anisaldehyde as *p*-Nitrophenylhydrazone.—The ether extract (IX, 1a) freed of the anisic acid by the sodium bicarbonate solution was concentrated by distilling off the ether under ordinary pressure. The residue contained crystals which were isolated by taking up the residue in ethyl alcohol and filtering. The alcohol-insoluble material, yellow-green in color, weighed 0.15 g. (5% of the starting material), had a m. p. 133° and proved to be anisil.[15]

The alcoholic solution which contained the anisaldehyde was added to a warm solution of *p*-nitrophenylhydrazine in dilute hydrochloric acid; yield 2.12 g. (83% of the theoretical)[16] of *p*-nitrophenylhydrazone of anisaldehyde; m. p. after recrystallization from ethyl alcohol, 162°.

(c) Lead Tetraacetate Required for Cleavage.—The equivalent was determined as described in II (1c). The mixture was kept at 50° for four hours. The oxidative cleavage of 1 mole of anisoin required 0.93 mole of lead tetraacetate in the presence of water and 0.97 mole in the presence of methyl alcohol.

(2) In the Presence of Ethyl Alcohol. Isolation of the Anisic Acid Ethyl Ester.—The cleavage of anisoin in the presence of ethyl alcohol was carried out exactly as described for benzoin (VIII, 2). The residue obtained by evaporation of the ether extract contained a crystalline substance which was separated by taking up in alcohol and filtering. The isolated substance (0.45 g., 16.5% of the starting material) had a m. p. 133° and was found to be anisil. The alcoholic filtrate and wash solution were combined and concentrated and the residue distilled *in vacuo;* 2.72 g. (0.01 mole) of anisoin yielded 1.02 g. (68% of the theoretical) of anisic acid ethyl ester, b. p. (8 mm.) 125–130°; b. p. (750 mm.) 267–269°. The ester after saponification with alkali and acidification yielded anisic acid (m. p. 182°).

X. Oxidation of α-Keto Alcohols with Lead Tetraacetate in Absence of Hydroxyl-forming Compounds.[17]

(a) Diacetyl from Acetylmethylcarbinol.—0.88 gram (0.01 mole) of freshly distilled acetylmethylcarbinol and 4.43 g. (0.01 mole) of lead tetraacetate in 30 cc. of absolutely water-free benzene was kept at 50° for four hours. After cooling the solution to room temperature the lead salt was separated by centrifuging and washed several times with benzene. The combined benzene solutions were heated with a mixture of 30 cc. of 20% hydroxylamine chlorohydrate, 30 cc. of 20% sodium acetate and 30 cc. of 10% nickel chloride at 80° for one hour with frequent shaking. By distilling off the benzene, 0.60 g. of nickel dimethylglyoxime was obtained which corresponded to 0.358 g. of diacetyl (41.6% of the theoretical).

(b) Benzil from Benzoin.—To a solution of 2.12 g. (0.01 mole) of benzoin (dried in high vacuum) in 25 cc. of absolutely dry acetic acid was added 4.43 g. (0.01 mole) of finely pulverized lead tetraacetate and the mixture kept at 50° for twenty-four hours with occasional shaking and exclusion of moisture. The solution was evaporated to dryness *in vacuo* at about 40–45° bath temperature and the residue completely extracted with ether. After shaking the ether extract with saturated sodium bicarbonate solution and evaporating to dryness, 1.75 g. of benzil (83.4% of the theoretical) with m. p. 94–95° (recrystallized from carbon tetrachloride and ethyl alcohol) was obtained.

(c) Anisil from Anisoin.—The oxidation of anisoin to anisil was carried out exactly as described for benzoin: 2.72 g. (0.01 mole) of anisoin yielded 2.0 g. (74% of the theoretical) of anisil with m. p. 133° and 0.30 g. (20% of the theoretical) of anisic acid,[18] m. p. 184.5° (recrystallized from water).

Acknowledgment.—Grateful acknowledgment is made to Dr. C. C. Lucas for assistance in preparing this manuscript in English as well as to H. N. MacFarland for preparing some of the keto acids used in this investigation.

(15) This substance, which is here a by-product, becomes the main product when working in the absence of hydroxyl-forming compounds (see Xc).

(16) After deduction of the anisoin used up in the formation of anisil.

(17) In this and the following experiments, the solvents used must be absolutely dry to avoid oxidative cleavage.

(18) Obtained by acidification of the sodium bicarbonate extract of the ether solution.

Summary

1. Under certain conditions lead tetraacetate effects quantitative oxidative cleavage of α-keto acids and α-keto alcohols. The reaction seems to be one of general application.

2. This reaction occurs only after formation of a vicinal hydroxyl pair and therefore has to be considered as a glycol cleavage.

3. The formation of the "pseudoglycols" takes place by addition to the keto group. Water, alcohols (*e. g.*, methyl, ethyl and benzyl alcohols) and hydrocyanic acid were found capable of such an addition.

4. In the absence of substances forming pseudoglycols by addition no reaction takes place between lead tetraacetate and α-keto acids, whereas α-keto alcohols are oxidized in good yield to their diketones.

5. The nature of the cleavage products is determined by the glycol-forming substance added.

6. In the presence of water, alcohols or hydrocyanic acid the products are as follows: (a) from 1 mole of α-keto acid and 1 mole of lead tetraacetate are obtained 1 mole of carbon dioxide and 1 mole of acid (or ester or keto nitrile). (b) From 1 mole of α-keto alcohol and 1 mole of lead tetraacetate are obtained 1 mole of acid (or its ester) and 1 mole of aldehyde (or ketone).

7. The present use of lead tetraacetate to detect vicinal hydroxyl groups in compounds of unknown constitution may be extended to the detection of the α-keto acid and α-keto alcohol groups, if one compares the reaction of the substance with lead tetraacetate in dry solvents with the behavior in the presence of compounds capable of forming pseudoglycols, as explained above.

8. The method of oxidative cleavage may be employed not only to determine α-keto acids quantitatively by the carbon dioxide evolved but also to distinguish them qualitatively from other keto acids (β, γ, · · ·, etc.).

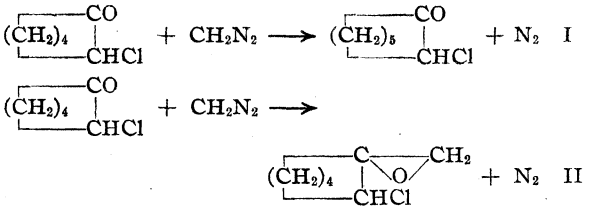
The Ring Enlargement of Two Cyclic Alpha-Chloroketones

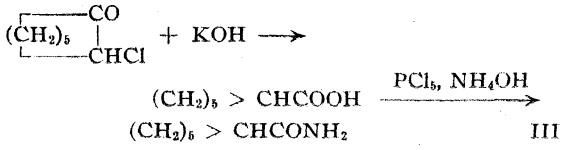
BY THOMAS R. STEADMAN[1]

A study of the reaction of diazomethane with cyclic α-chloroketones was undertaken in these laboratories in order that further light might be shed on the process of ring enlargement of cyclic systems. Giraitis and Bullock[2] have reported briefly on work similar in character to that described in the present paper. The present investigation has been confined to experiments based on Meerwein's mode of operation,[3,4] involving the introduction of nitrosomethylurethan at a suitable rate into a solution of the ketone in methanol containing a small amount of sodium carbonate. This is quite different from the method employed by Giraitis and Bullock,[2] who used diazomethane in ethereal solution.

The principal reactions in the case of α-chlorocyclohexanone may be represented by the following equations, although the actual intermediate may not be diazomethane



It is important to note that when the ring was enlarged, the methylene group entered the ring in such a manner that the chlorine atom remained alpha to the carbonyl group. This was shown by the fact that when the chloroketone was treated with alcoholic sodium hydroxide, cyclohexane carboxylic acid was obtained and identified by conversion to the amide:



This degradation was first recognized by Favorskii and Boshowski.[5]

(1) This investigation was begun by the author at the suggestion and under the direction of the late Prof. E. P. Kohler.

(2) Giraitis and Bullock, THIS JOURNAL, **59**, 951 (1937).

(3) Meerwein, *Chem. Zentr.*, **104**, II, 1758 (1933); German Patent 579,309.

(4) Kohler, Tishler, Potter and Thompson, THIS JOURNAL, **61**, 1057 (1939).

(5) Favorskii and Boshowski, *J. Russ. Phys.-Chem. Soc.*, **50**, 582-588 (1917); *C. A.*, **18**, 1476 (1924).

The possibility that β-chloroketones might also undergo the Favorskii degradation is considered unlikely. No evidence bearing directly on the point could be found in the literature, but such an eventuality would require that both the α- and the β-chloroketones should pass through a common intermediate, the α,β unsaturated ketone. This is an hypothesis difficult to accept. It is much more likely that the reaction is analogous to the benzilic acid rearrangement.

Attempts to secure a semicarbazone from the chloroketone proved futile, but it is common for α-halogen atoms to reduce the carbonyl activity of ketones in this respect.

The structure of 2-chloro-1-methylenecyclohexane oxide as formulated in Equation II above was proved by hydrogenation of the substance, thus forming cyclohexylcarbinol, which was readily identified as the phenylurethan.

From a typical experiment involving α-chlorocyclohexanone and diazomethane, there was obtained a 52% yield of pure α-chlorocycloheptanone and a 16% yield of pure 2-chloro-1-methylenecyclohexane oxide. It was estimated that the intermediate fractions from the distillation contained further yields of about 7.5% of the ketone and 8% of the oxide. Taking these materials into consideration, together with a distillation residue of 3%, it was possible to account for 86.5% of the ketone used. This compares favorably with the material balance reported by Kohler and his associates[4] for the reaction of cycloöctanone with diazomethane. The three to one ratio of ketone to oxide corresponds roughly with the similar ratio observed in the case of the unsubstituted cyclic ketone. However, it should be noted that the results of this experiment contrast sharply with the report by Giraitis and Bullock[2] that a quantitative yield of α-chlorocycloheptanone was obtained from α-chlorocyclohexanone and diazomethane in ethereal solution.

From the reaction of diazomethane with α-chlorocycloheptanone, three substances were isolated. One of them was recovered starting material, as indicated by its physical properties and an analysis. A second substance was tentatively identified as 2-chloro-1-methylenecycloheptane oxide. The third compound, α-chlorocycloöctanone, upon treatment with alcoholic alkali, gave cycloheptane carboxylic acid, which was identified as the amide.

After long standing in a stoppered flask under an atmosphere of air, the α-chlorocycloöctanone which had been obtained by careful fractional distillation under diminished pressure was found to contain a small amount of a white, crystalline compound. This was filtered off, washed free of α-chlorocycloöctanone with ether and then recrystallized from dilute hydrochloric acid. The recrystallized material proved to be suberic acid, as shown by an analysis and a mixed melting point determination with an authentic sample of suberic acid. Presumably suberic anhydride was formed by oxidation of the chloroketone and this transformed to the acid on recrystallization.

Despite the fact that a 10% excess of nitrosomethylurethan was used in the reaction with α-chlorocycloheptanone, 36.8% of the starting material was recovered in a good state of purity. The pure α-chlorocycloöctanone and the pure isomeric oxide were obtained in roughly equal amounts (the yields of ketone and oxide being 13 and 11.7%, respectively). The impure intermediate fractions were estimated to contain more of the starting material (15.4%) and further yields of α-chlorocycloöctanone (2.4%) and oxide (4.4%). These, together with distillation residues amounting to 10.8%, accounted for 94.5% of the starting material.

The work of Kohler and his associates[4] on the reaction of diazomethane with cycloöctanone and cyclononanone showed that these reactions were subject to steric hindrance due probably to both the lessened reactivity of the carbonyl group and the difficulty of introducing another methylene group into an already crowded ring system. Owing to the possibility of the interaction of several factors in the reactions studied in the present investigation, the interpretation of the experimental results is not easy. The fairly good yields of products obtained in the reaction of diazomethane with α-chlorocyclohexanone are comparable with those obtained under similar conditions in the case of cyclohexanone, demonstrating that α-chloro substitution has exercised no pronounced effect on the reactivity of the carbonyl group in this direction.

However, the lower yields of products resulting from the reaction of diazomethane with α-chlorocycloheptanone, when contrasted with the behavior of cycloheptanone under similar circumstances, lend support to the idea put forward by Stoll and Stoll-Comte[6] to explain by steric con-

(6) Stoll and Stoll-Comte, *Helv. Chim. Acta*, **13**, 1185 (1930).

siderations the difficulties encountered in synthesizing cycloalkanones with eight to thirteen ring members. The replacement of a hydrogen with a relatively larger chlorine atom in these ketones should tend to make more difficult the formation of rings of such size. This has been borne out by the finding that the reaction of α-chlorocycloheptanone with diazomethane gave rise to smaller yields of products and a lower ratio of ketone to oxide than resulted from the reaction of α-chlorocyclohexanone with diazomethane under similar conditions. The decrease in the yield of products may be ascribed to the lower degree of reactivity of the carbonyl group of α-chlorocycloheptanone as compared with that of α-chlorocyclohexanone. The decrease in the ratio of ketone to oxide is probably due to the steric hindrance offered to the introduction of a methylene group into the ring. An extension of the evidence offered herein would be highly desirable.

Experimental Part

α-Chlorocyclohexanone.—The chlorination of cyclohexanone in acetic acid solution according to directions by Bartlett and Rosenwald[7] resulted in 50–60% yields of α-chlorocyclohexanone, m. p. 22–23°.

α-Chlorocyclohexanone and Diazomethane.—In a 500-cc. three-necked, round-bottomed flask equipped with a thermometer, a dropping funnel, an outlet for nitrogen, and an efficient mechanical stirrer operated through a mercury seal, there was placed 133 g. (1 mole) of freshly distilled α-chlorocyclohexanone, 100 cc. of absolute methanol, and 1–2 g. of finely powdered anhydrous sodium carbonate. Over a period of about seven hours, 146 g. (1.1 moles) of nitrosomethylurethan was added dropwise to the well-stirred reaction mixture, which was cooled as necessary to maintain a temperature between 20 and 30°. When the evolution of nitrogen had ceased, the solution was filtered into a modified Claisen flask and the methanol, together with some methylethyl carbonate, removed by distillation at atmospheric pressure. By careful and repeated fractional distillations of the residue through an efficient column packed with three feet (91 cm.) of glass helices, it was possible to obtain 76.2 g. (52%) of α-chlorocycloheptanone, b. p. 87–88° (10 mm.), and 22.7 g. (16%) of 2-chloro-1-methylenecyclohexane oxide, b. p. 62–63° (10 mm.), m. p. −10 to −8°. The other fractions obtained in the final distillation (10 mm.) were: (1) 59–62°, 3.3 g.; (2) 63–64°, 3.6 g.; (3) 64–70°, 3.4 g.; (4) 70–80°, 3.0 g.; (5) 80–86°, 7.1 g.; (6) 86–87°, 2.4 g.; and a residue of 4.7 g. The ketone was a colorless, mobile liquid with a pungent odor, d^{20}_4 1.140 (Favorskii and Boshowski[5] reported d^{20}_4 1.133), $n^{20}D$ 1.4870.

Anal. Calcd. for $C_7H_{11}OCl$: Cl, 24.2. Found: Cl, 24.3.

By refluxing 15 g. (0.1 mole) of α-chlorocycloheptanone with alcoholic potassium hydroxide, approximately 4 g. (36% yield) of cyclohexane carboxylic acid was secured in a somewhat impure state. For purposes of identification, the liquid acid was treated with an excess of phosphorus pentachloride and the resulting acid chloride poured into concentrated ammonium hydroxide. After one treatment with active charcoal and two recrystallizations from water, white leaflets of cyclohexane carboxamide, m. p. 183–184° (uncor.), were obtained; reported,[8] 184°.

The oxide was also a colorless, mobile liquid with an odor much like that of the isomeric ketone, d^{20}_4 1.120, $n^{20}D$ 1.4763.

Anal. Calcd. for $C_7H_{11}OCl$: Cl, 24.2. Found: Cl, 24.1.

