presence of the catalyst than the reaction with the free base of methene V is without any catalyst. These observations are consistent with the assumption that the ready cleavage of tripyrrylmethane X is due essentially to the slowness of the reverse reaction of formation of the tripyrrylmethane. This assumption is also consistent with the course of the cleavages of N-methyl tripyrrylmethanes in which the effect of the N-methyl group has been shown to be due to hindrance of the condensation to tripyrrylmethane. Thus again we are led to regard the reactions involved in the formation of dipyrrylmethenes as a complex series of reversible reactions in which all possible cleavages and condensations take place. One is not justified in regarding these reactions as equilibria, however. The velocities of the competing reactions vary over a sufficiently wide range that products obtained after the usual reaction times allowed in organic work may not be the products thermodynamically most stable and, furthermore, the products obtained after a very short time may be different from those obtained in the normal time.

As a further illustration of the time dependence of these reactions, we may cite the cleavage of tripyrrylmethane IV in the presence of hydrogen chloride. A dry ether solution of this "stable" tripyrrylmethane becomes colored within a few hours after adding dry hydrogen chloride. The color deepens during the course of several weeks and crystals are slowly deposited upon the walls of the reaction vessel. These crystals were identified as the hydrochloride of methene IX, presumably resulting from the reaction shown in scheme (9).

$$\text{IV} + \text{HCl} \longrightarrow \text{XI (Chart I)} + \text{IX (Chart II)} \qquad (9)$$

The possibility of this reaction was discussed in our previous paper.[4d] Unfortunately, it has not been possible to isolate pyrrole XI from the reaction. This experiment lends support to the view that cleavage takes place at all bonds in tripyrrylmethane IV, the chief factor differentiating it from less stable tripyrrylmethanes being the rates of the reactions involved.

One of us, J. H. P., wishes to acknowledge his indebtedness to the Chemical Foundation for a post-doctoral stipend which made this investigation possible. The authors also wish to acknowledge the courtesy of the Carbide and Carbon Chemicals Corporation in furnishing the acetoacetic ester used in this work.

Experimental Part

Condensations of 3,5,4′-Tricarbethoxy-4,3′,5′-trimethyldipyrrylmethene (Methene V Base) with 2,4-Dimethyl-3-carbethoxy-pyrrole (Pyrrole II).—Four-tenths gram (0.001 mole) of the free base of methene V was dissolved in 20 cc. of pure dioxane, dried over 40% sodium amalgam and freshly distilled from sodium; 0.184 g. (0.0011 mole) of pyrrole II was dissolved in 5 cc. of dioxane, purified identically. The solution of pyrrole II was poured into the methene solution, which was shaken quickly. The empty flask was rinsed with 5 cc. of dioxane. The reaction flask was shaken for fifty seconds after the addition of the main portion of the pyrrole and was then poured into 200 cc. of ice and water. A colorless precipitate was formed with no evidence of methene. The product was filtered off, washed well with water and dried by suction in the dark. It was then dissolved in 15 cc. of 95% ethanol and diluted with water until the oil would come out immediately upon removing the flask from the hot-plate. A tiny crystal was added as a seed, and induced crystallization immediately; yield, 0.54 g. (95%) of tripyrrylmethane III, m. p. 190.5–191.5°.

The distillation of the dioxane is important. The methene color remains unchanged for at least fifteen minutes in dioxane decanted from sodium amalgam. The reaction was made to go with an experiment similar to that above except that the dioxane was decanted from sodium amalgam and 0.01 g. of powdered potassium bisulfate was added; yield, 98% of a material melting at 190–192°. A similar experiment was performed using distilled dioxane and potassium bisulfate. Fifteen seconds after mixing, the contents of the flask were poured into 200 cc. of ice and water containing 0.5 g. of sodium carbonate. The tripyrrylmethane was isolated and purified as described above; yield, 94%, m. p. 190–192°. The reaction follows a similar course in redistilled absolute ether: 0.4 g. of the methene was dissolved in 75 cc. of absolute ether, distilled from sodium into the flask. The alpha-free pyrrole was dissolved in 25 cc. of absolute ether, distilled into another flask. The solutions were protected from air by soda lime tubes. Upon mixing, the methene color faded to a light yellow within twenty seconds and this yellow color had disappeared within forty seconds more. The ether was distilled off on a steam-bath and the residue recrystallized as described above; yield, 0.540 g. (95%); m. p. 191–192°. Thus a single recrystallization gave a very pure product which also showed less tendency to darken in the air than most others.

Condensations of 3,5,4′-Tricarbethoxy-4,3′,5′-trimethyldipyrrylmethene (Methene V Base) with 1,2,4-Trimethyl-3-carbethoxy-pyrrole (Pyrrole VI).—Four-tenths of a gram (0.001 mole) of the free base of methene V and 0.199 g. (0.0011 mole) of the pyrrole VI were dissolved in 40 cc. of absolute dioxane, freshly distilled from sodium, and 0.01 g. of potassium bisulfate was added. The color faded to a light yellow and the mixture was poured into ice and water after three and one-half minutes. The product was a pale yellow solid with no evidence of unreacted methene. The suspension was seeded with a tiny crystal and allowed to stand overnight in the icebox before filtering. For the isolation of tripyrrylmethane VII, the following procedure was used. After filtering it was dried in air, warmed with 10 cc. of hexane, cooled and filtered; yield, 0.530 g. or 91%. This crude product melts at 151–153°. The m. p. may be raised by recrystallization from dilute methanol to 155–156°. A similar experiment was performed but the mixture was poured into ice and water after one minute. The original methene was isolated as described in the first experiment; yield, 40%.

A reaction mixture not containing potassium bisulfate was allowed to stand for one hundred minutes. There was no apparent change in color and no tripyrrylmethane could be isolated. A similar experiment was then allowed to stand for over two hours in direct sunlight and then overnight in the laboratory. There was no appreciable change in color in this time.

Preparation of 3,5,4′-Tricarbethoxy-4,3′,5′-trimethyldipyrrylmethene Hydrochloride (Methene V) from its Free Base and from its Carbinol-methyl-ether (Compound VIII).—Two-tenths gram (0.0005 mole) of chromatographically purified methene base V was dissolved in 75 cc. of absolute ether. The solution was cooled in an ice-bath and a stream of dry hydrogen chloride was passed in. As soon as the gas reached the solution a precipitate was formed. Hydrogen chloride was passed in for one minute and the flask was shaken for another minute. The product was filtered off rapidly; yield, of methene V, 96%. The experiment was repeated using an equivalent quantity (0.217 g.) of carbinol methyl ether VIII. This was dissolved in 50 cc. of ether and the methene precipitated without cooling; yield, 93%. In this experiment, as in the preceding, the precipitation of the methene salt was instantaneous.

Condensations of 3,5,4′-Tricarbethoxy-4,3′,5′-trimethyldipyrrylmethene Hydrochloride (Methene V) with 2,4-Dimethyl-3-carbethoxypyrrole (Pyrrole II).—Four-tenths gram of the free base of methene V was dissolved in 75 cc. of absolute ether distilled from sodium; 50 cc. of similar ether was cooled in ice while a strong stream of dry hydrogen chloride was passed in for twenty minutes; 0.167 g. of pyrrole II was dissolved in this solution and then poured rapidly with shaking into the methene solution. A copious precipitate formed which all redissolved within five seconds. The flask was shaken for two minutes and then the contents were poured into 150 cc. of cold 5% sodium hydroxide in a separatory funnel. The ether solution was washed with a second 150-cc. portion of cold sodium hydroxide and with two 100-cc. portions of cold dilute sodium chloride. (The salt was added to facilitate separation of layers.) The ethereal layer was evaporated and the residue recrystallized from dilute ethanol; yield of tripyrrylmethane IV, 0.52 g. or 91.5%, m. p. 191–192°.

The experiment above was repeated with the variation that the ethereal solution of hydrogen chloride was added to the methene free base before the addition of pyrrole II. A copious orange precipitate of the methene hydrochloride V separated immediately but practically all of it redissolved within ten seconds. After three minutes the pyrrole II was added in the solid state. After standing four minutes the solution was poured into sodium hydroxide and the tripyrrylmethane was isolated as described above; yield, 95% of a product melting at 187–188°.

The experiment may be performed with dry dioxane, using only 16 cc. as the solvent. The reaction is complete after fifteen seconds; yield of tripyrrylmethane IV after two recrystallizations from ethanol, 90%, m. p. 191–192°. When either dioxane or ether is used which is decanted from sodium or sodium amalgam, no reaction takes place until the addition of the hydrogen chloride. The yield in ethereal solution may be increased to 97.5% by bubbling in the hydrogen chloride for only five seconds and then evaporating the ether on the steam-bath.

Condensations of 3,5,4′-Tricarbethoxy-4,3′,5′-trimethyldipyrrylmethene Hydrochloride (Methene V) with 1,2,4-Trimethyl-3-carbethoxypyrrole (Pyrrole VI).—Four-tenths gram of the free base of methene V was dissolved in 100 cc. of absolute ether; 0.181 g. of pyrrole VI was added to the solution. It dissolved rapidly. Hydrogen chloride gas was passed into the solution without cooling for two minutes. As soon as the gas reached the solution a precipitate formed but after the first fifteen seconds apparently no more was formed. The flask was shaken at room temperature for three minutes after the addition of the hydrogen chloride and the solution was filtered; 5 mg. of the methene salt V was obtained, corresponding to a recovery of 1.1%. The filtrate was shaken for five minutes more without the formation of more precipitate, showing that the methene salt was not formed from the tripyrrylmethane VII which was present in the solution. The tripyrrylmethane was then isolated in a manner similar to that used for the isolation of tripyrrylmethane IV from hydrogen chloride solution; yield, 0.51 g. or 88%; m. p. 150–152°. Recrystallization from dilute methanol raised the melting point one degree.

When it was desired to isolate the reaction product after a shorter time, the reagents were dissolved in part of the ether and the other part was saturated with hydrogen chloride and then added all at once. An orange-colored precipitate formed immediately. In a typical experiment, the flask was shaken for two minutes after the addition of the hydrogen chloride and then filtered rapidly; yield of methene salt V, 11%; yield of tripyrrylmethane VII, isolated as above, 72%; m. p. 150–152°.

In a similar experiment, carbinol methyl ether VIII was substituted for methene base V, and 40 cc. of hexane was used as solvent. The methene salt was filtered off after two minutes; yield, 73%. The filtrate was practically colorless. On drawing air over it for a few minutes a solid separated, which was allowed to stand overnight, filtered and dried; yield, 24% of tripyrrylmethane VII. It is thus evident that hexane is less well adapted to the production of tripyrrylmethane than is ether, probably

because of the insolubility of the methene salt in hexane. When the experiment was varied by adding only one bubble of hydrogen chloride to prevent the formation of a large amount of methene salt, only a small amount of methene salt precipitated out and it was accompanied by tripyrrylmethane.

Isolation of Intermediates from the Reaction of 2-Formyl-3,5-dicarbethoxy-4-methyl-pyrrole (Aldehyde I) and 2,4-Dimethyl-3-carbethoxy-pyrrole (Pyrrole II).—Five hundred and six milligrams (0.002 mole) of aldehyde I and 334 mg. (0.002 mole) of pyrrole II were dissolved in 20 cc. of absolute ether freshly distilled from sodium. The solution was cooled to 5° in an ice-bath and dry hydrogen chloride was passed in for three minutes. The solution, which was originally colorless, slowly deepened to a light tan. It was poured into 200 cc. of cold 5% sodium hydroxide solution. The flask was rinsed with 20 cc. of ether. The ether and sodium hydroxide solutions were carefully but vigorously shaken for thirty seconds. The ether solution was washed rapidly with two 100-cc. portions of cold 5% sodium hydroxide and finally with two 100-cc. portions of dilute sodium chloride. The sodium hydroxide and sodium chloride solutions were run into an excess of cold dilute hydrochloric acid solution, precipitating the unchanged aldehyde II. This was thoroughly cooled in ice, filtered, and the colorless solid dried in air; recovery, 0.225 g. or 44.5% of a product melting at 124–125° without recrystallization; mixed m. p. with pure aldehyde I (m. p. 127°), 126–127°. One crystallization from dilute ethanol raised the m. p. to 125–126°.

The ether was evaporated on a steam-bath, leaving a sticky yellow residue, partly crystalline. This was recrystallized from dilute ethanol; yield, 0.535 g. or 47% of a yellowish solid, m. p. 191–192°; mixed m. p. with pure tripyrrylmethane IV (m. p. 191–192°) 191–192°.

To duplicate as closely as possible our postulated mechanism for the methene reaction, the following experiment was performed: 434 mg. (0.001 mole) of carbinol ether VIII, 254 mg. (0.001 mole) of aldehyde I and 167 mg. (0.001 mole) of pyrrole II were dissolved in 100 cc. of absolute ether and the solution treated as in the preceding experiment; recovery of aldehyde I, 215 mg. or 85%; yield of tripyrrylmethane IV, 490 mg. or 86%.

Further Examination of the Course of the Condensation of Aldehyde I and Pyrrole II. (a) In Concentrated Solution.—Five grams of aldehyde I and 3.34 g. of pyrrole II were dissolved by warming in 350 cc. of anhydrous ether and then cooled in an ice-bath. A moderate stream of dry hydrogen chloride was passed in. The first precipitation of methene salt V took place after two minutes. The gas was passed in for fifteen minutes and the flask was allowed to stand in the ice-bath for twenty minutes more. The precipitate was filtered and washed with 50 cc. of hexane; yield, 6.8 g. or 78.5%. After standing in the icebox overnight, 0.1 g. additional methene salt was obtained; total yield, 79.8%.

(b) In Dilute Solution.—Two hundred fifty-three milligrams of aldehyde I (0.001 mole) and 167 mg. of pyrrole II (0.001 mole) were dissolved in 100 cc. of absolute ether and treated as in the foregoing experiment. No change in color was visible for four minutes and the first precipitation of methene salt took place after fourteen minutes. The salt was filtered off after twenty-five minutes; yield, 0.270 g. or 61.5%. The filtrate was placed in the icebox for another hour and yielded 70 mg. or 16% additional methene salt. On standing another hour, 20 mg. or 4.5% additional methene salt was obtained. On further standing no more methene was obtained and the solution turned purple; total time, one hundred forty-five minutes; total yield, 82%.

(c) With Potassium Bisulfate.—One hundred twenty-seven milligrams (0.0005 mole) of aldehyde I and 167 mg. (0.001 mole) of pyrrole II were dissolved in 10 cc. of anhydrous dioxane and 0.01 g. of potassium bisulfate was added. The solution was allowed to stand in the dark with occasional shaking for an hour. It was then poured into 100 cc. of ice and water containing 0.5 g. of sodium carbonate and the tripyrrylmethane isolated as described in the first experiment; yield, 0.170 g. or 60% of tripyrrylmethane III, m. p. 190–191°. This experiment fails when commercial dioxane is used.

One hundred forty-two milligrams of tripyrrylmethane IV (0.00025 mole) and 64 mg. of aldehyde I (0.00025 mole) were dissolved by warming in 20 cc. of absolute dioxane and 10 mg. of potassium bisulfate was added. The solution turned an orange color. It was refluxed for thirty minutes and then poured into 200 cc. of ice and water containing 2 g. of sodium carbonate. A colorless solid precipitated which was filtered, washed and recrystallized from dilute ethanol; recovery, 0.130 g. or 91.5% of the tripyrrylmethane IV. The filtrate was acidified and cooled in ice. A colorless solid precipitated; recovery, 52 mg. or 81% of aldehyde I.

(d) Cleavage of Tripyrrylmethane IV by Aldehyde I in Dilute Solution for Comparison with (b).—Two hundred eighty-four milligrams (0.0005 mole) of tripyrrylmethane IV and 127 mg. (0.0005 mole) of aldehyde I[10] were dissolved in 100 cc. of absolute ether by shaking. The conduct of the experiment was as described in (b). The first precipitate appeared after twelve and one-half minutes; yields: after twenty-five minutes, 54.8%; after eighty-five minutes, 15% additional; after one hundred forty-five minutes, 7% additional; total reaction time, one hundred forty-five minutes; total yield, 77%.

Condensations of 3,5,3′5′-Tetramethyl-4,4′-dicarbethoxydipyrrylmethene (Methene IX) and 2,4-Dimethyl-3-carbethoxy-pyrrole (Pyrrole II).—Two hundred fifty milligrams (0.00073 mole) of methene IX and 134 mg. (0.0008 mole) of pyrrole II were dissolved in 20 cc. of absolute dioxane by warming and the solution was then cooled to room temperature; 10 mg. of potassium bisulfate was added and the solution shaken for several minutes. The red color had faded to a light yellow in twenty minutes. The reaction was allowed to stand for a total time of one hundred fifty-five minutes and then poured into ice and water. The yellow solid was filtered off, dried in air and recrystallized from dilute ethanol; yield, 340 mg. or 91% of tripyrrylmethane X, m. p. 193–194°. A similar experiment was performed with the variation that the solution was refluxed for five minutes and then poured immediately into ice and water; yield, 96% of tripyrrylmethane X, m. p. 188–190°. Extraction of the product

(10) It should be noted that 0.0005 mole of these reagents is equivalent to 0.001 mole of the reagents in (b).

with toluene–hexane followed by repeated recrystallization from dilute ethanol raised the m. p. to 205–208°.

The experiment was repeated using ether as a solvent. This is not satisfactory because of the low solubility of the methene in ether. With no added catalyst the reaction proceeded slowly. Tripyrrylmethane X began to separate from the solution after forty minutes. The ether was evaporated on a steam-bath; yield, 97%, m. p. 191–192°.

With dioxane as solvent but with the substitution of hydrogen chloride for potassium bisulfate, only the hydrochloride of methene IX could be isolated; yield, 100% of a product melting with decomposition at 206°. This exactly parallels the cleavage of the tripyrrylmethane X which gave a copious precipitate of the salt of methene IX after five seconds and a quantitative yield when filtered after one minute.

An attempted condensation of 2,4-dimethyl-3-carbethoxy-5-formylpyrrole with 2,4-dimethyl-3-carbethoxy-pyrrole to give tripyrrylmethane X in dioxane with potassium bisulfate as catalyst was unsuccessful under the conditions which succeeded in giving tripyrrylmethane IV from the corresponding aldehyde.

Cleavage of Tripyrrylmethane IV with Hydrogen Chloride.—One and one-tenth grams of tripyrrylmethane IV was suspended in 185 cc. of dry ether and cooled in an ice-bath. Dry hydrogen chloride was passed in for ten minutes. The tripyrrylmethane dissolved with a light yellow color which rapidly gave way to orange. After two hours the solution was cherry-red. It was allowed to stand in an icebox and was wrapped with a towel to protect it from light. After two days it was deep violet but no crystals had appeared. After one month crystals had begun to appear on the walls of the vessel. The mixture was then allowed to warm up to room temperature and to stand for one year. The mother liquor was drained off and neutralized with calcium hydroxide and then chromatographed over alumina using carbon tetrachloride as solvent. The colorless fore-runs contained a dissolved oil but no crystalline derivative was obtained from it.

The crystals on the wall of the vessel were dissolved in chloroform and chromatographed over calcium hydroxide to prepare the free base of the methene. The methene solution was evaporated to dryness and taken up in a mixture of 25% chloroform and 75% carbon tetrachloride (both solvents freshly treated with lime to remove acidic decomposition products). The methene layer developed below a much darker layer on the chromatogram and was separated and eluted with purified chloroform. The solution was evaporated in a weighed flask; yield, 0.223 g. or 33%. It was identified as methene IX by its decomposition point, 187°, and by hydrogenation to 3,5,3′,5′-tetramethyl-4,4′-dicarbethoxy-dipyrrylmethane, m. p. 229°.

Summary

1. It has been discovered that dipyrrylmethenes react with pyrroles with free alpha positions to form tripyrrylmethanes.

2. Application of this reaction permits direct velocity comparisons which make it possible to study the mechanism of the formation of dipyrrylmethenes.

3. It has been demonstrated by actual isolation that a tripyrrylmethane is an intermediate in a "normal" dipyrrylmethene synthesis.

4. It is inferred from comparisons of velocity that this dipyrrylmethene is an intermediate in the formation of the tripyrrylmethane and is, therefore, an intermediate in its own formation.

5. Cleavage of a "stable" tripyrrylmethane by hydrogen chloride alone has been demonstrated.

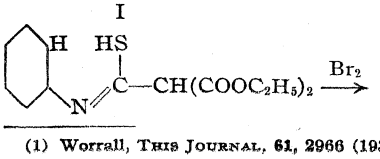
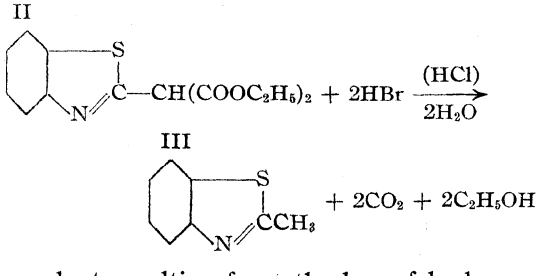
The Action of Bromine on Certain Thioamides

BY DAVID E. WORRALL AND ARTHUR W. PHILLIPS

The thioamide obtained by the action of two equivalents of *p*-tolyl isothiocyanate on ethyl acetonedicarboxylate reacts spontaneously with bromine.[1] In order to present a structural interpretation of the product formed here, a study of the action of bromine on the addition product of malonic ester and phenyl isothiocyanate is here reported. The course of the reactions involved can be outlined as follows





The product resulting from the loss of hydrogen bromide, and cyclization, forms a salt with alcoholic potassium hydroxide and also acts enolic toward a Grignard reagent. With hydrochloric acid, it undergoes hydrolysis and decarboxylation, to yield the well-known 1-methylbenzothiazole.

(1) Worrall, THIS JOURNAL, 61, 2966 (1939).

Experimental

Benzothiazole-1-diethyl Malonate.—To 10 g. of I, prepared from malonic ester and phenyl isothiocyanate dissolved in glacial acetic acid, was added slowly the molar equivalent of bromine in acetic acid. The mixture, which became turbid from the separation of small amounts of sulfur and other decomposition products, was immediately poured into water. After three crystallizations from alcohol, the new product was obtained in small needles, m. p. 138–139°; yield approximately 5 g.

Anal. Calcd. for $C_{14}H_{15}NO_4S$: C, 57.3; H, 5.1. Found: C, 56.9; H, 5.1.

II was soluble in cold concd. hydrochloric acid, separating unchanged on dilution with water. It changed into a powder in the presence of alcoholic potassium hydroxide, which was soluble in water and which was changed by hydrochloric acid into the original substance. A precipitate was formed and bubbles of gas escaped when an ether solution of the thiazole was mixed with methylmagnesium iodide from which the same thiazole was recovered on the addition of water.

1-Methylbenzothiazole from II.—Ten grams of II was heated for two hours with concd. hydrochloric acid, the mixture was diluted with water, filtered and steam distilled until the distillate was clear. Then an excess of alkali was added and steam distillation resumed. A colorless oil with a strong pyridine-like odor resulted. Its identity with an authentic sample of 1-methylbenzothiazole was confirmed by a boiling point determination, and an analysis.

1-Benzothiazoylacetylacetone.—The thiazole prepared from acetylacetone and phenyl isothiocyanate separated from ligroin in silky needles, m. p. 155°. It was rapidly changed by hot alkali, more slowly by acid, into methyl benzothiazole.

Anal. Calcd. for $C_{12}H_{11}NO_2S$: C, 61.8; H, 4.7. Found: C, 62.1; H, 4.5.

Summary

It has been shown that bromine converts the monothioanilide of carbethoxyethylmalonate into benzothiazoylmalonic ester, which is changed by hydrolysis into methylbenzothiazole.

3-Methyl-3,4-dihydroisoquinolines and 3-Methyl-1,2,3,4-tetrahydroisoquinolines[1]

BY WALTER S. IDE AND JOHANNES S. BUCK

Work in progress on the pharmacological effects of various substituting groups in the isoquinoline nucleus necessitated the preparation of a series of 3-methyl-3,4-dihydroisoquinolines and 3-methyl-1,2,3,4-tetrahydroisoquinolines (analogous to norhydrastinine and dihydronorhydrastinine). There are a number of scattered isoquinoline compounds with a 3-methyl group in the literature, but the methods of preparation vary widely and in many cases essential details are lacking. Most of the compounds are also substituted in the 1-position.

The authors therefore set out to devise a series of general reactions for the preparation of the desired 3-methylisoquinoline derivatives. By the method selected three series of compounds, containing as substituents 6,7-dimethoxyl, 6,7-methylenedioxyl and 6,7-dihydroxyl, were prepared and other series doubtless could be made in a similar way. The isoquinolines were prepared by cyclizing formyl-β-phenylisopropylamines (Bischler–Napieralski reaction). This required fairly large amounts of β-phenylisopropylamines. The methods of Mannich and Jacobsohn[2] and of Merck[3] for the preparation of these amines were not investigated since they depend on naturally-occurring materials and are therefore not general. The nitropropenyl method of Alles[4] also was not investigated. The most feasible route appeared to be a series of reactions similar to those used for phenethylamines[5,6] but attempts to prepare disubstituted α-methylcinnamic acids by the method of Bogert and Davidson[7] failed, the condensation of disubstituted benzaldehydes with methyl ethyl ketone not proceeding in the desired way. Recourse therefore was had to the Reformatsky reaction and the required α-methylcinnamic acids were prepared by condensing ethyl α-bromopropionate with the aldehyde, followed by the dehydration and saponification of the product. An alternative method used was the Claisen condensation of the aldehyde with ethyl propionate, followed by saponification. The α-methylcin-

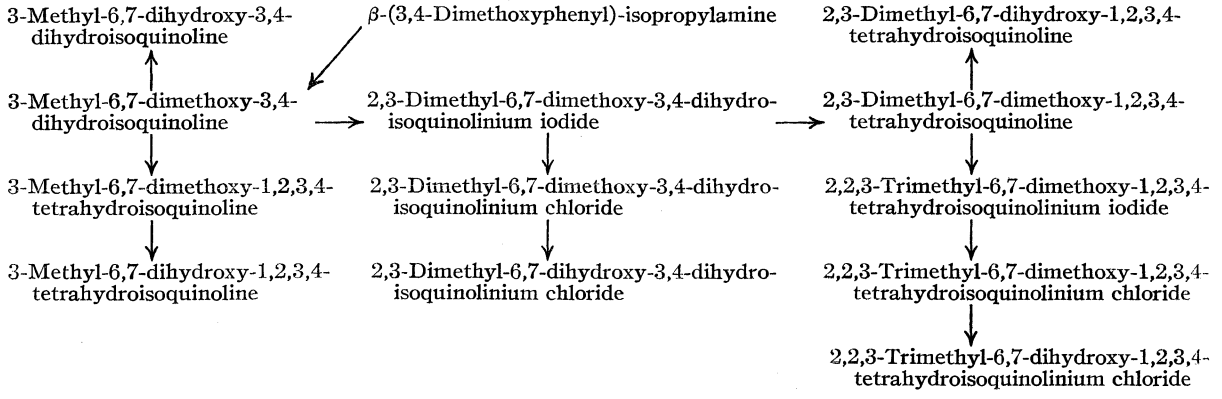
namic acid was reduced, the product amidated and the amine obtained by a Hofmann reaction.

The production of the various isoquinoline types from the substituted β-phenylisopropylamines can be best illustrated by the chart below (for the case of the 6,7-dimethoxy compounds). The reactions are all convenient and the yields at each stage are good, for the cases examined.



Experimental

α-Methyl-3,4-dimethoxycinnamic Acid. (a) **Claisen Method.**—17.3 g. (1.25 atoms) of sodium was "atomized" (not too finely) under toluene, and the toluene decanted. To the sodium was added, in one lot, a solution of 100 g. (1 mol) of veratric aldehyde in 350 cc. (5 mols) of ethyl propionate. The reaction was carried out in a large flask fitted with an efficient reflux condenser, and provision was made for water cooling the flask. A violent reaction took place and was controlled by cooling. After the reaction had subsided, the flask was allowed to stand for two hours, and water then added under a coal-gas atmosphere; 76 cc. (1.25 mol) of concd. hydrochloric acid was added to the aqueous solution and the excess of ethyl propionate removed by steam distillation. The residual oil was extracted with ether and the ether evaporated. The crude ester was saponified by 67 g. (2 mols) of potassium hydroxide dissolved in methyl alcohol; the alcohol was then evaporated and the acid precipitated by hydrochloric acid.

The corresponding 3,4-methylenedioxy acid was prepared similarly but occasionally almost explosive carbonization took place (possibly due to the sodium being too finely atomized) and extreme caution is therefore necessary.

(b) Reformatsky Method.[8,9]—Eighty-three grams (0.5 mole) of veratric aldehyde and 91 g. (0.50 mole) of ethyl α-bromopropionate were dissolved in 300 cc. of benzene and 35 g. of zinc (Baker 80-mesh, granular) added. The whole was refluxed gently for about one hour, then cooled and the benzene solution decanted from the zinc. After washing with dilute sulfuric acid, the benzene solution was dried over calcium chloride, and about one-half the benzene evaporated. After cooling, 40 cc. of phosphorus oxychloride was added cautiously in portions and the whole then heated on the bath for twenty to thirty minutes. After cooling, the purple solution was washed with ice water, then with 10% sodium hydroxide, and the benzene evaporated. Saponification of the residue (methyl alcoholic potassium hydroxide) followed by removal of the alcohol and acidification gave the acid as a pasty solid.

The crude acid, fractionated from benzene, gave two compounds, about 20% being the higher-melting one. The lower-melting compound, recrystallized from alcohol, forms white needles, melting at 144°.[10]

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.83; H, 6.35. Found: C, 65.03; H, 6.57.

The higher-melting compound from alcohol, consists of a white, granular powder, melting at 232°. It is probably the *trans* isomer.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.83; H, 6.35. Found: C, 64.94; H, 6.49.

α-Methyl-3,4-methylenedioxycinnamic Acid.[11]—This acid was prepared by either of the foregoing methods. Recrystallized from benzene it forms light yellow glittering needles, melting at 200°.

Anal. Calcd. for $C_{11}H_{10}O_4$: C, 64.05; H, 4.89. Found: C, 64.07; H, 5.11.

α-Methyl-3,4-dimethoxyphenylpropionic Acid.—This acid was prepared by a sodium amalgam reduction. The properties agreed with those described in the literature.[10]

α-Methyl-3,4-methylenedioxyphenylpropionic Acid.—This was also prepared by a sodium amalgam reduction and the properties agreed with those recorded.[11]

α-Methyl-3,4-dimethoxyphenylpropionamide.—The amide was prepared (a) by heating the ammonium salt in a stream of ammonia, for two hours at 220°, and (b) by running the acid chloride (thionyl chloride method) into aqueous ammonia containing sodium hydroxide. Recrystallized from benzene, it forms white flakes, melting at 109°.

Anal. Calcd. for $C_{12}H_{17}O_3N$: C, 64.54; H, 7.68. Found: C, 64.77; H, 7.64.

α-Methyl-3,4-methylenedioxyphenylpropionamide.—The preparation was carried out as in the foregoing case,

(13) Gunn, Gurd and Sachs, *J. Physiol.*, **95**, 485 (1939).

β-(3,4-Methylenedioxyphenyl)-isopropylamine.—The preparation is similar to that of the foregoing amine. After two distillations, the amine forms a slightly viscous, colorless liquid, with a faint, sweet, musty odor, boiling at 143–145° (11 mm.) and having n_D 1.5394 and d^{25}_4 1.1277. The yield was 40%.

Anal. Calcd. for $C_{10}H_{13}O_2N$: C, 67.00; H, 7.31. Found: C, 67.00; H, 7.00.

Other methods of preparation have been described,[2,3] and it has been mentioned by Gunn, *et al.*[13]

The **hydrochloride** forms bulky white aggregates of small rhombs when crystallized from alcohol. The melting point is 188° (*cf.* ref. 3, m. p. 183–185°).

Anal. Calcd. for $C_{10}H_{14}O_2NCl$: C, 55.67; H, 6.54. Found: C, 55.66; H, 6.60.

The salts described below were recrystallized until pure from absolute alcohol, with the addition of ether or ethyl acetate or both, unless otherwise noted. The solubilities are all very similar, the compounds being in general soluble in methyl and ethyl alcohols, very soluble in water, sparingly soluble in ethyl acetate, and practically insoluble in non-polar solvents. The melting points are corrected.

Summary

A number of 3-methyl-3,4-dihydroisoquinoline and 3-methyl-1,2,3,4-tetrahydroisoquinoline derivatives are described. The substituents are 6,7-dimethoxyl, 6,7-methylenedioxyl and 6,7-dihydroxyl. The compounds are closely related to norhydrastinine and dihydronorhydrastinine. A series of general reactions for their preparation is given.

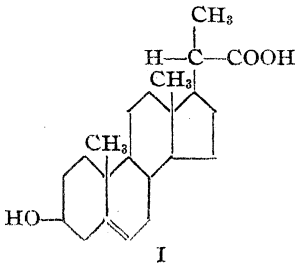
Brassicasterol. II. Degradation by Ozone

BY ERHARD FERNHOLZ AND HOMER E. STAVELY

In a previous communication[1] it was shown that completely hydrogenated brassicasterol, brassicastanol, is not identical with stigmastanol, the common hydrogenated derivative of the phytosterols stigmasterol, β-sitosterol, and α-spinasterol. This was somewhat unexpected since our analytical data favored an empirical formula with 29 carbon atoms, rather than one with 28 carbon atoms as originally proposed by Windaus and Welsch.[2] Analyses reported[1] for brassicasteryl *m*-dinitrobenzoate fitted almost equally well for a C_{28} or a C_{29} sterol but analyses for brassicastyl *m*-dinitrobenzoate definitely favored a C_{29} sterol. In spite of this, on the basis of ozonization experiments we are now forced to conclude that brassicasterol contains only 28 carbon atoms.



I

After addition of one mole of bromine to the nuclear double bond of brassicasteryl acetate, treatment with ozone and subsequent debromination, β-3-hydroxy-bisnorcholenic acid (I) was isolated, the same acid obtained by similar treatment of stigmasteryl acetate.[3] This degradation product accounts for the largest part of the molecule and leaves no doubt as to the position of the two double bonds and the hydroxyl group. Another sample of brassicasterol was ozonized under conditions favorable for the isolation of a volatile aldehyde, the other molecular fragment. A crystalline semicarbazone of the aldehyde was obtained which analyzed for six carbon atoms from the aldehyde. It is therefore conclusively proved that the empirical formula of brassicasterol is $C_{28}H_{46}O$.

A comparison of the properties of the aldehyde semicarbazones obtained by ozonizing ergosterol,[4] stigmasterol[5] and brassicasterol seems to indicate that the aldehyde from brassicasterol is slightly racemized 1-methylisopropylacetaldehyde, as shown in Table I. A mixed sample of the semicarbazone from brassicasterol with the semicarbazone of 1-methylisopropylacetaldehyde from ergosterol (m. p. 128) melted at 120–122°, showing no depression.

TABLE I

	Ethylisopropylacetaldehyde semicarbazone (from stigmasterol)	Methylisopropylacetaldehyde semicarbazone (from ergosterol)	Semicarbazone from brassicasterol
M. p., °C.	128	128	119
$[\alpha]D$	+9°	−52°	−40°
C, %	56.14	53.46	53.65
H, %	9.95	9.62	9.70
N, %	24.58	26.74	26.76

This is noteworthy because all precautions were taken to prevent racemization and in a trial run with ergosterol no racemization occurred. The assumption that brassicasterol contains a certain amount of an isomer with the opposite configuration on C_{24} seems to offer an attractive explanation for this observation, although it is also possible that brassicasterol contains a closely related isomeric sterol with a structurally differing side chain. Our degradation experiments leave, however, little doubt that formula II must be assigned to brassicasterol, which could be called 7,8-dihydroergosterol.

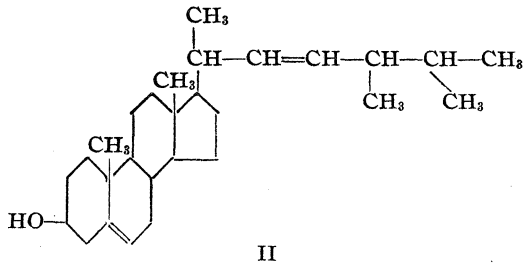
(2) *Ber.*, **42**, 612 (1909).
(3) Fernholz, *Ann.*, **507** 128 (193
(4) Guiteras, Nokamiya and Inhoffen, *Ann.*, **494**, 119 (1932).
(5) Guiteras, *Z. physiol. Chem.*, **214**, 89 (1933).



II

The difficulty of obtaining a pure sample of brassicasterol is also illustrated by a marked difference in the rotation of its hydrogenation product and pure ergostanol and their derivatives, except the *m*-dinitrobenzoate as shown in Table II.

TABLE II

	M. p., °C.	$[\alpha]^{25}D$
Brassicastanol	142	+24
Brassicastyl acetate	143	+15
Brassicastyl *m*-dinitrobenzoate	202	+14
Ergostanol	144	+15
Ergostyl acetate	145	+ 6
Ergostyl *m*-dinitrobenzoate	203	+13

In view of these discrepancies it was not possible to assume their identity in spite of the absence of mixed melting point depressions throughout the series without the more convincing evidence obtained by ozone degradation of brassicasterol.

The great structural similarity of stigmasterol and brassicasterol has led us to apply the partial debromination reaction recently described by us[6] for stigmasteryl acetate tetrabromide also to the brassicasterol derivative. A 22,23-dibromobrassicasteryl acetate of m. p. 236–238° was obtained.

Experimental

Ergostyl *m*-Dinitrobenzoate.—Five and one-half grams of ergostanol, 5 g. of *m*-dinitrobenzoyl chloride and 70 cc. of pyridine were heated for one-half hour on the steam-bath, then diluted with water, filtered, and recrystallized from ethanol–chloroform, m. p. 202–203°; $[\alpha]^{24}D$ +14° (12.7 mg. in 2.0 cc. chloroform, $\alpha^{24}D$ +0.09°, 1 dm. tube).

Anal.[7] Calcd. for $C_{35}H_{52}O_6N_2$: C, 70.43; H, 8.78. Found: C, 70.18; H, 8.66.

β-3-Hydroxy-bisnorcholenic Acid.—Brassicasteryl acetate (3.82 g.) was dissolved in chloroform and 1.34 g. of bromine (1 mole) in chloroform was added dropwise. After twice the theoretical amount of ozone had been passed through the solution it was evaporated *in vacuo* below 30°, and the residue debrominated with zinc and acetic acid. Water was added and the mixture extracted with ether, the ether washed with water and an excess of 2 *N* sodium hydroxide. A precipitate, which appeared between the ether and an aqueous layer, was washed with 2 *N* sodium hydroxide and ether, then acidified with dilute acid and extracted with ether. The ether was evaporated and the residue refluxed with alcoholic potassium hydroxide for two hours, water was then added and the mixture extracted with a large amount of ether. The ether residue was recrystallized from acetic acid, m. p. (dec.) 293°

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.23; H, 9.91. Found: C, 76.15; H, 10.10. Mixed m. p. with an authentic sample of β-3-hydroxy-bisnorcholenic acid showed no depression.

β-3-Hydroxy-bisnorcholenic Acid Methyl Ester.—The methyl ester was prepared from 160 mg. of β-3-hydroxy-bisnorcholenic acid by means of diazomethane; recryst. from aqueous methanol, m. p. 139–140°.

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.58; H, 10.10. Found: C, 75.45; H, 9.96.

A mixed m. p. with an authentic sample of the methyl ester of β-3-hydroxy-bisnorcholenic acid showed no depression.

β-3-Acetoxy-bisnorcholenic Acid Methyl Ester.—Seventy milligrams of β-3-hydroxy-bisnorcholenic acid methyl ester stood overnight in a solution of 0.3 cc. of acetic anhydride in 3 cc. of pyridine. The solvent was evaporated *in vacuo* and the residue crystallized from methanol, m. p. 138°.

Anal. Calcd. for $C_{25}H_{38}O_4$: C, 74.59; H, 9.54. Found: C, 74.77, 74.82; H, 9.47, 9.49.

A mixed m. p. with an authentic sample of β-3-acetoxy-bisnorcholenic acid methyl ester showed no depression.

Ozonization of Brassicasteryl Acetate.—Two grams of brassicasteryl acetate was suspended in 20 cc. of glacial acetic acid and an excess of ozone passed through the suspension. It was poured immediately into 100 cc. of water and distilled until no more oil drops distilled over. The distillate was neutralized with sodium bicarbonate, 200 mg. of semicarbazide hydrochloride was added, and more sodium bicarbonate to slight alkalinity. The semicarbazone crystallized on shaking. It was filtered, washed with water, and recrystallized from petroleum ether. The melting point could not be raised above 119° by recrystallization or sublimation; $[\alpha]^{23}D$ −39.4 ± 2.0 (8.65 mg. in 2.0 cc. of ethanol, $\alpha^{23}D$ −0.17, 1 dm. tube).

Anal. Calcd. for $C_7H_{15}ON_3$: C, 53.46; H, 9.62; N, 26.74. Calcd. for $C_8H_{17}ON_3$: C, 56.14; H, 9.95; N, 24.58. Found: C, 53.65; H, 9.70; N, 26.76.

A mixed m. p. with the semicarbazone of 1-methylisopropylacetaldehyde from ergosterol (m. p. 128) melted at 120–122°.

Brassicasteryl Acetate-22,23-dibromide.—Brassicasteryl acetate tetrabromide (180 mg.) was debrominated with sodium iodide by the method used for stigmasteryl acetate tetrabromide.[6] The product was crystallized from ethanol–benzene, m. p. 236–238°.

Anal. Calcd. for $C_{30}H_{48}O_2Br_4$: Br, 42.1. Calcd. for $C_{30}H_{48}O_2Br_2$: Br, 26.7. Found: Br, 27.9.