Hydrogenation of the oxide to cyclohexylcarbinol in 95% ethanol, using Raney nickel as catalyst, required much time. An equivalent amount of potassium hydroxide was used in the reaction mixture to absorb the hydrogen chloride formed. From 7.3 g. of oxide was obtained 3.15 g. of liquid, b. p. 81–86° (15 mm.), which was conclusively identified as cyclohexylcarbinol by conversion to a phenylurethan, m. p. 81.5–82.0° (cor.), mixed melting point with an authentic sample 81–82° (cor.). Since the phenylurethan of cycloheptanol has a melting point of 84–85°, it was thought advisable to perform a mixed melting point with an authentic sample of this phenylurethan: found, m. p. 78–80°.

α-Chlorocycloheptanone and Diazomethane.—Using the method outlined for α-chlorocyclohexanone, 143 g. (0.98 mole) of α-chlorocycloheptanone was treated with a 10% excess of nitrosomethylurethan. Three careful fractional distillations of the reaction mixture under diminished pressure permitted the separation of three products. The lowest boiling fraction was identified tentatively as 2-chloro-1-methylenecycloheptane oxide, 18.4 g. (11.7% yield), b. p. 84–86° (10 mm.), $n^{20}D$ 1.4848.

Anal.[9] Calcd. for $C_8H_{13}OCl$: Cl, 22.07. Found: Cl, 22.18.

The middle fraction was considered to be starting material, α-chlorocycloheptanone, 55 g. (38% recovered), b. p. 88–90° (10 mm.), $n^{20}D$ 1.4861.

Anal.[9] Calcd. for $C_7H_{13}OCl$: Cl, 24.22. Found: Cl, 24.18.

The highest boiling fraction proved to be α-chlorocyclooctanone, and was obtained in 13.0% yield (20.2 g.), b. p. 104–106° (10 mm.), $n^{20}D$ 1.4930, $n^{15}D$ 1.4952 (reported[10]: $n^{14.5}D$ 1.4938). The other fractions obtained from the final distillation (10 mm.) were: (1) 80–84°, 1.2 g.; (2) 86–87°, 2.6 g.; (3) 87–88°, 3.6 g.; (4) 90–91°, 7.4 g.; (5) 91–94°, 10.9 g.; (6) 94–101°, 2.3 g.; (7) 101–103°, 2.3 g.; (8) 103–104°, 2.3 g.; and distillation residues totalling 16.7 g.

Extension of the Favorskii degradation to α-chlorocyclooctanone confirmed the tentative identification. Treatment of the ketone with an excess of alcoholic sodium hydroxide gave cycloheptane carboxylic acid, which was readily identified by conversion to the amide, m. p. 192–193° (uncor.); reported,[11] m. p. 193–194°.

After standing for approximately six months in a stoppered flask under an atmosphere of air, the α-chlorocyclo-

octanone was found to contain a precipitate of a white, crystalline compound which was filtered off and washed free of α-chlorocycloöctanone with ether. Two recrystallizations of the substance from 5% hydrochloric acid resulted in a substance, m. p. 140.5–141°, which contained neither chlorine nor nitrogen. A mixed melting point determination with an authentic sample of suberic acid showed no depression of the melting point.

Anal.[9] Calcd. for $C_8H_{14}O_4$: C, 55.16; H, 8.11. Found: C, 55.28; H, 8.05.

Summary

Two alicyclic α-chloroketones have been found to undergo ring enlargement on treatment with diazomethane. From the yields of ketonic materials obtained, evidence has been adduced for the Stoll and Stoll-Comte[6] hypothesis regarding steric effects in certain alicyclic ring systems.

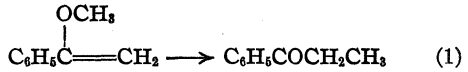
The Condensation of α-Methoxystyrene with Halogen Compounds

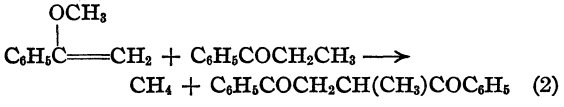
BY C. W. MORTENSON AND M. A. SPIELMAN

In addition to the normal rearrangement (1),[1]



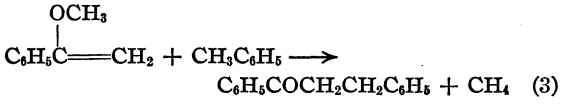
$$C_6H_5\overset{OCH_3}{\overset{|}{C}}{=}CH_2 \longrightarrow C_6H_5COCH_2CH_3 \quad (1)$$

α-methoxystyrene and a few similar enol ethers undergo a peculiar side reaction (2) in which the unchanged ether condenses with the rearrangement product to eliminate methane and form a γ-diketone. Later[2] it was discovered that at



$$C_6H_5\overset{OCH_3}{\overset{|}{C}}{=}CH_2 + C_6H_5COCH_2CH_3 \longrightarrow CH_4 + C_6H_5COCH_2CH(CH_3)COC_6H_5 \quad (2)$$

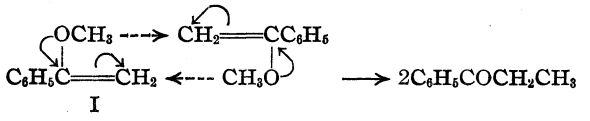
250° α-methoxystyrene also condenses with hydrocarbons such as toluene and cyclohexane (3).



$$C_6H_5\overset{OCH_3}{\overset{|}{C}}{=}CH_2 + CH_3C_6H_5 \longrightarrow C_6H_5COCH_2CH_2C_6H_5 + CH_4 \quad (3)$$

This reaction, so far as we know, has no analogy except, perhaps, in the recently discovered photolytic condensation of phosgene or oxalyl chloride with cyclohexane.[3] Only ethers capable of undergoing the rearrangement[4] also take part in the condensation, and it is evident that there is some common factor in the two reactions.

The hypothesis here advanced to account for the behavior of α-methoxystyrene is that both the rearrangement and the condensation involve the polarized hetero-enoid system in I. Collision, under the proper circumstances, of two such



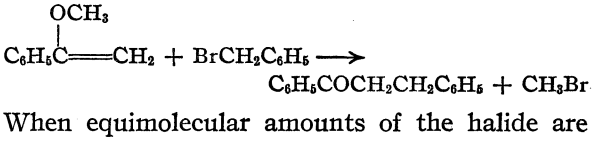
$$C_6H_5\overset{OCH_3 \dashrightarrow}{\overset{|}{C}}{=}\overset{\curvearrowleft}{CH_2}{=}CC_6H_5 \quad C_6H_5C{=}\overset{\curvearrowright}{CH_2} \dashleftarrow CH_3O \longrightarrow 2C_6H_5COCH_2CH_3$$

I

molecules leads to the so-called rearrangement which, in the light of such an interpretation, becomes an intermolecular alkylation. The mechanism explains why the reaction is of the second order and why the alkyl group on the oxygen atom of one molecule may, at the end of the reaction, turn up on the carbon atom of another.[1]

Collision of the polarized molecule I with a reactive but different molecular species leads to the condensation reaction. Attack should be at the anionoid center on the methylene carbon atom,[5] and in that event a reaction should take place with alkyl halides which are cationoid in their reactivity and definitely more polarized than hydrocarbons. A few typical halogen compounds of varying degrees of reactivity have been studied.

α-Methoxystyrene when heated with an eightfold excess of benzyl bromide yields β-phenylpropiophenone in 51% of the theoretical yield.



$$C_6H_5\overset{OCH_3}{\overset{|}{C}}{=}CH_2 + BrCH_2C_6H_5 \longrightarrow C_6H_5COCH_2CH_2C_6H_5 + CH_3Br$$

When equimolecular amounts of the halide are used, the yield is 35%, which is well above the 8% yield obtained from toluene under comparable conditions. *n*-Butyl bromide, containing a moderately active halogen atom, condenses in 28% yield, whereas bromobenzene does not react at all.

(2) Spielman and Mortenson, *ibid.*, **61**, 666 (1939).

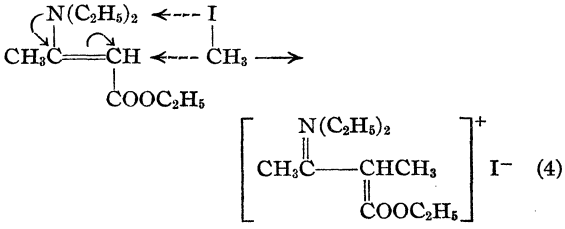
(3) Kharasch and Brown, *ibid.*, **62**, 454 (1940).

(4) The second order, intermolecular rearrangement of enol ethers (MacDougall, Lauer and Spielman, *ibid.*, **55**, 4089 (1933)) possesses only a formal similarity to the familiar first order, intramolecular rearrangement of allyl ethers (Kincaid and Tarbell, *ibid.*, **61**, 3085 (1939); Hurd and Schmerling, *ibid.*, **59**, 107 (1937)).

(5) The anionoid reactivity of α-methoxystyrene is shown by the avidity with which it adds water, alcohol, acids, etc. For terminology refer to Robinson, "Outline of an Electrochemical Theory of the Course of Organic Reactions," The Institute of Chemistry of Great Britain and Ireland, London, 1932.

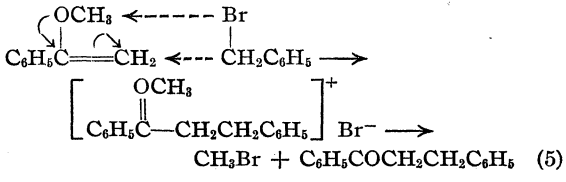
Ethyl chloroacetate yields 36% of ethyl β-benzoylpropionate and a trace of *sym*-triphenylbenzene. Benzoyl chloride heated with equimolecular amounts of α-methoxystyrene produces tribenzoylmethane in 9% yield; in large excess it gives 45% of the theoretical amount of *sym*-triphenylbenzene. The triphenylbenzene is the product of a side reaction and is not related to the condensation. It has its origin in the reaction of hydrogen chloride with α-methoxystyrene. Even at room temperature the ether gives triphenylbenzene in 54% yield simply on saturation with hydrogen chloride.

The condensation of α-methoxystyrene with alkyl halides has the appearance of a novel reaction, but in point of fact it has a close analogy in the addition of methyl iodide to ethyl β-diethylaminocrotonate (4).[6] The reaction between α-



(4)

methoxystyrene and benzyl bromide may be similarly formulated (5); the only real difference



(5)

is that in the former addition the nitrogen atom is sufficiently basic to form a stable salt, whereas the onium compound formed from α-methoxystyrene decomposes instantaneously.

Experimental Part

All condensations were carried out in Pyrex tubes heated in an electrical bomb furnace.

Condensation with Benzyl Bromide.—Ten grams of α-methoxystyrene and 76 g. of benzyl bromide were heated for seventeen hours at 220°. When the cooled bomb was opened, a slight pressure was evident. The unreacted benzyl bromide and the propiophenone formed by normal rearrangement were removed by vacuum distillation. An 8.3-g. fraction was collected at 150° (1 mm.). It soon solidified, and after one crystallization from alcohol yielded 8.0 g. of β-phenylpropiophenone; m. p. and mixed m. p. 72–73°.[7] No dibenzyl could be detected in the residues.

In order to identify methyl bromide as a reaction product a mixture of α-methoxystyrene and benzyl bromide was heated under a reflux while the effluent gas was passed into a boiling solution of sodium saccharin in butyl carbitol and water. N-Methylsaccharin separated on dilution; m. p. 132°.[8]

Condensation with *n*-Butyl Bromide.—A mixture of 4.6 g. of α-methoxystyrene and 105 g. of *n*-butyl bromide heated to 245° for thirty-six hours gave 1.7 g. of *n*-caprophenone boiling at 108–110° at 7 mm. It was characterized as the semicarbazone; m. p. and mixed m. p. 131–132°.[9]

Condensation with Ethyl Chloroacetate.—Ninety-seven grams of ethyl chloroacetate and 7.7 g. of α-methoxystyrene were heated to 200° for twenty-five hours. Fractionation yielded 90 g. of ethyl chloroacetate, 1.7 g. of acetophenone and 4.3 g. of ethyl β-benzoylpropionate; b. p. 143–145° at 6 mm. The semicarbazone melted at 138–139° and a mixed melting point was not depressed.

Anal. Calcd. for $C_{13}H_{17}O_3N_3$: N, 16.0. Found: N, 16.1.

The non-volatile residue upon treatment with ether gave 0.3 g. of *sym*-triphenylbenzene; m. p. and mixed m. p. 173–174°.[10]

Condensation with Benzoyl Chloride.—Equimolecular amounts of α-methoxystryene and benzoyl chloride (4.5 g. and 4.7 g., respectively) heated to 180° for seven hours gave 0.5 g. of a white solid, sparingly soluble in organic solvents. It melted at 210° and gave a ferric chloride color test. The melting point was not depressed by a synthetic sample of tribenzoylmethane.[11]

Similar heating of 5.2 g. of the ether with 134 g. of the acid chloride gave as the only identifiable substance 1.8 g. of *sym*-triphenylbenzene; m. p. and mixed m. p. 173–174°.[10]

Reaction between Hydrogen Chloride and α-Methoxystyrene.—Dry hydrogen chloride was passed into 2 g. of α-methoxystyrene for two hours. The reaction mixture solidified to a brown mass. Crystallization from alcohol–acetone gave 0.8 g. of triphenylbenzene; m. p. and mixed m. p. 173–174°.

Summary

α-Methoxystyrene condenses with benzyl bromide, *n*-butyl bromide, ethyl chloroacetate and benzoyl chloride, but not with bromobenzene. A methyl halide is eliminated and a phenacyl derivative is formed. An interpretation of the course of the reaction is presented.

Action of the Reagent Pyridine–Acetic Anhydride on *d*-α-Glucoheptose, *d*-Glucosamine and *l*-Fucose Oximes

BY E. RESTELLI DE LABRIOLA AND V. DEULOFEU

The action of pyridine–acetic anhydride on aldose oximes was studied first by Behrend[1] with glucose oxime. He obtained an oxime hexaacetate at low temperature and the *d*-gluconononitrile pentaacetate at a higher temperature. Wolfrom and Thompson[2] showed that Behrend's acetylated glucose oxime was a cyclic form and that another isomer could be obtained when working with Wohl's method. This isomer was an open-chain or *aldehydo*-glucose oxime hexaacetate and was an intermediate in the formation of the acetylated nitrile.

Deulofeu, Wolfrom and co-workers[3] subjected galactose oxime to the action of pyridine–acetic anhydride at low temperature and obtained a mixture of *aldehydo*-galactose oxime hexaacetate, galactononitrile pentaacetate and cyclic galactose oxime hexaacetate. This work showed that galactose oxime reacted in the open-chain form to give the first two compounds and in the ring or cyclic form to give the last-named substance. Deulofeu, Cattaneo and Mendivelzúa[4] subjected a series of aldose oximes to the same reagent and found that even at very low temperatures, *l*-arabinose, *d*-xylose, *l*-rhamnose and *d*-mannose oximes reacted in the *aldehydo* structure. The first three gave the acetylated nitriles. Above 30° mannose oxime gave the acetylated nitrile but below that temperature *aldehydo*-mannose oxime hexaacetate was obtained. Similar results were obtained by Wolfrom and Georges[5] with mannose oxime. The application of the method to cellobiose oxime by Wolfrom and Soltzberg[6] and to *d*-α-galaheptose oxime by Hann and Hudson[7] gave n both cases the acetylated open-chain form.

We have studied now the behavior of three other aldose oximes, *viz.*, *d*-glucosamine oxime, *d*-α-glucoheptose oxime and *l*-fucose oxime, when treated with pyridine–acetic anhydride. The first two always reacted in the open-chain form but only gave acetylated nitriles, even at −10°. No open-chain or cyclic acetylated oximes could be detected among the products of the reaction. A very different result was obtained with *l*-fucose oxime. At −10°, there was obtained an oxime pentaacetate, melting at 116°, which was identical with the compound isolated by Votoček[8] on preparing *l*-fuconononitrile tetraacetate by Wohl's method. A sample of this substance, which gave no nitrile reaction, was found to have a rotatory power of +44.9° (*l*-series).[9] This is a cyclic compound because on fusion or on treatment with acetic anhydride and sodium acetate, it does not change to a nitrile. Its rotatory power is also of the same order as that of the closely related derivative of galactose oxime, which rotates −27.5° (*d*-series). At higher temperatures, part of the oxime reacted in the open-chain form and *l*-fuconononitrile tetraacetate was easily isolated and was finally the main product. The acetylated nitrile rotated at −22.4°, a value lower than that established for *d*-galactononitrile pentaacetate (+43.2°). The sign of the rotation was in agreement with the rule formulated by Deulofeu[10] that when the acetoyl group on carbon two is on the left in the projection formula the rotation is in the *levo* direction.

It is a very difficult matter to correlate the results obtained with the different oximes. Hann and Hudson[7] have pointed out that there is a similarity between the stereochemical constitution of *d*-mannose and *d*-α-galaheptose, and the reaction of their oximes with pyridine and acetic anhydride. It is evident that according to the structure of the sugar, its oxime tends to react at low temperatures in a cyclic form (*d*-glucose); in the *aldehydo* structure (*l*-arabinose, *d*-xylose, *l*-rhamnose, *d*-α-galaheptose, *d*-α-glucoheptose and *d*-glucosamine); or in a mixed form (*d*-galactose and *l*-fucose). When reacting in the open-chain form, the acetylated nitrile or the acetylated

aldehydo oxime can be obtained as products. If we apply to the oximes of the aldoses the known information concerning the reactivity of aldoximes, then the formation of the acetylated nitrile or of the acetylated *aldehydo* oxime must be determined by preferential existence of *syn* or *anti* forms of the oxime, the first stabilizing as the oxime acetate. If we consider only the low temperature reaction, we find that *l*-rhamnose, *d*-mannose, *d*-α-glucoheptose and *d*-α-galaheptose oximes react in the open-chain form and are configurationally related in part, as their first three hydroxyl groups have the same spatial configuration. From their mutarotation, it has always been accepted that the aldose oximes have, at least in part, a cyclic structure, but it is evident that the oxygen rings must open easily under the action of the reagents.

l-Fucose and *d*-galactose are closely related in their configuration and their oximes react in the same manner to give derivatives of both the cyclic and open-chain forms. It must be noted that the acetate of the *aldehydo*-fucose oxime is unstable as only the acetylated nitrile can be isolated. On the other hand, *aldehydo*-galactose oxime hexaacetate can be obtained. Another difference is that, with fucose, the cyclic form predominates at low temperatures, while with galactose, the open-chain form predominates. The elimination of the fifth carbon atom of galactose, as in arabinose, determines an exclusive reaction in the open-chain form.

It is more difficult to relate the remaining oximes. Their different manner of reacting is a proof of the sensibility of the path of the reaction to the spatial constitution of the aldose. Glucose reacts at 0° exclusively in the cyclic form and the oxime hexaacetate is obtained, but the introduction of a glucose residue on the fourth carbon atom, as in cellobiose, or the transformation of the first hydroxyl into an amino group, as in glucosamine, or the elimination of the fifth carbon atom, as in xylose, determines that the reaction takes place exclusively in the *aldehydo* form.

Experimental

d-α-Glucoheptose Oxime.—*d*-α-Glucoheptose (1 g.) prepared by reduction of *d*-α-glucoheptonolactone,[11] was dissolved in 1 cc. of water and added to 10 cc. of alcoholic hydroxylamine solution prepared according to Wohl and List.[12] As no crystalline oxime separated spontaneously, the solution was concentrated under reduced pressure (20°) and a sirup was obtained that could not be induced to crystallize by drying with alcohol or by standing over sulfuric acid in a vacuum. A semi-crystalline solid was the best material obtained and this could not be purified by employing different solvents. The solid material could be used with success for the preparation of the acetylated nitrile.

d-α-Glucoheptononitrile Hexaacetate.—The oxime from 1 g. of *d*-α-glucoheptose was treated with a mixture (1:1) of 10 cc. of pyridine and acetic anhydride. In the several experiments the temperature was varied from −10 to 20°. The oxime dissolved more rapidly with increasing temperature of reaction. The solution was evaporated in a desiccator over sulfuric acid and potassium hydroxide, and crystals began to appear that when dried melted at 110–112° without purification. Pure material was obtained on recrystallization from alcohol; yield 1.5 g. (69%, basis *d*-α-glucoheptose), m. p. 113–114°, spec. rot. +24.1 (20°, D-line, $CHCl_3$). Zemplén and Kiss[13] record the constants: m. p. 112.5–113.5°, spec. rot. +24.6° (D-line, $CHCl_3$).

d-Glucosamine Oxime Hydrochloride.—Although this compound has been prepared by Winterstein,[14] the following method gave better yields. An alcoholic solution of hydroxylamine was prepared by dissolving 15 g. of hydroxylamine hydrochloride in 8 cc. of water, adding 15 g. of sodium dissolved in 100 cc. of absolute ethanol, filtering the precipitated sodium chloride and washing with 20 cc. of absolute ethanol (washings combined with filtrate). Glucosamine hydrochloride (20 g.), dissolved in the minimum quantity of warm water, was added to the above solution and, after twenty-four hours of standing, crystallization was initiated by seeding; yield 15 g. (70%), m. p. 166°. Impure crystals could be recovered from the mother liquor.

d-Glucosaminonitrile Pentaacetate.—Glucosamine oxime hydrochloride (1 g.) was treated with 12 cc. of the pyridine–acetic anhydride (1:1) mixture. In the several experiments the temperature was varied from −10 to 20°. After solution of the oxime, the reaction mixture was concentrated in a desiccator at 20° and crystals separated; m. p. 120°. Long prisms were obtained on recrystallization from alcohol; yield 1.8 g., m. p. 126°, spec. rot. +20.5° (20°, D-line, *c* 4.7, $CHCl_3$, 2-dm.). Neuberg and Wolff,[15] who prepared this substance by Wohl's method, recorded the melting point of 118–119° but gave no rotation.

Anal. Calcd. for $C_{16}H_{22}O_9N_2$: N, 7.25. Found: N, 7.25.

Mild Acetylation of *l*-Fucose Oxime.—*l*-Fucose oxime was prepared according to Votoček,[8] who recorded the melting point 188–189°; yield 1.8 g. from 2 g. of fucose, m. p. 185°. For the acetylation, lots of 0.5 g. of *l*-fucose oxime were treated with 5 cc. of the pyridine–acetic anhydride (1:1) mixture at the temperatures indicated in Table I. The solution obtained was concentrated under reduced pressure at room temperature. Concentration was continued for a short time after the appear-

ance of crystals, after which these were removed by filtration. These were crystals of *l*-fuconitrile tetraacetate; m. p. 176–177°. On further concentration, material was obtained which began to melt at about 115° and was a difficulty separable mixture of the cyclic-*l*-fucose oxime pentaacetate and the acetylated nitrile. Acetylation at −10° did not give crystals melting at 176°, but the nitrile was always present as the material isolated gave a faint nitrile reaction. Table I records the results of several experiments operated at different temperatures.

TABLE I

MILD ACETYLATION OF *l*-FUCOSE OXIME (0.5 G.) AT VARIOUS TEMPERATURES

Temp., °C.		−10	3	15	37	100
Wt., g., m. p.	115°	0.8	0.62	0.5	0.5	0.30
Wt., g., m. p.	176°	..	.12	.32	.36	.48

l-Fuconitrile Tetraacetate.—The material from several of the preparations described above was combined and recrystallized from alcohol, from which it was obtained as rectangular plates; m. p. 177°, sp. rot. −22.4° (20°, D-line, *c* 5.0, $CHCl_3$, 2-dm.).

l-Fucose Oxime Pentaacetate.—The product obtained by acetylation at −10° as described above, gave the nitrile test. Crystallization from alcohol did not separate the nitrile and the method of Deulofeu, Wolfrom and coworkers[3] for the purification of galactose oxime hexaacetate was employed. The crude preparation (1.5 g.) was recrystallized once from alcohol and this material was then boiled with 500 cc. of water, a portion dissolving. The mixture was cooled to 5°, maintained at this temperature for one hour, filtered and the filtrate extracted with chloroform. The crystalline material (plates) obtained on chloroform removal and recrystallization from alcohol gave a negative nitrile reaction; m. p. 116° (unchanged on further recrystallization), spec. rot. +44.9° (25°, D-line, *c* 3.35, $CHCl_3$, 1.894-dm.).

The acetylated oxime on heating at 135° for five minutes gave a sirup that crystallized on the addition of alcohol. The crystals melted at 115–116° and were the original substance. Unchanged material (m. p. 116°) also was returned on refluxing for fifteen minutes with acetic anhydride and sodium acetate.

Summary

1. A study has been made of the action of the reagent pyridine–acetic anhydride on the oximes of *d*-α-glucoheptose, *d*-glucosamine hydrochloride and *l*-fucose.

2. *d*-α-Glucoheptose oxime and *d*-glucosamine oxime react in an open-chain form to give the acetylated nitriles, even at low temperatures.

3. *l*-Fucose oxime reacts at low temperature in a cyclic form and cyclic-*l*-fucose oxime pentaacetate predominates among the substances obtained. At higher temperatures one part reacts in an open-chain form and *l*-fuconitrile tetraacetate is produced and predominates at 100°.

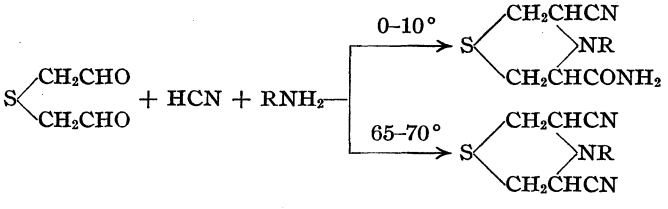
Studies in the Thiamorpholine Series. II. N-Alkyl Substituted Derivatives

BY HELEN I. MINER,[1] EDWIN O. HOOK[1] AND ROBERT D. COGHILL[2]

In the first paper of this series was described the reaction between thiodiacetaldehyde, hydrocyanic acid and ammonia to produce the half-amide, half-nitrile of thiamorpholine 3,5-dicarboxylic acid. The use of the Strecker reaction in this fashion for ring-closure in the thiamorpholine series has now been extended by using various aliphatic amines in place of the ammonia.

During the course of a study of the original synthesis in order to determine better reaction conditions, it was found that by allowing the reaction to proceed at temperatures of 65–70° instead of 0°, the dinitrile of the acid was obtained rather than the nitriloamide. This situation was also found to hold when methyl- or ethylamine was substituted for the ammonia, the dinitriles being formed at the elevated temperatures. These reactions can be expressed by the equations



In the cases of other amines, benzylamine formed only the dinitrile, while *n*-butyl-, *n*-amyl-, isoamyl- and *n*-heptylamine produced the nitriloamides. To date it has not been found possible to cause either reaction to take place with aniline.

Attempts have been made to hydrolyze these compound products to the corresponding N-alkyl

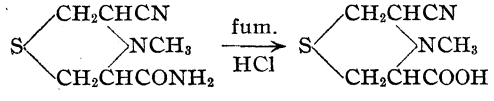
thiamorpholine-3,5-dicarboxylic acids, but so far with very meager success. The compounds are unstable and decompose under most of the reaction conditions used. The odor of hydrocyanic acid becomes quite pronounced and the material rapidly transforms into red or black tars. In one case, however, using cold fuming hydrochloric acid, the amide group of the N-methyl derivative was hydrolyzed to a carboxyl.



This nitrilo acid, when subjected to more strenuous conditions, also gave rise to colored tar-like products. Further attempts are being made to accomplish this hydrolysis in a satisfactory manner.

Experimental

All melting points are corrected.

3,5-Dinitrilothiamorpholine.—Fifty-three grams of acetalyl sulfide was hydrolyzed and the resulting solution of thiodiacetaldehyde concentrated to 100 cc. as previously described.[3] To this solution, held at a temperature of 0°, were added 4 drops of piperidine and 16 cc. of liquid hydrogen cyanide. After standing ten minutes 7 g. of ammonia gas was led in without cooling. The temperature rapidly rose to 70° and a crystalline material separated. This was filtered off, washed with ice-water and dried; yield, 13.9 g. or 43%. After recrystallization from 95% alcohol the product was obtained as four-sided plates which melted with decomposition at 214°.

Anal. Calcd. for dinitrile, $C_6H_7N_3S$: C, 47.0; H, 4.6; N, 27.4; S, 20.9. Found: C, 47.0; H, 4.5; N, 26.8; S, 21.0.

N-Alkyl Dinitrilothiamorpholines.—These were prepared as described above except for the substitution of methyl-, ethyl- and benzylamines for the ammonia. Table I portrays the melting points and analyses of these substances.

N - Alkyl - 3 - nitrilothiamorpholine - 5 - carboxamides.—These compounds were prepared as described for the dinitriles, except that during the addition of the amines the temperatures were kept below 10°. Liquid amines were added slowly from a dropping funnel. The melting points and analyses of these substances are given in Table I.

N-Methyl-3-nitrilothiamorpholine-5-carboxylic Acid.—Five grams of N-methyl-3-nitrilothiamorpholine carboxamide was dissolved in 50 cc. of cold fuming hydrochloric acid and allowed to stand for five days at 10° and an additional five days at room temperature. After removal of the hydrochloric acid *in vacuo* at low temperature the residue was taken up in 50 cc. of cold water, which dissolved the tarry material and left some crystals in suspension. These were filtered off, washed, and recrystallized from boiling water. They melted at 184–185° and decomposed aqueous sodium bicarbonate; yield, 0.6 g. (12%).

Anal. Calcd. for $C_7H_{10}O_2N_2S$: C, 45.15; H, 5.41. Found: C, 45.06; H, 5.35.

We gratefully acknowledge a grant from Sharp and Dohme which made possible a part of this work.

Summary

Several new N-alkyl substituted thiamorpholines have been prepared and described.

Studies in the Thiamorpholine Series. III. Derivatives of Thiamorpholine-3,5-dicarboxylic Acid

BY EDWIN O. HOOK,[1] HELEN I. MINER,[1] AND ROBERT D. COGHILL[2]

A study of thiamorpholine-3,5-dicarboxylic acid with the view to the preparation of possibly pharmacologically active products has been in progress since the original synthesis of the parent substance, described in the first paper of this series.[3]

The thiamorpholine nucleus with acid groups in the 3,5-positions seems to be reasonably stable to ordinary reactions. The sulfur atom has been oxidized by peroxide to sulfoxide and the carboxyl groups themselves can be esterified readily. The NH group, being alpha to both carboxyls, is apparently somewhat sterically hindered, as the hydrogen is replaced with comparative slowness by such reagents as carbobenzoxy chloride and ethyl chlorocarbonate.

The action of acetic anhydride on the acid leads to a compound which seems to be the anhydride of the acetyl derivative. This would seem to indicate, but not necessarily prove, that the thiamorpholine-3,5-dicarboxylic acid previously described had the meso (*cis*) structure, rather than the racemic (*trans*).

A description of the derivatives prepared is given.

Experimental

All melting points are corrected.

1-Oxothiamorpholine-3,5-dicarboxylic Acid.—One gram of thiamorpholine-3,5-dicarboxylic acid, 20 cc. of acetic acid and 5 cc. of acetic anhydride were mixed in a round-bottomed flask and cooled in an ice–salt-bath. One gram of 30% hydrogen peroxide was then added slowly during vigorous stirring. The reaction was now allowed to stand at room temperature for five days, during which time crystals separated. These were filtered off, washed with water and recrystallized from water; m. p. 242° (dec.). The yield was 0.69 g. (64%).

Anal. Calcd. for $C_6H_9O_5NS$: C, 34.8; H, 4.4; N, 7.8; S, 15.5. Found: C, 34.8; H, 4.6; N, 6.1; S, 15.6.

N-Acetylthiamorpholine-3,5-dicarboxylic Acid Anhydride.—This compound was obtained by adding thiamorpholine-3,5-dicarboxylic acid to boiling acetic anhydride; m. p. 143° (dec.).

Anal. Calcd. for $C_8H_9O_4NS$: C, 44.6; H, 4.2. Found: C, 44.4; H, 4.5.