Summary

On ozonizing brassicasteryl acetate, a C_{22} acid,

(6) THIS JOURNAL, **61**, 2956 (1939).

(7) Analyses herein reported are by Mr. J. F. Alicino, Fordham University.

β-3-hydroxy-bisnorcholenic acid, and a C_6 aldehyde are obtained. The empirical formula of brassicasterol is therefore $C_{28}H_{46}O$.

The C_6 aldehyde appears to be a partially racemized 1-methylisopropyl-acetaldehyde, which is a degradation product of ergosterol.

The structural formula of 7,8-dihydroergosterol is proposed for brassicasterol.

The Vitamin K Activity of Naphthoquinones

BY ERHARD FERNHOLZ, S. ANSBACHER AND H. B. MACPHILLAMY

Soon after McKee, *et al.*,[1] reported that vitamins K_1 and K_2 have a quinoid structure, publications from various laboratories appeared on the vitamin K activity of naphthoquinones. Because of its outstanding potency 2-methyl-1,4-naphthoquinone and its derivatives have been investigated most thoroughly. A discussion of the pertinent literature concerning this compound has been presented in a foregoing publication.[2] A suggestion also has been made to use 2-methyl-1,4-naphthoquinone as a basic standard for the assay of vitamin K;[3] under the conditions used in our laboratory one milligram contains 2000 units.

The following summarizes our assay results with other naphthoquinones: inactive, 1,2-naphthoquinone; weakly active in a dose of one milligram, 2,6-dimethyl, 2-allyl-, 2,3-diallyl-, 2-*n*-hexadecyl-,2-*n*-octadecyl-1,4-naphthoquinone; one unit per milligram, 1,4-naphthoquinone, 2-ethyl-, 2-propyl-, and 2-methyl-3-*n*-octadecyl-1,4-naphthoquinone; 20 units per milligram, 2,3-dimethyl-1,4-naphthoquinone; 70 units per milligram, 2-methyl-3-phytyl-1,4-naphthoquinone(vitamin K_1).

Thayer, *et al.*,[4] reported that 1,2-naphthoquinone is inactive whereas 1,4-naphthoquinone is active in a dose of 1 mg.; our results confirm this report. Almquist and Klose,[5] however, stated that they had obtained entirely negative results with the latter compound. The interesting contrast between the comparatively active 2,3-dimethyl-1,4-naphthoquinone and the rather weakly active 2,6-dimethyl-1,4-naphthoquinone[6] has been reported also by Tishler and Sampson.[7] There is some uncertainty concerning the activity of 2-ethyl-1,4-naphthoquinone. Thayer, *et al.*,[4] state that it is fully active at a level of 125 γ, and according to Tishler and Sampson it shows activity above 200 γ. In our experience the compound is not nearly as active as reported by Thayer, *et al.*, since 1 mg. was found to be necessary to give a unit response. The propyl derivative has been assayed and found inactive at a level of 0.4 mg.;[7] we found it active in a dose of 1 mg. Fieser, *et al.*,[8] originally reported that 2-allyl-1,4-naphthoquinone is very active but Thayer, *et al.*,[4] stated in the same issue of THIS JOURNAL that the compound was inactive in a dose of 2 mg. In a later paper Fieser, *et al.*,[9] agreed with Thayer. We also found that 2-allyl-1,4-naphthoquinone and 2,3-diallyl-1,4-naphthoquinone have little, if any, activity at a level of 1 mg. We have prepared and assayed the *n*-hexadecyl, *n*-octadecyl, and 2-methyl-3-octadecyl-1,4-naphthoquinones. These compounds have shown rather low potencies.[10] The last of the three, containing the methyl group in the 2-position, is definitely more active than the two others.

The long-chain naphthoquinones were prepared by chromic acid oxidation of the corresponding hydrocarbons. With the exception of the *n*-octadecyl compound, substitution of the naphthalene nucleus in the β-position was ensured by using the method of Barbot[11] for the production of β-substituted tetralin ketones. The ketones were reduced by the Clemmensen

(9) Fieser, Campbell and Fry, THIS JOURNAL, **61**, 2206 (1939).

(10) After this paper had been submitted a paper by Fieser [THIS JOURNAL, **61**, 3467 (1939)] appeared wherein it is postulated that vitamin K activity begins to appear as the alkyl groups are increased in size. Obviously our results do not support this idea.

(11) Barbot, *Bull. soc. chim.*, [4] **47**, 1314 (1930).

method and the resulting hydrocarbons dehydrogenated with sulfur to give the desired alkylnaphthalenes. In the case of the *n*-octadecyl derivative, naphthalene was substituted directly and the mixture of α- and β-naphthalene ketones separated according to the directions of Seidel and Engelfried.[12]

The starting material used in the preparation of the 2-methyl-3-octadecyl derivative was prepared by the catalytic hydrogenation of 2-methylnaphthalene to the corresponding tetralin derivative. That the product thus obtained is 2-methyl-5,6,7,8-tetrahydronaphthalene has been shown by Schroeter[13] and by Fieser and Jones.[14] Since condensation of this substance with stearyl chloride would lead to substitution only in the 3-position, experiments to prove the structure of this compound were not carried out.

We reported recently[15] that the minimum effective dose of vitamin K_1 depends much more on the assay period than does that of 2-methyl-1,4-naphthoquinone or of alfalfa concentrates prepared and investigated by us. While 15 γ of vitamin K_1 is required in our six-hour assay, only 1γ is needed if the test period is prolonged to eighteen hours. In similar fashion it is possible, therefore, that the activity of the long-chain naphthoquinones may be greater if an eighteen hour or longer test period is used. Although the number of naphthoquinones which could be tested for vitamin K activity could be greatly increased, from the present investigation it does not appear likely that the preparation of such compounds would lead to the discovery of a substance surpassing in activity 2-methyl-1,4-naphthoquinone.

Experimental Part

2-*n*-Pentadecyl-5,6,7,8-tetrahydronaphthyl Ketone.—The acid chloride[16] from 15 g. of palmitic acid was decanted into 100 cc. of carbon disulfide containing 8 g. of tetralin. Gradually 8 g. of anhydrous aluminum chloride was added and the reaction mixture allowed to stand overnight. After evaporating the carbon disulfide, the residue was decomposed with ice water and extracted with ether. The ether extract was washed with dilute alkali and dried over anhydrous sodium sulfate. The ether was removed and the remaining oil was distilled at 130–140° (about 1 mm.). The distillate solidified on cooling and was recrystallized from acetone. The yield was 12 g. (56%) of white crystals melting at 44–45°.

Anal. Calculated for $C_{26}H_{42}O$: C, 84.3; H, 11.4. Found: C, 84.2; H, 11.2.

2-*n*-Hexadecyl-5,6,7,8-tetrahydronaphthalene.—Ten grams of the above ketone was reduced according to the modification of the Clemmensen method described by Mikeska, *et al.*[16] The final product was distilled at 210–215° (about 1 mm.), yield 6 g. (63%) of hydrocarbon.

Anal. Calculated for $C_{26}H_{44}$: C, 87.6; H, 12.4. Found: C, 88.0; H, 12.1.

2-*n*-Hexadecylnaphthalene.—The above hydrocarbon was subjected to sulfur dehydrogenation according to the directions of Barbot.[11] Five grams of the tetralin derivative and 3 g. of sulfur were heated to 200–210° for five hours. The product was extracted with ether and the ethereal solution washed with dilute alkali. On evaporation of the dried solution an oil remained which distilled *in vacuo* at about 200° (1 mm.). The distillate solidified on cooling and was recrystallized from ether–methanol mixture giving about 1 g. (20%) of material melting at 45–46°.

Anal. Calculated for $C_{26}H_{40}$: C, 88.56; H, 11.44. Found: C, 88.24; H, 11.68.

2-*n*-Hexadecyl-1,4-naphthoquinone.—A solution of 1.5 g. of chromic acid in 3 cc. of 50% acetic acid was added dropwise to a suspension of 0.5 g. of 2-*n*-hexadecylnaphthalene in 10 cc. of glacial acetic acid. The reaction mixture was stirred rapidly during the addition. The temperature was then raised to 60° and the agitation continued for 1.5 hours at this temperature. The reaction mixture was then diluted with water and extracted with ether. The ethereal solution was washed with dilute alkali and dried over anhydrous sodium sulfate. After removal of the ether the solid yellow residue was crystallized from a small amount of ether yielding 0.2 g. (37%) of quinone melting at 80–81°.

Anal. Calculated for $C_{26}H_{38}O_2$: C, 81.6; H, 10.0. Found: C, 81.6; H, 10.3.

2-*n*-Octadecyl-1,4-naphthoquinone.—The compound was prepared as described for the above quinone. Four grams of 2-*n*-octadecylnaphthalene[16] (m. p. 58–59°) upon oxidation with 10 g. of chromic acid gave 1 g. (23%) of quinone melting at 84–85°.

Anal. Calculated for $C_{28}H_{42}O_2$: C, 81.9; H, 10.3. Found: C, 81.7; H, 10.4.

Methyl-3-*n*-heptadecyl-5,6,7,8-tetrahydronaphthyl Ketone.—This substance was prepared from 2-methyl-5,6,7,8-tetralin and stearyl chloride as described in the preparation of 2-pentadecyl tetrahydronaphthyl ketone. A yield of 5.0 g. (36%) of the ketone was obtained from 2.5 g. of 2-methyl tetralin and 5 g. of stearic acid. The material was crystallized from acetone, m. p. 64–65°.

Anal. Calculated for $C_{29}H_{48}O$: C, 84.4; H, 11.7. Found: C, 84.6; H, 11.6.

2-Methyl-3-*n*-octadecyl-5,6,7,8-tetrahydronaphthalene.—The above ketone was reduced as described for the preparation of 2-octadecylnaphthalene; 3.5 g. of ketone yielded 2.5 g. (72%) of hydrocarbon. The final product after recrystallization from ether–methanol mixture melted at 60–61°.

Anal. Calculated for $C_{29}H_{50}$: C, 87.4; H, 12.6. Found: C, 87.3; H, 12.8.

2-Methyl-3-*n*-octadecylnaphthalene.—Two grams of the above hydrocarbon was subjected to sulfur dehydrogenation as already described for the preparation of 2-hexadecylnaphthalene. After crystallization from acetone 0.7 g. (35%) of a product was obtained melting at 47–48°.

Anal. Calculated for $C_{29}H_{46}$: C, 88.25; H, 11.75. Found: C, 88.60; H, 11.30.

2-Methyl-3-*n*-octadecyl-1,4-naphthoquinone.—The oxidation of 0.5 g. of the above hydrocarbon with chromic acid gave 0.2 g. (37%) of quinone which melted at 95–97° after recrystallization from ether.

Anal. Calculated for $C_{29}H_{44}O_2$: C, 82.0; H, 10.4. Found: C, 81.7; H, 10.2.

Summary

The preparation and vitamin K activity of a number of naphthoquinones is described. None of these compounds surpasses or even approaches 2-methyl-1,4-naphthoquinone in activity.

o-Halide Synthesis of 10-Methyl-1′,9-methylene-1,2-benzanthracene

BY LOUIS F. FIESER AND JAMES CASON[1]

Since attempts to introduce methyl or hydroxyl groups into the interesting and reactive 1′,9-methylene-1,2-benzanthracene[2] (XIII) by direct substitution offered little promise of success a second synthesis was investigated which affords a route not only to the parent hydrocarbon but to various 10-substituted derivatives. The method embodies the general scheme of synthesis of anthracene derivatives introduced by one of us and Seligman.[3] This involves the preparation, through a Grignard reaction and reduction, of a suitable *o*-halide of a diphenylmethane, conversion through the nitrile to the acid and ring closure. The halogen may be introduced in various sequences into either aromatic ring, giving considerable flexibility to the method.

For the present application of the *o*-halide synthesis 7-acenaphthenone (IV) was required as starting material, and as the ketone heretofore has been accessible only by quite laborious processes,[4] a new method was sought. Marquis[5] observed that the corresponding alcohol is produced in low yield in the form of the acetate by the oxidation of acenaphthene with lead dioxide in acetic acid, and in connection with a study of the action of lead tetraacetate on other hydrocarbons[6] Dr. E. B. Hershberg noted that 7-acenaphthenyl acetate can be obtained more smoothly with the use of this reagent.[7] M. E. Gross then worked out a practical procedure for conducting the oxidation and this was employed initially in the present investigation. The experience of treating quantities of red lead with acetic acid for the preparation of a reagent for use in this solvent suggested that the operation might be dispensed with, and indeed it was found that acenaphthene can be converted smoothly and easily into the 7-acetoxy compound with red lead and acetic acid. The yield is equal to that obtained with purified lead tetraacetate, and considerable time is saved. The acetate is a liquid and is not easily freed from traces of acenaphthene and acenaphthenone, but pure crystalline 7-acenaphthenol is readily obtained in good over-all yield on saponification. Under the most favorable conditions found, oxidation with chromic acid and steam distillation of the product gave the pure ketone in reasonably good yield, and by this sequence of reactions 7-acenaphthenone is obtainable in quantity from the hydrocarbon in 47% over-all yield.

The further stages of the synthesis are indicated in the chart. The carbinol (V) resulting from the action of *o*-chlorophenylmagnesium bromide on 7-acenaphthenone was obtained in a crystalline condition only with considerable loss; the dehydration of the crude reaction product with acetic acid proceeded smoothly enough but in rather low over-all yield. The unsaturated compound VI crystallizes in brilliant orange prisms, while its dihydride VII is a colorless solid of lower

melting point. Conversion to the nitrile VIII proceeded well, and saponification of this rather hindered derivative was accomplished satisfactorily by refluxing with alcoholic alkali for a prolonged period (ten days). Decomposition occurred at higher temperatures, and other methods of hydrolysis were tried without success. The acid IX was cyclized in good yield to 10-acetoxy-1′,9-methylene-1,2-benzanthracene (X) by the zinc chloride–acetic acid–anhydride procedure,[8] and the acetate on reduction with zinc and alkali afforded 1′,9-methylene-1,2-benzanthracene (XIII), identical with the material previously described.[2] The over-all yield from acenaphthene in ten steps is 3.8%, as compared with 3.4% by the previous five-step synthesis.[2]

For the preparation of the 10-methyl compound XI it was desirable to effect cyclization of the acid IX under conditions most favorable for retaining the product in the anthrone form and avoiding enolization. The hydrogen fluoride method[9] appears superior to any other and has given good service in the synthesis of simpler 10-alkyl-1,2-benzanthracenes (56% yield), while the introduction of 9-alkyl groups is beset by greater difficulties and the yields are lower (14–35%[10]). The present case seems to be the most unfavorable yet encountered, for in a number of experiments under varying conditions cyclization of IX with hydrogen fluoride and treatment of the crude or crystallized product with methyl Grignard reagent afforded the hydrocarbon XI in no better than 1.2% yield, the bulk of the material being recovered as the crystalline anthranol XII. The anthranol is a sensitive substance and the yield on reduction to the parent hydrocarbon is lower than when the more stable acetate X is employed. By using adequate amounts of materials, a small supply of pure, pale orange 10-methyl-1′,9-methylene-1,2-benzanthracene (XI), m. p. 181–181.4°, was obtained and the hydrocarbon is being tested for carcinogenic activity, along with the 10-hydroxy compound XII.

The new hydrocarbon is of special interest because of its structural relationship to the potently carcinogenic 9,10-dimethyl-1,2-benzanthracene.[11]

Experimental Part[12]

7-Acenaphthenol (With M. E. Gross).—The "95% acenaphthene" (m. p. 92.5–93.5°) supplied by the Reilly Tar and Chemical Co. proved to be just as satisfactory for the preparation as recrystallized material (m. p. 93–93.5°) or a purer commercial grade (m. p. 93–93.5°). A solution of 154 g. of the crude hydrocarbon in 1.1 l. of glacial acetic acid (distilled over permanganate) was stirred mechanically at a temperature of 60–70° (maintained throughout the reaction) and treated with 820 g. of red lead (85–90%), added in 50-g. portions in the course of about forty minutes, a fresh addition being made on discharge of the red coloration. Very shortly after the addition of the oxidizing agent the test for lead tetraacetate with moistened starch–iodide paper was negative and the dark red, viscous solution was thereupon poured into 2 liters of water. The precipitated oil was extracted with 350 cc. of ether and then with 250 cc. of this solvent, and the washed extract was shaken with saturated sodium chloride solution and filtered through a layer of anhydrous sodium sulfate. After removal of the solvent, the **7-acenaphthenyl acetate** was distilled at 5 mm., b. p. 166–168° from a bath at 180–185°; the yield of material (containing small amounts of acenaphthene and acenaphthenone) was 170–175 g. The result was the same using lead tetraacetate.

For hydrolysis the acetate was refluxed with 40 g. of sodium hydroxide in 400 cc. of water and 275 cc. of methanol for two hours. Crystalline acenaphthenol began to separate almost immediately and the liquor acquired a dark violet color probably due to the presence of acenaphthenone. After cooling to 20° the product was collected, washed well with water, dried and recrystallized from benzene, using 2 liters of solvent, and after clarification with Norite concentrated to a volume of 1 liter. The first crop amounted to 117–121 g. of pure acenaphthenol in the form of colorless needles, m. p. 144.5–145.5°, unchanged on further crystallization from benzene or alcohol, and the mother liquor afforded 3–5 g. of pure material; yield 70.5–74% (from acenaphthene). The melting points 146°[13] and 148°[5] have been reported.

7-Acenaphthenone (With M. E. Gross).—A suspension of 100 g. of acenaphthenol in 300 cc. of glacial acetic acid was stirred mechanically and treated with a solution prepared by dissolving 43 g. of chromic anhydride in the minimum amount of water and diluting with 240 g. of acetic acid. The solution was added in the course of fifty minutes while maintaining a reaction temperature of 28–32° by external cooling. The acenaphthenol dissolved giving a green solution and, after stirring for an additional hour at the same temperature, this was poured into 6 liters of ice water and the precipitated ketone collected on a large Büchner funnel and washed well with water. As purification by direct crystallization or by vacuum distillation proved unsatisfactory, the moist product was distilled with steam, a method which proved very satisfactory. The distillate (35 liters) was cooled below 20° and the practically colorless ketone collected and dried. The acenaphthenone thus obtained melted at 118.5–120.5° and was satisfactory for the synthesis; the average yield in three runs was 64.5 g. (65%). Recrystallization from benzene–hexane (1:4) gave colorless needles, m. p. 121–121.5°.

7-(*o*-Chlorophenyl)-acenaphthylene (VI).—After trying numerous variations the following procedure was adopted as the most satisfactory. A solution of 45 g. of acenaphthenone in 125 cc. of benzene and 70 cc. of ether was added in fifteen minutes to the Grignard reagent from 7.8 g. of magnesium, 67.6 g. of *o*-bromochlorobenzene and 250 cc. of ether. After refluxing and stirring for forty-five minutes longer, the complex was decomposed with 55 cc. of saturated ammonium chloride solution and the benzene–ether layer was decanted from the pasty salt mass. By distilling most of the solvent and triturating the residue with hexane, crude **7-(*o*-chlorophenyl)-acenaphthenol-7** (V) was obtained as an almost colorless powder. By recrystallization from benzene the carbinol was obtained as colorless, elongated prisms, m. p. 216–218° with decomposition to the orange acenaphthylene derivative, but the yield of crystalline product was only 15–20% and the material was not analytically pure. For the best over-all yield it was found expedient to dehydrate the crude product of the Grignard reaction. For this purpose the initial benzene–ether extract was concentrated on the steam cone and the solvent removed by heating to 70° at the water-pump. The reddish-orange oil remaining was refluxed with 225 cc. of glacial acetic acid for one hour and the dark solution poured into 500 cc. of water and extracted with benzene. After washing the extract free of acid it was filtered through anhydrous sodium sulfate, concentrated and passed through a 2.5 × 13-inch tower of activated alumina and Supercel (1:1). The column was washed with benzene until the dark orange zone due to the unsaturated chloro compound (which migrates rapidly) had passed into the filtrate. The column must be large enough to retain a more strongly adsorbed substance forming a broad yellow zone. The benzene in the filtrate was replaced by methanol and the product crystallized from a volume of about 350 cc. with seeding and slow cooling. This gave 20.5–22.5 g. of orange elongated prisms, m. p. 100–102° (softening at about 96°). No further crystalline material was obtained from the mother liquor on concentration, but on removing the solvent and distilling the residue at 2 mm. a red oil was obtained which yielded 3 g. of satisfactory product, m. p. 98–102°; the total yield of material suitable for the hydrogenation was 33–36%. When the total crude reaction product was distilled directly the yield fell to 15%, and attempted crystallization of material dehydrated with acetic acid but not purified by chromatographic adsorption proved difficult and unsatisfactory.

For analysis a sample of distilled material was crystallized three times from methanol and obtained as yellow-orange cubic or elongated prisms, m. p. 104–104.4°.

Anal.[14] Calcd. for $C_{18}H_{11}Cl$: C, 82.25; H, 4.24; Cl, 13.52. Found: C, 82.15; H, 4.31; Cl, 13.33.

7-(*o*-Chlorophenyl)-acenaphthene (VII).—A solution of 32 g. of VI in 155 cc. of purified glacial acetic acid and 15 cc. of absolute ether was shaken with hydrogen at atmospheric pressure in the presence of 0.8 g. of Adams catalyst. The reaction was stopped after the absorption of one mole of hydrogen (three and one-half hours), for after saturation of the external double bond the aromatic nucleus is hydrogenated rather rapidly. After filtering and removing the solvent, the product distilled at 190–192° at 2 mm. (bath at 208–212°) as a light yellow oil which crystallized rapidly; yield 30.6 g. (95%). This material, m. p. 68–74°, was satisfactory for the next step. After three crystallizations from methanol a sample formed colorless elongated prisms melting constantly at 81–82°.

Anal.[15] Calcd. for $C_{18}H_{13}Cl$: Cl, 13.42. Found: Cl, 13.64.

***o*-(7-Acenaphthyl)-benzonitrile (VIII).**—A mixture of 35.6 g. of the chloro compound VII, 11.5 g. of cuprous cyanide (dried in vacuum at 100°), 3 cc. of acetonitrile and 31 cc. of pyridine was heated in an autoclave under nitrogen (initial pressure, 800 pounds) at 243–245° for twenty-five hours. (Longer heating lowers the yield: thirty-five hours, 74.5%; forty-eight hours, 66.5%; a run conducted for sixty hours at 255° gave a 20% yield of a very poor product). The reaction mixture was shaken with dilute ammonia solution and benzene and after filtering the two-phase system with suction, the benzene layer was separated, washed with ammonia solution, water and dilute hydrochloric acid, filtered by suction, and washed free of acid. The residue from the benzene solution was distilled at 3 mm., the nitrile passing over as a reddish oil at 208–212° (bath, 220–230°); yield 25.9 g. (87%). The sample for analysis was passed through a tower of alumina in benzene solution and crystallized three times from hexane. It formed small, colorless needles, m. p. 79.7–80.5°. Impure samples often melt at higher temperatures.

Anal.[15] Calcd. for $C_{19}H_{13}N$: N, 5.49. Found: N, 5.55.

***o*-(7-Acenaphthyl)-benzoic Acid (IX).**—A solution of 25.9 g. of distilled nitrile and 164 g. of potassium hydroxide in 1050 cc. of alcohol and 590 cc. of water was refluxed for 250 hours in a copper flask. The alcohol was expelled by distillation, water being added to maintain a volume of about 1200 cc., and the resulting hot aqueous solution was treated with Norite. The dark filtrate was acidified and cooled and the crude acid which separated was dried, refluxed in benzene with Norite and crystallized twice from benzene–hexane (1/1), giving 18 g. of acid crystallizing in soft, snow-white needles, m. p. 194–195°. The final mother liquor afforded 0.9 g. of pure product; total yield 69%. An additional crystallization from benzene–hexane gave a sample of constant m. p. 195–195.5°.

Anal. Calcd. for $C_{19}H_{14}O_2$: C, 83.18; H, 5.14. Found: C, 82.94; H, 5.29.

Attempts to shorten the reaction time by conducting the hydrolysis under pressure at higher temperatures resulted in extensive decomposition. After seventeen hours at 120° only 5% of acid could be isolated from the tarry product, and on heating for sixty-five hours at 100° extensive decomposition was evident and only 40% of the acid could be isolated. On one occasion the nitrile was saponified as described, but for only one hundred hours; an oil separated after distillation of the alcohol and this crystallized on prolonged scratching. Crystallization from benzene–hexane (Norite) afforded ***o*-(7-acenaphthyl)-benzamide, m. p. 177–180°,** in 32.5% yield. Three crystallizations from benzene gave nearly colorless blades, m. p. 182–182.8°.

Anal.[15] Calcd. for $C_{19}H_{15}ON$: N, 5.13. Found: N, 4.98.

The alkaline filtrate from the amide on suitable working afforded the acid in 40.5% yield. Treatment of the amide with amyl nitrite in acetic acid solution gave only a non-acidic, amorphous red material.

10-Acetoxy-1′,9-methylene-1,2-benzanthracene (X).—A mixture of 0.5 g. of the acenaphthylbenzoic acid IX, 3 cc. of glacial acetic acid, 2.5 cc. of acetic anhydride and a trace of zinc chloride was refluxed for one hour and water was added by drops to the hot solution until crystallization commenced. The acetoxy compound separated in fluffy, dull yellow plates, m. p. 171–178°; yield 0.45 g. (83%). Boiling with acetic acid caused decomposition, but alcohol proved satisfactory for recrystallization. A sample crystallized four times from this solvent formed fine, straw-colored needles, m. p. 175–179°, with softening at 171°. Further recrystallization did not give a product of sharp m. p.

Anal. Calcd. for $C_{21}H_{14}O_2$: C, 84.54; H, 4.73. Found: C, 84.66; H, 4.89.

1′,9-Methylene-1,2-benzanthracene.[2]—The acetate X (60 mg.) was reduced with zinc and alkali according to Martin[16] and the fluorescent toluene layer passed through a tower of alumina and Supercel. The material recovered from the filtrate on crystallization from alcohol afforded 15 mg. of 1′,9-methylene-1,2-benzanthracene, m. p. 122.5–123°, and 10 mg., m. p. 120–122° (51.5%). The pure sample showed no depression when mixed with the hydrocarbon prepared by the Elbs reaction.[2] Like the previous sample, the hydrocarbon appears colorless in artificial light and is a fluorescent greenish-yellow in daylight.

10-Methyl-1′,9-methylene-1,2-benzanthracene (XI).—Five grams of *o*-(7-acenaphthyl)-benzoic acid was cyclized by standing in 100 g. of anhydrous hydrogen fluoride for fifteen minutes. The dark red solution was poured onto ice and the yellow precipitate was collected, washed and dried in vacuum. Attempted crystallization of the moist product from aqueous acetone was unpromising, for although some crystals were obtained, considerable tarry material resulted. For the Grignard reaction it was found best to use the crude dried product. This was added in half-gram lots with good stirring to 5 equivalents of methylmagnesium chloride in 150 cc. of ether; after refluxing for forty-five minutes and decomposing with dilute acid, the washed ether layer was concentrated until most of the ether had been removed and taken up in about 30 cc. of hot benzene. On cooling, 2–2.5 g. (43–54%) of **1′,9-methylene-1,2-benz-10-anthranol** crystallized in slender, buff-

(14) Analysis by the Arlington Laboratories. Both this substance and its hydrogenation product are difficultly combustible.

(15) Analysis by H. S. Wight.

(16) Martin, THIS JOURNAL, **58**, 1438 (1936).

colored needles, m. p. 160–164° dec. (see below). The filtrate was taken to dryness and the residue heated briefly on the hot-plate to effect dehydration and put through an alumina–Supercel tower in benzene solution. The hydrocarbon collected from the highly fluorescent filtrate was clarified with Norite in alcohol and crystallized from about 15 cc. of this solvent, giving 50–90 mg. (1.1–1.9%) of material melting at 174–177.5°. Three further crystallizations gave a product of the constant m. p. 181–181.4°; the first crop formed fine, pale orange needles (26–47 mg.) and the mother liquors gave 10 mg. more of good material; yield of pure hydrocarbon, 0.8–1.2%.

Anal. Calcd. for $C_{20}H_{14}$: C, 94.45; H, 5.55. Found: C, 94.25; H, 5.77.

The **trinitrobenzene derivative** when prepared from pure hydrocarbon crystallized from alcohol in bright orange-red needles, m. p. 182.5–183.2°.

Anal. Calcd. for $C_{26}H_{17}O_6N_3$: N, 8.99. Found: N, 9.13.

This derivative is not suitable for use in purifying the hydrocarbon, for when the crude reaction product from the tower was treated with trinitrobenzene the complex was brown-black and melted at about 162° and was not improved on repeated crystallization. The dark red picrate is too unstable to be useful as a derivative.

Many variations were tried in the procedure of conducting the Grignard reaction. In boiling benzene or toluene, in cold benzene, or in ether at −70°, the yield was either as reported or lower. Lithium methyl in ether gave the same yield as the Grignard reagent, and the addition of the crude cyclization product in benzene rather than as a solid lowered the yield. The low yield even under the most favorable conditions seems to be due to extensive and rapid isomerization to the anthranol.

1′,9-Methylene-1,2-benz-10-anthranol (XII).—The material separated from the Grignard reaction mixture by crystallization from benzene proved to be the anthranol in an essentially pure condition. The substance is quite sensitive and rapidly turns red in boiling benzene or in cold dioxane. It is moderately soluble in ether or ligroin (b. p. 80–90°) and on three crystallizations from this solvent-pair formed pale yellow, fibrous needles, m. p. 160–164° with charring. The sample retained ligroin tenaciously and gave a satisfactory analysis only after drying for fifteen hours in high vacuum at 70°.

Anal. Calcd. for $C_{19}H_{12}O$: C, 89.03; H, 4.72. Found: C, 89.08; H, 4.85.

The substance is highly fluorescent in dilute alcoholic solution, and the addition of ferric chloride produces an orange-red coloration. Extensive decomposition occurred on attempted acetylation. The Bucherer reaction was tried at 140, 155, and 180° but gave only water-soluble products. On reduction of the anthranol with zinc and alkali, 1′,9-methylene-1,2-benzanthracene was obtained in 35% yield, and the result was the same using the crude cyclization product. That the yield was lower than from the acetate X is probably because of the great sensitivity of the anthranol and anthrone.

Summary

A synthesis has been developed for 1′,9-methylene-1,2-benzanthracene and its hitherto undescribed 10-methyl and 10-hydroxy derivatives starting with the reaction between *o*-chlorophenylmagnesium bromide and 7-acenaphthenone. A new method was found whereby the ketonic starting material can be produced readily in quantity. This consists in the oxidation of acenaphthene with red lead in acetic acid solution, saponification of the resulting 7-acetoxy compound and oxidation of 7-acenaphthenol to 7-acenaphthenone.

Erythrina Alkaloids. VII. Isolation and Characterization of the New Alkaloids, Erythraline and Erythratine

BY KARL FOLKERS AND FRANK KONIUSZY

The isolation of erythramine from the seeds of *Erythrina sandwicensis* Deg. and *Erythrina subumbrans* (Hassk.) Merr. was described recently.[1] It was stated in that paper that erythramine had been isolated from other species of *Erythrina*, but that it was found associated with another alkaloid of such similar properties that its isolation was more difficult. This other new alkaloid has been named erythraline.

By fractional crystallization of the hydriodides from the crude free alkaloids of *Erythrina glauca* Willd., with particular observance of the optical rotations, pure erythraline hydriodide was isolated as the major alkaloid and pure erythramine hydriodide as a minor alkaloid. A second minor alkaloid was also isolated as the hydriodide, and since it has been also characterized as new, it has been named erythratine. It was discovered later that pure erythratine base could be easily obtained directly by crystallization of the crude bases from ethanol, and the yield was twice that

(1) Folkers and Koniuszy, THIS JOURNAL, **61**, 1232 (1939).

obtained by fractional crystallization of the hydriodides. Erythraline and erythramine hydriodides have similar solubilities in ethanol and although prepared in this solvent their separation from it was not satisfactory. However, erythraline hydriodide was less soluble in water than the erythramine and erythratine hydriodides and their separation was satisfactory. The fact that erythraline hydriodide is the least soluble, and therefore the easiest to obtain pure, signifies that this alkaloid would probably be the only one isolated in those cases where only semi-micro quantities of the crude free alkaloid bases were available. It has been desirable to restrict these studies to authentic samples of seeds[2] and, since such samples are generally small, often only semi-micro quantities of bases are available for examination. On this basis, erythraline was isolated as the hydriodide from the seeds of *Erythrina variegata* L. var. *orientalis* (L.) Merr., *Erythrina Folkersii* Kruk. and Mold., *Erythrina velutina* Willd., and *Erythrina macrophylla* DC. The isolation of erythramine and erythratine as minor alkaloids from *Erythrina glauca* was facilitated by the large quantities of seeds of this species which were available.

Because of the close botanical relationship of *Erythrina velutina* forma *aurantiaca* (Ridl.) Kruk. and *Erythrina Grisebachii* Urb. to *Erythrina velutina*, it was considered that erythraline exists also in these, although the hydriodides were not prepared and crystallized after the amount of the free bases present in the seeds was determined.

Erythraline was isolated also from the seeds of *Erythrina fusca* Lour. as the pure free base directly from the crude free alkaloidal fraction. This direct isolation of the free base was considered a manifestation of the freedom of erythraline from its closely related alkaloids in this species and the distinct character of *Erythrina fusca*. In contrast to this was the failure to isolate pure erythraline base directly from the crude free alkaloidal fraction of *Erythrina velutina*. It has been preferred generally to isolate these alkaloids as the hydriodides.

It is to be emphasized from these studies (and others, as yet unpublished) on new *Erythrina* alkaloids that melting points alone of bases and salts (decomposition point for the latter) are unreliable as proof of homogeneity or identity. Mixtures frequently melt at the same temperature as one component. Microanalyses of mixtures of these alkaloids with identical or closely related empirical formulas may be confusing. The optical rotations after crystallizations are the best guide. Consequently, the identity of an individual alkaloid is established best by the combined data of melting points, optical rotations, analyses, and other derivatives if possible.

The results of the microanalyses of the free base, the hydriodide, and the hydrobromide have established the empirical formula of erythraline as $C_{18}H_{19}NO_3$; thus, it differs from erythramine, $C_{18}H_{21}NO_3$, by only two hydrogen atoms.

The microanalyses of the free base hemihydrate, the hydriodide, and the hydrobromide were all in agreement with the empirical formula $C_{18}H_{21}NO_4$ for erythratine.

The initial studies on the constitution of erythramine have been published[3] and their continuance will be described in a forthcoming paper and with new experiments concerning the structure of erythraline.

Hypaphorine was newly isolated from the seeds of *Erythrina glauca*, *Erythrina Folkersii*, *Erythrina fusca*, *Erythrina velutina*, and *Erythrina macrophylla*, and it undoubtedly exists in *Erythrina Grisebachii* and *Erythrina velutina* forma *aurantiaca*. Hypaphorine was re-isolated from *Erythrina variegata* var. *orientalis*.[4]

The relative pharmacological potencies of these *Erythrina* alkaloids are of interest. The threshold dose of erythramine hydrobromide for curare-like paralyzation of frogs was 7 mg./kg., injected intralymphatically.[3] Dr. Klaus Unna of the Merck Institute of Therapeutic Research has reported after preliminary tests that the threshold dose of erythraline hydrobromide was 8 mg./kg. frog, and that of erythratine hydrobromide was 75 mg./kg. frog.

The species names used in this paper are in accord with the recent taxonomic revision of *Erythrina* by Mr. B. A. Krukoff.[5,6]

Experimental Part

Isolation of Erythraline and Hypaphorine

Erythrina fusca **Lour. (Tamesis 9345).**—The 980 g. of seed powder was extracted first with 1500 ml. of petroleum

(2) The identity of the *Erythrina* seeds used in these studies was established either by accompanying herbarium material, which was determined by Mr. B. A. Krukoff at the New York Botanical Garden, or by other evidence which left no doubt regarding the identity.

ether for six hours in a Soxhlet. After distillation of the solvent, the yield of the yellow fat fraction was 77 g. (7.8%). The extraction of the seed powder was then continued for thirty-six hours with two 1500 ml. portions of methanol. This extract was concentrated by distillation and finally pumped out at 30° and 18 mm. to remove the last of the methanol. The 150 g. (15.8%) of gum-like residue was dissolved in 700 ml. of water, treated with 14 ml. of concentrated hydrochloric acid, and freed of residual emulsified oil droplets by extracting first with petroleum ether, then with chloroform. The clear aqueous solution was made just alkaline with sodium bicarbonate and extracted with ten 100 ml. portions of chloroform. The yield of crude erythraline, after complete solvent removal at 30° and 18 mm., was 1.829 g. (0.19%).

The hypaphorine may be isolated by treating the alkaline aqueous solution with hydrochloric acid, etc., as described for its isolation from *Erythrina sandwicensis*.[1] Data on hypaphorine from *Erythrina fusca* are in Table III.

Erythraline Base.—The 1.829 g. of crude alkaloids was recrystallized from absolute ethanol. The first crystallization yielded 1.348 g. of gummy crystals, the second yielded crystals of m. p. 55–65° and the third yielded crystals of m. p. 106–107°. Subsequent crystallizations did not alter the melting point; it remained constant at 106–107°. The yield was 0.6731 g. (0.068%). These white crystals of pure erythraline showed $(\alpha)^{27}D$ + 211.8, C = 0.944, absolute ethanol. They were dried at 60° and 2 mm. for thirty minutes before analysis.

Anal. Calcd. for $C_{18}H_{19}NO_3$: C, 72.70; H, 6.44; N, 4.71. Found: C, 72.55; H, 6.33; N, 4.88.

Erythraline base was much more stable than erythramine base and was stored in a black vial at ordinary temperatures and pressures.

Mixed melting points of erythraline (m. p. 106–107°) and erythramine (m. p. 103–104°) were as follows: 10 parts and 1 part, respectively, m. p. 88–94°; 5 parts and 5 parts, m. p. 90–96°; 1 part, and 10 parts, m. p. 93–97°

Erythraline Hydriodide.—A quantity of 94.4 mg. of analytically pure erythraline base was dissolved in 2 ml. of absolute ethanol and 47.5 mg. of sodium iodide was added. The solution was acidified with the calculated amount of glacial acetic acid. Yellow crystals of the hydriodide formed at 25°. They melted at 252–253° with decomposition and this constant was not changed by further recrystallizations. This melting or decomposition point varies somewhat with the rate of heating the bath. In the same bath, pure erythramine hydriodide melted at 245–245.5°, and the mixed salts melted at 247–249°, each with decomposition. Erythraline hydriodide showed $[\alpha]^{31}D$ + 177°, C = 0.322, water. A sample was dried at 25° and 2 mm. before analysis.

Anal. Calcd. for $C_{18}H_{19}NO_3 \cdot HI$: C, 50.83; H, 4.74; N, 3.29. Found: C, 51.01; H, 4.78; N, 3.38.

Erythraline Hydrobromide.—A quantity of 100 mg. of analytically pure erythraline was dissolved in 3 ml. of absolute methanol, acidified with 40% hydrobromic acid, and brought to the crystallization point with anhydrous ether. After twelve hours at 10°, white, granular crystals formed. They melted at 243° and showed $[\alpha]^{27}D$ +216.6, C = 0.500, water. The salt was dried at 25° and 30 mm. before analysis.

Anal. Calcd. for $C_{18}H_{19}NO_3 \cdot HBr$: C, 57.15; H, 5.32. Found: C, 57.30; H, 5.28.

Isolation of Erythraline, Erythramine and Erythratine

Erythrina glauca Willd. (Wortley 9242.)—A 10-kg. quantity of powdered seeds was extracted. The fourteen hours of extraction with petroleum ether yielded 940 g. (9.4%) of the fatty fraction. The thirty-three hour extraction with methanol yielded 1660 g. (16.6%) of a thick green gum. This gum was dissolved in 6 liters of water, made just acid to congo red with 100 ml. of concentrated hydrochloric acid, and clarified first with petroleum ether and then chloroform. Five liters of the clear solution was made alkaline with sodium bicarbonate at 10–15° and then extracted continuously with chloroform for five hours. The chloroform residue, which was pumped out at 30° and 2 mm. for four hours, weighed 19.3 g. (0.15%).

The 19.3 g. of crude alkaloidal bases was dissolved in 40 ml. of absolute ethanol and treated with 9.65 g. of sodium iodide and 3.86 g. of glacial acetic acid. After standing at 10° for twelve hours, 9.31 g. of mixed yellow hydriodides were obtained. Recrystallization of these hydriodides from 95% ethanol gave the following results: first crop, Fraction A, 5.45 g., m. p. 242–244.5°; $[\alpha]^{27}D$ +196.4; second crop, Fraction B, obtained by concentrating the mother liquor to one-half the volume, 0.341 g., m. p. 241–243°; $[\alpha]^{27}D$ +200.8; third crop, Fraction C, obtained by concentrating the mother liquor to one-half the volume, 0.99 g., m. p. 242°; $[\alpha]^{26}D$ +119°. The third crop or Fraction C was not only markedly different in optical rotation, but was white in color whereas the first two crops were yellow-orange in color. Table I contains the data on the fractional crystallization of 238.3 mg. of Fraction A.

TABLE I

CRYSTALLIZATIONS ON FRACTION A

Crystallization from water	Starting amt., mg.	Amt. recov., mg.	$[\alpha]^{25-28}D$, water	M. p., °C.	Fraction
First	238.3	188.0	+191.3	242	
	2nd Crop	13.8	+221	242	D
Second	168.0	132.0	+187.9	245	
Third	106.0	102.0	+176.9	249	E
Fourth	73.0	70.0	+177	249	F

Fraction D was shown by the physical constants to be pure erythramine hydriodide.[1] Larger amounts of erythramine hydriodide were obtained from the balance of Fraction A. A yield of 0.003% was obtained (based on seed powder).