N - Carbobenzoxythiamorpholine - 3,5 - dicarboxylic Acid.—A mixture of 2 g. of thiamorpholine-3,5-dicarboxylic acid and 5 g. of sodium bicarbonate was dissolved in about 20 cc. of water. The solution was treated with 6 cc. of carbobenzoxy chloride, added in four portions over a period of two hours. Between additions the mixture was shaken in the shaking machine and shaking was continued overnight (fifteen hours) to complete the reaction. The solution was then extracted three times with ether to remove benzyl alcohol and any unchanged carbobenzoxy chloride, treated with Norite for an hour at room temperature, and filtered. Upon acidification of the filtrate with hydrochloric acid, the product separated as an oil, which after standing overnight in an oven at about 40° became crystalline; yield, 2 g. (59%). Upon slow evaporation of a water solution of this material, colorless rectangular prisms were obtained which melted at 149.5–150°.

Anal. Calcd. for $C_{14}H_{15}O_6NS$: C, 51.7; H, 4.6; S, 9.9. Found: C, 51.6; H, 4.6; S, 10.2.

Diethyl Ester of Thiamorpholine-3,5-dicarboxylic Acid.—A mixture of 10 g. of finely-powdered thiamorpholine-3,5-dicarboxylic acid, 200 cc. of absolute alcohol, and 5 cc. of concentrated sulfuric acid was refluxed for twenty-four hours in a 500-cc. 2-necked flask fitted with a dropping funnel and an efficient fractionating column equipped with a total-condensation variable take-off stillhead. Ten cc. of dry benzene was added through the dropping funnel and distilled from the flask, first as the ternary mixture with alcohol and water boiling at 64°, and later as the binary mixture with alcohol boiling at 68°, until the distillation temperature had risen to the boiling point of pure alcohol. This procedure was repeated after the eighth hour of refluxing. Little or none of the distillate came over below 68°. After four hours of refluxing, the sulfuric acid was neutralized by the cautious addition of 10 g. of calcium carbonate, after which the mixture was filtered and the precipitate washed by trituration with a small amount of 95% alcohol. The alcohol was distilled from the combined filtrate and washings under reduced pressure and the residual sirup taken up in 25–30 cc. of water. The solution was made basic with sodium bicarbonate and extracted four times with 20-cc. portions of ether. After drying of the extract and removal of the ether the product was distilled *in vacuo*. A light yellow oil boiling at 154–156° at 3 mm. was obtained; yield, 8.3 g. (64%); $n^{20}D$ 1.4924.

Anal. Calcd. for $C_{10}H_{17}O_4NS$: S, 12.96. Found: S, 12.90. The ester formed a hydrochloride, m. p. 148°.

Anal. Calcd. for $C_{10}H_{18}O_4NSCl$: Cl, 12.49. Found: Cl, 12.45.

β-Diethylaminoethyl Ester of Thiamorpholine-3,5-dicarboxylic Acid (Trihydrochloride).—To 3.3 g. of the diethyl ester of thiamorpholine-3,5-dicarboxylic acid were added 50 cc. of freshly distilled β-diethylaminoethanol and 0.2 g. of sodium. The mixture was then refluxed for one and one-half hours in a flask fitted with an efficient frac-

tionating column equipped with a total-condensation variable take-off stillhead. The ethyl alcohol formed in the alcoholysis was fractionated from the mixture at frequent intervals. About 1.5 cc. of material boiling below 150° was separated during the course of the reaction. The excess β-diethylaminoethanol was removed from the reaction mixture by distillation on the steam-bath under reduced pressure, and the residue was dissolved in a small amount of ice-water. The solution was extracted three times with ether and the extracts washed three times with ice-water and dried. On passing hydrogen chloride into the ether solution the product separated as a dark tar which was recrystallized from *n*-butyl alcohol; m. p. 208°, (dec.); yield, 1.3 g. (17%).

Anal. Calcd. for $C_{18}H_{38}O_4N_3SCl_3$: C, 43.3; H, 7.7; N, 8.4; S, 6.4; Cl, 21.3. Found: C, 43.9; H, 7.8; N, 8.5; S, 6.2; Cl, 20.3.

γ-Diethylaminopropyl Ester of Thiamorpholine-3,5-dicarboxylic Acid (Trihydrochloride).—This substance was prepared in the same general fashion as just described for the β-diethylaminoethyl ester; m. p. 215° (dec.).

Anal. Calcd. for $C_{20}H_{42}O_4N_3SCl_3$: N, 7.97. Found: N, 7.98, 7.71.

Thiamorpholine - 3,5 - di - (β - diethylaminoethyl) - carboxamide.—A mixture of 1 g. of the diethyl ester of thiamorpholine-3,5-dicarboxylic acid and 1.5 g. of β-diethylaminoethylamine was heated to 160–170° for twelve hours in an open test-tube supported in a Wood's metal bath. Excess amine was removed from the reaction mixture by distillation on the steam-bath under reduced pressure. The residue was dissolved in 50 cc. of dry ether and the product precipitated as the hydrochloride by adding an ethereal solution of hydrogen chloride. The material so obtained was a tan-colored, very hygroscopic, crystalline solid. It was purified by dissolving in hot absolute alcohol, adding ether to the point of turbidity, and allowing to cool. After four such recrystallizations a pure white, practically non-hygroscopic product was obtained which decomposed in the neighborhood of 245°, depending on the rate of heating; yield, 1.1 g. (55%).

Anal. Calcd. for $C_{18}H_{40}O_2N_5SCl$: C, 43.5; H, 8.1. Found: C, 43.0; H, 8.3.

We gratefully acknowledge a grant from Sharp and Dohme which made possible a part of this work.

Summary

Some new derivatives of thiamorpholine-3,5-dicarboxylic acid have been prepared, several of them having interesting pharmacological potentialities.

The Structure of Trimethyl Glucurone

BY RICHARD E. REEVES[1]

Pryde and Williams[2] have prepared from glucurone a crystalline trimethyl derivative which they regard to be 1,2,4-trimethylglucurone (I). Although no evidence substantiating this structure has been presented, Marrack and Carpenter[3] also refer to the trimethylglucurone as having this structure. Such a substance on hydrolysis and oxidation might be expected to yield 2,4-dimethylsaccharic acid, which is wanted as a reference compound in this Laboratory.

When the trimethylglucurone, m. p. 129–130°, was prepared, its properties were found to resemble those of a methylfuranoside more than the methylpyranoside called for by structural formula I. On acid hydrolysis reducing sugar was liberated at the rapid rate characteristic of methylfuranosides.[4] Pryde and Williams have noted the rapid fall in rotation when trimethylglucurone is dissolved in methanol containing hydrogen chloride. It is now shown that this fall in rotation is accompanied by the formation of an isomeric trimethylglucurone, m. p. 90–91°, having a low rotation. This suggests the rapid mutarotation which Levene and Meyer[5] have observed for α- and β-methylfuranosides under similar conditions.

The high melting trimethylglucurone was hydrolyzed and oxidized to a dimethylsaccharic acid which was characterized as the crystalline diamide. When the crude dimethylsaccharic acid was esterified with cold ethereal diazomethane, no crystalline dimethylsaccharic acid esters or lactone esters were obtained; instead there was produced an unsaturated dimethyl lactone methyl ester (II) known to have its methyl groups on positions 2 and 5.[6] This

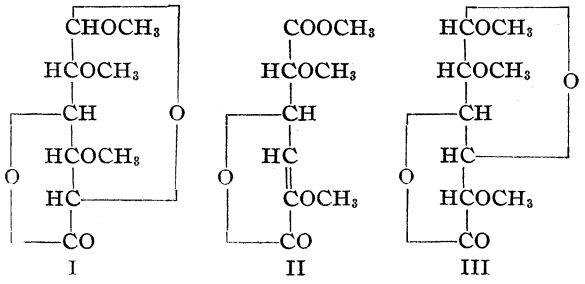
finding, together with the above-mentioned properties, make it appear that the furanoside structure III, 2,5-dimethyl-α-methylglycoside of glucurone, is probably the correct structure for the trimethylglucurone of Pryde and Williams. The low melting isomer and the diamide are regarded as 2,5-dimethyl-β-methylglycoside of glucurone and 2,5-dimethylsaccharic acid diamide, respectively.



Experimental Part

High-Melting Trimethylglucurone.—Pryde and Williams[1] report a 25% yield of this substance following three methylations of glucurone with silver oxide and methyl iodide. By the present procedure a 50% yield was obtained after one methylation. To 5.11 g. of glucurone was added 15 cc. of acetone and 20 cc. of methyl iodide. The vigorously stirred mixture was cooled in an ice-bath during the addition of 3 g. of silver oxide. The temperature was gradually raised to 45° with the addition of 27 g. of silver oxide during nine hours. Fifteen cc. of methyl iodide and 10 cc. of acetone were added and the mixture was then refluxed at 45–48° for five hours. The product was extracted with chloroform and crystallized from acetone by the addition of ether, a second and third crop being obtained from the mother liquors. After recrystallization 2.71 g. of 2,5-dimethyl-α-methylglycoside of glucurone, m. p. 129–130°, was obtained; sp. rot. (D-line) (24°) 151° (*c*, 0.4 in $CHCl_3$).

Low-melting Trimethylglucurone.—Trimethylglucurone, m. p. 129–130°, (372.6 mg.) was dissolved at 23° in 15 cc. of methanol containing 3.6% dry hydrogen chloride. After seventy minutes the rotation (1-dm. tube) became constant at −0.03°. The solution was evaporated to dryness *in vacuo* and, when the residue was redissolved in methanol and again taken to dryness, crystals formed in the distillation flask. Recrystallization from methanol and ether gave 270 mg. of 2,5-dimethyl-β-methylglycoside of glucurone, m. p. 90–1°, sp. rot. (D-line) (21°) 2.0° (*c*, 1.0 in H_2O); (24°) −2.3° (*c*, 0.9 in $CHCl_3$).

Anal. Calcd. for $C_9H_{14}O_6$: C, 49.53; H, 6.42; CH_3O, 42.6. Found: C, 49.24; H, 7.15; CH_3O, 42.85.

Kinetics of Hydrolysis.—Trimethylglucurone (94.6 mg.) m. p. 129–130° was refluxed in 50 cc. of 0.05 *N* hydrochloric acid and the reducing sugars were determined at intervals by the modified Hagedorn–Jensen procedure.[7] The results are given in cc. of 0.01 *N* thiosulfate required by 1 cc. of hydrolysate after refluxing for a stated length of time: 0 min., 0.11 cc.; 5 min., 1.76 cc.; 15 min., 3.91 cc.; 30 min., 4.65 cc.; 60 min., 4.49 cc. To minimize the effect of the gradual decomposition of reducing sugar a curve was drawn through the points and the velocity constant was calculated by the method of Guggenheim[8] for the first twenty minutes of the hydrolysis. The value was found to be $k = 1380 \times 10^{-5}$ min.$^{-1}$ for *N*/100 HCl at 100°, which is definitely within the range exhibited by most furanosides. When recalculated on the basis of natural logarithms the values found by Haworth and Hirst[4] for furanosides in 0.01 *N* acid at 100° range from 600×10^{-5} to $11{,}000 \times 10^{-5}$.

2,5-Dimethylsaccharic Acid Diamide.—Trimethylglucurone (100 mg.), m. p. 129–130°, was heated for four hours at 80–85° in 4 cc. of dilute nitric acid, sp. gr. 1.2. Nitric acid was removed by evaporating *in vacuo*, adding water and repeatedly evaporating to dryness *in vacuo*. The residue was then esterified by heating for three hours at 75° in a sealed tube with 4 cc. of methanol containing 2% dry hydrogen chloride. The hydrogen chloride was removed with silver carbonate. Attempts to obtain crystals from this ester both before and after vacuum distillation were unsuccessful. The sirup was dissolved in 2 cc. of methanol, cooled to 0°, and treated with ammonia gas. Crystals separated, and more were obtained by the addition of ether to the mother liquors; 43 mg. of crude material yielded 11 mg. of pure diamide, m. p. 169–170°, after three recrystallizations from ethanol.

Anal. Calcd. for $C_8H_{16}O_6N_2$: C, 40.68; H, 6.78; N, 11.88; CH_3O, 26.3. Found: C, 40.62; H, 6.77; N, 11.70; CH_3O, 26.46.

Unsaturated Saccharolactone Methyl Ester II.—Two hundred mg. of high-melting trimethylglucurone was hydrolyzed and oxidized with nitric acid as in the preparation of the diamide. The saccharic acid after removal of nitric acid and water was treated with 15 cc. of an 0.5 molar solution of diazomethane in ether, and allowed to stand at 0° for three days. The solution was filtered from a small flocculent precipitate, and concentrated to 3 cc. Forty mg. of crystals separated, which on recrystallization from acetone–ether melted at 85–86.5°. Mixed with the unsaturated lactone ester, m. p. 87–88°, prepared from saccharolactone methyl ester[9] the melting point was 86–87°.

Summary

Evidence is presented which indicates that the trimethylglucurone prepared by Pryde and Williams is the 2,5-dimethyl-α-methylglycoside of glucurone.

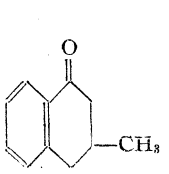
NOTES

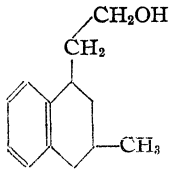
The Preparation of 3-Methyl-1-tetralone and β-[1-(3-Methyl-1,2,3,4-tetrahydronaphthyl)]-ethyl Alcohol

By W. E. Bachmann and W. S. Struve

In the course of an investigation β-[1-(3-methyl-1,2,3,4-tetrahydronaphthyl)] - ethyl alcohol (II) was required. The starting material for the preparation was γ-phenyl-β-methylbutyric acid, which was prepared from 1-allylbenzene according to the procedure of Carter.[1] Cyclization of the acid through its acid chloride by means of aluminum chloride gave 3-methyl-1-tetralone (I), whose structure was established by its conversion to β-methylnaphthalene by Clemmensen reduction and subsequent dehydrogenation of the product. By means of the Reformatsky reaction with methyl bromoacetate and subsequent dehydra-



I



II

tion of the resulting hydroxy ester, the ketone was converted into what is probably the methyl ester of 1-(3-methyl-3,4-dihydronaphthyl)-acetic acid, although the position of the double bond was not established. Reduction of the ester by means of sodium and alcohol yielded the desired alcohol (II). The alcohol reacted with phosphorus tribromide to give the corresponding bromide.

Experimental

3-Methyl-1-tetralone.—A mixture of 25.5 g. of γ-phenyl-β-methylbutyric acid, 20 cc. of thionyl chloride, and 5 drops of pyridine was allowed to stand at room temperature for a half hour. The thionyl chloride was evaporated under reduced pressure, 150 cc. of carbon disulfide was added and the solution was cooled in an ice–salt mixture. Twenty-two grams of aluminum chloride was added in portions and the mixture was refluxed for ten minutes. After hydrolysis of the complex with ice and hydrochloric acid, the organic layer was separated, the carbon disulfide was evaporated, and the residue was dissolved in benzene. The benzene solution was washed with dilute ammonium hydroxide and with water and the benzene was evaporated. The 3-methyltetralone distilled under reduced pressure as a colorless liquid at 94–96° at 0.3 mm.; weight, 16.7 g. (73%).

Anal. Calcd. for $C_{11}H_{12}O$: C, 82.5; H, 7.5. Found: C, 82.4; H, 7.4.

The **oxime** crystallizes from dilute alcohol as colorless needles; m. p. 122.5–123.5°.

Anal. Calcd. for $C_{11}H_{13}NO$: N, 8.0. Found: N, 7.8.

A mixture of 5 g. of the above ketone, 25 g. of amalgamated zinc, 50 cc. of concentrated hydrochloric acid, 25 cc. of water, and 2.5 cc. of acetic acid was refluxed for twenty-four hours, an additional 50 cc. of concentrated hydrochloric acid being added in portions over this time. The oil was extracted with ether, the ether extract was dried with anhydrous sodium sulfate, and the residue obtained by evaporation of the ether was distilled at 12 mm. pressure. The colorless distillate was heated for four hours at 200–220° with 2.3 g. of powdered sulfur. A small amount of copper bronze was then added and the heating was continued for ten minutes more. The mixture was extracted with ether, the filtered ether solution, after having been dried with anhydrous sodium sulfate, was evaporated, and the residue was distilled at 10 mm., giving 2.0 g. of colorless distillate which solidified on cooling to room temperature; m. p. 29–30.5°. After being purified through the picrate, the hydrocarbon melted at 34–35°. The mixed melting point with authentic β-methylnaphthalene gave no depression. The picrate melted at 115–116.5° and the mixed melting point with authentic β-methylnaphthalene picrate gave no depression.

Methyl 1-(3-Methyl-3,4-dihydronaphthyl)-acetate.—A mixture of 20 g. of 3-methyl-1-tetralone, 14.4 cc. of methyl bromoacetate, 48 g. of zinc, 480 cc. of dry ether, 480 cc. of dry benzene, and a small amount of iodine was refluxed for four hours, additional zinc and iodine being added at the end of each hour and an additional 14.4 cc. of methyl bromoacetate being added at the end of the second hour. The complex was decomposed with ice and hydrochloric acid, the organic layer was washed with ammonium hydroxide and then with water, and the benzene and ether were evaporated. The hydroxy ester was dehydrated by heating with 100 cc. of anhydrous formic acid on a steam-bath for fifteen minutes; water was added and the ester was extracted several times with benzene. The benzene extract was washed with dilute sodium carbonate solution and then with water, the benzene was evaporated, and the residue was distilled under reduced pressure, the yellowish liquid distilling at 130–133° at 0.4 mm. being collected; weight, 23 g. (85%).

Anal. Calcd. for $C_{14}H_{16}O_2$: C, 77.8; H, 7.4. Found: C, 77.6; H, 7.6.

β - [1 - (3 - Methyl - 1,2,3,4 - tetrahydronaphthyl)]-ethyl Alcohol.—To a boiling solution of 25 g. of the above ester in 125 cc. of absolute methanol was added 21.3 g. of sodium metal over a period of fifteen minutes. After the vigorous reaction had subsided, another 50 cc. of methanol was added. When all of the sodium had reacted, 100 cc.

(1) Carter, *J. Biol. Chem.*, **108**, 622 (1935).

of water was added and the mixture was refluxed for three hours. The mixture was cooled, acidified with dilute sulfuric acid, and extracted several times with benzene. The benzene extracts were extracted with 2 *N* sodium carbonate solution and with water, the benzene was evaporated, and the residue was distilled under reduced pressure, the colorless viscous liquid distilling at 134–137° at 0.4 mm. being collected; weight, 12.4 g. (57%).

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.1; H, 9.5. Found: C, 81.8; H, 9.4.

The acid obtained by acidification of the alkaline washings was esterified with methanolic hydrochloric acid, purified by distillation (7 g., b. p. 128–133° at 0.4 mm.), and this recovered ester could be used in subsequent reductions.

β - [1 - (3 - Methyl - 1,2,3,4 - tetrahydronaphthyl)]-ethyl Bromide.—A mixture of 5.0 g. of the above alcohol and 2 cc. of phosphorus tribromide was heated on a steam-bath for two hours. The mixture was taken up in benzene and washed with 2 *N* sodium carbonate solution and then with water. The residue obtained by evaporation of the benzene was distilled, the colorless liquid distilling at 137–140° at 0.4 mm. being collected; weight, 5.2 g. (75%).

Anal. Calcd. for $C_{13}H_{17}Br$: Br, 31.6. Found: Br, 31.8.

The Preparation of Pentaacetyl-*d*-gluconyl Chloride

BY CHARLES E. BRAUN, S. H. NICHOLS, JR., J. L. COHEN AND THEIS E. AITKEN

In the course of work being carried out in these laboratories a method has been developed for the preparation of pentaacetyl-*d*-gluconyl chloride in quantity. This new procedure, based upon that of Major and Cook,[1] involves much less manipulation and gives consistently good results. The details are presented here for those interested.

Anhydrous pentaacetylgluconic acid[2] (25 g. or 0.062 mole) was dissolved in 185 cc. of anhydrous ethyl ether and an excess of phosphorus pentachloride (15 g. or 0.072 mole) was added without cooling. The reactants were allowed to stand at room temperature from four to twelve hours (usually overnight). The excess phosphorus pentachloride was then filtered off on a sintered glass funnel, and the ethereal filtrate concentrated to about one-half of its volume *in vacuo* at room temperature. The concentrated solution was kept at zero degrees or below[3] for fifteen to twenty-four hours. The mother liquor was then decanted, *care being taken not to break up or disturb the crystals which had formed on the bottom of the flask.* The crystalline mass was next broken up, mechanically removed and filtered on a sintered glass funnel. After thorough washing with petroleum ether (Eastman Kodak Company, practical, b. p. 35–55°), the crystalline acid chloride was preserved *in vacuo* over calcium chloride and potassium hydroxide at room temperature.

The decanted mother liquor, after being concentrated *in vacuo* at room temperature to one-half of its volume, was allowed to stand at zero degrees or below for another twenty-four hours. The second crop of crystals thus obtained was treated as described above. The concentrated mother liquor which contained all of the phosphorus oxychloride was usually discarded. By this procedure pentaacetyl-*d*-gluconyl chloride was produced as large colorless crystals; m. p. 68–71°; $[\alpha]^{21}D$ +1.71° (alcohol-free chloroform, *c*, 4.38).

Anal. Calcd. for $C_{16}H_{21}O_{11}Cl$: Cl, 8.35. Found: Cl, 8.20.

The yields obtained in five typical preparations were 83%, 86%, 92%, 88% and 93%, or an average yield of 88.4%.

(3) At higher temperatures the yields are decreased appreciably due to the increase in solubility of the acid chloride in the anhydrous ether.

Additional Observations on the Vitamin K Activity of Quinones

BY ERHARD FERNHOLZ, H. B. MACPHILLAMY AND S. ANSBACHER

Several months ago we reported that phlorone (2,5-dimethyl-1,4-benzoquinone) has vitamin K activity,[1] an observation recently confirmed by H. J. Almquist.[2] In this connection it seemed of interest to investigate whether 2-methyl-5,6,7,8-tetrahydro-1,4-naphthoquinone possesses the great potency of the parent substance. The hydrogenated quinone, first synthesized by Chuang and Han,[3] was prepared by catalytic hydrogenation of 2-methyl-1,4-naphthoquinone. It was found to be active at 1 mg., a degree of activity which should be considered practically negligible, since it is common to a great number of quinones.

We have also studied the analogous hydrogenation product of vitamin K_1 (β,γ,5,6,7,8-hexahydrovitamin K_1). It showed no vitamin K activity, not even in a dose of 2 mg. In contrast to this, Fieser, Tishler, and Sampson[4] reported it to have slight activity, although the dosage is not indicated.

We wish to point out that we have prepared and assayed the naphthotocopherol and its quin-

oid oxidation product recently mentioned by Fieser, *et al.*[4] The latter authors gave no biological data for the oxidation product and stated that the tocopherol was active at 0.3 mg. We found that 1 mg. of the tocopherol was totally inactive, but the oxidation product was fully active at that dose.[5]

Experimental

2 - Methyl - 5,6,7,8 - tetrahydro - 1,4 - naphthoquinone.—A solution of 1.72 g. of 2-methyl-1,4-naphthoquinone in glacial acetic acid was completely hydrogenated using platinum oxide catalyst. The reaction mixture was decanted from the catalyst, diluted with water and extracted with ether. The ethereal solution was washed, dried and the solvent evaporated. The quinone was obtained by steam distilling a suspension of the crude hydroquinone in a ferric chloride solution. The distillate was extracted with ether, the extract dried and the solvent evaporated. The residue after recrystallization from light petroleum ether yielded 1.6 g. (94%) of quinone melting at 58–59°.

Anal. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.87. Found: C, 74.95; H, 6.71.

β,γ-5,6,7,8-Hexahydro Vitamin K_1.—One gram of the synthetic vitamin was hydrogenated as described above. The hydroquinone was oxidized with silver oxide in dry ether. The yield was 0.95 g. (95%) of yellow oil giving with alcoholic alkali a pink color which darkened to brown on standing.

Anal. Calcd. for $C_{31}H_{52}O_2$: C, 81.52; H, 11.47. Found: C, 81.17; H, 11.60.

Naphthotocopherol.—A mixture of 3.5 g. of 2-methyl-1,4-naphthoquinone, 5 g. of phytol, 5 g. of anhydrous zinc chloride and 50 cc. of xylene[6] was refluxed for twenty-four hours. The solvent was removed *in vacuo* and the residue taken up in ether. The ethereal solution was washed repeatedly with 2% potassium hydroxide solution containing hydrosulfite and finally with dilute hydrochloric acid and water. After drying and removal of the solvent, the remaining brown oil was taken up in petroleum ether (b. p. 40–60°), and extracted with Claisen alkali. The small amount of yellow oil obtained on working up the soluble portion gave the typical Dam–Karrer reaction for vitamin K_1.

The petroleum ether portion was washed, dried and the solvent evaporated. The residue was purified by chromatographic adsorption on activated alumina in petroleum ether solution. The yield was about 1.0 g. (13% based on phytol), of reddish-brown oil which strongly reduced an alcoholic silver nitrate solution in the cold.

Anal. Calcd. for $C_{31}H_{48}O_2$: C, 82.24, H, 10.70. Found: C, 82.48; H, 10.72.

Oxidation of Naphthotocopherol.—Two hundred milligrams of the above tocopherol was oxidized with ferric chloride in alcoholic solution. The reaction mixture was diluted with water, extracted with ether, and the ethereal solution washed, dried and concentrated. The residue was purified by chromatographing in petroleum ether solution on activated calcium sulfate. About 100 mg. (48%) of dark orange oil was obtained.

Anal. Calcd. for $C_{31}H_{48}O_3$: C, 79.43; H, 10.30. Found: C, 79.42; H, 10.03.

Collidine Treatment of 2-Bromocholestanone

BY ROBERT P. JACOBSEN

In the course of preparation of certain steroids for photochemical study, the author has had occasion to employ the collidine method of Butenandt, *et al.*,[1] for the splitting of hydrogen bromide from 2-bromocholestanone to form 1-cholestenone. On refluxing a collidine solution of the bromo compound for two hours, these workers obtained the α,β-unsaturated ketone (m. p. 95°, $[\alpha]_D$ + 64.5°) in 77% yield. Butenandt and Wolff[2] had earlier reported the preparation of 1-cholestenone (m. p. 111–112°, $[\alpha]_D$ −32.1°; oxime, m. p. 146–147°), in poor yield by the potassium acetate–acetic acid treatment of 2-bromocholestanone. This latter compound the German workers now call "hetero-Δ^1-cholestenone" and state that the "normal Δ^1-ketone" is the substance melting at 95°.

In the experience of the author, the collidine reaction appears to follow a less straightforward course than that indicated by Butenandt and his collaborators. 2-Bromocholestanone (m. p. 169°) was refluxed in collidine[3] for two, four, or six hours without effecting the complete fission of hydrogen bromide. After twelve hours of boiling, a non-homogeneous, crystalline, halogen-free product (m. p. 89–92° to a sludge which cleared at about 100°) was obtained in 74% yield. By repeated crystallization from methanol this gave a very small amount of material, m. p. 126–127.5° (nearly pure cholestanone), which showed no selective absorption[4] in the ultraviolet region between 2200 and 2600 Å. No pure 1-cholestenone could be obtained from the intermediate fractions by crystallization, although some sam-

(1) Butenandt, Mamoli, Dannenberg, Masch and Paland, *Ber.*, **72**, 1617 (1939).

(2) Butenandt and Wolff, *ibid.*, **68**, 2091 (1935).

(3) Obtained from the Research Department of the Barrett Company, 90% of the material boiling in the range 170.7–171.9°.

(4) Ultraviolet absorption measurements by Dr. P. A. Cole and Mr. C. Z. Nawrocki of this Laboratory.

ples[5] which melted at 93–96° showed an ultraviolet absorption maximum at 2275 Å. (log ϵ 4.07, cyclohexane). By brominating the combined intermediate fractions (0.5 g.) in cold acetic acid (5 cc.) there was obtained 0.20 g. of impure 1-cholestenone dibromide (effervesces at 85°). On allowing the filtrate to stand for a few minutes, hydrogen bromide was evolved and there separated 0.095 g. of needles, m. p. 152–156°. The dibromide liberated iodine on warming in an alcoholic sodium iodide solution but the needles did not. The latter on crystallization from methyl acetate melted at 169° and mixed with 2-bromocholestanone showed no depression. The crude dibromide was debrominated with sodium iodide or zinc dust in alcohol, or potassium iodide in 80% acetone, to give the corresponding unsaturated ketone, m. p. 102–104°. By repeating the purification through the dibromide, pure 1-cholestenone, crystallizing as a hydrate from 98% methanol or aqueous acetone, m. p. 107–108° ($[\alpha]^{24}D$ +65°).

These observations indicate that the collidine treatment of 2-bromocholestanone, under the conditions specified, gives principally a mixture of 1-cholestenone and cholestanone. The formation of the latter compound is not surprising in view of the work of Schwenk and Whitman,[6] who obtained cholestanone as the principal product of the treatment of 2-bromocholestanone with dimethylaniline.

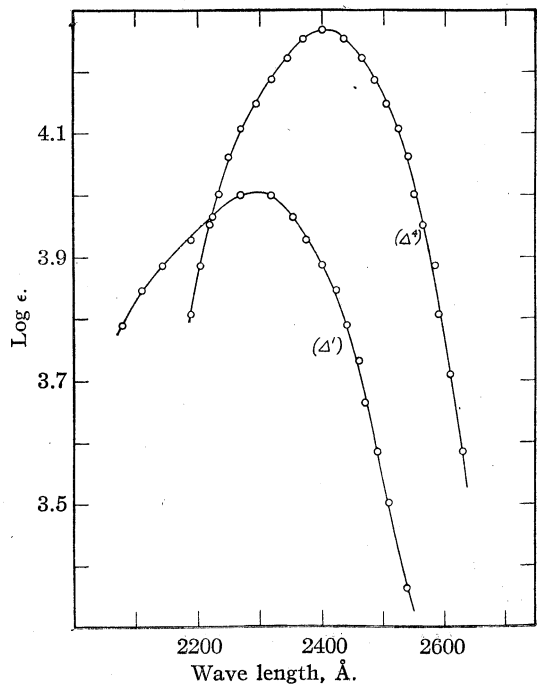

Fig. 1.

The ultraviolet absorption in alcohol of 1-cholestenone hydrate (calculated on the anhydrous basis) in the region of the maximum is compared with that of the Δ^4-isomer in Fig. 1.

The preparation of 1-cholestenone will be detailed later in connection with a report of photodehydrogenation studies now in progress.

(5) These properties correspond closely to those of the product (m. p. 95°) of Butenandt, *et al.*, who reported a maximum at 230 mμ (log ε 4.03).

WASHINGTON BIOPHYSICAL INSTITUTE
BETHESDA, MARYLAND RECEIVED APRIL 27, 1940

The Behavior of Certain Substituted Allenes toward the Meinel Color Test[1]

BY F. B. LAFORGE AND FRED ACREE, JR.

A method for the detection of conjugated double bonds has been proposed by Meinel[1a] based upon the treatment of the compound to be tested with one molecular equivalent of bromine in methanol solution. The isolated reaction product is then treated with a suspension of silver thiocyanate containing ammonium ferric sulfate. The formation of a red color of variable intensity depending upon the compound is indicative of the presence of a conjugated system of double bonds.

Conant and Jackson[2] have reported the formation of dibromo compounds along with the methyl hypobromite addition products when bromine in methanol solution is allowed to react on an unsaturated compound. Thus, while Meinel indicated that the methyl hypobromite addition product is responsible for the reaction with silver thiocyanate, there also is the possibility that the dibromo addition product might be the influencing factor in the reaction.

Meinel subjected a number of compounds to the test but did not include any that possessed a cumulated system of double bonds.

In studying the reaction of halogens[3] on compounds of this class it was of interest to determine whether or not they would also respond to the color test.

It was found that 1-phenyl-1,2-butadiene, 2,3-pentadiene, 1-cyclohexyl-2,3-pentadiene, and pyrethrone gave a positive reaction. When com-

pared with myrcene, 1-pentene and styrene dibromide, the approximate speed and the intensity of the color formation were greatest in the case of the 1-phenyl-1,2-butadiene and decreased in the order named with the other compounds.

Since compounds possessing a cumulated system of double bonds respond to the Meinel tests, the method is not specific for the conjugated system.