Fractions E and F were shown by the physical constants to be pure erythraline hydriodide. A yield of 0.03% was obtained. A sample for analysis was dried at 25° and 2 mm.

Anal. Calcd. for $C_{18}H_{19}NO_3 \cdot HI$: C, 50.83; H, 4.74; N, 3.29. Found: C, 50.68; H, 4.77; N, 3.16.

Fraction B was found to be a mixture of erythraline and erythramine hydriodides.

The data on Fraction C are in Table II.

Erythratine Hydriodide.—Fraction G of Table II, which had constant properties, was recognized as a new

TABLE II

CRYSTALLIZATIONS ON FRACTION C

Solvent	Starting amt., mg.	Amt. recov., mg.	$[\alpha]^{25-28}D$, water	M. p., °C.	Fraction
95% ethanol	99.0	79.2	+110.2	242–242.5	
Water	75.2	61.0	+108.4	242–242.5	
Water	56.1	47.9	+109.0	242–242.5	G

alkaloid and the base was named erythratine. A yield of 0.007% was obtained.

Anal. Calcd. for $C_{18}H_{21}NO_4 \cdot HI$: C, 48.66; H, 4.99; N, 3.15. Found: C, 48.67; H, 5.10; N, 3.13.

Direct Isolation of Erythratine Base.—It was discovered later that when the crude free alkaloidal fraction of *Erythrina glauca* (Wortley 9242) was dissolved in 95% ethanol, and allowed to stand, the erythratine base crystallized in a fairly pure condition. The 23.7 g. of crude alkaloidal bases from 12 kg. of seeds was dissolved in 72 ml. of 95% ethanol. On standing, crystals formed; yield, 2.7542 g. of m. p. 167.5–168° and $[\alpha]_D$ +138.6, absolute ethanol. They were recrystallized twice by dissolving in 20 ml. of absolute ethanol, distilling to 8 ml., and adding petroleum ether to incipient crystallization. The final yield of pure erythratine hemihydrate base was 2.16 g. (0.018%); m. p. (and mixed with base derived from the isolated hydriodide) 170°; $[\alpha]^{28}D$ +145.5, C = 0.371, absolute ethanol. The sample was dried at 100° and 0.01 mm. for twenty minutes for analysis.

Anal. Calcd. for $C_{18}H_{21}NO_4 \cdot {}^1/_2H_2O$: C, 66.66; H, 6.83. Found: C, 66.46; H, 7.02.

Erythratine hemihydrate base was more stable than either erythramine or erythraline, the crystals remaining pure on standing for over six months.

Erythratine Hemihydrate Base.—A sample of 296.9 mg. of pure erythratine hydriodide was converted to the free base by dissolving in water, adding sodium bicarbonate, and extracting with chloroform. Experiments with the *Erythrina* free bases are best done with bases so obtained. The pumped out base (210.6 mg.) was a clear gum. It was dissolved in 30 ml. of anhydrous ether and 10 ml. of petroleum ether was added. Flocculent material was filtered, and after concentration to 10 ml., white crystals formed. They melted at 168–169° and through four recrystallizations from anhydrous ether the constant value, m. p. 170–170.5°, was obtained. The crystals were dried at 25° and 2 mm. for analyses, $[\alpha]^{25}D$ +144.9, C = 0.159, absolute ethanol.

Anal. Calcd. for $C_{18}H_{21}NO_4 \cdot {}^1/_2H_2O$: C, 66.66; H, 6.83; N, 4.31. Found: C, 66.21; H, 6.61; N, 4.53.

The erythratine hemihydrate could not be converted to the anhydrous base by drying at 140° and 0.01 mm. for four hours. Less drastic conditions did not materially dehydrate the hemihydrate.

A sample of the pure erythratine hemihydrate was converted back to the hydriodide, and the properties were the same as those of the starting hydriodide; $[\alpha]^{26}D$ +113.3.

Anal. Calcd. for $C_{18}H_{21}NO_4 \cdot HI$: C, 48.66; H, 4.99; I, 28.65. Found: C, 48.49; H, 5.08; I, 28.82.

Erythratine Hydrobromide.—A sample of 50 mg. of pure erythratine hemihydrate was dissolved in 1 ml. of absolute ethanol and the solution was acidified with two drops of concentrated hydrobromic acid. The yield of hydrobromide was 39 mg., m. p. 241°. Recrystallization yielded 21.4 mg. of m. p. 241° also, $[\alpha]^{25}D$ +158.7, C = 0.258, water. The salt was dried at 25° and 30 mm. for analysis.

Anal. Calcd. for $C_{18}H_{21}NO_4 \cdot HBr$: C, 54.56; H, 5.59;

[a] It is recommended that the crude free alkaloid fraction be extracted before the hypaphorine hydrochloride is removed exactly as described in detail for *E. fusca* and *E. glauca*. This method is called the "preferred procedure" and the percentage figure obtained for the crude free alkaloid fraction expresses quite accurately the amount actually present. The

"alternative procedure," which consisted of the removal of the hypaphorine hydrochloride before the extraction of the crude free alkaloids, gives a slightly high value for the percentage of the crude free alkaloids because of the introduction of other substances. [b] Extracted with 95% ethanol. [c] By the "alternative procedure." See note *a*. [d] Erythraline hydriodide; m. p. 247°; $[\alpha]^{28}D$ +179.2, water. *Anal.* Calcd. for $C_{18}H_{19}NO_3 \cdot HI$: C, 50.83; H, 4.74. Found: C, 50.72; H, 5.18. Thus, the alkaloid in the seeds from Ceylon does not differ from the alkaloid in the seeds from Trinidad. The mother liquors from erythraline hydriodide were not examined further because of the small amount available. [e] Extracted with absolute methanol. It is generally preferred because of greater extracting power. [f] By the "preferred procedure." See note *a*. [g] See Expt. Part. [h] The 481.2 mg. of crude free alkaloids was dissolved in 0.4 ml. of absolute ethanol and treated with 240 mg. of sodium iodide and 94 mg. of glacial acetic acid. The 80.1 mg. of mixed hydriodides containing a little sodium acetate was recrystallized; yield, 20 mg., m. p. 239.5–241°, $[\alpha]^{28}D$ +197.2. *Anal.* Calcd. for $C_{18}H_{19}NO_3 \cdot HI$: C, 50.83; H, 4.74. Calcd. for $C_{18}H_{21}NO_3 \cdot HI$: C, 50.60; H, 5.15. Found: C, 51.01; H, 5.38. These properties are those of mixed erythraline and erythramine hydriodides. Two more recrystallizations from water yielded pure erythraline hydriodide, $[\alpha]^{26}D$ +178. The first mother liquor from the 20 mg. yielded crude erythramine hydriodide of $[\alpha]^{26}D$ +211.1. The accepted value is $[\alpha]D$ +220. The material was now exhausted. [i] A crystalline hydriodide was not obtained from the 40 mg. of crude free alkaloid. [j] The following three samples were combined: 363 g., Belaev 9220, Philippine Islands; 164 g., Haigh 9172, Ceylon; 211 g. Acuna 9164, Cuba. A sample of 700 g. was used after grinding. [k] The fatty fraction and the alcohol extractives were removed together by extracting for twenty-eight hours with methanol. The alcohol residue was dissolved in 300 ml. of water, made acid with hydrochloric acid, and extracted fifteen times with petroleum ether for removal of the fatty fraction. However, after making alkaline with sodium bicarbonate and extracting with chloroform, it was found that the expected semi-micro quantity of alkaloids was badly contaminated with extraneous material. This extraction experiment demonstrated that the "preferred procedure" described for *E. fusca* should be followed when semi-micro quantities of alkaloids are being extracted, and that chloroform extraction should follow the petroleum ether in the clarification step. [l] The 247.8 mg. of crude bases yielded 70.2 mg. of crude hydriodides, m. p. 234–238°. One recrystallization yielded 35.6 mg., m. p. 242–243°, $[\alpha]^{28}D$ +212.4. Two more recrystallizations yielded pure erythraline hydriodide, m. p. (and mixed) 249–250°, $[\alpha]D$ +177.4, 0.0035% yield. *Anal.* Calcd. for $C_{18}H_{19}NO_3 \cdot HI$: C, 50.83; H, 4.74. Found: C, 50.98; H, 5.06. The last 1 mg. of mother liquor hydriodides showed $[\alpha]D$ +238.5°. [m] The 2.087 g. of crude bases yielded 0.9784 g. of mixed hydriodides, m. p. 234–235°. Recrystallization yielded 0.744 g., m. p. 243–244°, $[\alpha]D$ +189.6°. One more recrystallization from water yielded pure erythraline hydriodide, m. p. (and mixed) 249°, $[\alpha]D$ +176.0, 0.056% yield. [n] An attempt was made to crystallize the crude free bases from ethanol as was done for the crude bases from *E. fusca*. However, pure erythraline could not be obtained because it could not be crystallized away from the accompanying alkaloids. The inseparable mixture showed m. p. 101–102°, $[\alpha]^{25}D$ +213 whereas pure erythraline showed m. p. 106–107° and $[\alpha]D$ +211. There was no depression in mixed melting points when this impure erythraline was mixed with pure erythramine or erythraline. [o] See discussion in the introduction of this paper. [p] The 1.8298 g. crude bases yielded 1.5928 g. mixed hydriodides, m. p. 229–230°, $[\alpha]D$ +148.3. After fractional crystallizations, only pure erythraline hydriodide was obtained as the major free alkaloid, although related alkaloids were present. It showed m. p. 249–250°, $[\alpha]D$ +176.6, 0.06% yield. *Anal.* Calcd. for $C_{18}H_{19}NO_3 \cdot HI$: C, 50.83; H, 4.74; N, 3.29; I, 29.86. Found: C, 50.54; H, 4.91; N, 3.13; I, 29.99.

Isolation of Alkaloids from Other Species of *Erythrina*.—The technique of fractional crystallization of the hydriodides of erythraline, erythramine, and erythratine from the seeds of *Erythrina glauca* has been described in detail. The significant data on the alkaloids as isolated from other species of *Erythrina* are summarized in Table III. In general, the amount of the crude free alkaloidal fraction was 0.2–0.4% for all of the species of *Erythrina* mentioned in Table III with the exception of *Erythrina variegata* var. *orientalis* and *Erythrina Folkersii*. These two species contained only traces of this alkaloid fraction. The 0.2–0.4% amount of this fraction was also true for *Erythrina sandwicensis* and *Erythrina subumbrans*.

Acknowledgments.—We are especially indebted to Mr. B. A. Krukoff for the task of obtaining the plant materials, for the determinations of plants, and for his suggestions and advice on botanical matters. We are greatly appreciative of the efforts of the many people who have aided materially in the collection of seed samples. The coöperation of Messrs. Douglass Hayman and Wilhelm Reiss on microanalyses was very valuable.

Summary

Erythramine and two new alkaloids, named erythraline and erythratine, have been isolated from the seeds of *Erythrina glauca* Willd. Erythraline was also isolated from the seeds of *Erythrina fusca* Lour., *Erythrina Folkersii* Kruk. and Mold., *Erythrina variegata* L. var. *orientalis* (L.) Merr., *Erythrina velutina* Willd., and *Erythrina macrophylla* DC.

Hypaphorine was isolated from all of the above mentioned species and all for the first time, with the exception of *Erythrina variegata* var. *orientalis* from which it had been previously isolated by others.

Erythraline and hypaphorine undoubtedly

exist also in *Erythrina velutina* forma *aurantiaca* (Ridl.) Kruk. and *Erythrina Grisebachii* Urb.

The crystalline erythraline and erythratine bases, their hydrobromides and hydriodides, have been described. Many microanalyses on several samples and from different species have shown that erythraline has the empirical composition, $C_{18}H_{19}NO_3$, and erythratine has the empirical composition $C_{18}H_{21}NO_4$.

Erythraline and erythramine were of comparable activity (7–8 mg./kg.) in causing a curare-like paralysis in frogs, whereas, erythratine had one-tenth of this activity.

The Introduction of Substituted Vinyl Groups. V. A Rearrangement Involving the Migration of an Allyl Group in a Three-Carbon System[1]

BY ARTHUR C. COPE AND ELIZABETH M. HARDY[2]

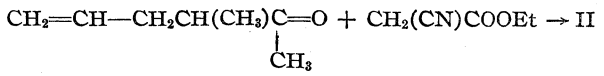
The (dialkylvinyl)-alkylcyanoacetic esters described recently[3] were stable compounds which were not altered in any way during purification. However, in the preparation of ethyl (1-methylpropenyl)-allylcyanoacetate, which was studied but not reported in the previous work, an unstable product was formed, which changed into a stable substance of higher boiling point after several distillations in vacuum. The structures of these compounds and the nature of the rearrangement have now been determined, and are reported in this paper.

The substance formed initially when the sodium derivative prepared from ethyl (1-methylpropylidene)-cyanoacetate was treated with allyl halides proved to be sufficiently stable to be isolated in a pure state if it was distilled at a pressure of 1 mm. Analysis and molecular refraction were in agreement with the structure of the normal alkylation product, ethyl (1-methylpropenyl)-allylcyanoacetate, I.

$$CH_3CH_2C(CH_3)=C(CN)COOEt \xrightarrow{NaOEt}$$

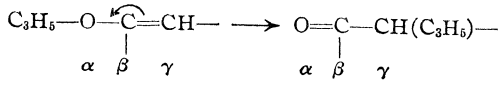
$$[CH_3CH=C(CH_3)C(CN)COOEt]^- Na^+ \xrightarrow{CH_2=CHCH_2X}$$

$$CH_3CH=C(CH_3)C(CN)COOEt$$
$$\quad\quad\quad

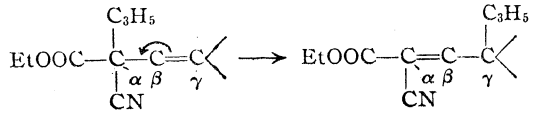


This appears to be the first case in which an allyl group has been observed to undergo a thermally induced α, γ shift in a three-carbon system. It seems probable, however, that this new rearrangement is similar in type to the Claisen rearrangement of allyl enol,[5,6] phenol[7,5,8] and vinyl[8b,9] ethers, and that it is motivated by similar forces.

In the Claisen rearrangement of ethers, an allyl group undergoes an α, γ shift from the electron attracting element oxygen to a carbon atom, and a carbonyl group is formed by migration of a double bond.



In the present case, an allyl group undergoes an α, γ shift from a carbon atom which is electron attracting by virtue of attachement to CN and COOEt groups to one which is less electron attracting. In the process the double bond which shifts becomes attached to the electron attracting carbon atom and conjugated with the CN and COOEt groups.



As in the thermal rearrangement of enol, phenol and vinyl ethers, the isomerization is dependent upon the presence of the allyl group. Three (1-methylpropenyl) alkylcyanoacetic esters, $CH_3CH{=}C(CH_3)C(R)(CN)COOEt$, in which R was methyl, propyl and butyl, were completely stable at much higher temperatures than are required to rearrange the allyl compound. Consequently a cyclic mechanism is regarded as probable.

If the mechanism postulated for the present rearrangement is correct, the isomerization is intramolecular and the allyl group is turned around during the shift. These points are being studied, as is the possibility that this type of rearrangement is general for appropriately substituted three carbon systems attached to allyl or substituted allyl groups.

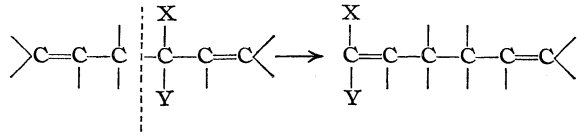
o-allyl phenol



Experimental Part

Ethyl (1-Methylpropenyl)-allylcyanoacetate (Formula I).—One-half mole of ethyl (1-methylpropylidene)-cyanoacetate[10] was converted to the sodium enolate in absolute ethyl alcohol and alkylated with allyl bromide by the general procedure described previously.[3] The reaction mixture was refluxed until it became neutral (forty-five minutes), cooled, diluted with water and extracted with benzene in the usual manner. The residue obtained on concentration of the benzene extract was distilled at a low pressure and superheating was avoided in order to minimize rearrangement. The first distillation gave 67 g. of crude ester, b. p. 90–143° (1 mm.), and 29 g. of tarry residue. The distillate was purified by shaking with 200

(9) Hurd and Pollack, *ibid.*, **60**, 1905 (1938).

(10) Prepared by condensing methyl ethyl ketone with ethyl cyanoacetate in the presence of piperidine acetate or ammonium acetate and acetic acid and removing the water formed by distilling benzene from the mixture. See Cope, THIS JOURNAL, **59**, 2327 (1937). The ester has been described by Scheiber and Meisel, *Ber.*, **48**, 259 (1915).

cc. of 20% sodium bisulfite solution for twelve hours and redistilling through a Widmer column. The yield of pure ester was 37 g. (34%); b. p. 94.5–96° (1 mm.); $n^{25}D$ 1.4609; d^{25}_{25} 0.9735; MD calcd. 58.10, found 58.54.

Anal. Calcd. for $C_{12}H_{17}O_2N$: N, 6.76. Found: N, 6.58.

The ester also was prepared by a similar alkylation using allyl chloride, but the yield was smaller (17%).

Ethyl (1,2-Dimethyl 4-Pentenylidene)-cyanoacetate (Formula II).—When the alkylation product prepared by the method described in the preceding section was purified by distillation at pressures of 15 to 20 mm., partial rearrangement occurred. A typical product had b. p. 141–148° (16 mm.); $n^{25}D$ 1.4683. This material was refractionated at 16 mm. several times in an effort to obtain a pure product, but each distillation resulted in a rise in both the boiling point and refractive index of each fraction. The various fractions were finally combined and refluxed for periods of one to five hours at pressures of 18 to 60 mm., and refractionated through a Widmer column after each period of refluxing until there was no further rise in refractive index or boiling point. The properties of the pure rearranged ester (Formula II) obtained in this way were: b. p. 147–148° (16 mm.); $n^{25}D$ 1.4780; d^{25}_{25} 0.9816; MD calcd. 58.10; found 59.63, exaltation +1.53.

Anal. Calcd. for $C_{12}H_{17}O_2N$: N, 6.76. Found: N, 6.50.

The rearrangement was practically complete after the ester I was refluxed for four hours at 18 mm., at which pressure the temperature of the refluxing liquid was 150–160°. There was little if any decomposition during the period of heating, and the yield of the rearrangement product (25–30%) differed from that of the normal alkylation product only by the amount to be expected because of the manipulative losses resulting from several distillations.

The rearrangement can be carried out more rapidly by refluxing the ester at atmospheric pressure (b. p. approximately 260°). A 12-g. sample of pure ethyl (1-methylpropenyl)-allylcyanoacetate (Formula I) was refluxed for twenty minutes at atmospheric pressure and then distilled in vacuum. The yield of the rearrangement product (Formula II, properties described above) was 8 g. Some high boiling material was formed at this temperature.

Thermal Stability of Other Ethyl (1-Methylpropenyl)-alkylcyanoacetates.—A 10-g. sample of ethyl (1-methylpropenyl)-propylcyanoacetate was refluxed for two hours at atmospheric pressure. There was only slight darkening of the liquid during heating, and on distillation in vacuum 9 g. of the pure ester was recovered, unchanged in boiling point and refractive index. Samples of ethyl (1-methylpropenyl)-ethylcyanoacetate and ethyl (1-methylpropenyl)-butylcyanoacetate[3] were also refluxed for two hours at atmospheric pressure. On distillation following the period of heating 80 to 90% of each of the pure esters was recovered.

Proof of the Structure of Ethyl (1-Methylpropenyl)-allylcyanoacetate (Formula I).—Several samples of the ester were hydrogenated in alcohol solution at room temperature, using a palladinized charcoal catalyst.[11] Complete reduction, which required two moles of hydrogen, was obtained only by several additions of catalyst, or preferably by purification of the partially reduced ester by distillation after the catalyst had become deactivated. The reduced ester (5.8 g. from the reduction of 7.1 g. of I) had b. p. 138–140° (25 mm.) and $n^{25}D$ 1.4358, in agreement with the properties of a known sample of ethyl (*s*-butyl)-propylcyanoacetate (see below).

The reduced ester described above was converted into a solid derivative by condensation with urea in the presence of alcoholic sodium ethoxide in the usual manner.[12] Hydrolysis of the intermediate iminobarbituric acid obtained from 5.8 g. of the ester gave a mixture of neutral and acidic material, from which the substituted barbituric acid was separated by extraction with dilute sodium hydroxide. The product obtained by acidification of the alkaline extract was purified by one crystallization from 50% alcohol. The yield of pure 5-propyl 5-*s*-butyl-barbituric acid,[13] m. p. 135–137°, was 0.6 g. (10%). The identity of this barbituric acid derivative was established by comparison with a known sample of 5-propyl-5-*s*-butyl-barbituric acid[14] prepared from the known ethyl (*s*-butyl)-propylcyanoacetate described below. The m. p. and mixed m. p. of the two samples were identical.

The known ethyl (*s*-butyl)-propylcyanoacetate referred to above was prepared from ethyl (1-methylpropylidene)-cyanoacetate.[10] Fifty grams of the alkylidene ester, 100 cc. of alcohol and 2 g. of palladinized charcoal catalyst were shaken with hydrogen at 15 to 30 lb. (1–2 atm.) pressure until reduction had become very slow and the theoretical amount of hydrogen had been absorbed (forty minutes). The catalyst was removed by filtration, the solvent distilled in vacuum, and the residue shaken with a 20% sodium bisulfite solution to remove any unreduced ester. The ester layer was combined with an ether extract of the sodium bisulfite solution, washed with dilute hydrochloric acid, and distilled through a Widmer column. The yield of pure ethyl (*s*-butyl)-cyanoacetate[15] was 37.5 g. (74%); b. p. 105–106° (11 mm.); $n^{25}D$ 1.4273; d^{25}_{25} 0.9617; MD calcd. 45.18, found 45.31.

Anal. Calcd. for $C_9H_{15}O_2N$: N, 8.28. Found: N, 8.28.

The ethyl (*s*-butyl)-cyanoacetate (30.3 g.) was converted into the sodium derivative by addition to a solution of sodium (4.14 g.) in 150 cc. of absolute alcohol. *n*-Propyl bromide (24.6 g.) was added and the solution refluxed for one and one-half hours. The reaction mixture was diluted with water and extracted with benzene. The benzene was distilled and the crude ester was purified by shaking with concd. ammonium hydroxide overnight to remove any remaining monoalkyl cyanoacetic ester. Distillation through a Widmer column gave 26.7 g. (73%) of ethyl (*s*-butyl)-propylcyanoacetate, b. p. 122.5–123.5° (11 mm.) $n^{25}D$ 1.4356; d^{25}_{25} 0.9378; MD calcd. 59.04, found 58.99.

(13) Shonle and Waldo, *ibid.*, **55**, 4649 (1933).

(14) The barbituric acid derivative identifies the ester obtained by reduction even though it was formed in low yield, for under the same conditions the ester of known structure also gave 5-propyl-5-*s*-butyl-barbituric acid in only 10% yield. Relatively large amounts of the same neutral by-product were formed from both samples of the ester.

(15) This ester has been described by Roger in French Patent 598,072, which records only b. p. 118° (17 mm.).

Anal. Calcd. for $C_{12}H_{21}O_2N$: N, 6.63. Found: N, 6.57.

Proof of the Structure of Ethyl (1,2-Dimethyl 4-Pentenylidene)-cyanoacetate (Formula II). Reduction.—Duplicate samples of the ester were reduced rapidly and quantitatively in alcohol solution at room temperature and pressure in the presence of palladinized charcoal, absorbing 105 and 107% of two molar equivalents of hydrogen. From the reduction of 5.8 g. of II, 3.0 g. of ethyl (1,2-dimethylpentyl)-cyanoacetate was obtained; b. p. 134–136° (12 mm.); $n^{25}D$ 1.4389.

Anal. Calcd. for $C_{12}H_{21}O_2N$: N, 6.63. Found: N, 6.50.

Condensation of the ethyl (1,2-dimethylpentyl)-cyanoacetate with urea, followed by hydrolysis, gave 5-(1,2-dimethylpentyl)-barbituric acid, m. p. 219.5–220.5°.

Anal. Calcd. for $C_{11}H_{18}O_3N_2$: N, 12.38. Found: N, 12.54.

Cleavage with Ammonia.—Seven grams of the rearranged ester (II) and 50 cc. of concd. aqueous ammonia were shaken for thirty hours. The ammonia was extracted twice with ether and the extract dried over potassium carbonate. Distillation gave 2.2 g. (60%) of *unsym*-methyl allyl acetone (3-methyl-5-hexene-2-one), b. p. 137–138°, $n^{25}D$ 1.4215. Evaporation of the ammonia solution left a crystalline residue which on recrystallization from alcohol gave 1.5 g. (54%) of cyanoacetamide, m. p. and mixed m. p. with a known sample 121–122°.

In order to be certain of the identity of the *unsym*-methyl allyl acetone produced by cleavage a known sample and solid derivatives were made. The ketone was prepared by the hydrolysis of ethyl allylmethylacetoacetate as described by Jacobi and Merling.[16] The ethyl allylmethylacetoacetate[17] was synthesized from ethyl allylacetoacetate.[18] The *unsym*-methyl allyl acetone had b. p. 137–138° (previously reported as 138–140°) and $n^{25}D$ 1.4218. Its semicarbazone (m. p. 84–85°) and 2,4-dinitrophenylhydrazone (m. p. 41–42°) were prepared by standard methods.

(16) Jacobi and Merling, *Ann.*, **278**, 11 (1894).
(17) James, *ibid.*, **226**, 207 (1884).
(18) Brühl, *J. prakt. Chem.*, **50**, 132 (1894).

Anal. of the semicarbazone. Calcd. for $C_8H_{15}ON_3$: N, 24.83. Found: N, 24.70. *Anal.* of the dinitrophenylhydrazone. Calcd. for $C_{13}H_{16}O_4N_4$: N, 19.17. Found: N, 19.35.

The semicarbazone and 2,4-dinitrophenylhydrazone prepared from the ketone isolated from the cleavage of II with ammonia were identical in m. p. and mixed m. p. with the derivatives prepared from the known ketone.

Synthesis of II from *unsym*-Methyl Allyl Acetone.—*unsym*-Methyl allyl acetone (9.3 g.), ethyl cyanoacetate (9.5 g.), ammonium acetate (0.8 g.), acetic acid (1.2 g.) and benzene (25 cc.) were refluxed under a constant water separator for one hour. The benzene solution was cooled, washed with water and distilled in vacuum. The reaction was incomplete, for 6 g. of ethyl cyanoacetate was recovered, but 5 g. (29%) of ethyl (1,2-dimethyl 4-pentenylidene)-cyanoacetate was obtained, b. p. 153–154° (23 mm.); $n^{25}D$ 1.4781. These properties are in good agreement with those of the ester II prepared by the thermal rearrangement of I.

Summary

Ethyl (1-methylpropenyl)-allylcyanoacetate rearranges readily on heating at temperatures between 150 and 260°, giving ethyl (1,2-dimethyl 4-pentenylidene)-cyanoacetate. In the rearrangement the allyl group migrates from the α to the γ carbon atom of a three carbon system, while the double bond in the latter shifts from the β, γ to the α, β position.

It appears probable that this rearrangement involving the migration of an allyl group in a three carbon system occurs for reasons similar to those responsible for the Claisen rearrangement of enol, phenol and vinyl ethers, and that the two types of rearrangement follow similar mechanisms.

BRYN MAWR, PA. RECEIVED DECEMBER 18, 1939

NOTES

A Method for Separating Para-hydrogen from Oxygen and Carbon Monoxide

By E. Bergmann, L. Farkas and L. Sandler

Para-hydrogen has often been used as a research tool for elucidating reaction mechanisms. In order to analyze the para–ortho ratio in the hydrogen, the hydrogen has to be separated from all gases taking part in, or formed by, the reaction, so that the ortho–para ratio is not changed by this process. In most cases satisfactory separation can be achieved by the use of liquid or solid air which freeze out most of the common gases. In two important cases, however, *viz.*, when oxygen or carbon monoxide is present, liquid hydrogen had to be used for the separation process. Since liquid hydrogen is not always available and its preparation is very expensive, we have tried to substitute a chemical method of separation for the physical one. For this purpose, solutions had to be found which absorb the above gases quantitatively without causing any appreciable para–ortho conversion during the absorption process.

Absorption of Oxygen.—To the quantitative absorption of oxygen a method was adapted which has been devised for the purification of nitrogen by Schlenk,[1] and which is based on the fast and complete reaction of triphenylmethylsodium solution[2] with gaseous oxygen. As diethyl ether as used by Schlenk and Marcus in their investigations, has a very high vapor pressure and dissolves the grease of the stopcocks, it was replaced by dibutyl ether, having a vapor pressure of a few mm. only at 20°. The solution prepared and filtered in the usual way was evaporated in a stream of pure nitrogen and dibutyl ether added gradually during this process.

The solution actually used was saturated with triphenylmethylsodium and contained an excess of this substance in solid form so as to render possible the uptake of a large amount of oxygen. The solution was kept in a shaking vessel, attached to the high vacuum apparatus by a glass spiral and remained in use for many months without renewal. The diffusion of the gas into the solution can be accelerated by cooling the solution and is completed within less than one minute.

The following two experiments characterize the above solution:

A lock system of 5 cc. capacity was connected through a very narrow capillary tube to a washing bottle containing about 20 cc. of the solution. It was found that when 130 cubic mm. (at S. T. P.) of oxygen passed through the capillary tube no measurable amount of oxygen (less than 0.005%) could be detected by a McLeod gage on the other side of the washing bottle.

In order to test whether any appreciable ortho–para conversion takes place in presence of the triphenylmethyl sodium solution, para-hydrogen was introduced into the shaking vessel (70 cc. capacity) containing the sodium compound (30 cc.). The half-life-time of the conversion under our conditions was two and one-half hours; thus, the conversion occurring during the short period of oxygen absorption is negligible. The conversion observed is most probably due to the presence of small quantities of free (paramagnetic) triphenylmethyl.

Absorption of Carbon Monoxide.—For the absorption of carbon monoxide the common cuprous oxide–ammonia solution was used. In the same arrangement as used in the case of oxygen, 500 cubic mm. (S. T. P.) of carbon monoxide (at an actual pressure of 70 mm.) were made to pass the capillary tube and again no trace (less than 0.005%) of the gas could be detected on the other side of the washing bottle.

The following experimental arrangement was used in an actual experiment, carried out at low pressure (10^{-2} mm.).[3] The gas mixture was collected in a bulb of 700 cc. to which a smaller vessel was attached, containing 40 cc. of the absorbing solution cooled, in order to accelerate the diffusion of the gas, and separated from the larger bulb by a stopcock. The gas mixture (40 cubic mm. at S. T. P.) was collected in the large bulb, the stopcock opened and the absorption vessel shaken for a few hours. A control experiment, carried out with a mixture of 20 cubic mm. of normal hydrogen and 200 cubic mm. of carbon monoxide showed that no carbon monoxide could be detected in a micro-conductivity cell after the process of absorption, indicating that the amount of carbon monoxide was reduced to at least 0.1%.

Under the conditions used, the half-life-time of the ortho–para conversion was found to be one hundred hours, although no special care had been taken to exclude from the cuprous oxide–ammonia solution divalent (paramagnetic) copper compounds which certainly are responsible for the greater part of the conversion observed. In any case the conversion during the period of absorption again is negligible.

It is obvious that the methods described may be useful in experiments with other hydrogen modifications, too, such as ortho-deuterium or mixtures of light and heavy hydrogen and hydrogen deuteride.

Solvolytic Reactions of Organic Halides

By Michael P. Balfe and Joseph Kenyon

While we cannot enter into the discussion of the kinetics of these reactions, which have been de-

scribed as unimolecular,[1] as bimolecular,[2,3] as either bimolecular or termolecular,[4] and as polymolecular,[5,6] the diversity of conclusions suggests, as indicated by Bartlett,[4] that the course of these reactions is not sufficiently simple to justify the application of the kinetic method.

Our present purpose is to comment on the mode of formulation of the solvated cation which is assumed as an intermediate in these reactions by Winstein.[6] In the hydrolysis of halides, Winstein's formulation $H_2O^+—C\lesssim$ leads to no difficulties, but is not generally applicable. The rearrangement of phenylmethylcarbinyl *p*-toluenesulfinate to *p*-tolyl-α-phenylethylsulfone,[7] a reaction which involves ionization in the same sense as the solvolytic reactions mentioned above, does not occur in solution in acetonitrile, but proceeds readily in solution in formic acid. The suggestion which seems best to explain this difference in behavior is that there is a difference between the solvating properties of the two solvents.

If solvation of the cation be assumed its formulation as $\begin{matrix}H\\HO\end{matrix}\!\!>C=O^+—C\lesssim$ would, in our opinion, imply that phenylmethylcarbinyl formate should be a major product of the reaction, whereas it is in fact a minor product. The alternative explanation, that by two successive solvolytic reactions the sulfinate is converted first into the formate and then into the sulfone, is not consistent with the stereochemical observations recorded in the communication referred to.[7]

We submit, therefore, that it is undesirable to assume that in these reactions there is solvation of carbonium cations by co-valency formation between solvent and cation.

Organolithium Compounds of Pyridine and Quinoline

BY HENRY GILMAN AND S. M. SPATZ

The halogen–metal interconversion reaction observed with *m*- and *p*-bromodimethylanilines,[1] mono- and dibromo- and iodocarbazoles and bromoanilines[2] suggested that corresponding reactions might take place with bromo- and iodopyridines and quinolines. We have found this to be the case. For example, 3-bromoquinoline and *n*-butyllithium react promptly, and carbonation of the reaction mixture gives a 52% yield of 3-quinolinecarboxylic acid. Under corresponding conditions 3-bromopyridine gives a 70% yield of nicotinic acid.

Perhaps the first evidence for the formation of Grignard reagents from 3-bromopyridine and 2-iodopyridine is to be found in a study by Harris.[3] Later, Overhoff and Proost[4] prepared 2-pyridylmagnesium bromide in quantity and obtained from it and benzaldehyde, phenyl-2-pyridylcarbinol. The formation of organolithium compounds from nitrogen heterocycles by means of other RLi compounds is of interest because it appears to be generally applicable, and because it establishes the possibility of selecting conditions to reduce the tendency of addition of an organolithium compound to the anil linkage. Under ordinary conditions, RLi compounds add promptly to the anil linkage. The reaction undoubtedly can be extended to poly-substituted nitrogen heterocycles containing functional groups in addition to bromine and iodine. For example, *o*-bromobenzoic acid and *n*-butyllithium give the lithium salt of *o*-lithiobenzoic acid, which on carbonation (followed by hydrolysis) gives a 31% yield of phthalic acid.[5] Details on the preparation and some reactions of the organolithium compounds of various nitrogen heterocycles will be published later.

A solution of 14.6 g. (0.07 mole) of 3-bromoquinoline in 50 cc. of dry ether was added rapidly to an ether solution of a slight excess of *n*-butyllithium. The reaction was carried out at −35° for fifteen minutes, at the end of which time the transparent reddish solution was carbonated by dry-ice. On working up the reaction mixture in a customary manner, there was isolated a 52% yield of 3-quinolinecarboxylic acid. Identification was established by comparison with an authentic specimen of the acid (m. p. 270–272°); in addition, the method of mixed melting points was also used with the ethyl 3-quinolinecarboxylate (m. p., 69.5°), prepared from the 3-quinolinecarboxylic acid.

The Preparation of Ferric Mesoporphyrin Chloride

BY T. HARRISON DAVIES*

Ferric mesoporphyrin chloride is readily obtained from ferric protoporphyrin chloride by reduction of the latter with hydrogen and palladium charcoal in alkaline methyl alcohol solution. The method leads to higher yields with less labor than the procedure of Fischer and Pützer[1] and Fischer and Stängler,[2] in which ferric protoporphyrin chloride is first reduced to mesoporphyrin by the action of formic acid and colloidal palladium and the iron is then reintroduced in acetic acid solution. The yields are higher and the general procedure is less troublesome than the method of Fischer and Röse,[3] in which ferric mesoporphyrin is obtained directly by heating ferric protoporphyrin in pyridine–methyl alcohol or pyridine–potassium methyl alcoholate solution in a bomb at 225°.

Experimental

Ferric protoporphyrin chloride (4 g.), prepared and recrystallized by the usual methods, is dissolved in 450 ml. of methyl alcohol and 50 ml. of 0.5 *N* potassium hydroxide. Palladinized charcoal (2 g. of a preparation 12% in palladium) is added. The mixture is refluxed with hydrogen bubbling until a test drop in a few ml. of 0.5 *N* sodium cyanide solution gives no evidence of the absorption bands of cyanide ferrous protoporphyrin upon reduction with a little sodium dithionite. About eight hours is ordinarily required. The solution is cooled and filtered. The catalyst, after thorough washing, drying, and shaking with air, can be used again. The filtrate is treated with 1 *N* hydrochloric acid to precipitate the metalloporphyrin. The latter is collected on a filter, washed with a little water and dried *in vacuo* over sodium hydroxide. The semi-crystalline material is dissolved in 100 ml. of chloroform containing 4 g. of quinine. The chloroform solution is added dropwise to 150 ml. of glacial acetic acid saturated with sodium chloride and held above 90° on a water-bath. During the addition, air is bubbled through the acetic acid to assist in the removal of the chloroform. The solution is allowed to cool slowly. After a few hours the crystalline ferric mesoporphyrin chloride is collected on a hardened filter, washed with 50% acetic acid, then with water, and finally dried over potassium hydroxide: yield in one preparation 2.7 g., in a second 3.2 g.

The absorption spectra of cyanide ferrous mesoporphyrin and of ethanolamine ferrous mesoporphyrin from this preparation were identical with those of a preparation of ferric mesoporphyrin chloride made by the method of Fischer and Stängler from an authentic sample of mesoporphyrin hydrochloride.

Reaction of *bis*-β-Chloroethyl Ether with Ethylenediamine

BY M. E. HULTQUIST AND E. H. NORTHEY

The reaction of *bis*-β-chloroethyl ether with ammonia, aliphatic monoamines, and aromatic amines and diamines is well known.[1,2,3,4] We sought a simpler method for the preparation of 4-(β-aminoethyl)-morpholine than the reaction of N-(β-bromoethyl)-phthalimide with morpholine followed by hydrolysis and found one in the action of *bis*-β-chloroethyl ether with a large excess of ethylenediamine.

To 1.875 kg. of 57.5% ethylenediamine (18 moles anhydrous) in a 5-liter flask equipped with agitator, reflux condenser and dropping funnel, 863 g. (6 moles) of *bis*-β-chloroethyl ether was added during one hour. Thirty minutes later, 505 g. of flake sodium hydroxide was added cautiously. The mixture was cooled and the precipitated salt filtered. The liquor was dried over solid sodium hydroxide and then distilled through a 60 cm. × 50 mm. packed column. After distillation of excess ethylenediamine, 370 g. (47.5% of theoretical) of 4-(β-aminoethyl)-morpholine boiling at 121–123° (68 mm.), b. p. 204.5° (768 mm.), was obtained as a water-white liquid with a refractive index of 1.4742 (25°). These values were in agreement with those of 4-(β-aminoethyl)-morpholine prepared by the phthalimide process.

Anal. Calcd. for $C_6H_{14}N_2O$: N, 21.55. Found: N, 21.4.

On fractionation of the residues, the following cuts were obtained: 50 g. 123° (68 mm.) to 164° (30 mm.); 69 g. 164–166° (30 mm.); 8.5 g. 166–200° (30 mm.); 7.3 g. 200–203° (30 mm.); 5.5 g. 203° (30 mm.) to 220° (4 mm.).

Fraction 2 was mainly ethylenedi-(4-morpholine). It solidified to a light yellow solid. After two recrystallizations from hexane, it was obtained as colorless, coarse prisms; m. p. 70–73°, setting point 71.3°. It was converted to the dihydrochloride by dissolving in alcohol and adding concentrated hydrochloric acid, then twice recrystallizing from dilute alcohol.

The dihydrochloride crystallized as colorless plates decomposing and subliming over 250°.

Anal. Calcd. for $C_{10}H_{22}O_2N_2Cl_2$: N, 10.3; Cl, 25.9. Found: N, 10.5; Cl, 25.7.

Fraction 4 was mainly *bis*-{2-[N-(β-aminoethyl)-amino]-ethyl} ether, a light yellow oil. It was converted to the tetrahydrochloride and recrystallized three times from methanol giving small, colorless, thin plates; m. p. 185–187°.

Anal. Calcd. for $C_8H_{26}ON_4Cl_4$: N, 16.7; Cl, 42.2. Found: N, 16.9; Cl, 41.6.

By increasing the proportions of ethylenediamine in the reaction to 6 moles to 1, a 58% yield of 4-(β-aminoethyl)-morpholine, based on *bis*-β-chloroethyl ether, was obtained.

Precipitation of Barium Sulfate in the Presence of Ammonium Chloride

BY J. T. MCHENRY, G. A. AMPT AND E. HEYMANN

It has been known for a long time that the analytical errors involved in the precipitation of the sulfate radical as barium sulfate are due to the presence of foreign material in the precipitate. Several explanations for the mechanism of this inclusion of foreign material have been considered.[1]

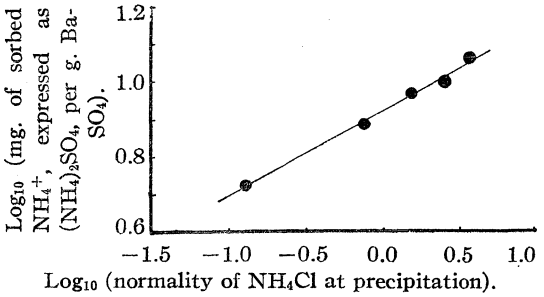

Fig. 1.

We performed a number of precipitations of barium sulfate by means of a barium chloride solution from sulfuric acid in the presence of ammonium chloride. To 200 ml. of boiling solution, containing 0.1859 equivalent of ammonium sulfate and varying amounts of ammonium chloride, 19.0 ml. of 1.96 *N* barium chloride solution was slowly added. Twenty hours after precipitation the precipitate was filtered, washed and dried in a vacuum desiccator.

The sorbed material was determined in two ways: (1) 1-g. aliquots were dissolved in 10 ml. of cold concentrated sulfuric acid, the solution poured into 200 ml. of boiling water, the liquid filtered, the precipitate washed and the filtrate made alkaline and distilled. The ammonia was collected in 0.1 *N* hydrochloric acid and the excess acid determined iodimetrically. Second extractions were carried out on the reprecipitated samples and the total extracted was regarded as the full amount of sorbed material, (2) one-gram aliquots were dissolved in 200 ml. of 50% sodium hydroxide by warming, the solution diluted to 500 ml. and then distilled. The ammonia was absorbed in 0.1 *N* hydrochloric acid. Both procedures gave results which did not differ by more than 4%.

Investigation of our precipitates, by a method first suggested by Hulett and Duschak,[2] showed that about 50% of the ammonia is present as sulfate.

Figure 1 shows that a linear relation exists between the logarithms of the amount sorbed and the ammonium chloride concentration (Freundlich's adsorption isotherm). It is, however, recognized that this empirical relation may also formally describe processes other than surface adsorption. Further it can be seen that barium sulfate, precipitated in the presence of *N* ammonium chloride contains 7.0 mg. of NH_4, expressed as ammonium sulfate, per 1 g. of barium sulfate.

The investigations of Kolthoff and MacNevin[3] and of Imre[4] indicate that the essential process in

the inclusion of foreign material in barium sulfate precipitates is a sorption on the initially formed primary crystallites. The growth of these will be such that most of the initially sorbed material does not find its way out of the internal "mosaic" structure of the macrocrystal (*cf.* also Darwin,[5] Smekal,[6] Balarew[1]).

This point is supported by our experiments in which the precipitates were treated by prolonged boiling with dilute sodium hydroxide (0.02–0.01 *N*). In Fig. 2 the percentage of ammonium salt distilled over as ammonia is plotted against the time of distillation. It is very significant that, in this case, ammonia distils over *very slowly, ten to fifteen hours being needed to expel most of it.* This is incompatible with adsorption on the external surface of the macrocrystals only. It can only be explained on the assumption that the contaminating salt is mainly present on an internal surface of the macrocrystal. The results of the distillation experiments would, moreover, be difficult to reconcile with the existence of secondary insoluble compounds (Karaoglanow[1]) or of solid solutions.[7] It is highly improbable that, in these cases, the total ammonia could be expelled by treatment with an alkali as dilute as 0.01 *N* sodium hydroxide.

It is not quite simple to visualize a satisfactory mechanism of the formation of macrocrystals which possess a mosaic structure. Kolthoff[1] suggests that the electrolyte, adsorbed on the primary nuclei, will influence crystallization in such a way that the lattice of the eventually formed macrocrystals will contain many imperfections. Another way of visualizing the formation of a mosaic structure would be found in the assumption that the primary crystallites will grow together on certain faces to irregular macrocrystals which possess a large internal surface.

Dissociation of Carbonic Acid in Ordinary and in Heavy Water

BY G. ALEXANDER MILLS

In general, acids are considerably weaker in heavy than in ordinary water. The ratio K^H/K^D, where K^H and K^D are the dissociation constants of the acid in H_2O and D_2O, increases with decreasing acid strength.[1] The ratio of the apparent first dissociation constants of proto- and deutero-carbonic acid has been accurately determined to be 2.68 at 25°.[2] This does not agree with the predicted value of 3.6 obtained from the function given by Rule and La Mer and recently confirmed by Martin and Butler. However, the acid strength should not be judged from the apparent dissociation constant.

In aqueous solution carbon dioxide is hydrated only to a small extent forming rather strong metacarbonic acid. The relationship between K_1, the hydration constant, K_t, the true first dissociation constant and K_a, the apparent first dissociation constant, is

$$\frac{(H^+)(HCO_3^-)}{(CO_2) + (H_2CO_3)} = K_a = \frac{K_tK_1}{1 + K_1}$$

If hydration of carbon dioxide is assumed to be the same in D_2O as in H_2O (the solubilities are very nearly identical) then $K^H{}_t/K^D{}_t = 2.68$. It has been possible to determine the total amount of carbonic acid in solution since carbon dioxide does not react immediately with water. In conjunction with conductivity data the true dissociation constant has been estimated therefore to be 4×10^{-4}.[3] From the smooth curve plot of $-\log K^H$ against[1] K^H/K^D the value of 2.9 is now obtained for the ratio. This compares more favorably with 2.68 than with 3.6, the value predicted on the basis of the apparent dissociation constant.

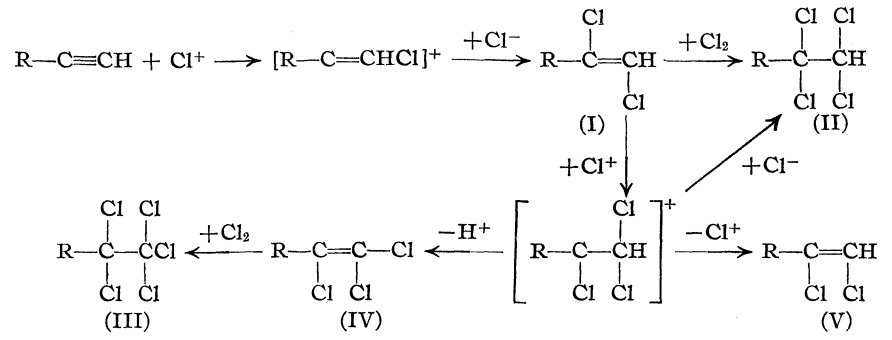
oxygen-containing solvents. This work has now been continued, particularly to study the effect of high proton concentrations in the chlorination reaction. For this purpose 1-hexyne was chlorinated as an emulsion in concentrated hydrochloric acid, 30%[4] sulfuric acid and 30%[4] phosphoric acid and as a solution in methanol previously saturated with hydrogen chloride. The various experiments gave complex mixtures of hexyne chlorides as shown in Table I. Fortunately the individual substances boil sufficiently far apart to permit their separation by fractional distillation through an efficient column.



It is noteworthy that *cis*-1,2-dichloro-1-hexene (V) was obtained in each case as well as the anticipated *trans* isomer (I) and that oxygen-containing compounds were not isolated. In methanol[2] and in water,[3] to which acid has not been added, the *trans* dichloride is obtained as well as oxygen-containing products.

The trichloride (IV) listed in Table I previously was formulated[3] as 1,2,2-trichlorohexane. It appears now that this compound actually is 1,1,2-trichloro-1-hexene and is the precursor of the pentachloride (III). Attempts[5] to prepare 1,2,2-trichlorohexane from 1-hexyne have failed. Neither *cis*- nor *trans*-1,2-dichloro-1-hexene could be made to add hydrogen chloride.

Chlorination of 2-chloro-1-hexene in carbon tetrachloride also failed to give the anticipated trichlorohexane, but yielded rather *cis*-1,2-dichloro-1-hexene (V) and 1,1,2,2-tetrachlorohexane (II). The following mechanism explains satisfactorily the various products obtained in the present investigation.

(4) Concentration by volume.

(5) Unpublished work, Chas. Welsh and G. F. Hennion.

The experimental procedure and analyses and physical constants for the products have been cited previously[3] and need not be repeated. However, the product having b. p. 90–93° at 10 mm.; $n^{25}D$ 1.4760; d^{25} 1.225 now is reported as 1,1,2-trichloro-1-hexene rather than as 1,2,2-trichlorohexane.

Remarks on "A New Method for the Cleavage of Unsaturated Fatty Acids"

BY DONALD PRICE AND RICHARD GRIFFITH

Under the above title Chi-yi Hsing and Kou-jen Chang [THIS JOURNAL, **61**, 3589 (1939)] report the application of Criegee's[1] lead tetraacetate oxidation to polyhydroxy fatty acids, which are readily obtained from the corresponding unsaturated acids by oxidation with alkaline permanganate. They describe in detail the oxidation of 9,10-dihydroxyoctadecanoic acid, the cleavage products of which were found to be pelargonic aldehyde and the hemialdehyde of azelaic acid.

These authors seem to have overlooked the fact that Criegee's method previously was applied to the same as well as other acids by Nunn and Smedley-MacLean, *Biochem. J.*, **29**, 2742 (1935),

(1) Criegee, *Ber.*, **64**, 260 (1931); *Ann.*, **481**, 263 (1930); **507**, 159 (1933).

with the identical results obtained by them. It was also applied similarly by Raudnitz, Schindler and Petru, *Ber.*, **68,** 1675 (1935), to the determination of the structure of aleuritic acid. More recently Mr. Daniel Swern of the Bureau of Agricultural Chemistry and Engineering, U. S. Department of Agriculture read a paper at the Boston meeting of the American Chemical Society on Sept. 12, 1939, entitled, "Action of Lead Tetraacetate upon Hydroxylated Oils, Fats, Fatty Acids, and Related Compounds."

Hydrogen Fluoride as a Condensing Agent. IX.[1] Reactions of Di- and Triisobutylene with Phenol

BY J. H. SIMONS AND S. ARCHER

In connection with other work, it became necessary to determine whether or not highly branched aliphatic olefins would react with aromatic compounds to give normal or cleaved products. It is known that in the presence of large amounts of sulfuric acid, diisobutylene reacts with phenol to give cleaved products, but with small quantities of the acid the uncleaved product is obtained.[2] The same olefin reacts with toluene in liquid hydrogen fluoride to give mono and di-*t*-butyltoluene.[3]

We have found that under conditions similar to those employed by Calcott and co-workers, di- and triisobutylene both react to give *p*-*t*-butylphenol as the only monoalkylated phenol. However, by employing milder conditions it was possible to effect condensation without cleavage in the case of diisobutylene. By using a small amount of 70% hydrofluoric acid at 0°, *p*-*t*-octylphenol was isolated unaccompanied by any cleavage products. Under the same conditions dodecylphenol was not isolated when the twelve-carbon olefin was employed, although even this might be accomplished under even milder conditions.

The triisobutylene used was the so-called "lower isomer," which consists chiefly of dineopentylethylene and methylneopentyl-*t*-butylethylene. The diisobutylene was the usual commercial product, dried and redistilled, the fraction boiling at 100–103° being used.

(1) For previous paper of this series, see THIS JOURNAL, **61,** 1821 (1939).

(2) Ipatieff, Pines and Friedman, *ibid.*, **60,** 2495 (1938).

(3) Calcott, Tinker and Weinmayr, *ibid.*, **61,** 1010 (1939).

Experimental

Phenol and Diisobutylene

A. Large Quantities of Hydrogen Fluoride.—To 121 g. of hydrogen fluoride contained in a copper flask, was added a solution of 94 g. of phenol in 300 cc. of carbon tetrachloride. One mole of the olefin was dropped in with constant stirring, the reaction being kept at 0°. After twenty-four hours the reaction was stopped and then treated in the usual way. Distillation gave 88 g. of *t*-butylphenol, m. p. 97–98.5°, 14 g. of a fraction boiling at 165–185° (28 mm.), and a residue of 41 g. The higher boiling fraction did not solidify even after standing for some weeks.

B. Small Quantities of Hydrogen Fluoride.—A mixture of 20 g. of 70% hydrofluoric acid, 56 g. of the olefin, and 47 g. of phenol was kept at 0° for forty-eight hours. After the usual treatment, distillation gave 35 g. of *p*-*t*-octylphenol, m. p. 82–83°, and recovered phenol. When mixed with an authentic specimen there was no depression in melting point.

Phenol and Triisobutylene

A. Large Quantities of Hydrogen Fluoride.—One mole of phenol was dissolved in 300 cc. of carbon tetrachloride and added to 122 g. of hydrogen fluoride maintained at 0°. To this mixture one mole of the olefin was added slowly. After being stirred for twenty-four hours, the reaction was stopped. Removal of the solvent left a residue of 206 g. of which 64 g. boiled at 152–160° (38 mm.) and melted at 96–97°. This was *t*-butylphenol. The remainder of the material boiled over a wide range and probably consisted of the polybutylphenols.

B. Small Quantities of Hydrogen Fluoride.—Equimolar quantities of the olefin and the phenol were mixed and added to 20 g. of 70% hydrogen fluoride. After sixty hours the usual procedure was followed and the product treated with Claisen solution.[4] The latter, when examined, did not give any compound that corresponded to a dodecylphenol. When 33 g. of anhydrous hydrogen fluoride was used with 105 g. of phenol and 174 g. of the olefin, for a reaction time of fourteen hours, 52 g. of *t*-butylphenol and considerable residual phenolic material were obtained.

Activity Coefficients in Concentrated Aqueous Solutions of Strong Electrolytes Described by Means of a Formula Containing the Mean Ionic Diameter as Single Parameter. II. Corrected Formulation

BY PIERRE VAN RYSSELBERGHE AND SYLVAN EISENBERG

In a previous paper of the same title[1] a formula with a single parameter was set up which provided

(1) P. Van Rysselberghe and S. Eisenberg, THIS JOURNAL, **61,** 3030 (1939).

a good description of the behavior of activity coefficients of concentrated aqueous electrolytes. The formula was tested successfully in a large number of cases besides those reported in our previous paper and we consider it as valuable in itself as a purely empirical contribution It has, however, no theoretical basis and we are very much indebted to Dr. H. C. Eckstrom for calling our attention to the fact that in formula (15) of this previous paper the quantity $F_{iw} = -kT \log Y$, calculated from Ursell's theory of imperfect gases should have been set equal to $N_i \Delta\mu_{iw} + N_0 \Delta\mu_{ow}$, N_0 being the number of molecules of solvent in the volume V and $\Delta\mu_{ow}$ the van der Waals contribution to the chemical potential of the solvent (other notations as in our previous paper), and not to $N_i \Delta\mu_{iw}$ alone. A complete calculation should take the solvent into account explicitly, but in our treatment it appears as the volume term. If one accepts the various other assumptions previously made, one has for the total van der Waals free energy of the solution (considered as a Gibbs free energy)

$$G_w = N_i \Delta\mu_{iw} + N_0 \Delta\mu_{ow} = kT \left[\frac{1}{2}\frac{N_i^2}{V} v + \frac{5}{64}\frac{N_i^3}{V^2} v^2\right] \quad (1)$$

Differentiating at constant pressure, temperature and N_0, we get the following contribution to the logarithm of the average activity coefficient of the ions:

$$\begin{aligned} \log f_{\pm w} &= \frac{\Delta\mu_{iw}}{kT} = \frac{1}{kT}\frac{\partial G_w}{\partial N_i} \\ &= \frac{N_i}{V} v + \frac{15}{64}\left(\frac{N_i}{V}\right)^2 v^2 + \frac{1}{kT}\cdot\frac{\partial G_w}{\partial V}\cdot\frac{\partial V}{\partial N_i} \\ &= \frac{N_i}{V} v + \frac{15}{64}\left(\frac{N_i}{V}\right)^2 v^2 - \\ &\qquad \left[\frac{1}{2}\left(\frac{N_i}{V}\right)^2 v + \frac{10}{64}\left(\frac{N_i}{V}\right)^3 v^2\right]\frac{\partial V}{\partial N_i} \quad (2) \end{aligned}$$

in which $\partial V/\partial N_i$ is the average partial molecular volume of the positive and negative ions. For the activity coefficient of the solvent we deduce similarly the contribution

$$\log f_{\pm ow} = \frac{\partial G_w}{\partial V}\cdot\frac{\partial V}{\partial N_0} = - \left[\frac{1}{2}\left(\frac{N_i}{V}\right)^2 v + \frac{10}{64}\left(\frac{N_i}{V}\right)^3 v^2\right]\frac{\partial V}{\partial N_0} \quad (3)$$

The first effect of the correction (indicated to us by Dr. Eckstrom) is that the term in C of formula (19) of our previous paper is multiplied by 2 and the term in C^2 by 3. Our first additional term in $\partial V/\partial N_i$ may significantly affect the dependence of the activity coefficient on C^2, since v and $\partial V/\partial N_i$ are likely to be of the same order of magnitude.

In an entirely rigorous treatment one should, moreover, take into account a term containing the partial volume $\partial V/\partial N_i$ which arises from the electrostatic portion of the free energy and which is always neglected in the case of dilute solutions. The variation of dielectric constant with concentration might also be considered. We shall examine these points in the complete reinvestigation of the problem which we are planning to carry out.

Neglecting, as a provisional approximation, the terms in $\partial V/\partial N_i$ in (2), *i. e.*, using the formula

$$\log_{10} f_{\pm w} = -0.5059 \frac{\sqrt{C}}{1 + \frac{a}{3.042}\sqrt{C}} + 2.20626 \times 10^{-3} a^3 C + 2.62692 \times 10^{-6} a^6 C^2 \quad (4)$$

we have redetermined the ionic diameters for the fifteen alkali halides studied in our previous paper, in the range of concentrations 0.1 to 3 molar. We found the following average values (in parentheses we give the definite decrease observed in all cases from 0.2 to 3 molar):

LiCl:	3.82	(3.86–3.74)
LiBr:	3.93	(3.95–3.90)

COMMUNICATIONS TO THE EDITOR

INHIBITION OF THE HYDROGENATION OF ETHYLENE BY NITRIC OXIDE

Sir:

Since the dissociation of ethane to yield ethylene and hydrogen is inhibited by nitric oxide,[1] one might expect the reverse reaction to be similarly affected. We find this to be the case. Times to 16% ethylene converted (by analysis) are given in the following table for mixtures of 180 mm. ethylene and 540 mm. hydrogen with and without 20 mm. nitric oxide.

Temp., °C.	t_{16} (min.) Pure	NO added	Ratio
500	38	48	0.79
550	6.2	13.5	0.46

The effect of the nitric oxide tends to fade out after about 20% reaction, just as in the case of the dissociation of *n*-butane.[2] The above ratios are therefore not a true measure of the maximum inhibition. There is little doubt, however, that the nitric oxide is more effective at the higher temperature.

Stavely[1] found that with 150 mm. of ethane at 620° the initial rates of pressure increase with and without addition of 20 mm. of nitric oxide were in the ratio 0.086. Although the dependability of pressure measurements is open to serious question, it is nevertheless evident that this result is in qualitative agreement with our data for the reverse reaction. A rough extrapolation of the latter gives 0.22 for the ratio at 620°. The maximum inhibition (at zero time) would be less than this.

We believe this is the first case in which forward and reverse reactions have been shown to be equally subject to inhibition.

INHIBITION OF ETHYLENE POLYMERIZATION BY NITRIC OXIDE

Sir:

A number of investigators have shown that the polymerization of ethylene is subject to acceleration by substances believed to give rise to radicals.[1] We find that the reaction is also subject to inhibition by nitric oxide. Thus, with 720 mm. of ethylene at 500° the time to 20% reaction is twenty-four minutes. Addition of 20 mm. of nitric oxide increases this to seventy-three minutes, the ratio of times being 0.33.

As in the hydrogenation of ethylene and the dissociation of *n*-butane,[2] the effect of nitric oxide fades out as reaction proceeds. The maximum effect is therefore greater than the data given above would indicate.

Since the polymerization of ethylene is subject to inhibition as well as acceleration, there can be little doubt that the reaction is of the radical chain type.

SODIUM SALT OF 2-METHYL-1,4-NAPHTHOHYDROQUINONE DIPHOSPHORIC ACID ESTER

Sir:

Fieser and Fry [THIS JOURNAL **62**, 228 (1940)] have described some sulfuric and phosphoric acid esters of substituted 1,4-naphthohydroquinones. In this Laboratory we have been occupied for some time with similar phosphoric acid esters and have also prepared such materials as were described by the above workers. In our syntheses we also isolated the intermediate phosphoryl chlorides and free phosphoric esters.

In particular we have investigated the pharmacology of the sodium salt of 2-methyl-1,4-naphthohydroquinone diphosphoric acid ester, and have found that by a slightly modified Ansbacher vitamin K eighteen-hour bioassay technique [*J. Nutrition*, **17**, 303 (1939)] the above material in doses of 0.6 to 0.8 gamma per chick administered subcutaneously reduces the clotting time to below ten minutes. Intravenously, the activity is similar, while the dose for oral effectiveness lies below 2 gamma, the minimum dose not yet having been determined. The lethal dose in mice by both

subcutaneous and intravenous administration is approximately 450 mg./kg. More complete pharmacological investigations will be reported elsewhere. All preliminary tests indicate an enormous margin of safety and absence of serious side reactions in any but the highest doses.

When it is considered that the anhydrous sodium salt has the molecular weight of 422 as compared with the molecular weight of 172 for 2-methyl-1,4-naphthoquinone, the most active material (0.5 gamma) hitherto reported, it appears that this sodium salt represents probably the most active antihemorrhagic substance known when compared on a molecular basis with methylnaphthoquinone. It also encourages speculation as to whether the antihemorrhagic effects of 2-methyl-1,4-naphthoquinone, of its reduced form, and of like substances, are not mediated through a phosphoric ester.

THE PHOTOCHEMICAL REACTIONS OF OXALYL CHLORIDE AND PHOSGENE WITH CYCLOHEXANE

Sir:

The occurrence of the hypothetical —COCl free radical has been postulated as an intermediate in certain photochemical reactions: notably in the formation of phosgene [Bodenstein, *et al.*, *Z. physik. Chem.*, **B3,** 459 (1929)] and in the photochemical decompositions of both phosgene and oxalyl chloride [Rollefson, *et al.*, THIS JOURNAL, **56,** 1089 (1934); **58,** 443 (1936)]. In line with the program under way in this Laboratory on chain reactions in solution involving atoms and free radicals, we have studied the photolysis of both phosgene and oxalyl chloride dissolved in cyclohexane. In both cases we have been able to isolate the acid chloride of cyclohexane carboxylic acid. The yields appear to be quantitative. The over-all reactions are

$$C_6H_{12} + (COCl)_2 \longrightarrow C_6H_{11}COCl + HCl + CO$$
$$C_6H_{12} + COCl_2 \longrightarrow C_6H_{11}COCl + HCl$$

The following experiment with oxalyl chloride is typical of the procedure used. A 100-cc. flask (Pyrex glass) containing 25.2 g. of cyclohexane (0.3 m.) and 9.6 g. of oxalyl chloride (0.075 m.) was illuminated by a 300-watt tungsten lamp placed immediately below the flask. The heat from the lamp kept the reaction mixture refluxing gently. Gases were evolved. These were collected after passing through a trap at −80° and shown to consist of equal parts of carbon monoxide and hydrogen chloride. After twenty-four hours, the reaction mixture was fractionated and it was found that 4.2 g. of oxalyl chloride had reacted to form 4.1 g. of the acid chloride of cyclohexanecarboxylic acid (b. p. 99–101° at 52 mm.). The calculated yield is 4.8 g. The identification of the product was made by a determination of the neutralization equivalent and the preparation of the amide, m. p. 185–186°.

Phosgene reacts with cyclohexane in a similar manner. In this case quartz apparatus was used (a quartz reaction flask with a quartz mercury arc). In both cases the reaction takes place in the liquid phase as shown by identical results obtained in experiments in which care was taken to shield the vapor phase.

There can be little doubt that the reaction of phosgene and oxalyl chloride with cyclohexane in the light takes place through a free radical or atom mechanism in which the formation of the —COCl free radical plays a conspicuous rôle. In the gas phase the primary process in the photolysis of oxalyl chloride and phosgene has been postulated as follows

$$(1)\quad COCl_2 \xrightarrow{h\nu} {-}COCl + Cl^-$$
$$(2)\quad (COCl_2) \xrightarrow{h\nu} {-}COCOCl + Cl^-$$
$$(\text{or } 2)\quad (COCl)_2 \xrightarrow{h\nu} 2\,{-}COCl$$

In solution the absorption of light appears to be accompanied by the same primary step. This must be followed by reaction of the photolytic fragments with the hydrocarbon solvent. We hope to elaborate on the mechanism in our next publication.

The method of direct carboxylation appears to be fairly general and has been applied to a number of saturated hydrocarbons and their halogen derivatives. We are now engaged in studying the carboxylation of other types of organic compounds and the effect of various catalysts. It is of importance that means other than light of inducing the reaction have been found (*i. e.*, small quantities of organic peroxides are quite effective).

We are actively engaged in working out the details of this investigation and we hope to publish a full report shortly.

RECEIVED JANUARY 18, 1940

NEW BOOKS

Molekülspektren und Molekülstruktur. I. Zweiatomige Moleküle. (Molecular Spectra and Molecular Structure. I. Diatomic Molecules.) By DR. GERHARD HERZBERG, Professor of Physics in the University of Saskatchewan. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1939. xvi + 404 pp. 169 figs. 15.5 × 22.5 cm. Price, RM. 21; bound, RM. 22.50.

In the first chapter, the author gives a short survey of the principles of the theory of atoms and of atomic spectra, essentially a collection of the formulas and concepts necessary for the subsequent molecular theory. An empirical treatment of the molecular spectra is presented in the second chapter. In about twenty-five excellent figures, the different spectral types are reproduced; their interpretation in band head schemes for vibrational analysis or Fortrat diagrams for rotational analysis are represented in figures and tables. The theory for the rigid rotator and for the harmonic oscillator are developed by classical and wave-mechanical methods; the selection rules and the formation of the infrared and Raman spectra are derived from the theory in the next chapter. The expansion of the simple theory to the anharmonic oscillator and the connection between potential curves and dissociation are treated; besides that the non-rigid rotator and the symmetric top model are considered. The wave-mechanical derivations show the symmetry properties of the rotational functions; after the introduction of the nuclear spin, the author gives the explanation for the ortho and para modifications of hydrogen, heavy hydrogen and nitrogen. In an appendix, the isotope effect on rotation and vibration is derived.

Chapter IV includes a general empirical treatment of the visible and ultraviolet bands, based on an electronic transition and the superposition of the vibrational and rotational motions of molecules. The selection rules and the intensity relations of the Franck–Condon principle are derived. There is presented a very thorough and critical treatment of those methods, by which the molecular constants may be obtained from the measured spectrum lines. Chapter V contains the finer details of electronic bands: the multiplicity of the electronic states and the coupling of the molecular rotation with the motion of the electrons. In twenty-five pages, all the known types of electronic bands are explained with excellent figures and with typical examples. Quadrupole radiation, Zeeman effect in bands and perturbations are dealt with briefly. In Chapter VI, the Aufbauprinzip and the problems of the derivation of the term scheme of a molecule from those of the separated atoms on one hand and from the united atom on the other are given, as well as the symmetry properties of the single electrons and of the terms containing equivalent or different electrons. We find there the Heitler–London theory of valence and its extension to other molecules, and the concept of the ionic bond and of the van der Waals bond. In Chapter VII, continuous and diffuse molecular spectra are explained by potential energy curves. Here is presented the determination of the dissociation and predissociation limits, one of the methods of the band spectra research which finds valuable application to chemistry and astrophysics. It is no surprise to find this chapter is just perfect, for Herzberg is the leading physicist in this field, and we owe to him its major development. All the different methods for getting the heats of dissociation for molecules are excellently described. In the concluding chapter, we find some term schemes and potential energy curves and, in addition, a table of the constants for the normal electronic states of all the diatomic molecules and their isotopes, as far as they are known. Besides that, a brief summary is given of some applications of the results of band spectra analysis to other fields of physics, chemistry and astrophysics. The very extensive indices of books, papers, authors and subjects facilitate the use of the book.

The book appears at a time when the subject is well established and is written by one of the leaders in the field. Herzberg has carried through many analyses of bands, has explained diffuse spectra and determined final values for the heats of dissociation of nitrogen and oxygen. He has described all the methods he used so comprehensively and lucidly that no one faced with a problem in molecular analysis can find a better presentation. There are other books which treat the wave mechanical theory more thoroughly, but none which is more useful to the experimenter. In 1932, Max Born told in a lecture that band spectra theory is not difficult at all, only very complicated. I had my doubts. But Herzberg's book seems to prove that Born was right. Herzberg shows that there are no difficulties; but he could not possibly eliminate the complexities.

Every experimenter in band spectroscopy looks forward to the appearance of the second volume treating polyatomic molecules.

HANS G. BEUTLER

Qualitative Analysis by Spot Tests. Inorganic and Organic Applications. By Dr. Ing. FRITZ FEIGL, Director of the Research Laboratory, Soc. Belge de Recherches et d'Etudes, Gand.-Emerit. Professor of Analytical and Inorganic Chemistry of the University of Vienna. Second English Edition, translated from the Third German Edition by JANET W. MATTHEWS, Ph.D., F.I.C. Nordemann Publishing Company, Inc., 215 Fourth Avenue, New York, N. Y., 1939. xv + 462 pp. 27 figs. 36 tables. 16 × 24.5 cm. Price, $7.00.

The appearance of the second English edition of Feigl within less than two years of the first attests both the importance and recognition of an indispensable chemical tool. This second English edition is an authorized translation of the Third German edition, a review of which was published by THIS JOURNAL, **60**, 2831 (1938). It does not,

however, include the theoretical part, separate publication of which is announced in an insert.

This second English edition contains 62 more pages, 3 more figures and 5 more tables than the first. The general arrangement and sequence is precisely the same as that of the first, *cf. ibid.*, **60**, 734 (1938), the substantial increase of material being rather evenly distributed over the whole book. A very substantial increase in the number of references to the literature is particularly noticeable. The subject index has been greatly improved and occupies 37 pages as compared with 15 in its predecessor.

ERNEST H. HUNTRESS

Applied Mathematics in Chemical Engineering. By THOMAS K. SHERWOOD, Associate Professor of Chemical Engineering, and CHARLES E. REED, Assistant Professor of Chemical Engineering, Massachusetts Institute of Technology. McGraw-Hill Book Company, Inc., 330 West 42nd Street, New York, N. Y., 1939. xi + 403 pp. 113 figs. 16 × 23.5 cm. Price, $4.00.

Teachers of physical chemistry and of chemical engineering commonly find that the great majority of their students cannot use the calculus as an effective tool in dealing with chemical problems. Even those who have taken Freshman and Sophomore courses in college mathematics commonly have difficulty in thinking of a derivative as anything else than the slope of a curve or of an integral as anything except the area under a curve. Most of them have trouble when the independent variable is time or temperature, or pressure, or volume, or mole fraction. They may be able to differentiate or integrate complicated functions covering the whole range of Peirce's Tables of Integrals but many of them are unable to set up the proper differential equations applicable to chemical or chemical engineering problems, or evaluate integration constants from the boundary conditions. Many teachers of chemistry handle this situation either by avoiding the use of calculus or by devoting the time in the chemistry classes to teaching calculus; and in their spare time they cuss the Mathematics Department. Sherwood and Reed have attempted to meet this pedagogical difficulty by writing a book covering the calculus and some other branches of mathematics with the illustrative examples taken mainly from the field of chemical engineering and chemical thermodynamics. The authors are justified in the claim made in the preface, "It should be possible for anyone with a good grounding in the calculus to follow the text without great difficulty." But a student who really had a good grounding in the calculus would find a large fraction of this text already familiar to him from his previous study, since much of the text is devoted to definitions of terms and explanation of mathematical procedures with the customary illustrations taken from geometrical problems to be found in any standard text on the calculus, supplemented by illustrations taken from chemical engineering which are not found in the texts written by mathematicians. It therefore appears that the text is really aimed at the student or professional chemical engineer whose previous grounding in the calculus is not good or at least partly forgotten so that he needs to renew his study of old material before tackling the problems drawn from chemical engineering and thermodynamics.

On the other hand, the book would not be suitable for a student with no previous knowledge of the calculus because too much that is fundamental is taken for granted, including the rules for the differentiation and integration of sums, products, ratios, surds, trigonometrical and exponential functions. Considerable systematic drill on the simpler parts of Peirce's Tables is essential for the mastery of the calculus and is not provided in this text. However, this is not a criticism because the book is not intended to be used in this way.

Although most of the book is devoted to the calculus, the other branches of mathematics discussed include infinite series (including Taylor's Theorem, Fourier's series and Bessel's Functions); numerical analysis (formulation of empirical equations to fit a set of data, numerical differentiation and integration and interpolation); graphical analysis including a discussion of logarithmic, polar and triangular graph papers and alignment charts; theory of errors, probability distribution curves and method of least squares.

The applications of the mathematical principles to chemical engineering are numerous and varied and are worked out in considerable detail in the text. In some cases the solution is given in generalized form and in others by highly specific numerical examples.

There are no practice examples for solution by the student scattered through the text but an appendix gives 38 problems of varied character, including some that are purely mathematical.

The authors in their preface say "Chemical engineering gives many indications of rapid advancement along quantitative and mathematical lines." This book will undoubtedly aid and stimulate this advancement as well as help many a laggard to keep up with the procession.

GRINNELL JONES

Vapor Charts and Special Tables for Turbine Calculations. By FRANK O. ELLENWOOD and CHARLES O. MACKEY, Professors of Heat-Power Engineering, Cornell University. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1939. iv + 43 pp. 21.5 × 28.5 cm.

The original "steam charts" first published by Professor Frank O. Ellenwood in 1914 showed the convenience in making calculations of having a chart of thermodynamic properties divided into many parts for easy reading. The present book of charts shows the thermodynamic properties of water, ammonia, dichlorodifluoromethane (freon), and air–water–vapor mixtures.

The steam charts employ specific enthalpy and log volume, the latter coördinates extending from 0.05 to 3500 cu. ft. per pound. A new chart for liquid water is also included accompanied by tables of jet velocities, squares of numbers, and barometric corrections. The design and test of performance of modern high pressure turbines requires a series of tedious and time-consuming calculations which will be much facilitated by the new charts.

Paper quality, type character, sharpness of intersections are everything that could be desired. The exact data

available have enabled the authors to prepare a set of tables which should possess a high degree of permanency.

FREDERICK G. KEYES

The Nature of the Chemical Bond and the Structure of Molecules and Crystals. By LINUS PAULING. Cornell University Press, 124 Roberts Place, Ithaca, New York, 1939. 429 pp. Price, $4.50.

The need for a modern and comprehensive discussion of the electronic structure of molecules, in particular as it affects their stability and their spatial configuration, has been keenly felt for some time and no other book could be more welcome than this treatise of Pauling. An idea of its scope may be given by a brief summary of contents. In order the chapter headings are as follows: I. Resonance and the chemical bond; II. The partial ionic character of covalent bonds and the relative electronegativity of atoms; III. The directed covalent bond. Bond strengths and bond angles. The magnetic criterion for bond type; IV. The resonance of molecules among several valence-bond structures; V. Interatomic distances and their relation to the structure of molecules and crystals; VI. Types of resonance in molecules; VII. The structure of molecules and complex ions involving bonds with partial double-bond character; VIII. The one-electron bond and the three-electron bond; IX. The hydrogen bond; X. The sizes of ions and the structure of ionic crystals; XI. The metallic bond; XII. A summarizing discussion of resonance and its significance for chemistry.

The author makes full use of the results of quantum-mechanical treatment of molecules but the presentation is substantially non-mathematical; as he says "The ideas involved...require for their understanding no more, or little more, mathematical preparation than the familiar concepts of chemistry." In the application of these general ideas to specific molecules examples are drawn from all fields of chemistry, so that an organic chemist will find in the book as much of immediate interest as, for instance, a specialist in the chemistry of complex inorganic ions.

The presentation, by and large, is lucid and a student with little more preparation than the four basic courses in chemistry should be able to digest most of the contents; yet even for one familiar with the field the reading will prove interesting and stimulating. Only few unimportant misprints and dubious statements have been noted in the text. To mention some: it would be desirable either to omit the numbers on the coördinate axes of figures like those on pp. 18 and 19 or to explain their meaning by giving the units; the statement on page 118 that a molecule resonates "with a high frequency" between two valence structures is unfortunate, if only from the pedagogical point of view. The reviewer objects to the casual manner in which the resonance energy is set equal to the free energy change (p. 189) without any discussion of the entropy changes accompanying the formation of a resonating structure.

Dr. Pauling has been so successful in his attack upon many of the problems in the field that his advocacy of the doctrine of the infallibility of Pasadenean research and the somewhat pontifical style in which this book is written are understandable and should not be taken amiss. The book is highly recommended to all who are not satisfied with the bond-dashes of a chemical text and wish to get a deeper understanding of their meaning.

G. B. KISTIAKOWSKY

Gmelins Handbuch der anorganische Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by E. PIETSCH. **Aluminum, Part A. Aluminum Alloys,** Supplementary Volume, Collection of Patents, Part I. By G. Apel. Verlag Chemie G. m. b. H., Corneliusstrasse 3, Berlin W 35, Germany, 1939. 880 pp. Price, RM. 72.

It is stated in the Preface that this Supplementary Volume covers all the patents on aluminum alloys which have appeared in Germany, England, France, Switzerland and the United States in the interval since the completion of the original volume on the subject (beginning of 1935) and up to February, 1938. Some 10,000 different specific combinations of elements are listed, the arrangement being alphabetical, based on the first letter of the symbols of the constituent elements. In a second column are given the percentage amounts of the alloying constituents; in a third the characteristics and uses of these combinations; and in a fourth column the patentee and the patent literature references. There is an additional list of the trade names or brands of aluminum alloys, with their manufacturer or inventor and their composition.

The concluding Part II of this volume is announced to appear by the end of 1939.

ARTHUR B. LAMB

Colloid Chemistry. (A Textbook.) By HARRY BOYER WEISER, Professor of Chemistry at The Rice Institute. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1939. viii + 428 pp. 103 figs. 15.5 × 23.5 cm. Price, $4.00.

Professor Weiser has rendered a further service to colloid science by writing this authoritative textbook. Apart from his own experimental contributions, he has been in a key position to observe the development of the subject as Chairman of the annual National Colloid Symposia for many years, and through the detailed consideration of the existing information with regard to inorganic colloids compiled in his previous three-volume monograph. Added to this is his power of clear and precise presentation.

This textbook is addressed to advanced undergraduate and graduate students and the purpose of the author is three-fold, "to acquaint the student with the foundations of colloid chemistry and with the role that the classical experiments have played in the development of the modern theories and applications of the subject; to formulate systematically and to correlate critically the theories underlying colloid chemical behavior; and to illustrate the widely diversified applications of the principles of colloid chemistry in such fields as the industrial arts, agriculture, and biology." However, it is the more purely scientific aspects of the subject that are chiefly dealt with, rather than applications and practical information.

The book is organized into six parts. The first occupies

one quarter of the text and deals with surface phenomena and the various manifestations of adsorption. Part II is the main section of the book. It deals with sols, their formation, purification, properties, constitution, stability and interaction with electrolytes and each other. Part III discusses gelatinous precipitates, jellies and gels. Part IV describes emulsions and foams; Part V, aerosols and solid sols. Part VI gives more extended consideration to contact catalysis, to dyeing and to colloidal clay.

This textbook is indispensable to serious students of the subject. It is attractively published and interestingly written.

JAMES W. MCBAIN

Biological Oxidation. By CARL OPPENHEIMER and KURT G. STERN. Nordemann Publishing Company, Inc., 215 Fourth Avenue, New York, N. Y., 1939. 317 pp. Illustrated. Price, $8.25.

The authors have divided their treatment of biological oxidations into two sections. In the first of these, the "General Part," which occupies the smaller half of the book, the theoretical aspects of oxidative enzymes are considered. Wieland's hydrogen activation theory and Warburg's interpretations of his experimental work are developed historically. Then the authors attempt to fuse these conflicting ideas into a "unitary theory" to represent the present status of an admittedly complex field. But unfortunately this scheme is not enough to make the present treatment a reasonably intelligible one. The writer feels that a more condensed and straightforward account with less emphasis on scattered literature references (there are 1383 in the book) would have been more acceptable.

The "Special Part" or second half of the book is most successful in its presentation of the chemistry of the enzymes. The following topics are treated: the hemin systems, the vitamin enzymes, the nucleotide derivatives, the quinoid mesocatalysts and the fumaric and citric acid systems. The material is complete, but not confusing, and is arranged in a logical way. Its careful study is full of reward for the reader.

The publisher, Dr. Junk of The Hague, Holland, is to be congratulated for the large number of valuable books he is now making available in the English language. It is hoped that he may soon be able to overcome the fairly abundant typographical errors, which in this particular volume are ever present and often confusing.

WILLIAM F. ROSS

Vitamin E. A Symposium held under the auspices of the Food Group (Nutrition Panel) of the Society of Chemical Industry on Saturday, 22nd April, 1939, at the School of Hygiene and Tropical Medicine, Keppel Street, London, W. C. 1, England. Published by the Society of Chemical Industry, Clifton House, Euston Road, London, N. W. 1, England, 1939. 88 pp. 13.5 × 21 cm. Price, 5/- post free.

This small book contains the papers presented at the Symposium, and the remarks made from the floor during the ensuing discussions. The Symposium was organized into three sections. Section I dealt with the "Chemical Structure and Properties of Tocopherol," and papers were presented by A. R. Todd, P. Karrer, A. Emmerle and Chr. Engel, and E. L. Smith and R. Bailey. As the Symposium occupied only one day, and there were many papers, the individual contributions were of necessity brief. As a consequence the papers cannot be regarded as complete reviews, for instance, those of Todd and Karrer (Dr. Karrer's paper was read by Dr. Bergel) in no way compare in extent or in critical value with reviews of the chemistry of vitamin E published elsewhere.[1] Nevertheless the brief papers serve admirably to define the position of various phases of vitamin E research at the time of the meeting. The paper by Emmerle and Engel contains a good discussion of their ferric chloride–α,α'-dipyridyl analytical method, and the paper by Smith and Bailey contains a critical discussion of all of the analytical methods in common use for the determination of tocopherols.