BUREAU OF ENTOMOLOGY AND PLANT QUARANTINE
U. S. DEPARTMENT OF AGRICULTURE
WASHINGTON, D. C. RECEIVED APRIL 10, 1940

Preparation of Phenylacetone

BY J. PHILIP MASON AND LEWIS I. TERRY

Phenylacetone has been prepared by several methods.[1] We have obtained it in a 32% yield from benzene, chloroacetone and anhydrous aluminum chloride.

Experimental

Forty-one grams (0.31 mole) of anhydrous aluminum chloride and 100 ml. of anhydrous benzene (free from thiophene) were put in a 500-ml. three-necked flask which was equipped with a mercury-sealed stirrer, a reflux water condenser and a small addition funnel. The top of the condenser was connected to a sulfuric acid trap and this trap was connected to a gas absorption bottle. The mixture was stirred, heated to refluxing on a steam-bath and 13.9 g. (0.15 mole) of chloroacetone was allowed to drop in slowly during a period of thirty minutes. After refluxing for five hours, the mixture was practically black. After cooling to room temperature, the reaction mixture was decomposed by adding water slowly through the addition funnel, stirring during the addition. When no more hydrogen chloride was evolved, 20 ml. of water and 20 ml. of concentrated hydrochloric acid were added. The benzene layer was separated and the aqueous layer extracted with four 25-ml. portions of benzene. All of the benzene solutions were combined and filtered. The benzene was distilled and the remaining viscous oil was distilled under reduced pressure. Nine grams of liquid boiling below 123° (20–22 mm.) was obtained. Approximately 10 g. of high-boiling liquid was left in the distilling flask.

Phenylacetone was recovered from the distillate by making the sodium bisulfite addition product, filtering, decomposing the addition product with sodium carbonate solution and steam distilling as long as any oil distilled. The distillate was extracted with ether, the ether solution dried over anhydrous magnesium sulfate and the ether distilled on a steam-bath. The phenylacetone was distilled under reduced pressure, b. p. 108–114° at 20–22 mm.; yield, 6.5 g. or 32%. The semicarbazone melted at 188°.[2]

Several variations of this procedure were tried in an effort to increase the yield. The yield was decreased by (a) decreasing the time of refluxing to one or two hours after the addition of the chloroacetone, (b) lowering the temperature of the reaction and allowing a longer time for its completion, (c) adding the aluminum chloride in small portions over a period of two hours to a boiling mixture of benzene and chloroacetone, and then refluxing for two hours. No change in the yield occurred when (a) the ratio of chloroacetone and aluminum chloride to benzene was increased, or (b) the ratio of aluminum chloride was increased from two equivalents to 2.5 equivalents.

Vapor Pressures of Trimethylphosphine, Trimethylarsine and Trimethylstibine

BY E. J. ROSENBAUM AND C. ROGER SANDBERG

We prepared pure samples of the methyl derivatives of phosphorus, arsenic and antimony for an investigation of their Raman spectra. Because of the paucity of data on the physical constants of these compounds we have measured their vapor pressures. Phosphorus methyl and antimony methyl were prepared from methylmagnesium iodide and the corresponding trichloride.[1] The crude phosphorus methyl was purified by precipitation with silver iodide,[2] washing thoroughly and heating gently in a vacuum to regenerate the phosphorus methyl. Arsenic methyl was prepared by a modification of the method of Renshaw and Holm.[3] A small amount of arsenic trichloride was condensed on zinc methyl cooled by a carbon dioxide–acetone bath, which was slowly removed until the reaction was complete. Then the bath was replaced and more arsenic trichloride was condensed. This procedure was repeated until all of the reagents were used up. The resulting double salt was decomposed with sodium hydroxide solution, forming arsenic methyl.

In all cases the products were dried over phosphorus pentoxide and fractionated many times, the final fractionation being in a vacuum. The vapor pressures of head and tail fractions agreed to within 1 part in 500. The Raman spectra of these compounds showed no lines which could not be attributed to the compounds themselves. This, of course, is not a very sensitive criterion of purity.

The vapor pressures were measured in the range −25 to +25° with a mercury manometer and a cathetometer. The temperatures were measured

with a type K potentiometer and a copper–constantan thermocouple calibrated against a thermometer which had been calibrated by the Bureau of Standards. The molecular weights were determined by the vapor density method.

The measured vapor pressures could all be represented by an equation of the conventional form: $\log p = A/T + B$. The values of the constants, the average deviation of the observed from the calculated vapor pressures and the values of certain derived quantities and of the molecular weights are given in the table.

Hydrogen Fluoride as a Condensing Agent. XI. The Reaction of Alcohols and Ethers with Benzene[1]

BY J. H. SIMONS AND S. ARCHER

Hydrogen fluoride has been found[2] to be an effective catalyst for alkylations in which aliphatic alcohols and ethers are used. We have now made additional studies of this reaction using primary, secondary, and tertiary alcohols and their ethers. Good yields were obtained with secondary and tertiary compounds at room temperature; but with primary compounds except benzyl alcohol and ether, 100° was necessary to obtain appreciable yields. *n*-Butyl alcohol and *n*-butyl ether both gave *s*-butylbenzene in about 20% yield. Benzyl alcohol and benzyl ether both gave a 65–70% yield of diphenylmethane at room temperature. From the reaction of isopropyl alcohol with benzene in a mole ratio of about one to seven, four compounds were isolated: isopropylbenzene, 1,4-diisopropylbenzene, 1,2,4-triisopropylbenzene, and 1,2,4,5-tetraisopropylbenzene, in yields of 22.4, 14, 26, and 28%, respectively. The ether gave the same products in yields of 26, 24, 25, and 8%. *t*-Butyl alcohol and *t*-amyl alcohol reacted with benzene, when the mole ratios were about one to seven, to give about 40% monoalkylated and 50% dialkylated products.

Several items of interest are noted from the above experimental results. Alcohols react more readily, *i. e.*, give a good yield at lower temperature, than the corresponding chlorides. For example, secondary chlorides reacted very slowly to give low yields in a twenty-four hour reaction time at room temperature, whereas secondary alcohols or ethers gave high yields at the same temperature. Although the mechanism of the reaction is unknown, one fact is obvious and may be a contributing factor when it is known. When the chlorides are used, hydrogen chloride is evolved; and for reactions at atmospheric pressure its thermodynamic activity in the reaction mixture must equal that for the gas at one atmosphere. When alcohols or ethers are used, water is a product of the reaction; and it remains in solution in the hydrogen fluoride. Its activity in this solution is very much lower than liquid water at the same temperature. For certain mechanisms this difference would contribute to the driving force of the reaction.

The other point of interest lies in the fact that when aluminum chloride is used as the condensing agent, the chlorides react more readily than the alcohols. Reasoning from this and also from the fact that chlorides can be made from the alcohols by treatment with aluminum chloride, the formation of the chloride may be postulated as the first step in the reaction. As the ease of reaction is in the opposite order when hydrogen fluoride is used, the reaction in this case may proceed through a different mechanism.

The ease of reaction of benzyl alcohol is a strong argument against the hypothesis that an olefin is an intermediate in the reaction. Such a mechanism has been postulated by McKenna and Sowa[3] for reactions between alcohols and benzene

in which boron trifluoride was employed. The formation of mesitylene from toluene and methanol in the presence of aluminum chloride reported by Norris and Ingraham[4] also supports this argument.

Calcott, Tinker, and Weinmayr[2a] reporting condensation reactions catalyzed by hydrogen fluoride state, "Dibenzyl ether gave benzyl isocyclic compounds while benzyl alcohol polymerized to 1,2,3,4,5,6-hexaphenylcyclohexane." In our hands, both the alcohol and the ether reacted to give diphenylmethane when treated with benzene and hydrogen fluoride. At room temperature and at 100° alkylation rather than polymerization was the only reaction.

Hydrogen Fluoride as a Condensing Agent. XII. Reactions of Methyl, Ethyl and Phenyl Compounds with Benzene and its Derivatives[1]

BY J. H. SIMONS AND H. J. PASSINO

The use of hydrogen fluoride to promote alkylations has been shown in recent publications from this Laboratory. We are now reporting a study of its use in conjunction with a variety of reagents of potential value for methylation, ethylation, and phenylation. An alcohol, ester and halide were used in investigating each alkylation, and other reagents were used in some cases. Ethylation proceeded with a variety of substances, namely: ethyl alcohol, ethyl iodide, ethyl chlorocarbonate, ethyl acetate, and ethyl ether. Ethyl alcohol and benzene at 200° gave very high yields of ethyl- and diethylbenzenes, while the other reagents gave varying yields with benzene and toluene. Ethylene was tried at 0°, but although indications of the formation of ethylbenzene were observed no product was isolated; and the reaction was not attempted at higher temperatures. Methyl alcohol, methyl acetate, and methyl iodide failed, however, to react with benzene, toluene, or phenol to give methylated products at temperatures up to 200°. The reaction between phenol and methyl alcohol resulted in the formation of anisole, instead of alkylated phenol. Phenol, phenyl acetate, chlorobenzene, and diphenyl ether all failed to give phenylated products, when treated with hydrogen fluoride and an aromatic compound at temperatures up to 200°. Acylation occurred when phenyl acetate was caused to react with benzene at 200° and some acetophenone and phenol were formed.

The formation of anisole led to the attempt at similar reactions. From a reaction between ethyl alcohol and phenol no phenetole was isolated although ethylation occurred, and phenol heated alone at 200° with hydrogen fluoride failed to give diphenyl ether. When diphenyl ether was heated alone with hydrogen fluoride at 210°, some splitting did occur as a small amount of phenol was isolated. The stability of the phenyl ethers is in marked contrast to the ease of reaction of the aliphatic ethers. Anisole has previously been made by the condensation of phenol and methyl alcohol using boron fluoride as the condensing agent.[2]

The failure of hydrogen fluoride to effect methylations is in contrast to the use of aluminum chloride for these reactions. Investigators[3] have recently been able to methylate using methyl alcohol and aluminum chloride. Methylations by means of methyl chloride in the presence of aluminum chloride are well known.

Very little tar formation was experienced with reactions at 200° with the exception of a few experiments in which phenol was used as a reagent.

Saponins and Sapogenins. XV. The Interrelationship of Echinocystic Acid and Oleanolic Acid

BY DAVID TODD, G. H. HARRIS AND C. R. NOLLER

Previous work[1] has indicated that echinocystic acid is closely related to other triterpenoid sapogenins but no derived products identical with those from other triterpenoids have been obtained in which the carbon skeleton remained intact. It has now been found that Clemmensen reduction of norechinocystenone or norechinocystendione gives a hydrocarbon which is identical

(1) Bergsteinsson and Noller, THIS JOURNAL, **56**, 1403 (1934); Noller, *ibid.*, **56**, 1582 (1934); White and Noller, *ibid.*, **61**, 983 (1939).

as determined by melting and mixed melting points, optical rotation and crystal form with oleanene III, obtained by Winterstein and Stein[2] from oleanolic acid. Inasmuch as the preparation of both hydrocarbons involves a Clemmensen reduction which Winterstein and Stein[2] have shown results in a molecular rearrangement in the case of oleanene III, and both hydrocarbons are decarboxylated derivatives, it is not possible to state that echinocystic acid and oleanolic acid have exactly the same skeletons but the possibility that such is the case is very likely.

Experimental

A solution of 0.132 g. of norechinocystenone in 250 cc. of 95% ethyl alcohol was added to 5 g. of amalgamated zinc. The mixture was boiled under a reflux condenser and a slow stream (2–3 bubbles per second) of dry hydrogen chloride was passed in for thirty-six hours. The solution was poured into an equal volume of water and evaporated to 50 cc. After dilution with water to 100 cc. the mixture was extracted with ether. The ether layer was washed with dilute hydrochloric acid, sodium hydroxide and water and dried over anhydrous sodium sulfate. After removal of the ether the residue was crystallized from methyl alcohol in which it is only slightly soluble, and then from acetone to a constant melting point of 224–225°; $[\alpha]^{25}D$ +31.3 ± 3°; c = 1.408 in toluene, l = 0.5 dm.

Anal. Calcd. for $C_{29}H_{48}$: C, 87.80; H, 12.20. Found: C, 87.79; H, 12.12.

The same product as determined by melting and mixed melting points was obtained on reducing norechinocystendione by the above procedure.

Oleanylene II and oleanene III were prepared from oleanolic acid[3] according to the procedures of Winterstein and Stein.[2] The oleanene III was crystallized twice from glacial acetic acid and then from acetone until its melting point was 216.5–220.5°[4]; $[\alpha]^{25}D$ +30.7 ± 3°; c = 2.082 in toluene, l = 0.5 dm.

A mixture with an equal part of the hydrocarbon obtained from norechinocystenone, m. p. 218–221.5°[4], melted at 216.5–221°. The melting points of the mixture and of the two pure products were taken simultaneously in the same bath. Slow evaporation of solutions of the hydrocarbons from both sources gave well formed hexagonal plates which were indistinguishable under a lens. The properties of oleanene III recorded by Winterstein and Stein[2] are m. p. 225–226°; $[\alpha]^{20}D$ +30.1, c = 1.76 in chloroform.

2,4-Dibromo-α-oestradiol

BY ROBERT BURNS WOODWARD

As evidenced by the investigations of Doisy,[1] Butenandt,[2] and Marrian,[3] the phenolic sex hormones are extensively halogenated under the conditions obtaining in the determination of the iodine number with the Rosenmund–Kuhnmann reagent. The number of halogen atoms consumed by one mole of the hormone varied widely with the conditions. Although both Butenandt and Doisy isolated halogen-containing products, these were insufficiently characterized and until further investigation must be regarded as of equivocal nature. Only in the case of equilenin has a definitely pure halogen-substituted hormone been prepared, *viz.*, monobromoequilenin, prepared by Girard, *et al.*,[4] likewise by the action of the Rosenmund–Kuhnmann reagent. On the other hand, Marrian and Haslewood[3] found that the methyl ethers of the hormones consumed approximately one mole of halogen quite smoothly in the iodine number determinations, and this result was confirmed by the isolation of monobromoestrone methyl ether and monobromoestriol methyl ether.

In the course of a related investigation, we have found that α-oestradiol is converted smoothly and almost quantitatively into a dibromoestradiol on standing overnight in alcohol solution with the theoretical quantity of N-bromoacetamide. Since no halogen was removed on treatment with alcoholic silver nitrate or potassium hydroxide, the product was not 2-(*or* 4)-10-dibromo-$\Delta^{1,4}$-oestra-

dienon-3-ol-17 (I, R_1 *or* R_2 = H *or* Br), nor the corresponding pseudo-bromide, 2-(*or* 4)-9-dibromo-α-oestradiol (II, R_1 *or* R_2 = H *or* Br). Consequently our product has the only alternative structure, 2,4-dibromo-α-oestradiol (III).

It is highly probable that the introduction of bromine by bromoacetamide will be of service in the case of other phenolic compounds which defy clean-cut halogenation by the more usual methods.

Experimental

One-half gram of α-oestradiol and 0.54 g. of recrystallized N-bromoacetamide were dissolved in 40 cc. absolute alcohol and the reaction mixture was allowed to stand at room temperature for about eighteen hours. By this time the originally faintly yellow solution had become almost colorless. The alcohol solution was evaporated on the hot plate to about one-third of its volume and allowed to cool, when the brominated product was precipitated by the addition of water. On crystallization from alcohol–water, 0.54 g. of 2,4-dibromo-α-oestradiol was obtained as beautiful colorless rosets of needles, melting at 215.5–216.5° (cor.) to an emerald-green liquid, with gas evolution. From the filtrate another 0.2 g. of the product was obtained by dilution with water and recrystallization.

Anal.[5] Calcd. for $C_{18}H_{22}O_2Br_2$: C, 50.20; H, 5.14. Found: C, 50.10; H, 5.13.

No turbidity developed when an alcoholic silver nitrate solution of the substance was allowed to stand for twenty hours, and the material was recovered unchanged after solution for an hour in alcoholic potassium hydroxide.

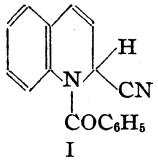
The Formation of Reissert's Compounds in Non-aqueous Media

BY ROBERT BURNS WOODWARD

By shaking quinoline with benzoyl chloride and an aqueous solution of potassium cyanide, Reissert[1] prepared 1-benzoyl-1,2-dihydroquinaldonitrile (I).