Section II of the Symposium dealt with "Physiological Action of Vitamin E and the Consequences of Vitamin E Deficiency." Papers in this group were contributed by J. C. Drummond, K. E. Mason, S. W. F. Underhill, T. Moore, A. J. P. Martin and K. R. Rajagopal, A. M. Copping and V. Korenchevsky, and A. L. Bacharach. The topics included a general discussion of the physiological aspects of vitamin E (Drummond, Moore, *et al.*); the relationship between the vitamin and the reproductive functions (Mason); the connection between vitamin E deficiency and the endocrine glands (Underhill); the effect of vitamin E deficiency on the weights of organs of male and female rats (Copping and Korenchevsky); and a critical discussion of the methods of bioassay (Bacharach). The papers in this group are uniformly good, although, again, the manuscripts are too brief to be classed individually as comprehensive reviews.

Section III of the Symposium dealt with "Clinical and Veterinary Uses of Wheat Germ Oil and Vitamin E Preparations." Papers in this group were presented by P. Vogt-Moller, E. Shute, D. W. Currie, C. R. MacDonald, and F. J. Browne. The papers in this group show a lack of agreement as far as the uses of vitamin E in human and veterinary medicine are concerned: it is claimed (V-M.) that 75% of the cases of habitual abortion are treated successfully; the usefulness of vitamin E in the treatment of this condition is denied, but it is claimed that success is achieved in 68% of the cases of threatened abortion (S.), while again habitual abortion is amenable to treatment with vitamin E, while threatened abortion is not (MacD.). Such disagreements as to the results and value of the clinical experiments are to be expected at the present stage in the development of vitamin E therapy, and much good cannot fail to result from an open discussion among the active workers in the field. These papers are presented with candor and restraint, and with an admirable regard for the variables and uncertainties involved.

The reports of the discussions of the various papers, while very brief [some of the discussions are reported in greater detail in *Angew. Chem.*, **52**, 427–430 (1939)] constitute one of the most interesting features of the book,

(1) (a) Karrer, *Helv. Chim. Acta*, **22**, 334 (1939); (b) John, *Angew. Chem.*, **52**, 413 (1939); (c) John, *Ergeb. Physiol. biol. Chem. exptl. Pharmakol.*, **42**, 1 (1939).

for these discussions serve to emphasize, even more than the papers themselves, unsettled questions and so point the way to future researches.

This Symposium, including among its members a large number of the foremost authorities in the various phases of vitamin E research, is a tribute to its promotors and to the Society which they represent and the little volume issued as a report is a most welcome addition to the rapidly growing literature on vitamin E. While the papers are presented by and for specialists in the field, nevertheless the general reader may gain from the book an accurate picture of the general knowledge concerning vitamin E as it existed last April, when such a congress of authorities from many nations was still possible.

LEE IRVIN SMITH

Nomogramme zum Mineral Bestimmen mit Röntgenstrahlen. (Charts for the Analysis of Minerals by X-Rays.) By M. MEHMEL. University of Rostock. Verlag der Deutschen Mineralogischer Gesellschaft e.V. through the Verlagsbuchhandlung Gustav Fischer in Jena, 1939. 13 charts. 21 × 29 cm.

The identification of crystalline compounds by means of their X-ray powder diffraction patterns has potential possibilities which have not yet been fully utilized. The recent tables of Hanawalt, Rinn and Frevel (*Ind. and Eng. Chem., Anal. Edition*, **10**, 475 (1938)) giving the spacings and relative intensities for 1000 compounds, represent the first big step toward making X-ray identification a practical working method. The Mehmel charts are essentially supplementary to data such as given in the Hanawalt tables. The charts give the diffraction diagrams for 17 minerals of interest in sedimentary petrography (quartz, calcite, clays, feldspar, etc.). Each pattern is represented by a series of vertical lines, the height of a line giving the intensity, and the lines being plotted against log sin Θ as abscissa. For each mineral there are three charts corresponding to Cu, Fe and Cr radiation. Since the charts give a direct picture of the diffraction pattern, they are a useful supplement to tabulated spacing data.

The wisdom of plotting intensity against log sin Θ seems to be very questionable. Plotting against Θ gives directly the appearance of the diffraction pattern, plotting against sin Θ crowds together the lines at large angle, and plotting against log sin Θ crowds the large angle lines still more. The only advantage to be had from plotting against log sin Θ comes from the fact that one chart will suffice to give the line positions for any wave length. In this series, however, since charts are given for three different wave lengths, there is no advantage to plotting against log sin Θ. The three charts for each structure would have been better spaced, and better suited to direct comparison, if plotted against Θ or 2Θ.

In order to make the identification of unknowns by powder patterns a working method, it would be ideal to have the tabulated spacing and intensity data, charts giving the appearance of the diffraction patterns, and the type of index suggested by Hanawalt which gives the strongest lines of various substances catalogued in order of decreasing spacing. An enormous amount of work is involved in the preparation of such tables and charts. It appears to the reviewer that before going farther with the preparation of a series of charts, the question of plotting against Θ rather than log sin Θ should be seriously considered. The charts are clearly labelled, well drawn, and of generous size. They appear to be quite accurate and reliable and will certainly find use.

B. E. WARREN

The Raman Effect and its Chemical Applications. By JAMES H. HIBBEN, Research Physical Chemist, Geophysical Laboratory, Carnegie Institute of Washington, with a Theoretical Discussion by JAMES H. HIBBEN and EDWARD TELLER, Professor of Physics, The George Washington University. American Chemical Society Monograph Series. Reinhold Publishing Corporation, 330 West 42nd Street, New York, N. Y., 1939. 544 pp. 72 figs. 15.5 × 23.5 cm. Price, $11.00.

For some time there has existed the need for a comprehensive survey in English on the Raman effect, and, in some respects, the present one may supply this need. The book is divided into three main sections of which the first, 122 pages, is devoted mainly to theory, the second discusses experimental results, their interpretation, and their applications to chemical problems and the third is an extraordinarily complete and useful bibliography.

The theoretical part treats in a clear and simple manner the rotations and normal vibrations of molecules, the infrared and Raman effect, and the far reaching conclusions that may be drawn from a consideration of the electric polarizabilities of molecules. The discussion of normal vibrations, polarizability, and the selection rules, is from a purely physical or intuitive point of view; no use is made of complicated dynamics or the intricacies of the group theory, and only a knowledge of elementary physics is necessary to understand the treatment given. A description of the fundamental modes of vibration is given for some of the important symmetrical molecules. The beginner and experienced worker alike will find the theoretical part of interest, but he may regret that additional chapters dealing with the subject in a more fundamental and complete manner are not included. It is regrettable that a more complete table of degeneracies and polarizations of permitted Raman lines for a larger variety of molecular types is not included, that the use of molecular spectra in thermodynamics is so briefly treated, and that the more familiar q and Q rather than Greek letters are not used to represent generalized and normal coördinates.

The second section of the book is divided into two parts, and it presents a survey and discussion of the experimental results for a large number of organic and inorganic compounds, respectively, both in their normal state of aggregation and in solution. In the case of gases and comparatively simple molecules in the liquid state for which fairly complete analyses of the spectra have been made, the results are given in moderate but not always sufficient detail; but since the great majority of molecules and solutions studied are too complicated to permit of exact treatment, a more or less qualitative point of view is adopted. This method of treatment has some value, but it is not as satisfying or illuminating as the exact one, and its extensive use often makes the content of the book descriptive rather

than analytical. An attempt is made to present the large mass of available material critically and to clarify, augment, or correct statements found in the literature, but the imposed brevity decreases the value of the effort somewhat; not infrequently the content consists of a mere abstract of results. In some cases, for example that of the intensity relations in the pure rotation spectrum of nitrogen, the fundamental importance of the results is not even stated. In spite of these defects, those working in the field may find the survey of results very useful and timesaving. Many applications of Raman spectra to chemical problems are clearly described, and data are to be found that have been published only in inaccessible journals.

In the last section of the book the reader will find an excellent bibliography arranged alphabetically according to authors, and an index of compounds whose Raman spectra have been studied. References to nearly two thousand papers are given.

The book contains a good many errors of one sort or another: thus, none of the calculated interatomic distances in Table 60 are in accord with either the accepted values or the values calculated from frequencies by more precise methods; the force constants in Table I are not precisely defined; the use of the term "symmetrical vibration" is confusing (pages 79 and 80); Fig. 11 represents ClCN as bent, when in fact this molecule is linear; equation 27 is wrong by a factor of 2π; and on page 221 the structural formulas of cedrene are confusing and apparently incorrect. The typography in this book is of indifferent quality; for example, the type used for the symbols M, D, K and Roman subscripts and superscripts is too large, the signs of integration are much too long and a capital T in place of the more acceptable t is used to represent time. There are typographical errors in equation 39, and in the one leading to 20.

We consider that this book will prove useful to those interested in the field. We also believe that the price is too high. This country has now taken the lead in scientific research, and the publication of books of a research character becomes our responsibility; it would be a pity if excessively high prices prevented the free circulation of such books among the very people for whom they are intended.

The System Calcium Oxide–Silica–Water at 30°. The Association of Silicate* Ion in Dilute Alkaline Solution

BY PAUL S. ROLLER AND GUY ERVIN, JR.

Knowledge of the compounds of hydrated calcium silicate and their equilibria is important in cement technology and in regard to the use of siliceous minerals in cement.

Hydrated calcium silicate is gelatinous at room temperature, regardless of method of preparation or time. However, the units of physical structure may be well-organized and definite, since X-ray analysis has shown that most inorganic gelatinous or amorphous materials are in reality crystalline, while all are crystalline (to X-rays) whose atoms or radicals are di- or monovalent.[1] A diffraction pattern has in fact been reported by Chassevant[2] for hydrous calcium silicate and has been corroborated by Foret.[3]

A high adsorption will be expected of the gelatinous silicate because of the minute size of the particles. Kolthoff and Moskovitz[4] observed that hydrous $Fe(OH)_3$ adsorbed $Cu(OH)_2$ up to 0.42 mole per mole. Weiser[5] found that gelatinous cupric ferrocyanide adsorbed potassium ferrocyanide continuously up to 0.85 mole per mole. The constancy of the x-ray diffraction pattern of the gel with varying ratios of alkali to copper[6] furnished direct proof of the adsorption character of the combination, although the possibility of a small amount of solid solution was not excluded. Similar results were obtained with the ferrocyanides of cobalt, nickel and manganese. A low adsorption was exhibited by lead ferrocyanide, which conformed to its coarsely crystalline character.

In general, owing to fineness of the microcrystals, solubility values for hydrous calcium silicate may be high. However, they will be generally reproducible if a similar state of growth of the microcrystals persists, so that active, or conversely normal, peripheral atoms are consistently dominant. The exclusively gelatinous character of calcium silicate formed at room temperature and lack of evidence of aging indicate the possibility of a fairly definite physical configuration and corresponding fairly definite solubilities.

The time required to reach equilibrium depends on the mode of experiment, the character of the starting materials and the degree of agitation. Fused calcium silicate may be decomposed with water, or, conversely, silica may be combined with dissolved calcium hydroxide. In both cases, observers have found that weeks or months may be required for complete reaction, particularly if agitation is poor; in side experiments with continuously rotated mixtures of silica gel and lime water of limited concentration we noticed that the concentration was decreasing appreciably after seven days. To expedite reaction, steel balls have been recommended for breaking up the

coagula.[7,8] A third method of experiment consists in precipitating hydrous calcium silicate and treating this with lime water. Because in this method the initial solid phase is a hydrous compound more or less closely related to the final products of equilibrium, a comparatively rapid approach to equilibrium would be expected. This in fact has been realized in the present work.

Chemical analysis has in the past frequently neglected the correction due to dissolved silica. The solubility of silica is relatively high at the lower lime concentrations and so will affect acid titration, conductivity measurement, and the apparent composition of the solid phase if the latter is estimated by difference. In the present work, separate analysis has been made for CaO and SiO_2 in the liquid and solid phases.

Experimental

The preparation of the calcium silicate and the equilibrium experiments were carried out in a three-necked flask which was contained in a water-bath controlled at 30.2° and was protected at all times from air by tested soda-lime tubes appropriately placed. The solid was prepared by the slow addition from a buret of 15–40 cc. of sodium metasilicate solution, preheated to 30.2°, to 2 liters of 15–50% saturated lime water, the mixture being stirred vigorously by means of a mercury-seal stirrer during the addition. About 300 mg. of flocculent precipitate was thus formed in the presence of excess calcium hydroxide in solution. After the precipitate had settled, the supernatant liquid was decanted, and the precipitate was washed by decantation and settling seven times with 500-cc. portions of lime water. The solid was then stirred with 2 liters of lime water of known concentration for twelve hours to five days until equilibrium had been well established. The supernatant liquid was then drawn off, filtered through a Jena G3 filter, and its analysis begun immediately. The wet solid was next drawn off for analysis into a stoppered centrifuge tube. In this tube it was washed with 10 times its volume of aqueous acetone of such concentration (50% or stronger) that a precipitate of calcium hydroxide just was avoided. Activity of calcium hydroxide in the wash solution was secured in this way sufficient for avoiding decomposition of the solid. The second wash was made with a stronger solution of acetone, or with pure acetone; this was followed by three washings with acetone and three with ether, after which the solid was filtered and allowed to dry. For solid phases in equilibrium with very dilute lime water (3 mmole of $Ca(OH)_2$/l. or less) the washing with acetone was omitted and a slight correction made for the calcium oxide in the centrifuged wet residue. The dry solid contained only about 0.05% Na_2O by spectrographic test.[8a]

All reagents were C. P. and were examined under the microscope for noticeable impurity. The lime water was made up by dilution, in the absence of carbon dioxide, of a filtered solution. The sodium metasilicate crystals were kept in a tightly stoppered bottle in a desiccator; 200 cc. of solution was made up as required. The solution always contained a small amount of carbonate that was determined by a sensitive turbidimetric method described elsewhere.[9] The carbonate was assumed to have reacted with the calcium hydroxide in solution, so that the equivalent amount of calcium oxide was subtracted in determining the composition of the solid phase. The correction amounted rather uniformly to 0.07%.

Hydroxyl was estimated by titrating 50 to 200 cc. with 0.1 *N* hydrochloric acid in the presence of phenolphthalein. Calcium was determined in the usual manner by precipitating as calcium oxalate, and titrating hot with 0.1 *N* potassium permanganate solution. Silica in solution was determined by the colorimetric method of King and Dolan[10] in which silicomolybdate is reduced with 1:2:4 aminonaphtholsulfonic acid containing sulfite. The solution of the reagent was kept in a refrigerator as directed. The standard silica solution was made up by dilution of a gravimetrically analyzed solution of sodium metasilicate. For constancy of standard it was found absolutely necessary to paraffin the bottles containing the metasilicate solutions. A calibration curve was used, and the precision of estimating silica was ±0.8%.

The solid phase was analyzed by dissolving in hydrochloric acid, evaporating to dryness in a platinum dish, and determining the silica by repeated dehydration in the usual way. The ignited silica was treated with hydrogen fluoride and the insoluble residue corrected for. The silica filtrate was analyzed for calcium as described.

Equilibrium and Reversibility.—The ratio CaO/SiO_2 in the solid phase (written for short C/S) is shown in Table I and Fig. 1 as a function of the concentration of Ca^{++} at equilibrium. There are four phase ranges, I, II, III and IV, of which II and IV are invariant with respect to concentration. All experimental points are included, except one in range IV where the initial washing out of the alkali had been neglected. In range I, which differs from IV in its much higher *p*H, omission of the same wash in two instances did not affect the consistency of the values obtained, and they were included in the total.

In these experiments, three factors were involved in the attainment of equilibrium: the time of contact (column 6), the direction of approach to equilibrium (column 7), and the nature of the solid phase. The direction is labeled S (synthesis) when the final solid phase was formed by combination of the initial solid with lime from

TABLE I

EQUILIBRIUM CONCENTRATIONS OF CALCIUM ION AT DIFFERENT RATIOS OF CaO TO SiO_2 IN THE SOLID PHASE

Phase range	Expt.	Millimoles/liter Ca^{++}	Activity Ca^{++}	CaO/SiO_2	Time of contact, days	Approach
I	1	20.67	6.87	1.401	5	S
	2	19.96	6.75	1.447	1	S
	3	19.90	6.74	1.417	5	S
	4	19.60	6.70	1.427	8	S
	5	17.51	6.32	1.387	1	S
	6	14.98	5.81	1.326	5	S
	7	13.53	5.51	1.309	5	S
	8	12.08	5.14	1.267	0.5	S
	9	9.81	4.54	1.235	1	D
	10	7.49	3.80	1.187	5	S
	11	6.99	3.62	1.168	1	D
	12	6.60	3.49	1.164	5	S
	13	4.89	2.82	1.116	5	S
	14	4.02	2.45	1.100	1	D
II	15	3.11	1.99	1.053	1	D
	16	3.10	1.99	1.048	5	S
	17	3.05	1.97	1.008	4	D
	18	3.11	1.99	1.014	1	S
	19	3.07	1.98	1.000	2	S
III	20	2.84	1.87	0.955	2	D
	21	2.69	1.79	.957	2	D
	22	2.57	1.72	.955	4	D
	23	2.24	1.54	.964	1	D
	24	2.09	1.46	.936	1	D
	25	2.07	1.44	.933	2	D
	26	1.64	1.19	.910	2	S
	27	1.60	1.17	.918	1	D
	28	1.60	1.17	.919	1	D
	29	1.37	1.03	.921	1	D
	30	1.18	0.902	.901	1	D
	31	0.990	.768	.895	2	D
IV	32	.897	.705	.869	4	D
	33	.923	.724	.854	4	D
	34	.900	.707	.852	2	D
	35	.900	.707	.819	2	D

a more concentrated solution than that in which the solid was formed. Conversely, the direction is labeled D (decomposition) when calcium oxide was released to a more dilute solution.

In range I, the same results were obtained after three hours as after five days, as may be seen from the following data (S direction):

	3 hr.	5 d.	3 hr.	5 d.	3 hr.	5 d.
Concn. Ca^{++} (mml./l.)	4.85	4.93	7.49	7.48	15.18	14.78
C/S in solid	1.110	1.116	1.188	1.186	1.326	1.326

To test reversibility in range I, a D approach was effected by diluting the mixture of expt. 5 (Table I). After one day of contact the results of expt. 11 were obtained, which agree very closely with those obtained by the reverse approach.

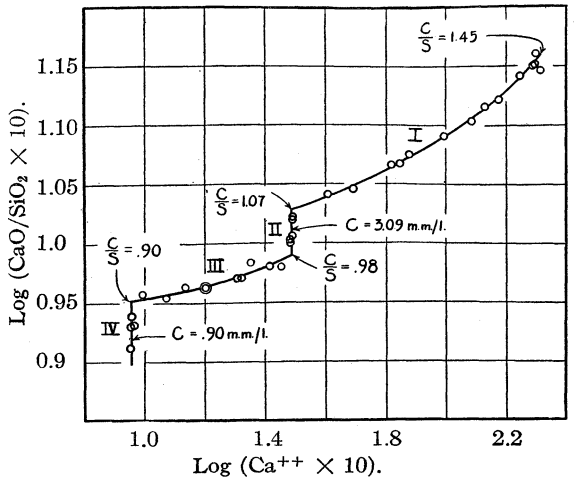

Fig. 1.—Mole ratio of CaO to SiO_2 in solid against concentration of calcium ion in solution (millimoles/liter).

The rapid and reversible equilibrium observed for range I also has been observed by Baylis.[11]

In range II no special tests were made, but the two directions of approach, and widely varying times, were used (Table I).

In range III, after one day of contact (D approach) a concentration of 2.57 mml./l. and a C/S ratio of 0.957 were obtained; the result after four days was 2.43 and 0.954, so that one day appeared adequate for attainment of equilibrium. However, in the reverse approach in the same region, it seemed that two days were required, since the results of expt. 26, which are comparable with those of expt. 27, were arrived at in not less than this time.

In range IV at least two days were required in a D approach to reach the invariant concentration, the greater time being due no doubt to comparative slowness of the compound transformation. It did not seem feasible to test reversibility in this range because of complete solution of the solid when it was treated with water in attempting to obtain a sufficiently low C/S ratio in preparation for an S approach.

The above tests indicate that the stirring times listed in Table I were sufficient; the consistency of the results for widely varying times and different directions of approach attests further to the establishment of equilibrium.

Nature of the Solid Phases

Because of their gelatinous adsorptive character, the composition of compounds in the solid phases may not be determined in the usual way.

(11) J. R. Baylis, *J. Phys. Chem.*, **32**, 1236–1262 (1928).

However, they may be identified by the application of physical chemical considerations. Two of these are: adsorption isotherm and ion product constant.

Evidence of Adsorption Isotherm.—The continuously changing composition and the rapid approach to equilibrium in ranges I and III are characteristic of adsorption. However, only part of the calcium oxide in the solid phase is adsorbed; the rest is combined in an adsorbing compound. Since in range I the C/S ratio was 1.07 to 1.45, the absorbent may be a 1/1, 4/5, 2/3 or 1/2 compound, etc. For a given ratio, the moles of calcium oxide adsorbed may be calculated with reference to any one of these possible combinations. In Fig. 2, the adsorption per mole of 2/3, 4/5 and 1/1 compound has been plotted against log concentration of Ca^{++} and against log activity of Ca^{++}, as for a Freundlich isotherm. Activity coefficient of Ca^{++} was calculated by the usual Debye–Hückel formula, $-\log \gamma_2 = 2.02 \sqrt{\mu} - 0.40 \mu$, the coefficient 0.40 being deduced from the data of Fosbinder[12] for calcium hydroxide.

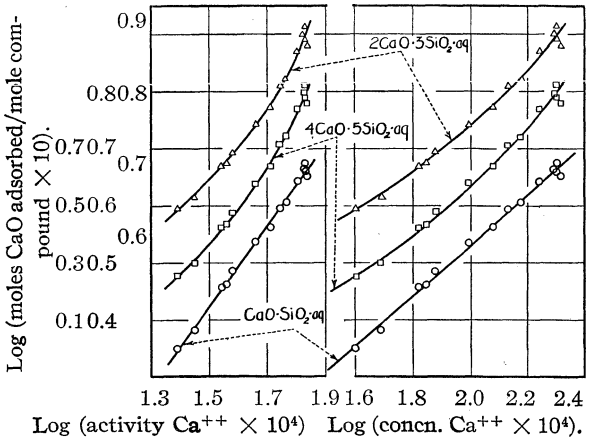

Fig. 2.—Freundlich adsorption isotherm plots for different assumed compounds (range I). (Ordinates reading from left to right are for 1:1, 4:5 and 2:3 compounds, respectively.)

It is observed that a straight line is obtained for a 1/1 compound, thus satisfying a Freundlich isotherm, but a curved line is obtained for a 4/5 compound, and a still more curved line for a 2/3 compound. Due to a fortuitous rate of increase in the activity coefficient for Ca^{++}, the same relations are obtained for concentration or activity but the distinctions are more pronounced for activity. It is inferred, therefore, that the adsorbing compound in range I is, empirically, $CaO \cdot SiO_2 \cdot aq$. The value of n in the Freundlich equation ($x/m = ac^{1/n}$) is 0.70 for activity and 1.13 for concentration.

According to Lefol[13] and to Cirilli,[14] calcium silicate retains one mole of water at high temperatures, and so this molecule is constitutional. The empirical monosilicate is probably, therefore, structurally the acid salt of orthosilicic acid, or $CaH_2SiO_4 \cdot aq$. The existence of orthosilicic acid is known from vapor tension measurements.[15,16] Its existence is demonstrated further by the wet preparation of thallous orthosilicate by Vesterberg and Willers.[17] For these and other reasons, we shall consistently adhere to the orthosilicate, rather than the metasilicate, terminology. However, the terminology is essentially immaterial as far as our conclusions are concerned.

The adsorption isotherm holds right up to lime saturation, so there is no indication of a silicate higher than the 1/1 compound. Furthermore, the mean maximum C/S ratio, corresponding to 20.7 mml. CaO/l. (somewhat in excess of true lime saturation, or 19.4 mml./l.),[18] was only 1.45, whereas even for a 3/2 compound a ratio more nearly equal to 2 would be expected due to adsorption. The apparent non-existence at 30° of $3CaO \cdot 2SiO_2 \cdot aq$., or of $2CaO \cdot SiO_2 \cdot aq$., may be explained by the difficulty of displacing the first two hydrogens of orthosilicic acid. Britton[19] found no break in the titration curve that would correspond to dissociation of these. Sodium orthosilicate has never been crystallized, even in the presence of a great excess of sodium hydroxide. Although Vesterberg and Willers obtained insoluble thallous orthosilicate, this occurred only under unusually favorable conditions, as by digestion of the insoluble 1:1 compound with concentrated thallous hydroxide.

Nacken and Mosebach[20] believed that they had prepared hydrated calcium orthosilicate on treating tricalcium silicate with water; however, on prolonging the experiment (which involved intermittent shaking) from 30 to 278 days, the C/S ratio dropped to 1.55 and 1.68 in two experi-

ments.[21] Beitlich[22] obtained a ratio of 1.95, from which he inferred the existence of an orthosilicate; however, he added solid lime to his mixture, and this may have become entangled in the gel or for some other reason did not dissolve completely. Moreover, a 2/1 compound would again require an appreciably higher ratio than 1.95 owing to adsorption.

In addition to the above, the following maximum ratios, corresponding to approximate lime saturation, have been reported: 1.4–1.5,[7,8,11,23,24] 1.5–1.6,[25,26] 1.6–1.7.[27,28,29] The adsorption character of the continuously increasing C/S ratio has generally been recognized, and usually a 1/1 compound has been assumed to be the adsorbent.

Range III was insufficiently large and the data insufficiently accurate to permit discrimination of the nature of the adsorbing compound by means of a Freundlich isotherm. The C/S ratio in this range was 0.98 to 0.90, so that the solid might be a 5/6, 4/5, 3/4, 2/3 or 1/2 compound.

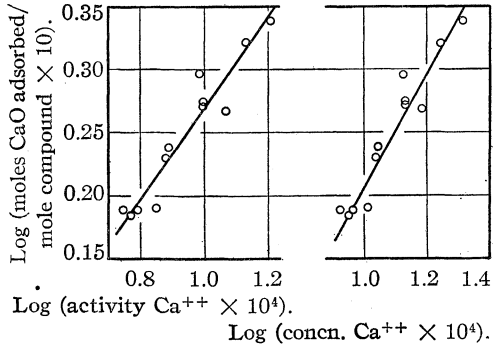

Fig. 3.—Freundlich adsorption isotherm plot for $3CaO \cdot 4SiO_2 \cdot aq.$ (range III).

It is observed from Fig. 3 that the assumption of an adsorbing compound having the formula $3CaO \cdot 4SiO_2 \cdot aq.$ satisfies the requirements of the isotherm. The value of the exponent n is for activity as variable, 2.2, and for concentration as variable, 2.7. The apparent agreement for a 3/4 compound does not exclude the possibility of any of the others. Its existence was independently inferred from an ion product study that will now be considered.

Evidence of Solubility Product Constant.—During the course of an adsorption isotherm, the concentrations of the ions are continuously changing, but if the adsorbent is one and the same compound, AB_n, then the product of the ion activities, $A \times B^n$, should be constant, and a plot of log A against log B should give a straight line of slope, n. The fulfillment of this condition may be used to ascertain the composition of the adsorbing compound. The activities A and B must of course be accurately determined as a prerequisite to the application of the method.

For the purpose of calculating the activities of the silicate ions, accurate values for dissolved silica were obtained in a special series of experiments in which the reaction flask was paraffined. After ample time, based on previous experience, had been allowed for equilibrium, the solution phase was analyzed. The paired values of silica and Ca^{++} are shown in Table II and plotted in Fig. 4. (The two lowest values for silica are in parentheses, as the color during analysis was unstable and the result therefore unreliable.) It is observed that silica increases continuously with decrease in Ca^{++}. The absence of a sharp change in passing from range I to range III may be due to the fact that the dissolved silica consists of several ions and molecules, so that a discontinuity for one of these is dulled by the presence of the others.

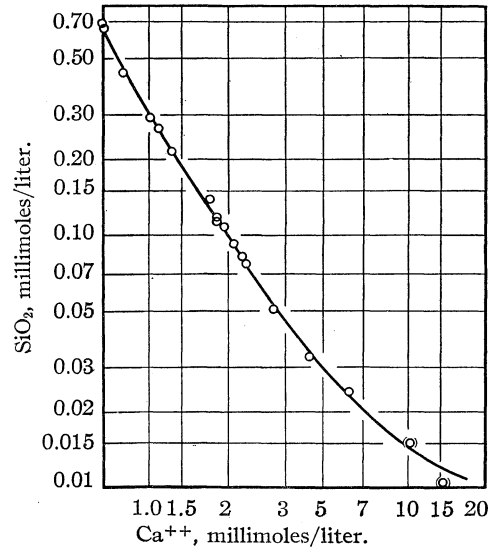

Fig. 4.—Variation of concentration of silica with concentration of calcium ion.

It is usually assumed that the silica in dilute alkaline solution is made up simply of $SiO_3^=$, $HSiO_3^-$, and H_2SiO_3. Following the orthosilicate terminology, we shall write these components $H_2SiO_4^=$, $H_3SiO_4^-$ and H_4SiO_4, respectively. The presence of the ions $SiO_4^{\equiv}$ and $HSiO_4^{\equiv}$ will be neglected on the basis of a trifling dissociation of the hydrogens from $H_2SiO_4^=$. If CaH_2SiO_4 is the adsorbing compound in range I, as the adsorption isotherm shows, then the product of the activities of Ca^{++} and $H_2SiO_4^=$ should be constant over the whole range of adsorption. To calculate the concentration of $H_2SiO_4^=$, it is necessary to know the ionization constants of the acid anions. These have been determined only approximately. For the ionization of $H_3SiO_4^-$ ($HSiO_3$), K_2 has been given as 10^{-12}[30,31] and 10^{-13}[32] and for the ionization of H_4SiO_4 (H_2SiO_3), K_1 has been given, respectively, as 10^{-10}, $10^{-9.7}$ and 10^{-9}. We have chosen for the calculation $K_1 = 10^{-9.8}$ and $K_2 = 10^{-12.4}$; these values are slightly less than the mean of the reported values, but the difference was partly premeditated since the thermodynamic constants, with which we are concerned, are smaller than the constants calculated, as in these citations, from *p*H measurement without correction for activity coefficients of the ions. K_W was taken equal to $10^{-13.8}$ from "International Critical Tables." OH^- was estimated by difference, assuming one charge per SiO_2. This assumption could be corrected on the basis of the calculated proportions of the silicate ions and a second approximation made, but the original assumption proved sufficiently accurate both in the present and in

subsequent calculations. In view of the dilute character of the solutions and lacking better information, the same activity coefficient was used for all ions of the same charge. γ_1, or that for singly charged anions and for OH^-, was taken from the equation of Flint and Wells[33] for OH^- in a solution of $Ca(OH)_2$. γ_2 was the same as that for Ca^{++}, and γ_3 (for use in subsequent calculations) was assumed by comparison with the values for a trivalent ion.[34]

From the above known values, the concentrations of $H_2SiO_4^=$, $H_3SiO_4^-$ and H_4SiO_4 have been calculated, as shown in Table II (case of non-association). For range I, a plot of log activity $H_2SiO_4^=$ against log activity Ca^{++} gives a straight line of slope equal to $-1/1$ (plot I′ of Fig. 5). This shows that the product of the activities of Ca^{++} and $H_2SiO_4^=$ is constant, and that the adsorbing compound is CaH_2SiO_4, or calcium monosilicate, in agreement with the adsorption data.

$H_3SiO_4^-$ being the only remaining silicate ion, one would expect that the compound of range III would be $Ca(H_3SiO_4)_2$, so that a plot of log activity $H_3SiO_4^-$ against log activity Ca^{++} should give a straight line of slope $-1/2$. Plot III′ of Fig. 5 shows that a straight line is obtained, but the slope instead of being $-1/2$ is much too high at about $-2/1$. The impossible compound $Ca_2H_3SiO_4$ is therefore indicated, and the apparent linearity of the plot is fortuitous.

The reason for the high slope is that the silica in solution is increasing much more rapidly with decreasing Ca^{++} than it should in order for an acid silicate to be satisfied. The consequent high rate of increase in calculated $H_5SiO_4^-$ could be reduced by choice of a smaller constant than $10^{-9.8}$ for K_1, which would transfer the silica to H_4SiO_4 from $H_3SiO_4^-$. Calculation shows, however, that to approach the theoretical slope of $-1/2$, K_1 would have to be reduced to a very low value, 10^{-12} or less. This is about equal to or less than K_2, which is not only untenable, but would lead to predictions of very high hydrolysis for sodium disilicate ($Na_2O\cdot 2SiO_2$ or $NaHSiO_3$), instead of only 5% or so obtained by Bogue[35] and by Harmon.[36]

An alternative to the compound $Ca(H_3SiO_4)_2$ is an addition compound of the type $nCaH_2SiO_4\cdot Ca(H_3SiO_4)_2$. For this the ion product $(Ca^{++} \times H_2SiO_4^=)^n \times (Ca^{++} \times [H_3SiO_4^-]^2)$ would have to be constant. However, in order to approach a steady value of the product, n, it is found, would have to be unreasonably large. Substituting the activities of $H_2SiO_4^=$, $H_3SiO_4^-$ and Ca^{++} of Table II, n would have to be about 8 for a reasonably steady value of the product. This corresponds to the hypothetical compound $9CaO\cdot 10SiO_2\cdot aq.$, which is not only unexpected and irregular, but is so close to the molar ratio of calcium oxide to silica in the solid phase as to allow for practically none of the undoubted adsorption by the gelatinous solid.

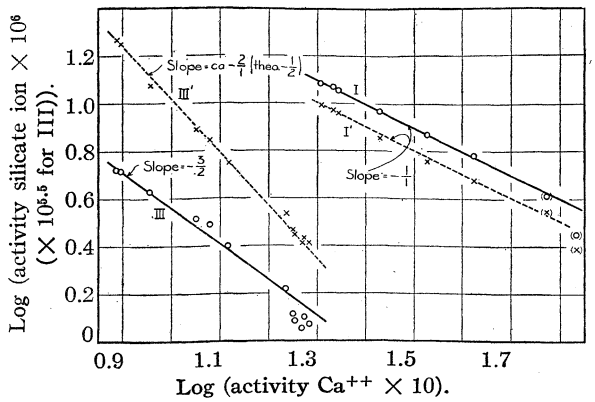

Fig. 5.—Test of compound by solubility product constant.

We were thus led to the presumption that association of silicate ion takes place, even at the high dilution of silicon dioxide and high pH of the solutions. However, association could not be considered as having advanced to the colloid stage. The proof of this is as follows. A solution of $Na_2O\cdot 2SiO_2$ has a pH that is about the same as for the present solutions, about 10.7 and up, depending on the concentration;[35,36] comparison may therefore be made with $Na_2O\cdot 2SiO_2$ solution as respects the properties of dissolved silica. Harmon[37] and Ganguly[38] found for such a solution practically complete molecular diffusion at concentrations up to 0.3 N. Ganguly[39] and Burgess and Krishnamurti[40] observed no colloidal scattering at concentrations of the order of 2 N. Finally, Main[41] saw in the results of viscosity measurement no evidence of colloidality for concentrations up to 3 N.

It seemed reasonable therefore to assume that association was confined to a molecular-type of compound, and in the first instance to a dimer, so that corresponding to $SiO_4^{==}$, $HSiO_4^{=}$, $H_2SiO_4^{=}$, $H_3SiO_4^{-}$ and H_4SiO_4, a new series of ions was to be considered, which in the order of decreasing alkalinity is $Si_2O_6^{==}$, $HSi_2O_6^{=}$, $H_2Si_2O_6^{=}$, $H_3Si_2O_6^{-}$, and $H_4Si_2O_6$. As far as the possibility of combination of Ca^{++} with any of the latter ions to form a compound in range III is concerned, we may rule out $Si_2O_6^{==}$, the most alkaline anion, because the ratio CaO/SiO_2 would be 1/1 which is greater than any of the experimental ratios in range III. Compound formation with the next most alkaline ion, $HSi_2O_6^{=}$, is feasible, as will be shown. For the sake of completeness we have also considered in great detail the independent possibility of combination with the still more acid anion, $H_2Si_2O_6^{=}$, and also the possibility of combination with $H_3SiO_4^{-}$ in the new situation of association. The former compound would require a slope of $-1/1$ in plotting log activity $H_2Si_2O_6^{=}$ against log activity Ca^{++}. However, here again, as for the case of nonassociation, the rate of increase of silica in solution is so great that a very small ionization constant would be required for $H_3Si_2O_6^{-}$ and for H_4SiO_4. The expected hydrolysis of $Na_2O{\cdot}2SiO_2$ would again then be very much greater than is actually found. The postulate of a tetra polymer did not avoid the calculated high degree of hydrolysis. With respect to the possible compound $Ca(H_3SiO_4)_2$, the same impasse of high hydrolysis existed as before.

The combination of $HSi_2O_6^{=}$ with Ca^{++} to give $Ca_3(HSi_2O_6)_2{\cdot}aq.$ (or empirically $3CaO{\cdot}4SiO_2$) would require a slope of $-3/2$. This slope was readily realized in preliminary test. The problem that remained was to determine accurately the magnitude of the various equilibrium constants. For this purpose we have the four ionization constant equations for H_4SiO_4 (K_1), $H_3SiO_4^{-}$ (K_2), $H_3Si_2O_6^{-}$ (K_{II}) and $H_2Si_2O_6^{=}$ (K_{III}), the equations of association (1), of solubility product constant (2) and (3), and of conservation of mass (4).

$$\frac{\gamma_2 H_2Si_2O_6^{=}}{\gamma_1^2(H_3SiO_4^{-})^2} = K_S \quad (1)$$

$$\gamma_2^3\gamma_3^2(Ca^{++})^3 \times (HSi_2O_6^{=})^2 = K_{S.P.}(C_3S_2) \quad (2)$$

$$\gamma_2^2\, Ca^{++} \times H_2SiO_4^{=} = K_{S.P.}(CS) \quad (3)$$

$$H_4SiO_4 + H_3SiO_4^{-} + H_2SiO_4^{=} + 2H_3Si_2O_6^{-} + 2H_2Si_2O_6^{=} + 2HSi_2O_6^{=} = SiO_2 \quad (4)$$

By substituting into (4), equation (5) is obtained for range III in which each of the silicic acid unknowns is replaced one by one by a function of the different constants as unknown, whose coefficient is a function of Ca^{++}, OH^{-} and the activity coefficients.

$$\frac{MK_W/K_1}{o^{3/2}c^{3/4}} + \frac{M}{\gamma_1 o^{1/2}c^{3/4}} + \frac{o^{1/2}MK_2/K_W}{\gamma_2 c^{3/4}} + \frac{NK_W/K_{II}}{\gamma_1 o^2 c^{3/2}} + \frac{N}{\gamma_2 o c^{3/2}} + \frac{K_{S.P.}(C_3S_2)}{\gamma_3 c^{3/2}} = SiO_2 \quad (5)$$

in which, $M = (K_W/K_{III})^{1/2}K_{S.P.}^{1/4}(C_3S_2)K_S^{-1/2}$, $N = 2K_W/K_{III}K_{S.P.}^{1/2}(C_3S_2)$, o = activity OH^{-}, c = activity Ca^{++}.

By making use of (3) instead of (2), a similar equation is obtained for range I

$$\frac{AK_W/K_1}{o^2 c} + \frac{A}{\gamma_1 o c} + \frac{K_{S.P.}(CS)}{\gamma_2 c} + \frac{BK_W/K_{II}}{\gamma_1 o^3 c^2} \frac{B}{\gamma_2 o^2 c^2} + \frac{BK_{III}/K_W}{\gamma_3 o c^2} = SiO_2 \quad (6)$$

in which $A = K_W/K_2K_{S.P.}(CS)$, $B = 2K_S{\cdot}(K_W/K_2\,K_{S.P.}(CS))^2$.

Since the same ultimate unknowns enter in both equations (5) and (6), their solution is not independent, but is conditional and based on successive approximations. In equation (6), the unknown terms of greatest weight are the second and third, so this equation is solved for $K_{S.P.}(CS)$ and K_2 (from A) after substituting for the other unknowns their values obtained from a previous sufficiently close solution of (5). By combining in the latter the second and the less important third term containing the substituted value of K_2, the number of unknowns is reduced to five. The general solution of the resultant equation led however to absurd negative values. This is due to the fact that in the range of pH under consideration, H_4SiO_4, $H_3Si_2O_6^{-}$ and $HSi_2O_6^{=}$ are very small (compare Table II under association), so that treating the corresponding terms as independent unknowns was virtually the same as introducing arbitrary unknowns whose effect on the solution of an inexact (observational) equation is arbitrary. Therefore these terms were converted into knowns by substituting for K_1, K_{II} and K_{III} values based on the electrometric titration results previously referred to. Naturally the solution depends upon the substituted values, but since the combined magnitude of these averaged only 4% of the total, small errors of quantitation would be immaterial. The solution of the reduced equation (5) gave values for $K_{S.P.}(C_3S_2)$ and for $K_W/K_{III}K_{S.P.}^{1/2}(C_3S_2)$(from N).

In every case the actual solution was carried out by applying the method of least squares to the

observational equations and solving the resultant normal equations simultaneously. The precision was estimated from the residuals,[42] or the differences in silica found and calculated.

The results of the solution may be summarized as follows: $K_S = 2200 \pm 150$; $K_2 = 10^{-12.16 \pm .02}$; $K_{S.P.}(CS) = 2.53 \pm 0.10 \times 10^{-8}$; $(K_W/K_{III})^2 \cdot K_{S.P.}(C_3S_2) = 1.37 \pm 0.10 \times 10^{-23}$; $K_{S.P.} \cdot (C_3S_2) = 1.37 \times 10^{-21}$ (based on $K_{III} = 10^{-12.8}$); $K_1 = K_{II} = 10^{-9.8}$, and $K_{III} = 10^{-12.8}$ (all assumed from electrometric results).

K_{III} in the above tabulation was taken as different from the determined value of K_2 because of anomalies[19,31] observed in the titration of sodium silicate in the range of pH dominated by the second ionization constant, and it was taken as less because of the somewhat high value of K_2 compared to the mean of the electrometric values.

K_2 it may be noted is very much smaller than K_{II} even though the valence of the respective acids $H_3SiO_4^-$ and $H_3Si_2O_6^-$ is the same. The greater ionization of $H_3Si_2O_6^-$ may be explained by the electrical screening effect of the additional SiO_2 in the dimer ion.

From the above values of the equilibrium constants, the concentrations of the different silicic acids have been calculated in Table II under association; also given is their sum and the percentage deviation of the experimental silica from the latter. From the table, log activity $H_2SiO_4^=$ and log activity $HSi_2O_6^=$, corrected to zero deviation, have been plotted in Fig. 5 against log activity Ca^{++}. The resultant graphs, I and III, respectively, are within the limit of error straight lines of theoretically correct slope $-1/1$ and $-3/2$. That the correct slope was previously gotten in range I for the case of non-association is explained by the small degree of association in this range due to the relatively low concentration of SiO_2.

In view of its non-existence (non-precipitation) in range III, the product of the ion activities for CaH_2SiO_4 should be less than $K_{S.P.}(CS)$ in this range. Making use of the values of Table II, this is confirmed for each of the determinations of range III, except that the low group of first five determinations (*cf.* Fig. 5) deviates in the wrong direction by an average of 3%. Likewise the product of the ion activities for $Ca_3(HSi_2O_6)_2$ should be less than $K_{S.P.}(C_3S_2)$ in range I. Surmounting the obstacle raised by the approximate character of K_{III} and hence of $HSi_2O_6^=$ (and this alone), the equivalent condition is $(\gamma_2 Ca^{++})^3(\gamma_2 H_2Si_2O_6^=)^2 \cdot (\gamma_1 OH^-)^2 < N^2/4 < 1.37 \times 10^{-23}$. This is found to be satisfied by each of the determinations of range I.

By comparison of the respective $K_{S.P.}$, it is noted that the (intrinsic) solubility of CaH_2SiO_4 is 1.7 times that of $CaCO_3$. If the monosilicate were crystalline instead of gelatinous, its solubility product would presumably be less. The solubility of $Ca_3(HSi_2O_6)_2$ (based on K_{III} equal to $10^{-12.8}$) is slightly less than that of $CaCO_3$.

The association of silicate ion explains the peculiar result of a decided increase in pH with increase in concentration, even for solutions of buffer character.[35,36] By equation (1) an increase in concentration results in the loss of two acid anions and gain of only one acid anion of nearly equal ionization constant, so the pH must also increase with concentration.

Because of the high value of 2200 for the association constant, comparatively much $H_2Si_2O_6^=$ and little $H_3SiO_4^-$ should be present in a solution of $Na_2O \cdot 2SiO_2$. This condition is indicated by the comparatively low depression of the freezing point of a solution of this substance. Harmon[43] found, for example, that in a solution that is 0.102 molar with respect to Na_2O the depression is 0.548° for sodium metasilicate but only 0.415° for the disilicate. However, (in the orthosilicate terminology) since $Na(H_3SiO_4)$ dissociates into four ions per mole of Na_2O (or more depending on hydrolysis and dissociation), while $Na_2(H_2SiO_4)$ dissociates into three ions (or more), a greater depression would be expected for the disilicate. Thus, for the comparable salt Na_2CO_3, at a concentration that is 0.10 molar with respect to Na_2O the depression is 0.444°, whereas for $NaHCO_3$ the depression is 0.702° and therefore considerably higher ("International Critical Tables"). The difference in behavior between HCO_3^- and a supposedly exclusive $H_3SiO_4^-$ is too great to be explained by differences in ionization constant or activity coefficient, but is accounted for by molecular association of $H_3SiO_4^-$. An abnormally low depression of the freezing point by sodium disilicate is also seen in the measurements of Kahlenberg and Lincoln.[44] The vapor pressure lowering[43] and the dew-point depression[45] are also comparatively low.

TABLE III

INVARIANT CONCENTRATIONS AND SOLID PHASES IN EQUILIBRIUM

Millimoles/liter CaO	Millimoles/liter SiO_2	Ratios	Compounds (Hydrated) Formulas
3.09	0.090	$CaO \cdot SiO_2 + 3CaO \cdot 4SiO_2$	$CaH_2SiO_4 + Ca_3(HSi_2O_6)_2$
.900	.931	$3CaO \cdot 4SiO_2 + CaO \cdot 2SiO_2$	$Ca_3(HSi_2O_6)_2 + CaH_2Si_2O_6$ or $Ca(HSiO_3)_2$

Invariant Ranges.—The invariant concentrations and the compounds in equilibrium therewith are given in Table III. The silica concentration for the upper invariant point was interpolated from the curve of Fig. 4. The value for the lower invariant point was the average of two accurate analyses carried out in the paraffined flask. A solution containing 0.924 millimole of CaO/l. was diluted one-third with water; after four days of stirring the concentration of Ca^{++} was 0.900 millimoles/l. and of SiO_2, 0.936 millimole/l. On a one-fold dilution of the latter solution, the concentrations after three days were, respectively, 0.900 and 0.926. The *p*H of the solutions, measured colorimetrically with acyl red, was 10.3–10.5. The values for Ca^{++} agree with those independently obtained when analyzing for the solid phase (Table I).

The existence of an invariant concentration corresponding to our value of 3.09 millimoles CaO/l. is indicated by the work of Thorvaldson and Vigfusson,[8] who decomposed tri- and dicalcium silicate with water till a steady state was reached. When their results are replotted as C/S ratio in the solid against concentration, a large break is observed at about 4 millimoles/l. for the trisilicate and at 2 millimoles/l. for the disilicate, both at a C/S ratio as in the present work close to 1/1. Shaw and MacIntire[7] found that uniform adsorption of calcium hydroxide by silica gel held to approximately 2.5 millimoles/l. when an arrest occurred; an arrest at about 3.5 millimoles/l. is shown by the results of Maffei[46] and at about 2 millimoles/l. by the results of van der Burgh,[24] who used twenty-four hour shaking periods. In treating silicate melts with lime water, Kühl and Mann[23] observed an arrest at 2.3 millimoles/l. and C/S ratio of 1/1.

The lower invariant concentration was early recognized by Le Chatelier,[27] who repeatedly extracted precipitated calcium silicate and obtained an arrest at 0.93 millimole CaO/l. The results of Baylis[11] in the same type of experiment show invariance at about the same concentration. Tavasci,[25] in decomposing tricalcium silicate with water, corroborated Le Chatelier's value; he believed, however, that an arrest occurred also at 0.55 millimole/l. In treating silica gel with lime water over a long period of time, Jolibois and Chassevant[26] obtained an invariant concentration of 0.95 millimole/l. The value obtained by Beitlich[22] in the same reaction was 0.75 millimole/l.; this, however, is low because the author did not take into account, in the conductivity measurements, the presence of silica in solution.

If the new solid that makes its appearance in range IV were silica, the concentration of silica would be expected to be equal to or greater than the solubility of gelatinous silica in water, which according to Lenher and Merrill[47] is 2.7 millimoles/l., and according to Hitchen[48] is 3.3 millimoles/l. However, the actual value of 0.931 millimoles/l. (Table III) is much lower, so the solid phase is not silica. The next less alkaline anion after $HSi_2O_6^{\equiv}$ is $H_2Si_2O_6^{=}$, and, in the monomer series, $H_3SiO_4^{-}$. Combination of either of these anions with Ca^{++} would result in the compound $CaO \cdot 2SiO_2 \cdot aq$. Having eliminated silica, calcium disilicate is therefore strongly indicated to be the compound that makes its appearance in the second invariant range. It may be noted that hydrated calcium disilicate occurs naturally as the mineral okenite.

It is easily shown that the ion activity product for $CaH_2Si_2O_6$ is equal to

$$\frac{N}{2}\frac{1}{\gamma_1 OH^-}\frac{1}{\gamma_2^{1/2}Ca^{++1/2}}$$

and that the product for the other possible form of the disilicate, namely, $Ca(H_3SiO_4)_2$, is $1/K_S$ times this. Substituting for Ca^{++} and OH^- (assuming one charge per SiO_2) from Table III, $K_{S.P.}$ for $CaH_2Si_2O_6$ is calculated to be $1.69 \pm 0.06 \times 10^{-7}$, and $K_{S.P.}$ for $Ca(H_3SiO_4)_2$ $7.68 \pm 0.60 \times 10^{-11}$. The mean activity of the solute at saturation is given by the square and cube roots of the respective $K_{S.P.}$, and is, respectively, 4.11×10^{-4} and 4.25×10^{-4}. The practical identity

(48) C. S. Hitchen, *Bull. Inst. Mining and Met.* No. **364**, 26 pp. (1935).

of the values shows that the free energy of formation of calcium disilicate is the same whether the solid arises from the monomer or dimer forms; it would appear, therefore, that there is only one disilicate which may be formed indifferently from one or the other of the anions. The disilicate is intrinsically 2.6 times as soluble as the monosilicate. The ion product in range III is less than $K_{S.P.}$ for either $Ca_2H_2Si_2O_6$ or $Ca(H_3SiO_4)_2$, as is proper.

In view of the consistent rapid approach to equality of the CaO/SiO_2 ratio in solid and in solution, and the closeness of the ratios in invariant range IV, it is likely that calcium disilicate dissolves congruently in the next less-alkaline univariant range and is the last remaining compound. No hydrated silicate richer in silica than the disilicate is known in nature.

Summary

Hydrated calcium silicates are gelatinous. The effects to be expected from this in a phase rule study are discussed briefly.

Measurements were made of the ratio of CaO to SiO_2 in the solid phase, and of the concentrations of CaO and SiO_2 in solution at 30.2°. Equilibrium and reversibility were tested for.

Four phase ranges were distinguished; in two of these the concentrations were invariant. Adsorption of CaO by the solid phases occurred throughout. The compositions of the hydrated compounds, deduced from considerations of adsorption isotherm and solubility product constant, were: (1) $CaO \cdot SiO_2$ (CaH_2SiO_4), (2) $3CaO \cdot 4SiO_2$ ($Ca_3(HSi_2O_6)_2$), (3) $CaO \cdot 2SiO_2$ (indifferently either $CaH_2Si_2O_6$ or $Ca(HSiO_3)_2$). The invariant concentrations for the mixture of (1) and (2) were: 3.09 millimoles CaO/l. and 0.090 millimole SiO_2/l. and for the mixture of (2) and (3), 0.900 millimole CaO/l. and 0.931 millimole SiO_2/l.

The assumed exclusive presence of the simple ions $SiO_3^=$ and $HSiO_3^-$, or in the more rational and preferred orthosilicate terminology, $H_2SiO_4^=$ and $H_3SiO_4^-$, was inconsistent with the existence of the only alternatives of $Ca(H_3SiO_4)_2$ or any reasonable double compounds of the latter with CaH_2SiO_4. It was necessary to assume therefore that association took place in the dilute alkaline solutions. The postulate of two sets of silicate ions, based on an association equilibrium between $H_3SiO_4^-$ and $H_2Si_2O_6^=$, led to reasonable and concordant results. The association constant, solubility product constants, and one of the ionization constants, were calculated to a known precision. A high tendency toward association is evidenced.

Isotopic Composition of Oxygen in Carbonate Rocks and Iron Oxide Ores

BY MALCOLM DOLE AND ROBERT L. SLOBOD[1]

Introduction

In recent years the isotopic composition of oxygen in various natural substances has been the subject of a number of investigations beginning with the research of Manian, Urey and Bleakney,[2] who studied stony meteorites and terrestrial silicate rocks. Unfortunately, after these workers had performed the difficult task of recovering the oxygen from these rocks by reaction with graphite and carbon tetrachloride vapors at 1000°, their methods of isotopic analysis were too inaccurate to demonstrate any significant differences between the various samples of oxygen; thus their specific gravity determinations of 0.47 cc. of water were accurate only to ± 63 γ[3] or 29% in the O^{18} abundance ratio while their more accurate mass spectrographic abundance measurements had for their average error 2.5%, which is equivalent to 6 γ. They found no significant variations in the isotopic composition of the oxygen between the stony meteorites and terrestrial silicate rocks, and they concluded that the absolute value of the abundance ratio O^{18}/O^{16} is 0.973/500. In a slightly more accurate mass spectrographic investigation of this abundance ratio in the oxygen from the thermal decomposition of

(2) S. H. Manian, H. C. Urey and W. Bleakney, THIS JOURNAL, 56, 2601 (1934). This paper contains many references to earlier investigations concerning possible variations in the abundance of isotopic elements in meteors.

(3) The symbol refers to excess density of sample over that of normal water in parts per million; a negative value of γ means that the sample of water is lighter than normal. In this paper we shall take purified Lake Michigan water as being our standard of normal water.

lead dioxide, Smythe[4] obtained 0.994/500. Since both of these values are within the experimental error equal to the rounded-off ratio 1/500, we shall adopt the latter for the calculations of this paper.

Urey and Greiff[5] estimated the statistical mechanical partition functions for the molecular species CO_2^{16}, CO_2^{18}, H_2O^{16}, H_2O^{18}, from which they calculated that if carbon dioxide gas is brought into equilibrium with liquid water at 0°, the O^{18} isotope will concentrate in the gas phase until its abundance ratio becomes 1.046/500 or +10.3 γ. Weber, Wahl and Urey[6] checked this prediction experimentally. Urey and Greiff calculated also the isotopic exchange equilibrium constants for many other reactions, but the carbon dioxide–water equilibrium is the one of interest to us here. A relatively large variation in the oxygen isotope ratio in natural substances was first demonstrated by one of us,[7] who found that if the oxygen isotope ratio O^{18}/O^{16} in Lake Michigan water is taken as 1/500, then that of atmospheric air is 1.029/500 or 6.6 γ. This abnormality in the distribution of the heaviest oxygen isotope may be caused by the equilibrium

$$O_2^{16} + 2H_2O^{18}\,(g) \rightleftharpoons O_2^{18} + 2H_2O^{16}\,(g) \quad (1)$$

being set up in the stratosphere at −50° under the action of the ultraviolet light from the sun, or it may be due to the isotopic exchange equilibrium existing on the surface of the earth

$$2H_2O^{18}\,(l) + CO_2^{16}\,(g) \rightleftharpoons 2H_2O^{16}\,(l) + CO_2^{18}\,(g) \quad (2)$$

followed by the irreversible reaction

$$CO_2^{10}\,(g) + H_2O^{0}\,(l) \xrightarrow{\text{chlorophyll}} (HCHO^{6.6})_x + O_2^{6.6} \quad (3)$$

as suggested by Greene and Voskuyl.[7] In Eq. (3) the superscripts on the oxygen symbols represent the value of γ for each sample of the element.

Since the exact or average temperature at which reaction (2) takes place is unknown at the present time and since the extent of irreversibility of reaction (3) is also unknown, we cannot state definitely the mechanism giving rise to the greater abundance of O^{18} in the atmosphere. We are inclined, however, to the theory postulated by Greene and Voskuyl, because it is believed by geologists that all our atmospheric oxygen arose through the agency of the photosynthesis reaction. The theory of Greene and Voskuyl is also substantiated in part by the work of Morita, Goto and Titani,[8] who decomposed cane sugar in the presence of deuterium-free hydrogen, obtaining thereby 73% of the oxygen of the sugar in the form of water whose density could be measured. They found that the average γ-value of the water obtained in this way was 4.6 γ (6.6 γ was predicted by Greene and Voskuyl assuming no exchange of the sugar oxygen with the oxygen of water); if the oxygen of the sugar had been obtained entirely from water, its γ-value would naturally have been zero.

Continuing the study of oxygen isotope abundance ratios, we decided to investigate carbonate rocks and iron oxide ores, not only because of the interest in these important rocks and because of the ease in recovery of the oxygen in the form of water, but also because ores precipitated during widely different geologic eras could be obtained, thus making it possible to study the isotopic composition of the oxygen as a function of age. There was the additional possibility that some inferences might be drawn from the data concerning the origin of the oxygen in the rocks; *i. e.*, whether the oxygen came from water or from the air.

Part I. Carbonate Ores

Experimental

Density Measurements.—The most sensitive method of detecting slight variations in oxygen isotope ratios is the well-known totally submerged float method. The chief improvement adopted by us in this research was the use of a platinum resistance thermometer to measure the temperature of floating equilibrium of the float. In the first measurements a fairly large cylindrical quartz float, volume 10 cc., which balanced at 29.9° was used, but although this float was more sensitive than the smaller, 1 cc. Pyrex float used later, see Fig. 1, and did not have to be corrected for expansion with rise of temperature, we abandoned it in favor of the Pyrex "swimmer" which reached floating equilibrium at 25.0°; because the latter was not "pressure sensitive" and because the smaller size of the float enabled us to reduce from 60 to 15 cc. the volume of water actually used in the density measurement. In Fig. 2 we illustrate the velocity of the quartz swimmer as a function of depth of immersion; naturally a pressure correction had to be applied for each measurement, not only for

the weight of water above the float, but also because of variations in barometric pressure from day to day. In all the calculations of density obtained from the velocity readings on the Pyrex swimmer, the expansion of the latter with rise of temperature was corrected for by taking 9.6×10^{-6} as the volume coefficient of expansion of Pyrex. The density of a large sample (300 cc.) of standard water

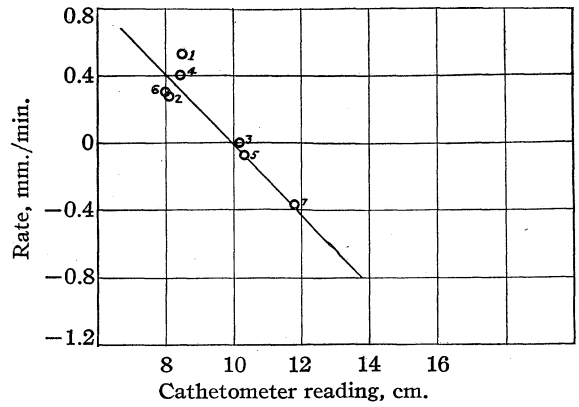

Fig. 2.—Velocity of float as function of position in water.

was compared with that of a 300-cc. sample of a light water, using both the Pyrex and quartz floats. All samples of water, both the standard and the light water, were purified and distilled in exactly the same way. With the Pyrex float the light water gave a γ-value of -12.9 while -12.8 γ was obtained with the quartz float; thus, despite the different floats, temperatures and correction factors employed in the two comparisons, the results were identical within the experimental error of 0.1 γ.

Most of the density measurements using the Pyrex float were made during a three-month interval; the data of Table I indicate that no significant change in the temperature of floating equilibrium of the Pyrex swimmer in the standard water occurred during this period (the samples of standard water were taken from the same large stock of laboratory distilled water). Furthermore, no pressure dependence of the floating temperature is indicated and in the nineteen measurements recorded, only four give results deviating from the mean by more than 0.22 γ. The average fluctuation is 0.17 γ. Apparently the small 1 cc. cylindrical Pyrex swimmer is a satisfactory float.

Occasionally it was found necessary to clean the Pyrex float with a warm solution of mixed concentrated nitric and sulfuric acids.

The wooden box containing the Mueller bridge of the platinum resistance thermometer was housed in a larger wooden air constant temperature bath, lined with two layers of $^3/_4$-inch (2-cm.) celotex, whose temperature was maintained constant at 30° to a few hundredths of a degree. The platinum thermometer of 20 ohms resistance (at 0°) could not be immersed directly into the water under investigation because the electric current flowing through the thermometer during a measurement caused too great a heating effect in the small sample of test water, although a two-volt rather than a six-volt battery was used as the source of bridge current. The platinum thermometer was therefore placed in the inner bath of the constant temperature water-bath whose outer bath temperature was controlled by the usual mercury–toluene thermostat, relay, heating and cooling coils arrangement. The temperature of the outer water-bath which fluctuated about ±0.002° was varied at will by a screw mechanism on the contact wire of the thermostat; the temperature of the inner bath through which water slowly circulated from the outer bath varied about ±0.0002° while the tempera-

ture of the test water remained even more constant. The constancy of the temperature of the inner bath can be judged from the data plotted in Fig. 2 (the number by each circle indicates the order in which the observations were made) where the maximum variation from the straight line corresponds to a fluctuation in temperature of 0.0001° (except for the first measurement, which was probably taken before temperature equilibrium was reached).

The velocity of the float was observed and measured with a travelling telescope, millimeter scale and stop watch. By taking measurements both on the slightly hotter and slightly colder sides of the temperature of floating equilibrium, the latter could be interpolated quite accurately from a plot of the observed velocities and temperatures such as illustrated in Fig. 1. We believe that the actual density measurements were obtained with an error less than $\pm 0.1\ \gamma$, and that our chief sources of error were contained in the chemical reactions used in liberating the oxygen from the rocks and in the process of purifying and distilling the impure condensates from the reduction experiments.

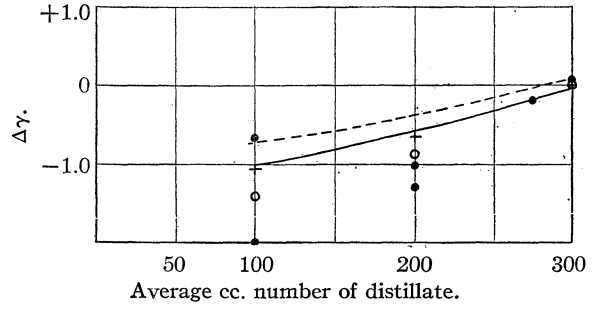

Fig. 3.—Change in water density on distillation: ○, standard water; +, sample (C) of D-free water; ●, sample (B) of D-free water.

Purification and Distillation of Water Samples.—The more accurate density measuring apparatus required much more careful preliminary treatment of the water than that used in our previous investigations. As Greene and Voskuyl[9] have recently stated, "It should be remembered that a number of successive distillations are usually made in the purification of samples of water so that although the change in density caused by a single distillation is small, the total change occasioned by the purification may be significant. The fact that this change in the case of deuterium-free water is different from and less than the change with ordinary water must also be taken account of in determinations of the deuterium–protium ratio by the method of densities." We adopted the following procedure in the treatment of the 300-cc. samples in the first case (when using the large quartz swimmer) and the 40 cc. samples in the second case. The 300-cc. samples of water were placed in a 500-cc. Pyrex distilling flask, and completely distilled from alkaline permanganate through a two foot (61-cm.) 30 mm. Pyrex tube packed with copper oxide and heated to 550°. All the water was distilled in this purification step to avoid any isotopic fractionation; the copper oxide column effectively prevented any permanganate solution spray from contaminating the condensate. The sample was then distilled from acid permanganate in a flask fitted with a bulb spray trap through a block tin condenser. The middle 100-cc. fraction was used in the density determination. To check the density measurements, the entire sample, including the 100 cc. rejected initial and end fractions, was redistilled as before. By recombining the various distillation fractions, the accumulation of errors due to repeated isotopic fractionation was prevented. The treatment of the 49-cc. sample was similar except that the bulb spray trap was steam-jacketed to prevent additional fractionation in the column, and the various glass connections and the glass to block-tin joints were made tighter since it was found that no water could be lost during the distillations without isotopic fractionation errors entering in. The sample taken for analysis consisted of the eleventh to the twenty-fifth cc. of the forty cc. sample, and the distillation rate was adjusted to a speed of one cc. per minute. The 15 cc. middle fraction was out-gassed with a water pump for one minute at 35° with continuous shaking, and allowed to stand in the constant temperature bath for half an hour before making the float velocity observations.

The standard Lake Michigan water taken from the large stock of laboratory distilled water was purified and distilled in exactly the same way as the test samples. We discuss below the question of the density differences between our standard water and the water used by other investigators.

Several experiments were performed to test the isotopic fractionation of the water in our distilling apparatus. For this purpose large (450-cc.) samples were used, the first 50 cc. of water to be distilled was rejected, the next three 100-cc. portions were separately collected and their densities measured. The 500-cc. distilling flask was equipped with a steam-jacketed spray trap and the water condensed in a block-tin condenser. Sample A (represented by the open circles in Fig. 3) was the standard water, Sample B (closed circles of Fig. 3) was nearly deuterium-free water whose oxygen was air oxygen, and Sample C was water that resulted from two electrolytic fractionations to remove the deuterium, γ-value equal to -16 (represented by crosses in Fig. 3). Changes in density only are plotted in Fig. 3, the curves being adjusted vertically to coincide at the density of the third 100-cc. portion whose density, theoretically, should be nearly identical with that of the water before distillation. The dotted line in Fig. 3 represents the changes in density to be expected on the basis of one theoretical plate in the case of D-free water and the solid line, the density changes for normal water. These calculations were made using the Rayleigh distillation formula and the fractionation factors adopted by Greene and Voskuyl.[9] The observed changes are within a few tenths of a part per million of the theoretical; in one case the distillation of D-free water produced smaller changes in density than the normal water, as expected, but in the case of Sample B the density changes were larger and fluctuated more. Evidently this last distillation was not carried out in the same manner as the other two; perhaps the water was actually impure so that the γ-values of Fig. 3 represent a change in the purity of the water. In the dis-

(9) C. H. Greene and R. J. Voskuyl, THIS JOURNAL, **61**, 1342 (1939).

tillations of the 40-cc. samples we calculate that the 15-cc. distillate was 0.58 γ lighter than normal in the case of the standard water and 0.41 γ lighter than the original sample in the case of D-free water. The difference between the changes in the two distillations, 0.17 γ, is negligible in view of the experiments to be described. We conclude that an uncertainty of about ± 0.2 γ results from isotopic fractionations on distillation in our experiments.

Reduction of the Carbonate Ores.—Most of the carbonate ore experiments were performed on Grenville marble from the Gouverneur Marble Quarry, Gouverneur, N. Y. The Grenville formation is one of the oldest geologic deposits, with a reputed age of 1.2 billion years. Niagara dolomite and Pennsylvania limestone of the La Salle formation, about 0.5 billion year old, and clam shells of recent origin also were investigated. All of these carbonate samples were supposed to be laid down from large bodies of water (oceans); we did not investigate any carbonate rocks precipitated from fresh water. Some synthetic barium carbonate made in the following way was also studied. Five liters of water whose oxygen came from the air were prepared and in this water anhydrous barium chloride was dissolved. Carbon dioxide also containing atmospheric oxygen was obtained by burning charcoal in dry, carbon dioxide-free air. After passing the gases from the charcoal combustion over hot copper oxide and calcium chloride, they were then mixed with ammonia and passed into the barium chloride solution contained in several absorption vessels connected together in series. Barium carbonate was precipitated, the nitrogen and some of the ammonia sweeping out through the absorption system. When the last absorption bottle showed traces of the carbonate, the process was stopped, the barium carbonate filtered off, and the filtrate returned to the absorption bottles. The barium carbonate was dried at 160°, the water vapor being condensed and added to the filtrate. In this way barium carbonate was prepared containing oxygen of known isotopic composition provided no fractionation of the oxygen isotopes occurred in the precipitation. We discuss this point below.

The natural carbonate rocks were broken up in a rock crusher to pebble size and treated in two different ways to eliminate the oxygen. The easiest method to accomplish this consists in the treatment of the rock with hydrochloric acid, followed by reduction of the carbon dioxide evolved with hydrogen over a nickel catalyst to methane and water. A large quantity of the rock was placed in a tall Pyrex tube and 6 *N* hydrochloric acid dropped on the rock at a constant rate using a constant head device. The apparatus was so arranged that the spent acid and calcium chloride solution could automatically siphon off. After the evolved carbon dioxide had been passed through a glass wool spray and dust trap and through a drying chamber, it entered the electrically heated catalyst chamber along with practically D-free hydrogen with the hydrogen–carbon dioxide volume ratio slightly in excess of four to one. The catalyst was pumice supported nickel heated to 280–300°. The water resulting from the reduction was condensed in a water condenser and the last traces frozen out in a dry ice–acetone trap. The yield was about 90% of the theoretical, assuming the rock to be pure calcium carbonate.

Since the exact isotopic composition of the hydrogen was not known, although it was nearly D-free, the methane resulting from the reduction was burned with air over hot copper and the density of the resulting water determined.

From isotopic fractionation considerations this method of winning the oxygen is not entirely satisfactory since the acid treatment leaves one third of the carbonate oxygen in the calcium chloride solution, thereby giving rise to the possibility of isotopic fractionation. To measure the extent of this uncertainty several samples of Grenville marble were pyrolyzed in iron tubes at high temperatures (from 800–1000°), the thermally evolved carbon dioxide stored over glycerol in 50-liter acid bottles, and later reduced to water and methane as in the acid treatment. The efficiency of the thermal decomposition method was about 80%.

All the data collected in the carbonate rock research are presented in Tables II and III.

TABLE II

DENSITY DATA OBTAINED IN PRELIMINARY EXPERIMENTS

No. of sample	Description of water	γ
1	Lake Michigan water	+0.35
2	Lake Michigan water	+ .32
3	Lake Michigan water	+ .44
4	Tank No. 1 CO_2 in large excess reduced with tank H_2	−4.92 −4.73
5	Tank no. 1 CO_2 reduced with tank H_2 in stoichiometric proportion	−3.77 −3.61
6	Water from combustion in air of CH_4 from expt. 5	−4.98 −5.30
7	Tank H_2 combined with air O_2	−6.39 −6.26
8	Tank no. 2 CO_2 reduced with excess D-free H_2	−8.59 −8.69
9	Water from combustion in air of CH_4 from expt. 8	−8.56 −8.69
10	Water from combustion in air of D-free H_2 similar to that used in expt. 8	−8.69 −8.65

Discussion

We must first consider the density of the standard water we have chosen as a reference in relation to purified Lake Michigan water, and in relation to standard waters selected by other investigators. In this research we made one density measurement on three samples of purified Lake Michigan water with the results given in Table II, 1, 2, and 3. The average of these data, 0.37 γ, indicates that the laboratory distilled water is slightly lighter than the purified lake water, but in another research more recently performed,[10] Mr. J. A. Swartout could detect no difference between the two waters greater than ± 0.1 γ. In Mr. Swartout's research more than one density measurement was made on each sample, so that

26	Acid treatment of special barium carbonate	−9.6	−9.6	− 8.59 − 8.53	+15.2	5.6

we consider his results more reliable. In any case the difference is so slight that we shall consider it negligible.

It is more difficult to demonstrate the relation between our standard and standards used in other researches. Greene and Voskuyl[9] found that Cambridge, Massachusetts, tap water is 0.61 γ lighter than Lake Michigan water, Hall and Jones[11] found that Lake Mendota (Madison, Wisconsin) water is 0.3 γ lighter than Lake Michigan water, but Greene and Voskuyl found Lake Mendota water to be +0.16 γ heavier than Lake Michigan water. Greene and Voskuyl found the density of purified ocean water taken one mile off shore at Gloucester, Mass., to be 1.8 γ greater than their standard while we found[10] water taken 45 miles off shore at Gloucester to be 1.7 γ heavier than our standard. If we correct this measurement to the Greene and Voskuyl standard, we obtain +2.3 γ for the density of ocean water which agrees with the value found by Greene and Voskuyl for ocean water taken about 200 miles East of Cape Race, Newfoundland (Lat. 45° 13′ N.; Long. 49° W.). Incidentally this last water could hardly be considered as coming from the "Mid-Atlantic" and must consist very largely of arctic current water. From this point of view there seems little reason to believe that water from 45 miles off Gloucester should be different from Greene and Voskuyl's "Mid-Atlantic" water; hence we conclude that we should apply the correction of −0.6 γ to bring our standard water into coincidence with Greene and Voskuyl's standard. However, in an earlier publication Greene and Voskuyl[7] give +6.0 γ as the density of water containing normal hydrogen and atmospheric oxygen whereas our new result recently published[10] would be +7.0 γ instead of 6.6 γ if to the latter we applied a correction of 0.4 (two-thirds of 0.6 γ, which would be the contribution due to oxygen isotopic fractionation). Because

(11) N. F. Hall and T. O. Jones, THIS JOURNAL, **58**, 1915 (1936).

of these conflicting lines of evidence we shall leave unsettled for the time being the exact difference between Cambridge, Mass., tap water and Lake Michigan water.

The difference in γ-values for water samples 4 and 5 of Table II indicates that the carbon dioxide should be reduced with hydrogen in excess while the data for samples 6 and 7 indicate that D-free hydrogen should be used in the catalytic reduction. Experiments 8, 9, and 10 prove clearly that the use of D-free hydrogen is justified and that the method of hydrogen analysis by combustion of the unused hydrogen and methane produced in the catalytic reduction is sound.

In Table III are collected all the density data obtained in the carbonate experiments. For some inexplicable reason the first density measurements of the water from the methane combustions gave too low results since water made from air and containing no deuterium has for its minimum density, $-8.9\ \gamma$; yet in some of the experiments listed in Table III we found $-9.9\ \gamma$ and $-10.1\ \gamma$. Toward the end of this research, the reduction of the carbon dioxide from the acid treatment of the Grenville marble was repeated and the density of the water formed in the reduction and in the methane combustion carefully redetermined with the results given under experiment no. 16 of Table III. The density of the water obtained from the reduction of the carbon dioxide agreed well with that obtained in the first experiment, no. 15 of Table III, thus indicating that the early results on the water from the carbon dioxide reduction were correct, but the density of the water from the methane combustion was different from the earlier figure, yet entirely reasonable and close to the expected value. For this reason we have disregarded the early data on the densities of the water from the methane combustion and estimated the correction to be applied to bring the hydrogen of the water to normal from the later more accurate results. If the hydrogen were completely D-free, the correction would be $-15.5\ \gamma$[10]; all the corrections used in Table III are within one part per million of this figure.

The last column of Table III contains the values of the excess density over normal water of the water containing the oxygen under consideration and normal hydrogen. First of all it is interesting to note from experiments 11 through 16 that no significant difference (*i. e.*, any difference greater than 1 part per million) exists between the isotopic composition of the oxygen in the oldest rocks (Grenville marble) and the youngest (clam shells). We can make the tentative conclusion, therefore, that there has been no change in the isotopic composition of the oxygen in the oceans (from which these rocks were precipitated) over a period greater than a billion years. We must assume in making this last statement that the oxygen at present in the rocks is identically the same oxygen that was originally in the rocks when they were first laid down. Nier and Gulbransen[12] have recently similarly demonstrated in a mass-spectrographic study of the carbon isotopes in Grenville carbonates and clam shells that no apparent change in this ratio has occurred during a period of 1.2 billion years.

From Table III it is evident that a slight difference exists between the data obtained in the acid treatment of the rocks and in the thermal decomposition. The average value of γ for the acid treatment on the Grenville marble (omitting no. 17) is $9.2\ \gamma$ whereas the thermal decomposition of the Grenville marble gave $7.9\ \gamma$ as the average difference in density omitting the data obtained in experiments 20 and 22 in which some of the carbon dioxide liberated was lost. In experiment 17 the Grenville marble was decomposed with hydrochloric acid made by dissolving anhydrous hydrogen chloride in water made from the oxygen of the air. This experiment was performed to see whether the isotopic composition of the oxygen in the water of the acid solution influenced in any way the isotopic ratio of the oxygen in the liberated carbon dioxide, but as the results indicated very little effect was noted; increase in the density of the water due to the oxygen by $6.6\ \gamma$, changed the final results for experiment 17 by only $0.7\ \gamma$. The reason for the absence of any pronounced effect here is the rapidity with which the carbon dioxide is evolved, insufficient time being allowed for equilibrium with water to be attained. Since no measurable fractionation of the oxygen isotopes at the high temperatures of the thermal decomposition is to be expected, we can accept the thermal decomposition result, $7.9\ \gamma$, as giving the true oxygen isotope ratio, 1.034/500, in the carbonate rocks.

The difference between 9.2 and 7.9, or $1.3\ \gamma$, must be explained by the isotopic fractionation which takes place when the carbonate is decomposed by the acid. Whether fractionation also

(12) A. O. Nier and E. A. Gulbransen, THIS JOURNAL, **61**, 697 (1939).

occurs at the time of the precipitation of the carbonate was tested by studying the synthetic barium carbonate made in two ways. In experiments 24 and 25, the carbonate was precipitated by adding carbon dioxide made from oxygen of the air to water made from oxygen of the air. If, on liberation of the carbon dioxide, no isotopic fractionation had taken place at any step in the process, the γ-value of the water obtained by the carbon dioxide reduction should be equal to 6.6, but the value 8.5 was found, Table III. This difference, 1.9 γ, is slightly greater than the value 1.3 γ mentioned above, but it is sufficiently close to it to conclude that a greater fractionation of the oxygen isotopes occurs when the carbonate ion decomposes than when it forms. Some barium carbonate was also prepared by adding carbon dioxide containing oxygen of the air to normal water. In this case one would expect the density of the water resulting in experiment 26 to be $\frac{1}{3}$ (6.6 + 6.6 + 0), or 4.4 γ. Actually 5.6 γ was found, or 1.2 γ greater than expected. This also agrees well with the difference, 1.3 γ, found between the results of the acid and thermal treatments of the carbonate.

Having reached the conclusion that the oxygen isotope fractionation probably occurs mainly when the carbonate is decomposed rather than when it is precipitated, it is possible and of interest to suggest a mechanism to explain the excess value of the atomic weight of oxygen in the rocks. When carbon dioxide is brought into equilibrium with water, the heavier isotopes of oxygen concentrate in the carbon dioxide phase, the fractionation factor for the O^{18} isotope being 1.047 at 0° and 1.039 at 25° as Urey and Greiff have calculated.[5] When this carbon dioxide dissolves in ocean water whose oxygen is 1.2 γ heavier than Lake Michigan water, the calcium carbonate precipitated should contain oxygen whose γ-value (when converted to water) is the average of the oxygen in the water and in the carbon dioxide. Thus at 0° we have for the carbon dioxide a γ-value equal to 11.5 and for the water, 1.2 γ, the average being $\frac{1}{3}$ {2(11.5) + 1.2} or 8.2 γ. At 25° a similar calculation yields 7.0 γ as the theoretical value for the oxygen in the carbonate rocks. Unfortunately no measurements have been made of the γ-value of the oxygen in atmospheric carbon dioxide and we do not know the average temperature to use in calculating the fractionation factor; however, our experimental result, 7.9 γ, is slightly less than that calculated for 0°, and thus agrees with the theory reasonably well.

Part II. Iron Oxide Ores

Experimental

Composition of the Ores.—The iron ores studied were classified geologically as follows: first, a sample from the Soudan mines in the Vermillion range representing an ore of the Keewatin period, 1.5 billion years old; second, a Middle Huronian iron ore from the Mesabe range (Biwabik iron formation), 1.0 billion years old; third, a Silurian iron ore of the oölitic type from Clinton, N. Y., 375 million years old; and fourth, another Silurian ore of the same age, also from Clinton, containing small fossils. Since the data obtained in the case of the last two ores made us suspect that they might contain carbonates whose oxygen would probably be quite different in isotopic composition from the oxygen of the iron oxide, the ores were analyzed with the results given in Table IV.

TABLE IV

COMPOSITION OF SILURIAN IRON OXIDE ORES IN PER CENT.

	H_2O	Fe	Ca	CO_2	Residue unreactive to acid
Oölitic	1.4	34.2	7.29	8.1	16.2
Fossil	1.2	23.9	13.25	28.7	7.0

The Keewatin ore contained no detectable water, but 450 g. of the Middle Huronian ore evolved 20 cc. of water (4.4%) on being heated to red heat in a slow stream of nitrogen. No detectable carbonate was present in either the Keewatin or Middle Huronian ore.

Reduction of the Ores.—All the ores were reduced in Pyrex tubes heated to 600° in an electric furnace; the hydrogen used was practically deuterium-free, and the water formed was first condensed in a water condenser and then the last traces frozen out in a dry-ice–acetone trap. The reduction usually lasted from thirty to sixty hours.

Purification of Samples and Density Measurements.—In all of the iron ore experiments the water distillation and density measurement technique was exactly the same as that described in Part I of this paper. The data are collected in Table V where the last column gives the final corrected γ-value for the oxygen in the ores.

Discussion

From experiments 1, 2, and 3 it is evident that the oxygen in the iron oxide of the Keewatin and Middle Huronian ores has the same isotopic composition as the oxygen in water, within the experimental uncertainties, but the data are not accurate or conclusive enough for us to state whether the oxygen corresponds to the oxygen of ocean water or to that of fresh (rain) water. Probably the former is the case since the average of the three reductions is +0.9 γ, fairly close to +1.2 γ, which is the value for the oxygen in ocean water. In expt. 3, 83.5% of the ore was reduced,

TABLE V

DATA OBTAINED IN THE ISOTOPIC ANALYSIS OF IRON ORES

Expt.	Type of ore	Ore, g.	Water obtained, cc.	Density of water		Correction for hydrogen	Density of water due to oxygen
1	Keewatin	400	51	−13.80	−13.67	+14.9	+1.2
2	Middle Huronian	450	61	−13.57	−13.57	+15.2	+1.6
3	Middle Huronian	310	87.5	−14.7	−14.7	+14.6	−0.1
4	Silurian (oölitic)	350	46	−11.62	−11.43	+15.0	+3.5
5	Silurian (fossil)	345	41	−10.06	−10.06	+14.6	+4.5

assuming it to be pure hematite, so that one might be inclined to give greater weight to the result for this experiment, yet we can think of no reason why a partial reduction of the ore at red heat should favor one or the other of the isotopes. We can conclude definitely, however, that the Keewatin and Middle Huronian ores contain very little, if any, oxygen which was in the atmosphere before being bound to the iron. The conclusion of the geologists that these ores were formed by precipitation from water seems to be completely substantiated.

The presence of the carbonates in the Silurian ore may have been responsible for the greater density of the water obtained on reduction of these ores by virtue of either of the following sets of reactions

$$CaCO_2 \xrightarrow[\text{heat}]{} CaO + CO_2$$
$$CO_2 + 2H_2 \longrightarrow 2H_2O + CH_4 \quad (4)$$

$$FeCO_3 \xrightarrow[\text{heat}]{} FeO + CO_2$$
$$FeO + H_2 \longrightarrow Fe + H_2O \quad (5)$$

since the oxygen in the carbonate ores is heavier than normal. Of reactions (4) and (5) the latter seems the more probable as ferrous oxide would be reduced more readily than carbon dioxide, yet we estimate that some carbon dioxide must have been reduced to give a total of 41 cc. of water which is more than complete reduction of all the iron oxides present would yield. We conclude that enough water was formed from the oxygen of carbonates in both the fossil type and oölitic type experiments to account for the small excess in observed density.