I

This compound was remarkable in that it split on hydrolysis into benzaldehyde and quinaldinic acid. The availability of a considerable number of substances differing from Reissert's original compound only in the nature of the acyl group would afford the possibility of a new general method for the reduction of carboxylic acids to aldehydes. However, the ready hydrolysis of many aliphatic acid chlorides vitiates Reissert's original method.

In an attempt to surmount this difficulty, we have investigated the formation of Reissert's compound in non-aqueous media. Dieckmann and Kämmerer[2] observed the formation of the substance in unstated amount while investigating the action of quinoline and other tertiary bases in accelerating the formation of benzoyl cyanide from benzoyl chloride and hydrogen cyanide in ether solution. We found that the formation of acyl cyanide was largely preponderant when benzoyl chloride was used and exclusive in the case of acetyl chloride, either on conducting the reaction in ether or other inert solvents, or on using quinoline as its own solvent. No reaction was observed when acetonitrile, benzonitrile, ether, dioxane, acetone or chloroform was substituted for water in the original procedure of Reissert.

On the other hand, quinoline and potassium cyanide reacted smoothly with either benzoyl or cinnamoyl chloride[3] in liquid sulfur dioxide to give the corresponding aroyl dihydroquinaldonitrile in excellent yield. The use of acetyl chloride, however, led to the formation of intractable dark mixtures from which no pure product could be isolated.

The striking difference in this case between liquid sulfur dioxide and the organic solvents is in consonance with the probable ionic character of the reaction.

Experimental

1-Benzoyl-1,2-dihydroquinaldonitrile.—Ten grams of benzoyl chloride, 10 g. of quinoline (freshly distilled *in vacuo*) and 7 g. of potassium cyanide were placed in a pressure bottle. After approximately 35 cc. of liquid sulfur dioxide had been added, the bottle was sealed and allowed to stand with occasional shaking for twenty-four hours. The sulfur dioxide was then allowed to evaporate, and the residue washed successively with water, dilute hydrochloric acid and ether. On crystallization from alcohol of the white powder so obtained, 16 g. of 1-benzoyl-1,2-dihydroquinaldonitrile separated as glistening needles, m. p. 154–155°, of a very faint greenish tinge which was lost on two further crystallizations.

ELECTROPHORETIC ISOLATION OF CONSTITUENTS OF RAGWEED POLLEN EXTRACTS*

Sir:

Dialyzed extracts of giant ragweed pollen were studied with the Tiselius[1] moving boundary technique at approximately *p*H 7.4 and 1.5°. Employing the Philpot–Svensson[2] cylindrical lens system to visualize the boundaries, we have found a major constituent which is negatively charged, unpigmented and migrates more slowly than the pigmented constituents. The latter are also negatively charged. The major unpigmented constituent may constitute as much as 75% of the material in fresh extracts when estimated by the criterion of the integration of the Philpot–Svensson curves. Similar Longsworth[3] diagrams have been obtained. The unpigmented fraction is highly skin reactive in individuals with ragweed hay fever. It may be introduced into the skin by electrophoresis in these cases by the positive pole even though the substance is negatively charged at the *p*H employed. The electrical mobility of the unpigmented constituent is 0.5×10^{-5} cm. sec.$^{-1}$ in 0.05 *M* phosphate buffer at *p*H 7.0.[4] Variations have been observed in the pigmented portions of the electrophoretic diagrams and apparently depend on the extent and nature of the dialysis as well as the age and treatment of the pollen grains.

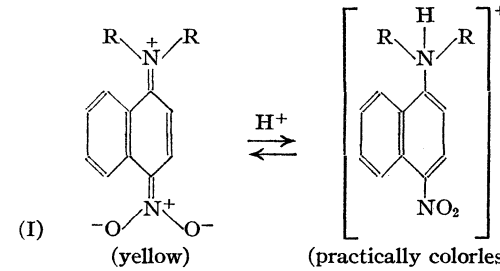
THE STERIC INHIBITION OF RESONANCE

Sir:

It has been shown recently[1] that the concept of the steric inhibition of resonance offers an adequate explanation for the differences in acidity observed with trinitrotriphenylmethanes.

Using exactly the same reasoning, we have attacked this problem from a different point of view, *i. e.*, by a consideration of the basic strengths of substituted 4-nitro-1-naphthylamines.



The electron pair of the amino nitrogen atom (upon which depends the basicity of the molecule) is no longer present in the resonance isomer I. If the alkyl groups in I are large, they will inhibit the ability of the group R_2N- and the benzene ring to become coplanar. The result of this must be a diminution in resonance. This reduction in resonance by steric hindrance should result in an increase in the electron density at the amino nitrogen atom and thus lead to an increase in basicity. We have shown that the basicity of the substituted amine (I, R = CH_3) is much greater than that of the unsubstituted amine (I, R = H) and that this difference is far too great to be explained by an inductive effect of the methyl groups.

The decrease in resonance reduces the polar character of these molecules[2] and should consequently lower the melting points (if other crystal

structure factors remain essentially constant). The values in Table I show that the melting points decrease markedly with increasing size of the alkyl groups.

THE BIOLOGICAL ACTIVITY OF SYNTHETIC PANTOTHENIC ACID

Sir:

The lactone of the "acid fragment" of pantothenic acid has been identified as α-hydroxy-β,β-dimethylbutyrolactone by Stiller, Keresztesy and Finkelstein.[1] The coupling of the synthetic *dl*-lactone with β-alanine in 50% yields, as determined by microbiological assay, and assuming the inactivity of one isomer, has been reported by Weinstock and co-workers.[2] In the present investigation the yield from the coupling reaction was 88%, and definite evidence was found for the inertness of the unnatural isomer.

When equimolecular amounts of 1 *N* sodium hydroxide, β-alanine and the lactone[3] are mixed at 0°, 50% coupling takes place almost immediately as determined by a Sörensen formol titration for free amino nitrogen. Upon standing no further coupling occurs. Instead, the remaining hydroxide ion disappears during the course of an hour, due probably to the saponification of the uncoupled lactone. If instead of equimolecular amounts, the ratio of lactone to β-alanine to 1 *N* sodium hydroxide is made 3:1:1, a 55% coupling occurs immediately, again followed by the disappearance of hydroxide ion. If now to this same solution an amount of 10 *N* sodium hydroxide equivalent to the amount of free β-alanine remaining is added, 51% of this remainder likewise couples. Upon repetition of the procedure, the % of the remainder of the β-alanine which couples falls off rapidly. The results of a typical experiment are summarized in Table I.

(1) As reported by Williams and Major, *Science*, **91**, 246 (1940).
(2) Weinstock, Arnold, May and Price, *ibid.*, **91**, 411 (1940).
(3) Prepared according to the directions of Kohn and Neustadter, *Monatsh.*, **39**, 295 (1918).

TABLE I

	Milliequivalents of				Total % conversion
	β-alanine	hydroxide ion	Lactone	*dl*-pantothenic acid	
Present at start	540	540	1680	0	..

Added at end of 3 hr.	0	100	0	0	
Present at end of 4 hr.	68[a]	< 1[b]	..	472[c]	88

[a] By Sörensen formol titration. [b] Acid to phenolphthalein. [c] By difference.

At the end of the experiment, the solution was biologically assayed with chicks,[4] and found to contain 3,680,000 chick filtrate factor units, corresponding to 36 units per mg. of *dl*-pantothenic acid. Natural pantothenic acid has been stated to contain 71 chick units per mg.[5] This points to the inactivity of one enantiomorph in the synthetic preparation.

At the same time a mixture of 10 g. of the *dl*-lactone and 7 g. of β-alanine was incorporated in 1000 g. of heated diet and biologically assayed. Slight but definite activity was observed, calculated to correspond roughly to a coupling *in vivo* of 0.06% of the mixture. This indicates that none of the activity of the pantothenic acid solution at the level fed (corresponding to 2.1 mg. of *dl*-pantothenic acid per 100 g. of diet) may be attributed to the presence of unchanged starting materials.

NAPHTHOQUINONE OXIDES

Sir:

Since 2-methyl-1,4-naphthoquinone oxide can be converted very easily and efficiently [Fieser, *J. Biol. Chem.*, **133**, 391 (1940)] into the isomer phthiocol, it was somewhat surprising to discover

that the substance surpasses phthiocol by far in vitamin K activity. The observation that the pure oxide [Fieser, Campbell, Fry and Gates, THIS JOURNAL, **61**, 3216 (1939)] is fully effective in the chick assay at a dosage of 5 γ prompted the investigation of other oxides of 2-alkyl and 2,3-dialkyl 1,4-naphthoquinones, and it was found that the hydrogen peroxide procedure [Fieser, *et al.*, *loc. cit.*] provides a convenient route to a number of substances of both types. Farnesylnaphthoquinone oxide [found: C, 78.88; H, 8.16] and phytylnaphthoquinone oxide [found: C, 79.91; H, 9.76] were obtained as nearly colorless oils showing, respectively, very weak and weak (500 γ) antihemorrhagic activity. These substances are cleaved by alkali to a mixture of 2-hydroxy-1,4-naphthoquinone and its 3-alkyl derivative. Crystalline oxides were obtained from 2,3-dimethyl-1,4-naphthoquinone [m. p. 104–104.5°, found: C, 71.26; H, 5.09; active at 25 γ] and 2-methyl-3-cinnamyl-1,4-naphthoquinone [m. p. 85–86°, found: C, 78.94; H, 5.47].

Vitamin K_1 was converted in nearly quantitative yield into the 2,3-oxide, which was obtained as an almost colorless oil [found: C, 79.85; H, 9.69]. Any uncertainty as to the structure is eliminated by the observation that the absorption spectrum corresponds closely with that of 2,3-dimethyl-1,4-naphthoquinone oxide. The K_1 oxide shows antihemorrhagic activity of about the same order as the vitamin (1.5 γ) and gives no purple-blue color with alcoholic alkali. The properties of the oxide are of interest in connection with the reports of Fernholz, Ansbacher and coworkers [THIS JOURNAL, **61**, 1613 (1939); *Proc. Soc. Exptl. Biol. Med.*, **42**, 655 (1939)] stating that they have isolated from alfalfa concentrates a nearly colorless substance of high potency which does not give the Dam–Karrer color test characteristic of vitamins K_1 and K_2. However, in our hands, there is no great difference in the ratio of the effective dose of the oxide and of vitamin K_1 when assayed by the six and eighteen hour method.

We have found that the oxides of vitamin K_1 and of methylnaphthoquinone can be reduced smoothly to vitamin K_1 hydroquinone and methylnaphthohydroquinone with sodium hydrosulfite in aqueous alcohol, even at room temperature. This lends plausibility to the hypothesis that the high potency of the oxides is due to a reduction in the organism to the corresponding quinones or hydroquinones; possibly the 2-methyl oxide is converted in part into the comparatively inactive phthiocol.

MISCIBILITY OF CARBON DIOXIDE AND WATER UNDER HIGH PRESSURE

Sir:

Wiebe and Gaddy [THIS JOURNAL, **62**, 815 (1940)] report the solubility of carbon dioxide in water and make the following statement: "The compositions of the gas and liquid phases at 12° and 600 atm. were identical." My understanding of the behavior of carbon dioxide–water systems is that compression at 12° to about 47.7 atm. will change the phases from a gas (predominantly carbon dioxide) and liquid (mostly water) to a gas (mostly carbon dioxide), a liquid (mostly carbon dioxide), and a liquid (mostly water). Further attempts to compress the system will cause the gas phase to change to a liquid (mostly carbon dioxide) phase and leave at its disappearance two liquids, one predominantly water and the other predominantly carbon dioxide.

Their data show that compression of the two phases increases the carbon dioxide content of the water phase only from 0.03 mole fraction to less than 0.04 mole fraction. Lowry and Erickson [*ibid.*, **49**, 2729 (1927)] indicated that the water concentration in the liquid carbon dioxide was much lower than the above concentration of carbon dioxide in the water phase. Wiebe and Gaddy [*ibid.*, **61**, 315 (1939)] state the mutual solubility of water and carbon dioxide as liquid–liquid system is affected by pressure to only a slight extent.

These statements appear contradictory to the above quotation of identical phases. Any critical phenomena in this region would be of the liquid–liquid critical solution type and not of the type reported by Kuenen [*Commun. Phys. Lab. Univ. Leiden*, **4** (1892)] for the carbon dioxide–methyl chloride system. To become mutually soluble, it is normally expected that the two phases approach each other in composition. A consideration of the probable behavior of these two phases upon compression indicates a possible explanation of the above contradictions. At 10 to 20°,

carbon dioxide is relatively close to its critical temperature and is more compressible than water. At low pressures the predominantly water phase is the more dense but the increase of pressure to about 200 atm. and about 500 atm. at 10 and 20°, respectively, would cause the two immiscible fluids to reach the same density.

I know no reason to believe that the same density makes the two phases miscible but the formation of a relatively uniform suspension of the two phases might occur. Unless the possibility of this reversal in the positions of the two phases in the equilibrium cell were recognized, experimental results might indicate a critical state had been reached. Details of the manipulation of the equilibrium cell and quantitative results at the high pressures in the reported region of complete miscibility should show whether the proposed explanation of the unusual results is tenable.

REDISTRIBUTION REACTIONS

Sir:

Recently Calingaert and co-workers[1] have described a "hitherto unrecognized type of intermolecular exchange of organic radicals" which they term "redistribution reactions." These reactions are characterized by equilibrium constants which are independent of temperature through the temperature range employed, and which have values that agree with the idea of a random distribution of the exchanging radicals to within the precision of the data obtained.

In view of the large amount of experimental work done by these authors already, it seems justifiable to point out that, while such reactions have not hitherto been recognized as a type, their existence need not surprise one; and, furthermore, given any of the reactions so far studied, the *equilibrium* results obtained could have been predicted about as closely as the experiments justify the idea of random exchange of radicals.

The significance of these reactions lies, first, in the fact that, to the precision to which a modified Redgrove[2] rule would apply, values of ΔH would be zero in all cases. Thus in every type of exchange studied certain bonds are broken and others are formed, but the latter are always identical with the former except for slight steric effects. For $\Delta H = 0$, $K = e^{\Delta S^0/R}$, and ΔS^0 for random distribution should be measured by the relative external symmetry numbers of the molecules involved in the equilibrium; *e. g.*, in the type reaction

$$\underset{\sigma = 12}{R_4M} + \underset{12}{R'_4M} \rightleftharpoons \underset{2}{2R_2R'_2M} \qquad (1)$$

$$\Delta S^0_\sigma = R \ln \frac{12^2}{2^2} = 7.11 \text{ units or } K = 36$$

where σ is the external symmetry number. By the nature of the reactions studied, the only remaining appreciable contributions to ΔS^0 would lie in the effect of the redistribution of mass on the translational entropies, and on the redistribution of principal moments of inertia on the possible rotational entropies. Based on six specific redistributions from systems typified by the left-hand side of equation 1, the former of the two mentioned contributions (*i. e.*, mass redistribution) averages 0.076 entropy unit (a heat effect of about 27 small calories at 350°K.); and, assuming stretched molecules and free rotation, the average of the upper limit of the second contribution to ΔS^0 mentioned above is, for the same six reactions, 0.86 entropy units (a heat effect of about 300 small calories at 350°K.).

It is therefore not surprising that the controlling factor in determining the equilibrium state for such reactions is the value of ΔS^0_σ, or randomness of distribution.

THE ISOMERIZATION EQUILIBRIUM OF *n*-BUTANE AND *i*-BUTANE AND THE THIRD LAW OF THERMODYNAMICS

Sir:

Recently complete measurements in this Laboratory of the thermal properties of the two butanes from 11°K. to their respective boiling points furnish values for the entropies of the gases at their normal boiling points. For *n*-butane $S^\circ_{272.66°K.} = 72.05 \pm 0.2$ e. u.; for *i*-butane $S^\circ_{261.44°K.} = 67.54 \pm 0.2$ e. u. These values, together with available heat capacity data on the gas, yield a value of $\Delta S^\circ_{298.1} = -3.7 \pm 0.3$ e. u. for the reaction

n-butane(g) ⟶ *i*-butane(g)

(2) Redgrove, *Chem. News*, **116**, 37 (1917).

The work of Moldavskii and Nizovdima[1] upon the equilibrium constant for this reaction from 70–150°, combined with the measurement of Montgomery, McAteer and Franke[2] at 27° furnishes an independent value for the entropy difference of the two isomers. Two of these equilibrium measurements, at 27° (Montgomery) and at 70° (Moldavskii) were made in the liquid phase at pressures of about 3 and 10 atmospheres, respectively. The constants were calculated to the gas phase with fugacity data for *n*-butane[3] and *i*-butane[4] reported by Sage, Webster and Lacey. The assumption that the liquid follows Raoult's law is in accord with the results of Montgomery, *et al.*[2] The other equilibrium measurements were made in the gas phase by a flow method. The heat of isomerization -2200 ± 200 cal./mole was obtained from the slope of a $\log K - \frac{1}{T}$ plot. Essentially a straight line was obtained, which indicates that over the temperature range in question ΔH is constant to within a small fraction of the experimental error in the equilibrium values. This constancy of ΔH has been confirmed by statistical mechanical calculation.

From the equilibrium data two values of ΔS°_{298} for the isomerization reaction may be obtained, one using the measured heat[5] (A), the other using the heat of isomerization from the slope of the plot (B). These two values are compared with our experimental value of ΔS°_{298} (C) in Table I.

TABLE I

n-C_4H_{10} (g) = i-C_4H_{10} (g)

ΔS°_{298} cal./deg./mole	Source of data
-2.1 ± 0.6	Equilibrium measurement (Montgomery, *et al.*[2])
	Heats of combustion (Rossini[5])
-3.7 ± 0.3	Thermal data to 11 °K. *n*-butane submitted for publication in THIS JOURNAL
	i-butane, unpublished data
-4.0 ± 0.8	Temperature coefficient of equilibrium constant. Montgomery *et al.*,[2] and Moldavskii and Nizovdima.[1]

The agreement between (B) and (C) is well within experimental error. There is thus at present no reason to doubt[6] the practical applicability of the third law of thermodynamics to these compounds.

The assistance of the Standard Oil Development Company in portions of this work is gratefully acknowledged.

NEW BOOKS

Die exakten Methoden der Mikromassanalyse. (The Exact Methods of Titrimetric Microanalysis.) By Dipl.-Ing. JOSEF MIKA. (Die chemische Analyse. Edited by WILHELM BÖTTGER, Hannover. XLII. Band.) Ferdinand Enke Verlag, Hasenbergsteige 3, Stuttgart W, Germany, 1939. xii + 180 pp. 19 figs. 16.5 × 25 cm. Price, RM. 18; bound, RM. 19.60.

The author limits himself to a discussion of such titrimetric methods as can be applied to samples of approximately 10 microequivalents, *i. e.*, 1 to 10 milligrams of material. As a rule it is tried to attain a relative precision of 1 part in a thousand. Methods giving a relative precision of 10 parts in a thousand are included, however, if they offer practical advantages. Hundredth normal standard solutions are suggested for the use with burets of approximately 1 ml. total capacity, which permit delivery and determination of volume with a precision o 0.001 to 0.0001 ml.

In the general part are discussed: the recognition of the end-point with the use of colorimetric, potentiometric, and conductometric methods; the concentration of the standard solutions and the determination and accuracy of their titer; burets, pipets, and aliquot partition; storing of standard solutions; containers for the titrated solutions, stands for titration; apparatus for potentiometric and conductometric titrations; and the testing for purity of the reagents and the water used as solvent. The special part comprises: neutralimetry with the use of dyestuff indicators and of potentiometric and conductometric indication of the end-point; oxidimetry, redox indicators, and electrometric indication; titrations based on the formation of precipitates or complexes with the use of colori-

metric, potentiometric, and conductometric indication. Author index and subject index complete the book.

The treatment of the subject is critical and the problems arising in the small scale performance of titrations are properly emphasized. The book is highly recommended to those interested in the field. Even if the reader should not be willing to agree with the author in all points, he will be compensated by the stimulating originality of the presentation of the subject. The author is a student of Friedrich Emich and he has dedicated the book to his teacher.

A. A. BENEDETTI-PICHLER

Essentials of College Chemistry. By G. H. WHITEFORD, Ph.D., Professor of Chemistry, and R. G. COFFIN, M.S., Associate Professor of Chemistry, Colorado State College. Second edition. The C. V. Mosby Company, 3523 Pine Blvd., St. Louis, Missouri, 1939. 534 pp. 32 figs. 14.5 × 22 cm. Price, $4.00.

Teachers who do not wish to overwhelm the beginner with discouragingly large reference texts will be interested in this book. At first sight it seems to be an expanded form of carefully prepared lecture notes. The order is the conventional one and the assignments (chapters) are of such length as to encourage further readings. Most of the references are to material in the *Journal of Chemical Education* or *Industrial and Engineering Chemistry*. Historical material and factual data are minimized, allowing each instructor to present material of his own selection during the class and lecture hours or by use of references.

The book has an unusual feature in the inclusion of three chapters entitled "General Review." These review chapters take the form of a series of questions followed by groups of terms under various titles such as "Laws, Theories, Topics, Terms." Many instructors present material of this kind in mimeographed form but this is the first instance that has come to the reviewer's attention, where this type of review is included in the text. The review chapters correspond to the three-term academic year. The authors have included numerous exercises, a 6-page glossary, no photographs, 96 drawings on 32 plates, a 3-table appendix, and a 19-page 2-column index.

C. R. CONARD

Volumetric and Phase Behavior of Hydrocarbons. By BRUCE H. SAGE, Assistant Professor of Chemical Engineering, and WILLIAM N. LACEY, Professor of Chemical Engineering, California Institute of Technology. Stanford University Press, Stanford University, California, 1939. xli + 299 pp. 188 figs. 16 × 23.5 cm. Price, $5.00.

In this book, which is admirable in its self-sufficiency, the authors have presented a qualitative treatment of the fundamental principles relating to the volumetric and phase behavior of hydrocarbons. Separate chapters are devoted to the behavior of single, two, three and multi-component systems. Other chapters cover such subjects as: the phase rule, partial quantities, fugacities, ideal and non-ideal solutions, and the retrograde phenomena.

The omission of the concept of the pseudo-critical point weakens the chapter on multi-component systems. The inclusion of a chapter dealing with the computation of the isothermal pressure correction to such thermodynamic properties as the entropy and the enthalpy from volumetric behavior data would have added to the value of the book.

No quantitative data or correlations that can be used in making volumetric or phase behavior calculations are presented. This will no doubt be a disappointment to many. However, the fundamental principles presented in this volume will be quite helpful to the physical chemist and chemical engineer in developing such correlations from data already available and in revising them as new data become available. In this respect the book should prove to be of much industrial and academic value.

W. C. EDMISTER

Lecture Demonstrations in General Chemistry. By PAUL ARTHUR, Assistant Professor of General and Analytical Chemistry, Oklahoma Agricultural and Mechanical College. McGraw-Hill Book Co., Inc., 330 West 42nd Street, New York, N. Y., 1939. xvi + 455 pp. 113 figs. 14.5 × 21 cm. Price, $4.00.

A lecture demonstrator of long years of experience may be able to dispense with a guide in conducting experiments in general chemistry before large classes. An interested, gifted person may even devise new and unusual experiments and in time become renowned for his accomplishments. Time to gain experience and unusual aptitude are gifts seldom afforded the young man charged with such duties. To him, "Lecture Demonstrations in General Chemistry," by Paul Arthur, substitutes the years of Dr. Arthur's experience for an apprenticeship that in most cases is a trying one.

Within the compass of four hundred and fifty pages, the author presents complete instructions for conducting over one thousand experiments. Demonstrations are provided illustrating all principles that would commonly be included in a comprehensive course in inorganic chemistry. The principle to be illustrated is set forth under each experiment, followed by explicit quantitative details regarding the procedure to be employed. Abundant references are provided in each instance, including publications almost as recent as the date of publication of the book. The inclusion of so much modern material justifies the recommendation of the purchase of this volume by either the experienced demonstrator or the untutored novice.

H. S. LUKENS

Handbook of Chemical Microscopy. By ÉMILE MONNIN CHAMOT, B.S., Ph.D., Professor of Chemistry, Emeritus, and CLYDE WALTER MASON, A.B., Ph.D., Professor, Chemical Microscopy and Metallography, Cornell University. Volume II. Chemical Methods and Inorganic Qualitative Analysis. Second edition. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1940. xi + 438 pp. 233 figs. 15 × 23.5 cm. Price, $5.00.

The subject of chemical microscopy, unlike some branches of microchemistry, has grown to maturity and its

principles and procedures have been well-established and thoroughly tested over a period of years.

The revision of Volume II reflects this maturity in that the changes have not been extensive. The first two chapters dealing with manipulative methods and methods of applying reagents have some new material and new references added. The number of cuts has been increased by about fifty, with the result that twenty-seven new pages have been added. The chapters on the separation and qualitative detection of specific elements and groups have been brought up to date by adding recent references and making necessary changes in the text. The authors have continued their critical attitude toward the many new tests which have been published, and take the view that, in many cases, the methods have not been adequately studied from the standpoint of interfering ions. New tests under such conditions can often lead to erroneous conclusions when applied to an unknown mixture. Hence, the volume continues to be a thoroughly workable and practical guide in the application of the microscope in qualitative analysis, and not merely a compendium of isolated tests. The mature microscopist in his work on problems in his field should seek new methods and tests, but he will do well to evaluate his methods and technique by the criteria set forth in this volume.

Because of the proper balance between the academic and practical side of microscopy, this handbook continues to be an excellent text for teaching the subject.

L. T. HALLETT

Handbuch der Lebensmittelchemie. A. BÖMER, A. JUCKENACK and J. TILLMANS. Vierter Band. **Fette und Öle. Lipoide, Wachse, Harze, Ätherische Öle.** (Handbook of Food Chemistry. Vol. IV. Fats and Oils. Lipoids, Waxes, Resins, Ethereal Oils.) Editorial direction of J. GROSSFELD. Verlag von Julius Springer, Linkstrasse 22–24, Berlin W 9, Germany, 1939. xxi + 966 pp. 247 figs. 17.5 × 26 cm. Price, RM. 135; bound, RM. 138.60.

Sponsored by an editorial board headed by J. Grossfeld and including besides A. Juckenack, E. Bames, B. Bleyer and J. Grossfeld, there has appeared another volume, the eighth in order of completion, of the "Handbuch der Lebensmittelchemie." In its general pattern and excellence of quality it follows its predecessors; the combined efforts of a group of specialists are concentrated within its covers.

Approximately one-half of this volume had been written by the one time dean of German fatty oil chemists, the late A. Bömer, J. Grossfeld collaborating. A long chapter on general methods for the examination of edible fats (326 pp.), followed in turn by one on the preparation of fats and their constituents (54 pp.) and another on the occurrence, recovery and properties of the food fats (278 pp.), is the contribution of this pair to this volume. The latter chapter is divided into three parts, *viz.*, the occurrence, recovery, properties and composition of individual vegetable fats and oils; animal fats and oils treated in a somewhat similar manner; and artificially altered, or processed, fats. These chapters are up to date with respect to time of publication, and include among other topics that of the preparation of fatty acids by oxidation of the paraffin hydrocarbons.

The remaining chapters of this volume are devoted to the microscopical examination of oil-bearing seeds and fruits (44 p.), the contribution of C. Griebel; the lipoids (51 p.) (fat-soluble vitamins) by Wm. Halden; waxes, resins, ethereal oils and fruit essences (Fruchtäther) (94 p.) by R. Grau; the German laws pertinent to fat production (37 p.) by H. Holthöffer with a brief Austrian supplement by E. Bames who also wrote the section on foreign laws (13 p.). A table summarizing the simpler physical and chemical constants of 424 fatty oils and nine others pertinent to the analysis and technology of fatty oils complete this volume.

This volume, in particular the first half, may be regarded in a sense as a memorial to the late Prof. A. Bömer. It is an invaluable and authoritative aid not only to those working in the field of fatty oil chemistry itself but in the larger one of food chemistry.

H. A. SCHUETTE

Semimicro Qualitative Analysis. By WILLIAM LLOYD EVANS, ALFRED BENJAMIN GARRETT and LAURENCE LARKIN QUILL, The Ohio State University. Ginn and Company, 15 Ashburton Place, Boston, Massachusetts, 1940. 245 pp. 30 figs. 20.5 × 27.5 cm. Price, $2.00.

This is another addition to the rapidly increasing number of text-books and manuals on semi-micro qualitative analysis. The authors are to be commended for presenting their material in a logical, well-arranged fashion. They have obviously adopted a conservative policy and have deliberately set out to follow as closely as possible the usual macro-qualitative scheme of analysis.

In general each group is covered in the laboratory by a series of precipitation and separation reactions, confirmatory reactions, and supplementary reactions. Then the group is studied as a whole. Finally, numerous review and supplementary questions are given. Most of the equations are given both in the molecular and ionic forms. In regard to the ionic equations, it is the opinion of the reviewer that it would have been better if the authors had adopted the convention of writing ions for only those substances that furnish a high concentration of ions. Thus, $Cd^{++} + H_2S \rightleftarrows CdS + 2H^+$ is preferable to $Cd^{++} + S^{--} \rightleftarrows CdS$ in the precipitation of sulfides by hydrogen sulfide from acid solution. Similarly, precipitations with ammonium hydroxide are better expressed by ionic equations in which the NH_4OH is written in the molecular form. That the authors are not always consistent in this respect is shown in several instances, for example the dissolving of cadmium sulfide in nitric acid (p. 47) and the less satisfactory equation for dissolving copper sulfide in nitric acid (p. 170).

Throughout the book the authors have attempted to be concise and yet clear. This object has been attained by careful arrangement of the material, by the use of numerous charts, diagrams and flow-sheets, and by the use of cross references. The last quarter of the book is devoted to an adequate discussion of theoretical principles. The book is bound in loose-leaf form which has the obvious advantage of lying flat on the laboratory bench and of facilitating the removal of report sheets which are in-

cluded in the volume. At the same time durability is necessarily sacrificed, for, unless handled carefully, the book will undoubtedly suffer badly in physical condition during a semester's work. It is unfortunate that such an excellent work should be a "one year" book.

Instructors who favor the semi-micro method of teaching qualitative analysis will find in this book a well-presented course, flexible enough to be adaptable to varying conditions of available time and equipment.

STEPHEN G. SIMPSON

The Chemists' Yearbook 1939. Founded by F. W. ATACK, M.Sc.Tech., D.Sc. (Manc.), B.Sc. (Lond.), Fellow of the Institute of Chemistry. Edited by E. HOPE, M.A. (Oxon), D.Sc. (Manc.), Fellow of Magdalen College, Oxford. Chemical Publishing Co. of New York, Inc., New York, N. Y., 1939. 1257 pp. 10 × 15.5 cm. Price, $6.00.

In this edition of the Yearbook the sections dealing with general properties of inorganic and organic compounds have been enlarged, the chapter on crystallography revised, the atomic weights brought up to date and the table of alkaloids improved. A comparison with the 1923 copy of the same book shows that while some new topics have been added and old ones changed, yet, by and large the book has remained the same in size and subject matter. In fact many pages have been transposed without change into the later editions.

About one-third of the book is text material. This includes detailed instructions for analyses and examination of many substances ranging from the usual inorganic qualitative analysis scheme to discussions of fuels, clays, tobacco, hydrogen ion, essential oils, milk products, etc. Approximately 3000 organic and 1500 inorganic compounds are listed. This is to be compared with 4400, 4950 and 5000, 4000, respectively, for two comparable American handbooks. The Yearbook contains very little of the data of Physics and the mathematical section is quite brief. A number of sections are included which are not found in similar American handbooks. Among these are: Patent Law and Chemical Invention, Notable Dates in the History of Chemistry, Tobacco, Coal Tar, Cellulose and Paper, Leather Analysis, Lubricants, Tanning Materials, Paints and Pigments, Identification of Dyestuffs, Agricultural Chemistry, Textile Fibers, Analysis of Clays, Firebricks and Silica Material, Analysis of Portland Cement.

Unfortunately the price is out of line with that of the corresponding American books.