Acknowledgments

We are greatly indebted to the Alexander Dallas Bache Fund of the National Academy of Sciences for a grant with which the platinum resistance thermometer and accessory equipment was purchased, as well as to Northwestern University for a grant from its research fund. We wish to thank Mr. J. S. Brown of the St. Joseph Lead Company for going to the trouble and expense in providing us with several large sections of Grenville marble, and particularly do we wish to thank Professor C. H. Behre, Jr., and other members of the Department of Geology and Geography at Northwestern for aid in procuring geologic samples and for many helpful suggestions.

Summary

1. Improvements in density measuring apparatus have been developed and applied to the isotopic analysis of oxygen in carbonate rocks and iron oxide ores.

2. A study of Grenville marble, Niagara dolomite and Pennsylvania limestone and clam shells, all carbonates of widely different geologic age, reveals no significant difference in the isotopic composition of the oxygen in the rocks as a function of age.

3. The oxygen of the Grenville marble when liberated as carbon dioxide with acid and reduced with hydrogen gives water 9.2 p. p. m. heavier than normal, but when the carbon dioxide is driven out of the rock thermally, the resulting water is only 7.9 p. p. m. heavier. The difference in these two data is attributed to the isotopic fractionation which takes place when the carbonate ion is decomposed by acid.

4. The observed value of 7.9 p. p. m. can be explained quantitatively with the aid of the isotopic exchange equilibrium theory of Urey and Greiff.

5. The oxygen in iron ores of the Keewatin and Middle Huronian ages does not differ significantly in its isotopic composition from that of oxygen in normal water, the slight excess density observed in the experiments on the oölitic and fossil type Silurian ores is probably due to the presence of carbonates in the ores.

The Bromine–Bromine Distance in the Dibromides of *cis*- and *trans*-Stilbene[1]

BY JAMES D. McCULLOUGH

The configuration of the products resulting from the addition of halogens to the double bonds of *cis* and *trans* isomers has been of considerable interest in connection with the problem of restricted rotation about the resulting single bond.

Weissberger has measured the electric dipole moments of the stilbene dichlorides[2] and dibromides[3] in benzene solution. His results are shown in Table I. The difference in moment for a given pair of isomers indicates a lack of free rotation in at least one member of the pair, since completely free rotation in both members would lead to identical moments. The low moment of the *meso* dibromide is an indication that the bromine atoms are restricted to the *trans* position or nearly so, the slight deviation from zero moment being possibly due to thermal vibration.

TABLE I

ELECTRIC DIPOLE MOMENTS

	meso	*dl*
Stilbene dichlorides	1.27 *D*	2.75 *D*
Stilbene dibromides	0.4–0.9 *D*	2.8 *D*

Rate studies have been made in this Laboratory by Young, Pressman and Coryell[4] for the reaction between potassium iodide and the dibromides of various pairs of *cis–trans* isomers. It was found for each pair investigated that the rate of reaction of the *trans* derivative is faster and the heat of activation smaller than for the corresponding *cis* derivative. Young and Pressman[5] have attributed these differences to restriction of the rotation about the single bond between the two carbon atoms carrying the bromine and have correlated the specific reaction rate constants with the configurations postulated on the basis of preferred orientation due to this restriction. It was in connection with this work that the present problem presented itself and the author is indebted to Dr. Young and Mr. Pressman for the pure crystalline materials used in this investigation.

Although free rotation about the carbon to carbon single bond in question in the stilbene dibromides would seem highly improbable in the crystalline solids, there is, it seems, a high degree of probability that if there is a preferred orientation in the liquid or dissolved state the same or very nearly the same orientation will also be assumed by the molecules on entering the crystal.

Taking 1.54 Å. as the carbon to carbon single bond distance, 1.91 Å. for the carbon to bromine distance, and tetrahedral bond angles, one may calculate the expected bromine–bromine separation for the absolute *cis* position to be 2.82 Å. and for the absolute *trans* position 4.57 Å. Thermal vibration at room temperature would make the average separation for *cis*-restricted molecules greater and for *trans*-restricted molecules less than these calculated values.

For purposes of describing the configuration about the bond, use is made of the azimuthal angle, ϕ, such that ϕ is 0 for the *cis* position and 180° for the *trans*. Using the above angles and distances, the bromine separation, l, then becomes

$$l = [7.95 + 6.48\ (1 - \cos\phi)]^{1/2}$$

The method employed in measuring this distance was the radial distribution treatment essentially as described by W. V. Medlin.[6]

In this treatment the radial distribution function, $4\pi r^2 \rho(r)$, is given by the following summation over all lines observed on the photograph

$$4\pi r^2 \rho(r) = 4\pi r^2 \rho_0 + \frac{2r}{\pi} \sum_{i=1}^{i=\infty} s_i I_i \sin s_i r$$

where $s = 4\pi \sin \Theta_i/\lambda$, Θ_i being the Bragg angle or one-half the scattering angle for the ith line on the film, λ the wave length of the X-rays and I_i the intensity of the ith line.

The above function represents the product of scattering powers in volume elements which are separated by the distance r as a function of this distance. The magnitude of these maxima will be proportional to the products of the atomic numbers of the atoms involved. When one particular

kind of atom is much heavier than any of the others present, as is the case in the present study, maxima due to the interaction of these heavy atoms with each other may be so strong as to blank out all other effects. Thus bromine–bromine interaction will be $(35)^2$ as compared to 35×6 for bromine–carbon and $(6)^2$ for carbon–carbon or in the approximate ratio of 35:6:1.

The crystalline samples of the *meso*- and *dl*-stilbene dibromides were finely ground and passed through a 200-mesh sieve. The resulting powder was packed with only slight pressure into capillary tubes with a bore of about 0.3 mm. The cylinders thus formed were then pushed out of the capillary by means of a stiff wire and mounted in the X-ray camera. No collodion or other binder was used in holding the samples together.

Filtered radiation from a copper target was employed in a cylindrical camera of 5 cm. radius. Both of the photographs used showed 35 measurable lines, covering a range of $\sin \theta/\lambda$ out to 0.375 for *trans*-stilbene dibromide and to 0.318 for *cis*-stilbene dibromide. The intensities were estimated both visually and with the aid of microphotometer tracings made on the Smith–Leighton–Hensen microphotometer at Stanford University, the two methods giving values in fairly good agreement. The weaker lines did not show on the tracings so it was necessary to rely entirely on the visual estimates for their intensities.

The relative intensities so obtained were corrected by means of the Lorentz and polarization factors and multiplied by a factor $e^{-B \sin^2 \theta}$ following the procedure of Medlin, so as to reduce the importance of the lines at large scattering angles. In both cases a value of $B = 7.5$ was used. Medlin has shown, and it was tested in this case as well, that the positions of the maxima are quite independent of the value of B.

The results of the summations are shown in Fig. 1, the constant term $4\pi r^2 \rho_0$ being omitted. In the case of *trans*-stilbene dibromide (the *meso* compound), only one maximum is observed and that at 4.50 Å. The small shelf just under 3 Å. may be due to carbon–bromine interaction caused by a carbon atom and a bromine atom not directly bonded to each other, but each bonded to a common third atom. The calculated distance for such a case is 2.8 Å. The large maximum is without doubt due to bromine–bromine interaction and the distance 4.50 Å. corresponds to nearly the complete *trans* position which, as pointed out before, would require a separation of 4.57 Å. The distance 4.50 Å. corresponds to an azimuthal angle of 154° or a displacement of 26° from the full *trans* position assuming a static model.

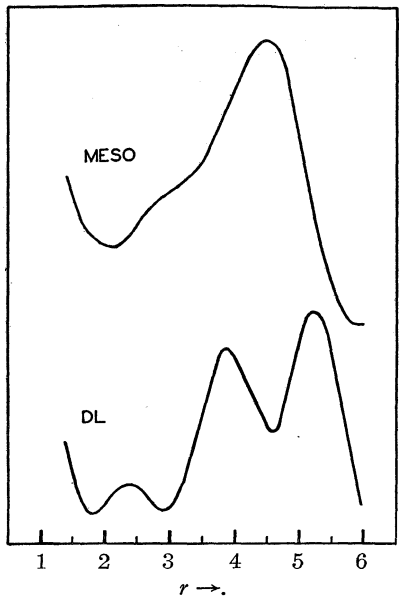

Fig. 1.—Radial distribution functions for the stilbene dibromides.

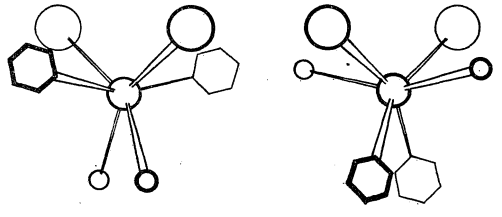
There is also the possibility that the single large maximum in this case is the resultant of two different pairs of bromine–bromine distances of nearly the same magnitude, one of them being within the molecule and the other due to bromines in different molecules. For example, the bromine separation within the molecule might be that for the full *trans*, 4.57 Å., and that for the pair on adjacent molecules about 4.4 Å., giving the observed peak at 4.50 Å. as an unresolved doublet. Only a more complete structure determination could answer this question. In spite of this difficulty, it still may be said safely that the bromine atoms are close to *trans* in configuration.

The function for *cis*-stilbene dibromide (the *dl* mixture), shows three maxima in the range covered, one small one at 2.40 Å. and larger ones at 3.85 and 5.25 Å. The value 2.40 is too small to be attributed to a bromine–bromine separation where the two atoms are not directly bonded to each other since the minimum distance between non-bonded bromine atoms in crystalline bromine at liquid air temperature is 3.30 Å. and twice the van der Waals radius is 3.80 Å. the normally

expected closest distance of approach of non-bonded atoms. The smallness of the peak, too, would eliminate it as being due to bromine–bromine interaction and it is therefore attributed to unresolved carbon–bromine interaction, from the bonded distance for these atoms of 1.91 Å. and the non-bonded separation of 2.82 Å. The maximum at 5.25 is to be attributed to a bromine separation in different molecules because the distance is greater than that for full *trans*. The remaining peak at 3.85 appears, therefore, to be the one due to the bromine atoms within the molecule. This distance corresponds to an azimuthal angle 90°. It is interesting to note that the bromine separation is only slightly different from twice the van der Waals radius for bromine which is 3.80 Å. If the phenyl groups were fully *trans* to each other, the bromine azimuthal angle would be 60°, requiring a separation of only 3.35 Å., which is less than twice the van der Waals radius. The tendency of the phenyl groups to be *trans* to each other would be opposed by the repulsion of the bromine atoms and the observed structure may be the resultant of these two forces. A second configuration with the phenyl groups 30° from *cis* to each other is also permitted by the observed bromine separation. In this case the bromine atoms would again be brought as close as possible to each other by the tendency of the phenyl groups to get apart. These two possibilities are shown in Fig. 2.



A B

Fig. 2.—Configurations permitted for the dibromide of *cis*-stilbene, looking down the axis of the bond between the two carbon atoms to which bromine is bonded. The circles represent in order of decreasing size, bromine, carbon and hydrogen atoms. The phenyl groups are indicated by means of hexagons. No significance is to be attached to the absolute sizes or scale used.

These findings lend support to the postulate of Young and Pressman and are in fairly good agreement with the electric dipole moments found by Weissberger[2] and shown in Table I.

In order to estimate the dipole moments expected for the observed bromine separation, the molecules were considered as being made up of two C_6H_5CHBr groups joined together by a carbon–carbon bond and rotated with respect to each other through the angle ϕ. If the component of the electric moment of the C_6H_5CHBr group perpendicular to the axis of the bond by means of which the two are joined is represented by m, and if polarization is neglected, the molecular dipole moment, μ, is given by the function, $\mu = 2m \cos(\phi/2)$.

The value of m was estimated by making use of the electric moment for benzyl bromide which was found by Mohler[7] to be 1.88 D. The moment of a C–H bond taken as 0.4 D[8] was subtracted vectorially and the component of the remainder perpendicular to the C–H bond was taken assuming tetrahedral angles. This procedure gives a value of 1.7 D for m. Making use of the values of ϕ calculated from the bromine–bromine distances, this leads to a moment of 0.8 D for the *meso* dibromide, which falls in Weissberger's range, and 2.4 D for the *dl* dibromide as compared to the observed value of 2.8 D. In this simplified treatment the phenyl groups have received no special attention and the same function is assumed for both the *meso* and the *dl* dibromides.

The author is indebted to Dr. William G. Young and David Pressman for their kindness in making available the crystalline dibromides from which the X-ray powder photographs were prepared.

Summary

The bromine–bromine separations in the molecules of the crystalline stilbene dibromides have been measured by means of the radial distribution treatment of X-ray powder photographs. The separation was found to be 4.50 Å. in the *meso* dibromide and 3.85 Å. in the *dl* dibromide. In the former, all like groups are *trans* to each other, while in the latter the bromine atoms are as close to each other as the van der Waals radius for bromine will permit. The results support the postulate of Young and Pressman and are in agreement with the electric dipole moments found by Weissberger.

The Anomalous Strength of *n*-Butyric Acid

BY H. O. JENKINS AND J. F. J. DIPPY

Thermodynamic dissociation constants[1] are now available for the saturated aliphatic *n*-acids extending from formic to nonoic acid and the following features have become apparent. In the first place there is a very pronounced fall in dissociation constant in going from formic to acetic acid. Second, although the general trend is for the acid strength to diminish as the alkyl chain lengthens and to approach a limiting value in the higher members of the series, there is a distinct increase in K in proceeding from propionic to *n*-butyric acid, and it has been suggested[1a] that this enhancing influence still persists in the succeeding *n*-acids (elevation of the dissociation constant being attributed to some interaction between the hydrogens of the γ-carbon and the carboxyl group). Further consideration is now given to this anomaly.

Undoubtedly some correlation exists between the length of the alkyl chain and the corresponding acid strength. For a working hypothesis we shall be concerned with the distance separating the carbon of the carboxyl group and the terminal carbon atom, or the terminal hydrogen in the case of formic acid. Table I gives these distances r (the carbon–carbon valency angle being taken as 109° in propionic acid) and the dissociation constants for the first three members of the series.

TABLE I

Acid	r (A)	$1/r^6$	$10^5 K$	$5 + \log K$
Formic	1.06	0.705	17.72	1.248
Acetic	1.54	0.075	1.75_5	0.244
Propionic	2.54	.004	1.33_5	.125

The distances are unambiguous, that is, they are not affected by the presence or absence of free rotation, and a plot of log K against $1/r^6$ reveals linearity (see Fig. 1). Moreover, a relation of this type predicts a limiting value for the dissociation constant of a *n*-aliphatic acid as the alkyl chain lengthens. The equation to the line using Napierian logarithms is $\ln K = a + b/r^6$ where b has the value 3.7×10^{-48} in absolute units; this approximates to $N\alpha_0\mu^2/RT = 10^{-46}$ where N is the Avogadro number, R the gas constant, T the absolute temperature if α_0, the polarizability of the carbon–carbon bond, is taken as 0.5×10^{-24} and μ, the inducing dipole, as $2D$.

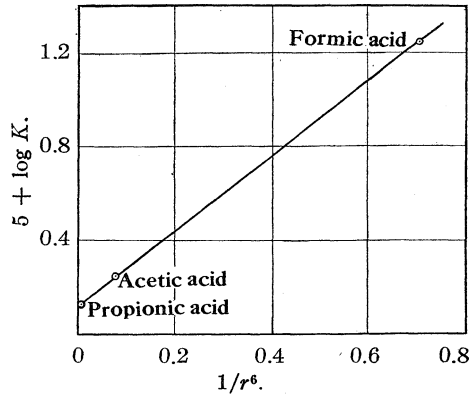

Fig 1.

Now proceeding to *n*-butyric acid and higher members of the series, we are confronted with the possibility that free rotation moves the γ-carbon atom from one extreme of a *cis* position, where it is in close proximity to carboxyl, to the other extreme of a *trans* position. An average distance is evidently needed and we shall use $(\bar{r}^2)^{1/2}$ the root mean square distance between the ends of the structure; this has been calculated for *n*-butyric acid to be 3.36 Å. by the method of Eyring,[2] assuming complete free rotation about the valence bonds and no distortion of valency angles. The formula is

$$\bar{r}^2 = c_1^2\{n + 2(n-1)\cos\theta + 2(n-2)\cos^2\theta \ldots + 2\cos^{n-1}\theta\}$$

where c_1 is the distance between consecutive carbon atoms and is the supplement of the carbon–carbon valency angle, taken as 109°. However, since this distance in the *n*-butyric acid molecule is larger than the corresponding distance in the propionic acid molecule, while K for butyric acid (1.50×10^{-5}) is also larger than that for propionic acid ($1.33_5 \times 10^{-5}$), clearly *n*-butyric acid is anomalous, using the linear relation as criterion. To bring butyric acid into conformity with the linear relationship, the distance r (as determined by graphical interpolation) should be 1.8 Å. and not 3.36 Å. as calculated from Eyring's formula. Two suggestions can be made as

(1) (a) Dippy, *J. Chem. Soc.*, 1222 (1938); (b) Harned, *et al.*, THIS JOURNAL, **55**, 652, 2379 (1933); (c) **56**, 1042, 2039 (1934).

(2) Eyring, *Phys. Rev.*, (2) **39**, 746 (1932).

to how the effective distance is decreased. First, the hypothesis of completely unhindered rotation in the *n*-butyric acid molecule may be abandoned. A consideration of the geometry of the system reveals that the minimum distance of approach of the terminal carbon atom to the carbon atom of the carboxyl group is considerably less than the root mean square value and equal to 2.5 Å.; thus it seems very likely that the rotation is practically frozen in the *n*-butyric acid molecule which thus exists in a "*cis*" configuration. In this connection it should be noted that the strengths of simple monobasic olefinic acids of the *cis* configuration are always greater than their *trans* isomers; this is well illustrated by the crotonic acids (10^5 *K; trans* 2.03, *cis* 3.6) which have a carbon system comparable to *n*-butyric acid. Furthermore, there is now considerable evidence of restricted rotation about a single bond, derived from dipole moment, infrared absorption spectra, Raman spectra and heat capacity studies; for instance, in the case of formic acid Bauer and Badger[3] have reason to believe that the hydroxyl group is firmly established in the *cis* position. A *cis* configuration for butyric acid is favored by the facts that the C–CH_3 and C–O dipoles are of opposite sign and that their mutual potential energy is greater than kT, the energy of thermal agitation. It is likely nevertheless that in order to account adequately for the complete restriction of rotation, other influences beside dipole attraction will have to be taken into consideration, such as the London attraction which has been used by Weissberger to explain the dipole moments of disubstituted diphenyl derivatives, and the fact that *cis*-dichlorethylene is the more stable[4] of the two isomerides at 300°. The dipole attraction, however, must play a part, and be less potent the higher the temperature. As the temperature is raised, therefore, we would expect the dissociation constant of butyric acid to fall; Harned and Sutherland[5] record the temperature of maximum K for butyric acid as 8°, whereas for acetic, propionic, and other acids[6] differing in strength by more than an order of 10, the corresponding values lie between 20 and 25°. Thus we have in *n*-butyric acid some factor entering which influences the "normal" temperature change of K exemplified by acetic acid and propionic acid, and at the same time the butyric system is the first in the homologous series in which the extent of freedom of rotation determines the effective distance r. Since this complicating factor of the existence of a restricting potential must occur in all the higher fatty acids extending from *n*-butyric acid, their strengths must be abnormally high. As a further consequence of this valeric and isovaleric acids should show a temperature dependence of K similar to that of *n*-butyric acid and not to propionic acid. Work on this problem is now proceeding.

Again, another factor which helps to reduce the effective distance in the *n*-butyric molecule is the extreme flexibility of the four carbon system compared with that obtaining in the three carbon system of propionic acid. An electron diffraction investigation of the valency angles in the *n*-butyric molecule would contribute materially to the solution of the anomaly of this acid.

Summary

A linear relationship has been discovered between the logarithms of the dissociation constants of formic, acetic and propionic acids, and the inverse of the sixth power of r, the distance separating the carbon of the carboxyl and the terminal group of the acid. This relationship predicts a limiting value for the higher acids. The slope of the line shows good agreement with a theoretical expression. As a deduction from this relationship the abnormality already recognized to exist in *n*-butyric acid has been interpreted in terms of the existence of a restricting potential in the molecule; this is in harmony with conclusions reached in infrared absorption, Raman spectra, heat capacity, and dipole moment studies.

Hydrogen Fluoride as a Condensing Agent. X.[1] Rearrangements

BY J. H. SIMONS, S. ARCHER AND D. I. RANDALL

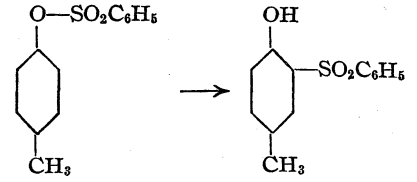
It has been found that a number of rearrangements commonly catalyzed by other condensing agents are also promoted by hydrogen fluoride. A few examples are reported here.

The exchange of alkyl groups by two aromatic compounds has been demonstrated repeatedly when aluminum chloride is employed.[2] Thus, polyamylbenzenes react with benzene to give monoamylbenzene.[3] We have found that *t*-butylbenzene reacts with phenol in the presence of hydrogen fluoride at 0° to give benzene and *t*-butylphenol, the latter in yields of about 10%. No attempt was made to carry out this conversion at higher temperatures, although it has been reported that disproportionation increases with temperature, when cymene is treated with aluminum chloride.[4]

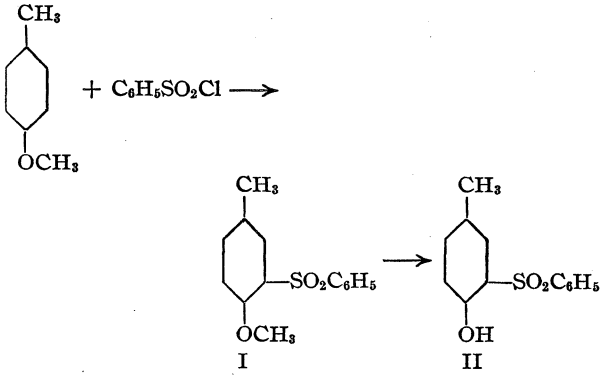
The conversion of a ketoxime to an anilide has been carried out in the cold using an acetic acid–hydrogen fluoride mixture, and also an ether–hydrogen fluoride mixture. Benzophenone oxime undergoes the Beckmann rearrangement with phosphorus pentachloride almost quantitatively, whereas with hydrogen fluoride under the conditions we employed only a 72% yield of benzanilide was obtained.

It has been reported previously that hydrogen fluoride would not effect a Fries rearrangement at room temperature.[5] This statement was amply confirmed by our observations of the behavior of phenyl acetate. A mixture of the ester and hydrogen fluoride gave no appreciable amounts of rearranged product. However, when warmed to 100° it was found that rearrangement to the *p*-acylphenol did take place, although there was much to be desired with respect to smoothness and yield.

A reaction similar to the Fries is the conversion of a phenol sulfonate to an hydroxy sulfone. Thus, in the presence of hydrogen fluoride at 100° *p*-cresyl benzenesulfonate was converted to 2-hydroxy-4-methyl-diphenyl sulfone in yields of 10%.



The hydroxy sulfone was synthesized by allowing *p*-cresyl methyl ether to react with benzenesulfonyl chloride in the presence of aluminum chloride to give I. The methoxy sulfone was then treated with aluminum chloride at an elevated temperature to produce the hydroxy sulfone II.



Due to the strong ortho directing tendency of the methoxy group it is reasonably certain that the sulfonyl radical entered the position ortho rather than meta to the methoxyl. At any rate, the synthesized sulfone was identical with the one obtained from the rearrangement.

We wish to thank Prof. E. H. Cox of Swarthmore College for a sample of *p*-cresyl sulfonate.

Experimental

Reaction of Phenol with *t*-Butylbenzene.—One-half molar quantities of phenol and the alkylbenzene were mixed and added to 70 g. of hydrogen fluoride at 0°. The reaction was allowed to proceed with stirring for a period of thirteen hours, after which time it was poured onto ice, neutralized, taken up in ether, and dried. There was isolated from the reaction mixture, 2.6 g. of benzene, identified by conversion to a dinitro derivative, and 7.5 g. of *p*-*t*-butylphenol, m. p. and mixed m. p. 98–99°.

Beckmann Rearrangement of Benzophenone Oxime.—Five grams of the ketoxime was dissolved in 75 cc. of acetic acid and the solution then was added slowly to 86 g. of hydrogen fluoride at 0°. After standing overnight the mixture was warmed on the steam-bath to remove the more volatile acid. Upon cooling the solution was diluted with water, the precipitate filtered and washed, and then

(5) Fieser and Hershberg, *ibid.*, **61**, 1272 (1939).

recrystallized from dilute ethanol. The melting point and mixed melting point was 161–162°. The yield was 3.6 g. (72%). A mixture of 145 g. of hydrogen fluoride, 7 g. of the oxime, and 150 cc. of dry ether was made at 0° and then kept at room temperature for twenty-four hours. After removal of hydrogen fluoride and subsequent recrystallization from a methanol–water solvent, 5 g. of benzanilide representing a 72% yield was obtained. When the reaction was carried out using phosphorus pentachloride as the agent for the isomerization, 8 g. of the oxime gave 7.2 g. of the anilide.

Fries Rearrangement of Phenyl Acetate.—A solution of 33 g. of the ester in 75 cc. of pentane was placed in a copper bomb; 20 g. of hydrogen fluoride was added, the vessel sealed and heated for twenty-four hours at 100°. The mixture was then poured onto ice and neutralized. The dark red organic layer was ether extracted, dried, and distilled; 11 g. of an impure solid fraction was obtained which after recrystallization from ligroin melted at 108–110°. It was converted to the semicarbazone in the usual way. The derivative melted at 195–198°. When admixed with a sample of the semicarbazone of *p*-hydroxyacetophenone, m. p. 198–199°, there was no depression in melting point.

Rearrangement of *p*-Cresyl Benzenesulfonate.—Ten grams of the ester was dissolved in 400 cc. of ligroin and placed in a copper bomb; 140 g. of hydrogen fluoride was added, the bomb closed and heated at 100° for fourteen hours. The mixture was processed in the previously described manner, the ether solution finally being extracted with a 10% sodium hydroxide solution. Acidification of the latter precipitated 1 g. of the hydroxy sulfone, m. p. 135–136°.

Preparation of 2-Methoxy-4-methyl-diphenyl Sulfone (I).—One-tenth of a mole of *p*-cresol methyl ether and one-tenth mole of benzenesulfonyl chloride were dissolved in 50 cc. of carbon disulfide. To this solution, 15 g. of aluminum chloride was added gradually. When the catalyst had all been added, the mixture was refluxed on the steam-bath for five hours, and the solvent was removed. The residue was cooled and dilute hydrochloric acid was added cautiously. The organic solid which remained was washed with water by decantation, filtered, washed again, and then recrystallized from dilute ethanol to give 18.5 g. of the sulfone, m. p. 137–138°. The yield was 71% of the theoretical.

Anal. Calcd. for $C_{14}H_{14}O_3S$: S, 12.21. Found: S, 11.84.

Preparation of 2-Hydroxy-4-methyl-diphenyl Sulfone (II).—Six grams of aluminum chloride was intimately mixed with 3 g. of the methoxy sulfone (I), placed in a 50-cc. round-bottomed flask, and heated in an oil-bath to 140°. The temperature was maintained at 140–150° for two hours. Upon cooling, the mixture was treated with dilute hydrochloric acid and thoroughly freed from attendant salts. The mass was then dissolved in 10% sodium hydroxide, the solution filtered, and then acidified. The precipitated hydroxy sulfone was recrystallized from diluted ethyl alcohol to give 2.6 g. of pure sulfone, m. p. 137–138°. From the mother liquor there was obtained another 0.1 g. of pure sulfone, making the total yield 95% of the theoretical.

A mixed m. p. determination with the sulfone obtained from the rearrangement was 136–137°. A mixture of the hydroxy and methoxy sulfones (I and II) melted at 105–112°.

Summary

Hydrogen fluoride has been used to effect a number of exchange reactions or rearrangements of organic compounds. The following are examples: *t*-butylbenzene reacted with phenol to form *t*-butylphenol and benzene. Benzophenone oxime rearranged to benzanilide. Phenyl acetate rearranged to *p*-hydroxyacetophenone. *p*-Cresyl benzenesulfonate rearranged to 2-hydroxy-4-methyl-diphenyl sulfone.

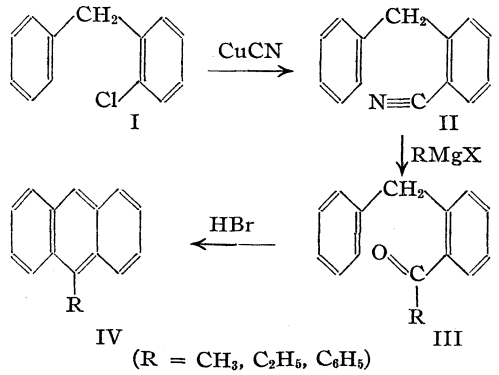
A New Route to 9-Alkyl- and 9-Arylanthracenes

BY CHARLES K. BRADSHER

Recently Bergmann[1] observed that hydrolysis of the acetal of *o*-benzylbenzaldehyde in boiling hydrochloric acid gave not only the expected aldehyde (III, R=H), but also a small amount of anthracene. From this observation and from considerations which we shall discuss later, we concluded that *o*-benzyl phenyl ketones (III) should cyclize to form 9-alkyl- and 9-arylanthracenes (IV).

The required ketones were obtained from



I II III IV

(R = CH_3, C_2H_5, C_6H_5)

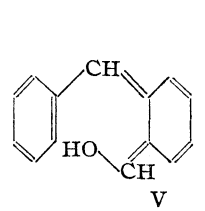
(1) E. Bergmann, *J. Org. Chem.*, **4**, 1 (1939).

o-benzylbenzonitrile (II) by the Grignard reaction. The nitrile (II) was prepared by two methods, the first of which, the action of lead thiocyanate on *o*-benzylbenzoic acid, did not seem capable of wide application and was discarded in favor of the action of cuprous cyanide on *o*-chlorodiphenylmethane (I). The latter compound was prepared by reduction of the benzohydrol obtained when phenylmagnesium bromide was allowed to react with *o*-chlorobenzaldehyde.[2] One would expect that Grignard reagents from a wide variety of aryl halides might be substituted for phenylmagnesium bromide, providing a means for the synthesis of a number of *o*-chlorodiphenylmethanes.

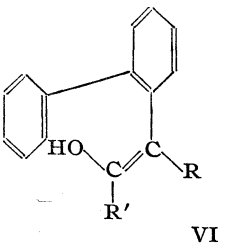
Three *o*-benzylphenyl ketones (III) were prepared, the phenyl, the methyl and the ethyl, of which only the first has been prepared previously.[1] Cyclization was effected by refluxing the ketones for four days in a mixture of hydrobromic and acetic acids. The expected hydrocarbons (IV) were obtained in yields ranging from 69% in the case of the ethyl ketone (III, R = C_2H_5) to 80% in the case of the methyl (III, R = CH_3). It is interesting to note that the phenyl ketone (IV, R = C_6H_5), despite the greater size of the phenyl group, cyclizes in a yield (75%) comparable with that of the alkyl ketones.

Bergmann[1] regarded the cyclization of *o*-benzylbenzaldehyde as a "modification of the Elbs synthesis of anthracene derivatives" and proposed a mechanism based on that advanced by Cook[3] for the latter reaction.

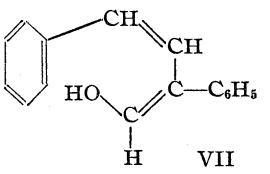
In our opinion, the cyclization of the aldehyde may be better understood if comparison is made instead with two other reactions which take place under similar conditions, *i. e.*, in boiling mineral acids. The first is the ring closure used by us in the synthesis of phenanthrene derivatives and for which we have recently proposed as an intermediate, a carbonyl compound of type VI[4] (here written in the enol form). The other comparable reaction is the formation of β-phenylnaphthalene from two molecules of phenylacetaldehyde. Carter and Van Loon[5] have suggested that the intermediate in this reaction is the enol VII. If *o*-benzylbenzaldehyde is represented in the enol form and this structure compared with those of



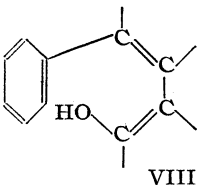
V



VI



VII



VIII

the proposed intermediates, it will be seen that the feature common to all three is the β-(β-styryl)-vinyl alcohol system (VIII). It seems reasonable that the terminal hydroxyl on such a completely conjugated system would activate the *ortho* position of the aromatic ring so that cyclization could take place with the loss of water.

Although perfectly aware that the sum of these speculations does not constitute a proof, we do consider that the assumption of such an intermediate forms a satisfactory working hypothesis. Further, by assuming that cyclization is preceded by enolization[6] we may explain the slow rate at which the anthracene hydrocarbons are formed since it would not be expected that *o*-benzylphenyl ketones would exist in the enolic form to any great extent.

A further study is being made of compounds containing the β-(β-styryl)-vinyl alcohol system, and work is in progress on the extension of the synthesis reported in this paper to the preparation of 1,2-benzanthracene derivatives.

Experimental

***o*-Chlorobenzohydrol** was prepared by the action of phenylmagnesium bromide on *o*-chlorobenzaldehyde by a procedure essentially that of Tschitschibabin and Sheshler.[2] It was obtained as a colorless oil of b. p. 170–176° (5 mm.) and in a yield of 76%. The material crystallized on standing, m. p. 62–65°.

***o*-Chlorodiphenylmethane (I).**—A mixture of 49.7 g. of *o*-chlorobenzohydrol, 10 g. of iodine, 10 g. of red phosphorus, 500 cc. of acetic acid and 50 cc. of water was refluxed for twenty-nine hours. The excess red phosphorus was then filtered off and the filtrate poured on ice and extracted with ether. The ethereal extract was washed with ice-cold 10% sodium hydroxide solution to remove the acids and the free iodine. The solution was dried, concentrated and the residue distilled under re-

(2) This synthesis of *o*-chlorodiphenylmethane is essentially that used previously by Tschitschibabin and Sheshler, *J. Russ. Phys.-Chem. Soc.*, **56**, 149 (1925).

(3) Cook, *J. Chem. Soc.*, 487 (1931).

(4) Bradsher, THIS JOURNAL, **61**, 3131 (1939).

(5) Carter and Van Loon, *ibid.*, **60**, 1077 (1938).

(6) It should be pointed out that the Bergmann mechanism likewise involves enolization as its first step.

duced pressure. The fraction boiling at 144° (5 mm.) weighed 37.4 g. (81%) and was water-white.

o-**Benzoylbenzonitrile (II).** (a) **From *o*-Benzoylbenzoic Acid.**—The nitrile was prepared by the method of Bergmann[1] in yields of 35–50%.

(b) **From *o*-Chlorodiphenylmethane.**—By heating *o*-chlorodiphenylmethane with 10.8 g. of cuprous cyanide for twenty-three hours at 250°, and working up the product in the usual manner, the nitrile was obtained as a colorless oil, b. p. 160–164° (4 mm.); yield 10.3 g. (54%). A forerun of *o*-chlorodiphenylmethane (4.6 g.) was recovered.

o-**Benzylacetophenone (III, R = CH_3).**—A Grignard reagent was prepared in ether from 28.4 g. of methyl iodide and 5.4 g. of magnesium. Most of the ether was distilled off, 14.6 g. of *o*-benzylbenzonitrile added in 100 cc. of dry benzene, and the solution refluxed overnight. The mixture was decomposed by the addition of 20% ammonium chloride solution and the benzene layer separated. This layer was extracted with ice-cold 2 *N* hydrochloric acid, the acid layer separated, refluxed for one hour to hydrolyze the imine hydrochloride, cooled and extracted with ether. The ethereal extract was evaporated and the residue distilled under reduced pressure. The ketone, a yellow oil, b. p. 167° (5 mm.), crystallized on standing; yield 11.5 g. (72%). A sample recrystallized from petroleum ether was obtained as white needles, m. p. 49–50°.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.7; H, 6.7. Found: C, 85.5.; H, 6.8.

9-Methylanthracene (IV, R = CH_3).—A mixture of 2 g. of *o*-benzylacetophenone, 20 cc. of acetic acid and 20 cc. of 34% hydrobromic acid was refluxed for four days. Upon cooling, the product solidified and was collected and recrystallized from methanol. It was obtained as flat yellow needles, m. p. 80–81°; yield 1.45 g. (80%). The melting point was not raised by repeated recrystallization.

Anal. Calcd. for $C_{15}H_{12}$: C, 93.7; H, 6.3. Found: C, 93.4; H, 6.4.

o-**Benzylpropiophenone (III, R = C_2H_5).**—This ketone was prepared by the action of an excess of ethylmagnesium bromide on *o*-benzylbenzonitrile in a manner analogous to that employed in the synthesis of *o*-benzylacetophenone. The product was a yellow oil, b. p. 156° (3 mm.), and was obtained in a yield of 73%.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.7; H, 7.2. Found: C, 85.6; H, 7.3.

The phenylhydrazone was prepared by refluxing the ketone for three hours with phenylhydrazine in alcohol. Recrystallized from alcohol, it was obtained as white needles, m. p. 97–98°. These were unstable and decomposed on standing for two days.

9-Ethylanthracene.—This hydrocarbon was obtained by refluxing 2.05 g. of the above ketone with acetic and hydrobromic acids in a manner analogous to that employed in the synthesis of 9-methylanthracene. The product, recrystallized from methanol, was obtained as yellowish irregular plates, m. p. 58–59°; yield 1.3 g. (69%).

Anal. Calcd. for $C_{16}H_{14}$: C, 93.2; H, 6.8. Found: C, 93.0; H, 7.1.

o-**Benzylbenzophenone** was prepared by the method used in the preparation of the other two ketones, except that hydrolysis of the imine hydrochloride required two hours of refluxing. The product was obtained as a yellow, very slightly fluorescent oil,[7] b. p. 199–200° (3 mm.) and in a yield of 82%. On seeding, the ketone crystallized to a yellowish solid, m. p. 50–52°.

9-Phenylanthracene was prepared by refluxing 2.06 g. of the above ketone with acetic and hydrobromic acids as in the preparation of the other hydrocarbons. The product formed fluorescent plates on crystallization from ethanol, m. p. 154–155°; yield 1.44 g. (75%). Upon concentration of the mother liquor, an additional 0.1 g. was obtained, m. p. 153–155°.

Anal. Calcd. for $C_{20}H_{14}$: C, 94.5; H, 5.5. Found: C, 94.4; H, 5.8.

Summary

A new and general method has been found for the synthesis of 9-substituted anthracene hydrocarbons.

The theory has been presented that the cyclization involved is one characteristic of the β-(β-styryl)-vinyl alcohol system.

DURHAM, NORTH CAROLINA
RECEIVED DECEMBER 11, 1939

(7) Bergmann, ref. 1, who prepared this ketone by refluxing the imine hydrochloride for *six* hours with dilute hydrochloric acid, reported that the oil had an intense green fluorescence. This difference undoubtedly is due to the formation of more 9-phenylanthracene during the longer period of refluxing.

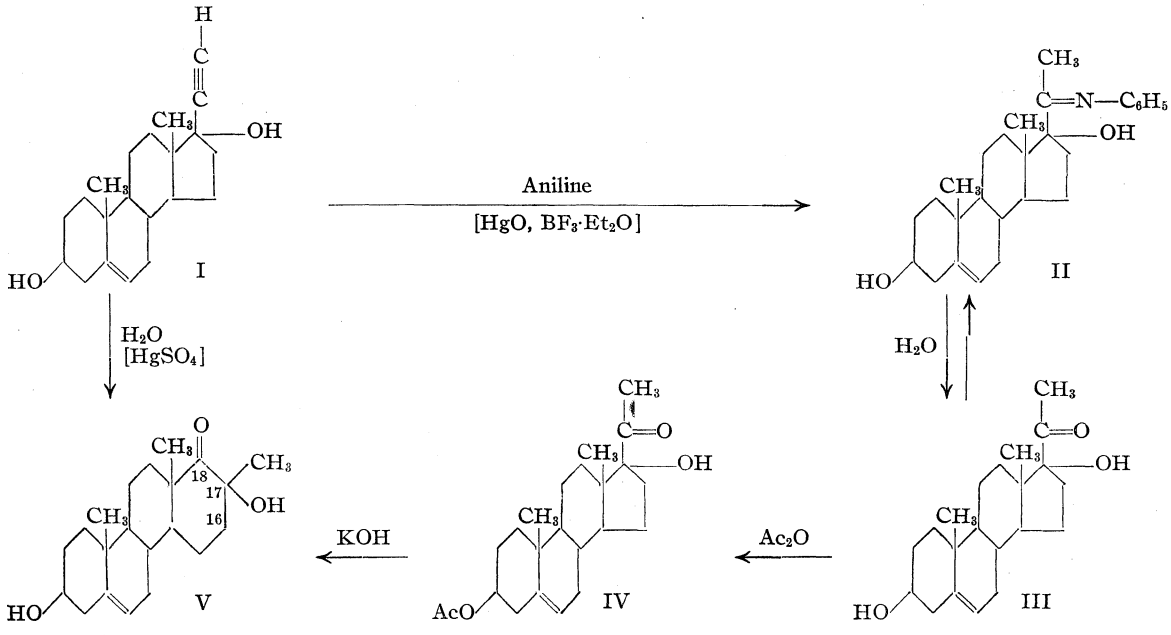
The Preparation of Δ^5-Pregnenediol-3,17-one-20 from Δ^5-17-Ethynyl-androstenediol-3,17

BY HOMER E. STAVELY

The transformation of Δ^5-17-ethynyl-androstenediol-3,17 (I) into the hydroxy ketone III has been studied by Ruzicka and Meldahl,[1] who added acetic acid to the acetylene bond and then saponified the resulting acetate. An identical compound was obtained by Stavely[2] by the direct hydration of the acetylene compound in the presence of mercuric sulfate.



Degradation studies by Ruzicka, *et al.*,[3] have revealed the very noteworthy fact that this product cannot have the expected structure III. Oxidation of the corresponding acetylated and hydrogenated hydroxy ketone (presumed to have the side chain structure of III) led to a keto acid without the loss of any carbon atoms, instead of giving the expected acetate of *trans*-androsterone. To explain this unlooked for result Ruzicka proposed that in the preparation of substance III from the corresponding 17-ethynyl compound a rearrangement into a structure V had occurred, which readily explains the oxidation into the keto acid. Although the formulation of the compound V may be hypothetical in its details, there is not much doubt that a transformation of a five-membered into a six-membered ring must have occurred. The name chrysopregnane is now proposed for the parent hydrocarbon of the series to express the relationship to chrysene as well as to pregnane. Compound V should then be named Δ^5-3,17-dihydroxy-18-keto-chrysopregnene.

Since the appearance of an article by Loritsch and Vogt,[4] who condensed 1-heptyne and 3-octyne with aniline in the presence of ether–boron fluoride and mercuric oxide catalysts, and split the anils into the corresponding ketones, the reaction has been applied by me to ethynylandrostenediol (I). While this work was in progress Goldberg and Aeschbacher[5] described in a preliminary form an anil obtained by the condensation of the same compounds, using mercuric chloride as a catalyst. It seems certain that their anil is identical with the one described in this paper.

The anil (II) seems to be hydrolyzed on standing in aqueous methanol, although the reaction is not complete even on prolonged heating. Apparently an equilibrium between ketone and anil

is established. Separation of the ketone III from the mixture was difficult, but after acetylation it was possible to remove the sparingly soluble anil acetate and obtain both products in pure form. Since ketone IV is not identical with the acetate of the chrysopregnane ketone V, it was probable that the acetate of Δ^5-pregnenediol-3,17-one-20 (III) had been obtained. In order to prove this assumption the acetate IV was oxidized with chromic acid and from the neutral fraction was isolated the acetate of dehydroandrosterone as the semicarbazone. When saponification of the acetoxy group of IV was attempted by heating with methyl alcoholic potassium hydroxide, the alcohol obtained was identical with Δ^5-3,17-dihydroxy-18-keto-chrysopregnene (V). In view of the rearrangement of IV to V, it seems remarkable that Reichstein[6] can subject the 3-acetates of his natural adrenal steroids with 17-hydroxyl and 17-acetyl groups, such as his substance L, to alkali saponification without a similar rearrangement. However, he points out[7] that all pregnane derivatives obtained by the interaction of ethylmagnesium bromide or acetylene with 17-ketoandrostane compounds belong to the same series (precipitated by digitonin), designated as the 17(α)-series; whereas natural adrenal steroids belong to the 17(β)-series (not precipitated by digitonin). Therefore, it would seem that only members of the 17(α)-series are susceptible to rearrangement into chrysopregnane compounds. The anil II and the ketone IV appear to be sensitive to dilute acid also. By splitting the anil with dilute acid and acetylating, a product was isolated which is not identical with IV or with the acetate of V. The influence of both acid and alkali on these compounds is being more extensively investigated.

Experimental

Δ^5-Pregnenediol-3,17-one-20-anil (II).—A mixture of 1 g. of Δ^5-17-ethynyl-androstenediol-3,17, 500 mg. of mercuric oxide, 0.3 cc. of ether–boron fluoride catalyst,[8] and 5.0 cc. of dry aniline was allowed to stand at room temperature for a week. The excess aniline was then removed by steam distillation, and the flask was cooled and saturated with hydrogen sulfide. The next morning the mixture was thoroughly extracted with ether, the ether washed with water, dried over sodium sulfate, evaporated to dryness and the residue crystallized from aqueous methanol; yield, 500 mg., m. p. 148°, $[\alpha]^{23}D$ −196 ± 2.0° (12.3 mg. in 2.0 cc. chloroform, 1 dm. tube, α^{23} −1.20).

Anal.[9] Calcd. for $C_{27}H_{37}O_2N$: C, 79.56; H, 9.15. Found: C, 79.61; H, 9.60.

Using mercuric chloride as a catalyst,[5] a better yield was obtained by working up the reaction mixture as above, instead of by the method used by Goldberg and Aeschbacher.

Δ^5-Pregnenediol-3,17-one-20 (III).—From the aqueous methanol mother liquor of the anil crystallization, after standing for about ten days, another crop of crystals was isolated. After purification the substance analyzed for Δ^5-pregnenediol-3,17-one-20, sinters at 158°, m. p. 161–163°.

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.85; H, 9.71. Found: C, 75.60; H, 9.61.

Δ^5-3-Acetoxypregnenol-17-one-20 Oxime from (III).—Fifty milligrams of Δ^5-pregnenediol-3,17-one-20 was acetylated in pyridine and acetic anhydride overnight. The solvents were removed in a vacuum and the residue heated with 50 mg. of hydroxylamine hydrochloride, 50 mg. of potassium acetate and 10 cc. of ethanol for two hours. Water was then added, the precipitate filtered, washed with water, dried, and recrystallized from benzene–petroleum ether; m. p. 254–256°.

Anal. Calcd. for $C_{23}H_{35}O_4N$: C, 70.92; H, 9.08. Found: C, 71.15; H, 9.29.

Separation of Δ^5-3-Acetoxypregnenol-17-one-20 (IV) from Δ^5-3-Acetoxypregnenol-17-one-20-anil.—Two grams of the crude anil II was refluxed with aqueous methanol for twenty-eight hours. The products crystallized on cooling, but melted over a 30° range and were a mixture. The crystals were dried and acetylated by standing at room temperature overnight in pyridine and acetic anhydride. The solvents were removed in a vacuum and the residue dissolved in a large volume of methanol. On cooling 700 mg. of beautiful crystals separated, m. p. 232–234° after recrystallizing twice from methanol–ether. The mother liquors yielded 200 mg. more; $[\alpha]^{24}D$ −176 ± 2.0° (13.0 mg. in 2.0 cc. of chloroform, 1 dm. tube, α^{24} −1.14).

Anal. Calcd. for $C_{29}H_{39}O_3N$: C, 77.46; H, 8.75; N, 3.13. Found: C, 77.60; H, 8.68; N, 3.39.

The mother liquors were concentrated to a small volume and the Δ^5-3-acetoxypregnenol-17-one-20 precipitated by addition of water. After drying, the precipitate was crystallized as beautiful needles from benzene–petroleum ether; yield, 520 mg.; m. p. 196–198°; $[\alpha]^{23}D$ −61 ± 1.5° (9.2 mg. in 2.0 cc. chloroform, 1 dm. tube, α^{23} −0.28).

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.76; H, 9.16. Found: C, 74.06; H, 9.24.

Oxidation of Δ^5-3-Acetoxypregnenol-17-one-20 (IV) to 3-Acetoxydehydroandrosterone.—To 100 mg. of Δ^5-3-acetoxypregnenol-17-one-20 in 4.0 cc. of glacial acetic acid, 43 mg. of bromine in acetic acid (1 mole) was added dropwise with cooling. Chromic oxide, 170 mg. dissolved in acetic acid, was added and the mixture allowed to stand for twenty hours at room temperature. Since no oxida-

tion was apparent, the flask was heated to 45° for four hours. Methanol was added to destroy excess chromic acid, then 200 mg. of zinc dust, and the mixture heated on the steam-bath for one hour. The solution was concentrated in a vacuum. After addition of water, it was extracted with ether. The ether extract was washed with 1 *N* potassium hydroxide and with water, dried over sodium sulfate, and evaporated to dryness. The residue weighed 45 mg. It was refluxed with semicarbazide hydrochloride and potassium acetate in ethanol for an hour, water was added, the precipitate filtered, washed with water and ether, and recrystallized several times from chloroform–ethanol. Seventeen milligrams of pure 3-acetoxydehydroandrosterone semicarbazone was obtained, m. p. 275–278°. A mixed m. p. with an authentic specimen showed no depression.

Anal. Calcd. for $C_{22}H_{33}O_3N_3$: C, 68.18; H, 8.59. Found: C, 67.90; H, 8.88.

Δ^5-3-Acetoxypregnenol-17-one-20 Oxime from (IV).—The oxime was prepared from the ketone in the usual manner. It was crystallized from benzene–petroleum ether, m. p. 253–256°; mixed m. p. with the 3-acetoxy oxime prepared from the Δ^5-pregnenediol-3,17-one-20 isolated directly from the products of the anil hydrolysis showed no depression.

Anal. Calcd. for $C_{23}H_{35}O_4N$: C, 70.92; H, 9.08; N, 3.60. Found: C, 70.71; H, 9.21; N, 3.79.

Rearrangement of Δ^5-3-Acetoxypregnenol-17-one-20 (IV) to Δ^5-3,17-Dihydroxy-18-keto-chrysopregnene (V).—Fifty milligrams of Δ^5-3-acetoxypregnenol-17-one-20 was refluxed with 3% methanolic potassium hydroxide for two hours. The alkali was neutralized with carbon dioxide, the solution concentrated, and water added. The precipitate was filtered, washed with water, and crystallized in beautiful hexagonal prisms from acetone, m. p. 278–280°; $[\alpha]^{22}D$ −104° (9.8 mg. in 2.0 cc. dioxane, 1 dm. tube, α^{22} −0.51). A mixed m. p. with Δ^5-3,17-dihydroxy-18-keto-chrysopregnene prepared by the direct hydration of Δ^5-17-ethynyl-androstenediol-3,17[2] showed no depression. The specific rotations of the two substances were the the same.

Summary

Δ^5-17-Ethynyl-androstenediol-3,17 and aniline have been condensed in the presence of ether–boron fluoride and mercuric oxide catalysts to form Δ^5-pregnenediol-3,17-one-20-anil.

The anil is partially hydrolyzed by contact with water to form Δ^5-pregnenediol-3,17-one-20. The acetate of this substance has been oxidized to 3-acetoxydehydroandrosterone, thus proving its pregnane structure.

By saponification of Δ^5-3-acetoxypregnenol-17-one-20 with methyl alcoholic potassium hydroxide a rearranged product is obtained for which the name Δ^5-3,17-dihydroxy-18-keto-chrysopregnene is proposed. The substance is identical with the ketone obtained by the direct hydration of Δ^5-17-ethynylandrostenediol-3,17.

The Isolation of Keturonic Acids. II[1,2]

BY L. T. CREWS, J. P. HART AND M. R. EVERETT

The authors are reporting the isolation of crystalline brucine salts of keturonic acids prepared by oxidation of *l*-xylose, *l*-arabinose and *d*-glucosamine, together with a new type of oxidation product, an anhydride of a dicarbonyl sugar, from oxidized levoglucosan. Brucine keturonates also have been prepared from oxidized *α*-*d*-glucoheptose and *l*-fucose but to date these salts have not been separated completely from accompanying non-reducing substances. Ultimate analysis and melting point determinations of the reported preparations are given in Table I and other properties of these substances in Table II.

Experimental

Oxidation of the 1% carbohydrate solutions, preparation of the mixed barium salts, and isolation of the crystalline brucine salts were conducted according to the general methods of Hart and Everett.[2] Yields of mixed barium salts from 4-g. quantities of the carbohydrates were as follows: *l*-xylose, 4.1 g.; *l*-arabinose, 3.0 g.; and *d*-glucosamine hydrochloride, 1.7 g. Reducing barium salts could not be obtained from oxidized levoglucosan solutions but during concentration of the barium salt solution *in vacuo* the substance designated as ketolevoglucosan crystallized directly. Non-reducing barium salts could be precipitated from the mother liquor by the addition of acetone.

Brucine-*l*-xyloketuronate.—A solution of this salt was prepared from 3.75 g. of the mixed barium salts obtained from oxidized *l*-xylose. The reducing brucine salt began to crystallize during concentration of the solution *in vacuo*. After two hours in the refrigerator it was filtered off, washed with alcohol and ether and dried in a desiccator. The yield was 2.5 g. The salt was recrystallized from water.

Brucine-*l*-araboketuronate.—A solution of this salt was prepared from 2.9 g. of the mixed barium salts obtained

OPTICAL ROTATIONS, REDUCING EQUIVALENTS AND COLOR REACTIONS[e]

Brucine-	Color reactions: Naphtho-resorcinol	Bial	Molisch	$[\alpha]^{25}D$[a]	*d*-Glucose equivalent by Sumner's method[b]: Salt	Calcd. for free acid
l-Xyloketuronate	Pink	Negative	Brown	−29.5°	0.23	0.81
l-Araboketuronate	Pink	Negative	Brown	−13°	.20	.71
d-Chitoketuronate	Orange	Negative	Red purple	−50.5°	.34	1.15
Ketolevoglucosan	Red purple	Green[d]	Negative	−62°	[c]	

[a] For 1% aqueous solutions. [b] For 2 mg. per ml. concentrations of the salts. [c] For crystalline ketolevoglucosan, 0.52; calcd. for the anhydrous substance, 0.55; Folin–Wu equivalent for crystalline ketolevoglucosan, 0.26. [d] Color developed slowly. [e] M. R. Everett and Fay Sheppard, *Proc. Soc. Exp. Biol. Med.*, **34**, 7 (1936).

from oxidized *l*-arabinose. Crystals appeared during concentration *in vacuo*. The mixture was then placed in the refrigerator for twenty-four hours and filtered. A second crystalline fraction obtained by concentrating the mother liquor *in vacuo* proved to be non-reducing. The first fraction was recrystallized several times by dissolving in hot water and adding five volumes of alcohol. The yield of recrystallized salt was 0.78 g. This keturonate was difficult to free from a small contamination of non-reducing salt. With repeated recrystallization, properties of this substance approached those of the brucine *d*-xyloketuronate isolated by Hart and Everett.[2] Ultimate analysis indicated the presence of an extra mole of water of crystallization in the *l*-arabinose derivative and the melting point of this brucine salt was 8° lower than that of brucine-*d*-xyloketuronate. The mixed melting point was intermediate (Table I). If future experimentation confirms these indications of similarity, *d*-xyloketuronic acid will be shown to have the structure postulated by Everett and Sheppard,[3] namely, *l*-xyloketo-5-uronic acid according to the classification of Hart and Everett.[4]

Brucine-*d*-chitoketuronate.—A solution of this salt was prepared from 1.95 g. of the mixed barium salts obtained from oxidized *d*-glucosamine hydrochloride. Concentration *in vacuo* gave a crystalline fraction of reducing salt that was filtered off after twenty-four hours in the refrigerator. The salt was recrystallized by dissolving in hot water, adding four volumes of alcohol and placing in the refrigerator for two hours. After filtering, washing with alcohol and ether and drying in the desiccator the yield was 0.52 g. This salt lost no weight upon heating to 175° for several hours *in vacuo* over phosphorus pentoxide. Ultimate analysis indicated a brucine salt of a nitrogen-free anhydroketuronic acid. The authors have therefore provisionally designated the acid as *d*-chitoketuronic acid, with the position of the reducing carbonyl group undetermined.

Ketolevoglucosan.—A well-crystallized barium-free substance separated during concentration of the barium salt solution prepared from oxidized levoglucosan. After placing in the refrigerator for several hours it was filtered off, washed twice with cold water and recrystallized from water. The yield was 0.65 g. of recrystallized substance from 4.0 g. of levoglucosan. The substance reduced Sumner's reagent at room temperature, contained no titratable acid group and was very sparingly soluble in water at room temperature (1% aqueous solution could be obtained by warming). It lost no weight upon heating to 156° *in vacuo* over phosphorus pentoxide. Hydrolysis with 0.6 *N* sulfuric acid for 2.5 hours on a boiling water-bath caused a gradual diminution in specific rotation from −62 to −34° together with a 33% decrease in reducing power (Sumner's method). The Sumner/Folin–Wu ratio of reducing equivalents also changed from 1.99 to 1.45, indicating hydrolysis of the anhydride linkage.[3,5] Subsequent oxidation of the hydrolyzate with bromine for forty-eight hours at 25° caused a 50% loss of reduction, which indicated the appearance of an aldose radical during hydrolysis. The original reducing substance was not affected by similar bromine oxidation. The derivation and properties of this product of levoglucosan oxidation indicate that it is the anhydride of a dicarbonyl sugar.[6]

(5) M. R. Everett and Fay Sheppard, THIS JOURNAL, **60**, 1792 (1938).

(6) In view of the present ambiguity in dicarbonyl sugar nomenclature and the possible need for naming several new dicarbonyl sugars whose preparation we are attempting, the following suggestions are made:

1. That the group name for sugars with two potential aldehyde radicals be *alduroses* and that their configurations be referred to the parent polyhydric alcohols. Example: *d-sorbitoaldurose* for the identical structures, 6-aldehydo-*d*-glucose and 6-aldehydo-*d*-gulose.

2. That the group name for sugars with one potential aldehyde

Determination of the position of the reducing carbonyl radical necessitates the preparation of larger quantities of ketolevoglucosan.

Molecular Weights of the Anhydro Derivatives.—The ordinary cryoscopic method for determination of molecular weight could not be employed due to the slight solubility of ketolevoglucosan in ordinary solvents and the limited quantities of *d*-chitoketuronic acid available. Barger's method as modified by Rast[7] gave satisfactory results in control determinations of the molecular weight of glucose but it proved entirely inapplicable to the anhydro derivatives under investigation. A series of dilutions lost water to an intermediate glucose standard, probably because of gradual association or polymerization of the anhydro derivatives. Rast's camphor method[8] gave the following molecular weight values: 330 for ketolevoglucosan, 1100 for brucine *d*-chitoketuronate and 350 for pure levoglucosan. These values are approximately dimolecular but levoglucosan has been shown by the ordinary cryoscopic method to be monomolecular. A common interpretation would imply that the anhydro derivatives reported here are also monomolecular.

and one potential ketone radical be *keturoses* and that their configurations be referred to the parent ketoses, as in the suggested nomenclature for keturonic acids.[4] Examples: *l-sorbo-6-urose* for the identical structures, *d*-gluconose and *l*-idonose; and *d-fructo-1-urose* for *d*-glucosone.

This terminology avoids multiple naming, is generally applicable and suggests functional relations of these sugars to their uronic acid oxidation products. Present indications are that the dicarbonyl sugar anhydride isolated by the authors is 1,6-anhydro-*l*-sorbo-6-urose (1,6-anhydro-gluconose) but the temporary designation as ketolevoglucosan is preferred until the position of the second carbonyl radical is proven.

(8) Kamm, "Qualitative Analysis," John Wiley and Sons, New York, N. Y., 1932, p. 131.

Summary

1. *l*-Xyloketuronic acid and *d*-chitoketuronic acid have been isolated as crystalline brucine salts.

2. The keturonic acid similarly isolated from oxidized *l*-arabinose solutions resembles *d*-xyloketuronic acid closely but complete identity of these acids has not been proven.

3. An anhydride of a dicarbonyl sugar has been isolated from oxidized levoglucosan solutions.

The Action of Aromatic Amines on 3-Nitro-6-iodonitrostyrene

BY DAVID E. WORRALL AND FREDERICK BENINGTON

Whereas nitration of 2-chloro- and 2-bromonitrostyrene does not entirely inhibit its addition capacity for certain aromatic amines,[1] the halogenated derivatives are not as reactive as nitrostyrene itself. We now find that the analogous iodo derivative closely parallels nitrostyrene in all its reactions with nitrogen bases.

Experimental

α-Nitro-β-(2-iodophenyl)-ethylene.—Iodobenzaldehyde prepared through the diazo reaction[2] from *o*-aminobenzaldehyde[3] was condensed with nitromethane in the presence of triethylamine; yield, after steam distillation, 65–70%. It separated from alcohol as pale yellow needles, m. p. 113–114°. On oxidation with potassium permanganate it gave 6-iodo-3-nitrobenzoic acid[4] which recrystallized from alcohol in long yellow needles, m. p. approx. 190°.

Anal. Calcd. for $C_8H_6INO_2$: C, 34.8; H, 2.2. Found: C, 35.2; H, 2.5.

α-Nitro-β-(6-iodo-3-nitrophenyl)-ethylene.—Prepared by nitration of the above compound using fuming acid, it was obtained from alcohol as tiny pale yellow needles, m. p. 145–146°.

Anal. Calcd. for $C_8H_5IN_2O_4$: C, 30.0; H, 1.5. Found: C, 30.2; H, 1.3.

The product from bromination of the iodo compound separated as an oil on treatment with a warm alcoholic solution of potassium acetate. On mixing with fuming nitric acid, it solidified and was recrystallized from alcohol in yellow prismatic needles, m. p. 136–137°.

Anal. Calcd. for $C_8H_4BrIN_2O_4$: C, 24.0; H, 1.0. Found: C, 24.4; H, 1.2.

It was observed to form an addition compound with *p*-toluidine, but was not further investigated.

The same procedure previously developed[1] was used for the preparation of the addition compounds. The products, yellow or orange-yellow and deeper in color than the parent nitrostyrene, were recrystallized from alcohol, separating as narrow plates or prismatic needles. The melting points frequently were not sharp and were always accompanied by decomposition so that they varied with the rate of heating. Difficulty was experienced in preparing the *o*-toluidino compound as it did not always separate even on long standing. The anilino derivative formed only after several days. The *o*- and *m*-anisidine derivatives formed more readily than the corresponding toluidine. The hydroxylamino and semicarbazido products were colorless.

The Condensation of Butyraldehyde and Aniline

BY M. S. KHARASCH, ISADORE RICHLIN AND FRANK R. MAYO

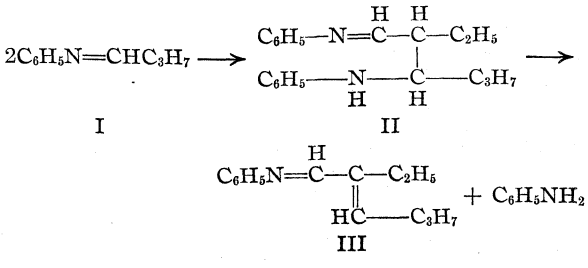
Introduction

Two general types of structure have been suggested for the dimeric Schiff bases, the cyclic structure by Ingold and Piggott,[1] and the aldol-type structure by Miller and Plöchl.[2] The weight of chemical evidence is in favor of the latter. The work of Eibner is particularly convincing.[3] Our research has been concerned with the determination of the structure of the compounds formed by the condensation of *n*-butyraldehyde and aniline in neutral and in acid media.

Discussion of Results

Two products have thus far been isolated from the reaction of aniline and *n*-butyraldehyde in neutral media: one, a monomeric Schiff base (as the hydrogen cyanide addition product), by Rampini, and the other, its dimer, by Williams.[4]

We have found that in the presence of even small amounts of acid, a yellow oil is formed during the condensation. The same oil is formed by treating the crystalline dimer with small amounts of organic acids or by allowing the dimer preparation to stand for several days. In the latter case, the catalyst is the butyric acid formed by atmospheric oxidation, since a similar preparation, carried out in an evacuated bomb-tube, will not produce the oil unless acid had been previously added. Rampini noted this oil but did not investigate it; his failure to obtain the dimer was due to his using aldehyde containing acid. It has been shown by us that this oil is the anil of α-ethyl-β-propylacrolein, formed as follows



(1) Ingold and Piggott, *J. Chem. Soc.*, **121**, 2793 (1922); **123**, 2745 (1923).

(2) Miller and Plöchl, *Ber.*, **25**, 2020 (1892).

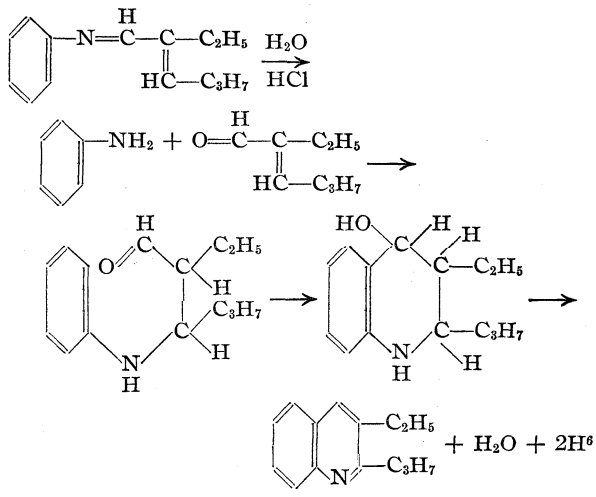
(3) Eibner, *Ann.*, **318**, 58 (1901); **328**, 121 (1903); **329**, 210 (1903).

(4) Rampini, *Ber.*, **25**, 2038 (1892); Williams, U. S. Patent 1,908,093. May 9, 1933; *C. A.*, **27**, 3854 (1933).

The structure, III, for the oil has been confirmed in several ways. Synthetically, we have prepared the same compound from aniline and α-ethyl-β-propylacrolein. Analytically, we have recovered benzanilide and acetanilide in good yields by treating the oil with benzoyl chloride and acetyl chloride, respectively; and we have prepared the 2,4-dinitrophenylhydrazone and semicarbazone of α-ethyl-β-propylacrolein by the use of the hydrazine and semicarbazide. Molecular weight determinations and elementary analyses are consistent with the molecular formula proposed.

The production of the oil of above structure seems to require that II be the structure of the dimer. This is in accord with the work of Miller, Plöchl and Eibner.[2,3] Catalytic reduction of the dimer indicates that one mole of hydrogen is taken up per mole of dimer to form a diamine. The diamine character of the reduction product is shown by its forming a dihydrochloride and a diacetyl derivative. Furthermore, the dimer exhibits properties which one would expect from a compound so closely related, in structure and in formation, to aldol. Both the elimination of aniline to form the oil (analogous to the formation of crotonaldehyde from aldol), the low boiling point (below that of the oil) and the range of the boiling point (about 50°) are indications of dissociation. Cryoscopic molecular weight determinations in triphenylmethane agree with those calculated for the dimer, while in camphor, at a temperature higher by 80°, they indicate 40–50% depolymerization.

The Condensation in the Presence of Acid.—The most general syntheses of the quinoline compounds are those in which a primary aromatic amine is condensed with an aldehyde or ketone in the presence of a mineral acid.[5] We have considered the action of concentrated hydrochloric acid on: (a) mixtures of *n*-butyraldehyde and aniline, (b) the dimer, (c) a mixture of α-ethyl-β-propylacrolein and aniline and (d) the anil of α-ethyl-β-propylacrolein. We have obtained in each instance 2-propyl-3-ethylquinoline. We believe that the formation of the quinoline from α-ethyl-β-propylacrolein anil, which at first glance seems remarkable, may best be explained as follows



Thus, the anil must be hydrolyzed so that aniline can add to the carbon-to-carbon double bond. The subsequent reaction[5] and the hydroxytetrahydroquinoline intermediate[7] in the crotonaldehyde-aniline reaction have been described previously.

Experimental Part

The Preparation of Butylidene Aniline Dimer.—Aniline, freshly distilled from zinc dust *in vacuo*, and freshly distilled *n*-butyraldehyde are mixed in equimolar proportions. The immediate separation of water and the evolution of heat require constant stirring and cooling under the water-tap. The flask is stoppered and allowed to stand for eighteen to twenty-four hours, by which time the reaction mixture is an almost solid mass of the crystalline dimer. This is crystallized from alcohol. The purest material in the best yields is obtained by taking the utmost precautions to avoid the presence of acid; this is accomplished by adding to the reaction mixture a small amount of aqueous sodium carbonate, and by adding the same to the crystallization media. Yields up to 78% of the product melting at 92.5° are obtained.

Anal. Calcd. for $C_{20}H_{26}N_2$: C, 81.61; H, 8.88; N, 9.51. Found: C, 81.49, 81.75; H, 8.88, 8.89; N, 9.41, 9.64.

Molecular Weight Determinations.—The average of ten molecular weight determinations in triphenylmethane by Rast's method[8] at two different concentrations is 281.4 (±12), compared with the value of 294.4 calculated for the dimer. The same determinations carried out in camphor, m. p. 176.7–176.9°, give values from 176 (5% solution) to 251 (10% solution) for the dimer, indicating dissociation. The low boiling point, 130–180° at 25 mm., and its range indicate dissociation. If water and acid be excluded, up to 75% of pure crystallized material may be recovered from a vacuum distillation of the crystals.

(5) For references to the Skraup and Doebner-Miller syntheses, see Sidgwick, "The Organic Chemistry of Nitrogen," Oxford, 1937, pp. 544 ff.

(6) The hydrogen here indicated is found to reduce the monomeric Schiff base present to N-*n*-butylaniline (see experimental part).

(7) Edwards, Garrod and Jones, *J. Chem. Soc.*, **101**, 1376 (1912).

(8) Rast, *Ber.*, **55B**, 1051 (1922).

Hydrogenation of the Dimer.—By the use of a nickel catalyst[9] and hydrogen at 100 atmospheres pressure, the dimer is hydrogenated quantitatively. In the hydrogenation, one mole of dimer takes up one mole of hydrogen. The hydrogenated material is a heavy, viscous oil of boiling point 240–245° at 20 mm. A diacetyl compound is formed which has a melting point of 131°.

Anal. Calcd. for 1,3-diacetanilido-2-ethylhexane, $C_{24}H_{31}N_2O_2$: N, 7.24. Found: N, 7.47.

Anil of α-Ethyl-β-propylacrolein.—In the presence of small amounts of acid, as when old butyraldehyde is used, or as when as little as 0.03 mole % of acetic or butyric acid is added to the reaction mixture, the product from the condensation of butyraldehyde and aniline is a yellow oil of boiling point 146–148° at 15 mm. The crystalline dimer may or may not precipitate during the course of the reaction. Similarly, if an acid-free preparation is allowed to stand in air for several days, the oil is formed. The crystals are stable for much longer periods of time when the reaction is carried out in tubes from which the air is carefully evacuated. That acid and not air is responsible for the instability of the crystals is shown by their rapid decomposition in the presence of acid and absence of air. Analyses show that the oil differs from the crystalline dimer by one molecule of aniline per mole.

Anal. Calcd. for $C_{14}H_{19}N$: C, 83.47; H, 9.57; N, 6.96. Found: C, 83.64; H, 9.40; N, 6.95, 6.97.

A series of ten concordant determinations, some in triphenylmethane by Rast's method and some in freezing benzene by Beckmann's cryoscopic method gave an average value of 208.4 (±15) compared with the calculated value of 201.3 for $C_{14}H_{19}N$.

Treatment of the oil in benzene with excess benzoyl chloride at room temperature gives a 93% yield of benzanilide. Treatment of the oil with excess acetyl chloride in hot pyridine gives a 60% yield of acetanilide. The identities of these compounds were confirmed by melting points and mixed melting points with known samples.

The use of 2,4-dinitrophenylhydrazine–sulfuric acid reagent according to the directions of Ferrante and Bloom results in the production, either from the oil or from α-ethyl-β-propylacrolein, of the 2,4-dinitrophenylhydrazone of the latter.[10] In either case, the yield is 83%. The melting point of both substances is 119–120°, and mixed melting points demonstrate their identity. Similarly, a hot aqueous solution of semicarbazide hydrochloride reacts with either the oil or with α-ethyl-β-propylacrolein to give the known[11] semicarbazone of melting point 132°. The yield from the oil is 60% and the identity of the semicarbazone with that from the known aldehyde is shown by mixed melting point.

Synthesis of the Anil of α-Ethyl-β-propylacrolein from Aniline and α-Ethyl-β-propylacrolein.—α-Ethyl-β-propylacrolein is prepared from butyraldehyde in 58% yield by the method of Raupenstrauch.[12] It boils at 171–172° at 747 mm. When equimolar quantities of aniline and the acrolein are mixed, reaction takes place within five minutes as shown by the separation of water. After standing for two days, distillation of the mixture gives 70% yield of a product of boiling point 146–148° at 15 mm. Reactions of this compound with benzoyl chloride, acetyl chloride, semicarbazide hydrochloride and 2,4-dinitrophenylhydrazine give the same derivatives as those obtained from similar reactions with the oil from aniline and butyraldehyde.

Preparation of 3-Ethyl-2-propylquinoline.—We have used as a reference material the 3-ethyl-2-propylquinoline formed by the method of Kahn and purified through the picrate by the method of Spady.[13] Our product boils at 182–184° at 23 mm. The boiling point recorded by Kahn was 290–292° at atmospheric pressure. We have also obtained the material by the action of concentrated hydrochloric acid on butylidene aniline dimer and the anil of α-ethyl-β-propylacrolein. In each case the reaction proceeded for twenty to twenty-four hours at room temperature and 0.05 mole of aldehyde or its equivalent was used. The experiments are summarized in Table I.

TABLE I

PREPARATION OF 3-ETHYL-2-PROPYLQUINOLINE

Form of reactants	Moles of HCl per mole aniline[a]	Yield of 3-ethyl-2-propyl-quinoline, %[d]
Aldehyde and amine[b,c]	0.1	20
Aldehyde and amine	.5	58
Aldehyde and amine	1.0	79
Aldehyde and amine	1.5	60
Aldehyde and amine	2.0	56
Aldehyde and amine	5.0	54
Butylidene aniline dimer	1.0	50
α-Ethyl-β-propylacrolein	2.0	10
Anil of α-ethyl-β-propylacrolein	2.0	15
Aniline and the anil of α-ethyl-β-propylacrolein	1.0	20

[a] The hydrochloric acid used was concentrated aqueous reagent, approximately 12 *N*. The use of both anhydrous hydrogen chloride and of the concentrated acid diluted 20:1 gave poorer yields. [b] The aldehyde and amine were present in proportions of 2:1, in accordance with the directions of Kahn, although the reaction requires only 3:2 proportions. It was found, however, that the use of 3:2 proportions did not vary the yield significantly. [c] The best yields are obtained when the aldehyde and amine are first mixed and the hydrochloric acid then added. Adding the hydrochloric acid over a period of either five minutes or thirty minutes gave the same results. [d] Calculated on the basis: $3C_3H_7CHO + 2C_6H_5NH_2 \rightarrow C_{14}H_{17}N + C_6H_5NHC_4H_9 + 3H_2O$.

Identification and Determination of 3-Ethyl-2-propylquinoline.—The quinoline, either pure or in a mixture, was diluted with about one-third its volume of 95% alcohol. It was then treated with an excess of saturated alcoholic picric acid. The picrate precipitated immediately. After crystallization from alcohol the picrate melts at 161–163°. Since 3-ethyl-2-propylquinoline is the only quinoline formed, we have been able to use this as a quantitative method.[14] Analyses of mixtures containing 0 to 4 parts by weight of aniline to 3-ethyl-2-propylquinoline have yielded 98–100% of the theoretical picrate. In general, better

results are obtained if the quinoline fraction is separated from the tars by distillation before the determination.

By-products of the 3-Ethyl-2-propylquinoline Preparation.—The reaction mixture of the Doebner–Miller synthesis, when distilled, gives, besides the water and unchanged reagents (all of which distill below 120° at 15 mm.), two rather well-defined fractions. The first, b. p. 120–200°, consists of N-*n*-butylaniline and 3-ethyl-2-propylquinoline; the second, b. p. over 200° at 15 mm., is made up of tarry materials which may contain tetra- and di-hydro-quinolines (whose homologs have been previously reported as being present in other Doebner–Miller syntheses) and complicated polymerization products. We have confirmed the presence of N-butylaniline (67% of the yield predicted on basis of ethylpropylquinoline formed) as a by-product by the formation of its hydrochloride, m. p. 112–114° (recorded, 114°),[15] and N-butyl-N-phenyl-N′-α-naphthylurea, m. p. 277°. The hydrochloride gave neutral equivalents of 181, 182 and 185, compared with a calculated value of 185. The naphthylurea, a new compound, was prepared by the method of French and Wirtel,[16] and it has the same m. p. as that formed from known N-butylaniline. A mixed melting point showed no depression.

Anal. Calcd. for the N-butyl-N-phenyl-N′-α-naphthylurea, $C_{21}H_{22}N_2O$: N, 8.80. Found: N, 9.03.

In attempting to form the methiodide of 3-ethyl-2-propylquinoline of melting point 172°, described by Kahn,[13] we were able to isolate a material of this melting point. This compound, however, was unstable and gave neutral equivalents on titration with alkali varying from 320 to 381 (theoretical for the hydriodide is 341), showing that it was not a quaternary salt. When we attempted to form the methiodide from highly purified quinoline (through the picrate as above described), the material formed had a m. p. 160–165° and was not titratable with alkali. This is probably the true quaternary methiodide.

Anal. Calcd. for 3-ethyl-2-propylquinoline methiodide, $C_{15}H_{20}NI$: I, 37.28. Calcd. for 3-ethyl-2-propylquinoline hydriodide, $C_{14}H_{18}NI$: I, 38.63. Found (by Fajans' method): I, 37.11.

That the compound described by Kahn was probably the quinoline hydriodide was shown by its formation on passing anhydrous hydrogen iodide through a low-boiling ligroin solution of the pure quinoline. The melting point of this hydriodide was 171–172° and the material was titratable with base. A mixed melting point with the material originally isolated from treatment with methyl iodide was 169–171°.

Summary

1. The condensation of butyraldehyde and aniline in acid and neutral media has been studied.

2. The structure of the dimer of butylidene aniline has been established as well as that of the compound formed from it by the loss of aniline.

3. 3-Ethyl-2-propylquinoline has been prepared in several ways. A mechanism has been suggested for the Doebner–Miller synthesis.

4. The following new compounds have been prepared: the anil of α-ethyl-β-propylacrolein, 1,3-diphenylamino-2-ethylhexane, its diacetyl derivative, α-ethyl-β-propylacrolein-2,4-dinitrophenylhydrazone, N-butyl-N-phenyl-N′-α-naphthylurea, and 3-ethyl-2-propylquinoline hydriodide and methiodide.

Spectroscopic Evidence for Hydrogen Bonds: SH, NH and NH_2 Compounds

BY WALTER GORDY[1] AND SPENCER C. STANFORD[2]

Introduction

The hydrogen bond theory,[3] which asserts that under certain conditions a proton may form a bond, or bridge, between two electronegative atoms such as N or O, was proposed by Latimer and Rodebush[4] in 1920. Earlier isolated cases of this type of bonding had been recognized.[5] The wide occurrence of hydrogen bonds, however, has just begun to be realized, largely through measurements of infra-red absorption spectra. The importance of these bridges is evidenced by the fact that chelation, and association between like and unlike molecules, resulting from hydrogen bonds, in turn cause appreciable variations in boiling points, freezing points, viscosities, dielectric constants, heats of mixing and of vaporization, vapor pressures, etc., of many compounds in the liquid and solid states as well as in solution. These bonds also play an important role in the determination of protein structure.[6]

Infrared spectroscopy is particularly well suited

to the study of hydrogen bonds because it gives direct information about the particular groups of the molecule which participate in the formation of the bonds. For this reason it is generally recognized as superior to methods based on measurements of other physical properties. The usual approach in the spectroscopic method is to observe the effects of the bonding on the group which donates the proton. The bonding weakens the binding force of this group and hence shifts its vibrational band to lower frequencies. The strength of the bond can be estimated from the magnitude of the shift.[7] Also, for hydrogen bonds between unlike molecules it is possible in the same way to compare the intrinsic strengths of organic bases by the effects which these different bases, when used as solvents, will produce on the spectrum of the proton donor group of a suitable solute.[8] In undertaking the present investigation we sought to extend the hydrogen bond theory by discovering other molecules which would donate their proton in hydrogen bond formation. Compounds containing SH, NH or NH_2 were selected because of their importance, especially in biological phenomena, and because they have not been studied extensively by the infrared method.

Instrument.—Although a prism spectrometer was used as a resolving instrument, much better resolution was obtained than is possible with the usual prism instrument. The current was amplified by a Moll thermal relay. Large reflecting mirrors made possible effective use of a 60° rock salt prism, of 7 × 6 cm. face, through which the light was passed twice to increase the dispersion. It was found that with this prism better results could be obtained in the regions studied than with a 60°, 4 × 6 cm., fluorite prism, which was available. The design of the Wadsworth–Littrow type of instrument which was used has been described fully by Strong.[9]

Discussion

SH Compounds.[10]—Numerous instances of hydrogen bonding with the first period elements carbon, nitrogen, oxygen and fluorine have been verified by infrared absorption spectroscopy and other physical methods.[3,11] It was thought for a long time that hydrogen bonding between elements of the second period or between first and second period elements did not exist. For example, Sidgwick[12] has emphasized the improbability of hydrogen bonding with an atom in the second period of elements, saying that as we pass from OH to SH and from hydrogen fluoride to hydrogen chloride the electron acceptor power of the hydrogen practically vanishes. Recently, however, evidence for the association of hydrogen chloride and for the formation of complexes, through hydrogen bonding, between chlorine and an element of the first period has been obtained.[13]

It is known that hydrogen sulfide and the mercaptans are not associated. The molecular weights of some of the mercaptans in benzene solution have been shown to be normal, and in the lower mercaptans the boiling points are less than the corresponding alcohols, in spite of their higher molecular weight. In the present investigation it is shown that spectroscopic methods confirm these conclusions. With regard to the formation of hydrogen bonds between sulfur and elements of the first period, Huggins[11a] states that he knows of no examples of hydrogen bridges joining a sulfur atom with another electronegative atom. He suggests, nevertheless, the possibility of such bridges, saying that they would undoubtedly be very weak. Lassettre[11b] says that molecular weight data show that SH groups do not form hydrogen bonds to any appreciable extent.

The alcohols, with low acidity constants, act as proton donors in complex formation with amines and oxygenated solvents.[14] Although there is a dearth of information on the acidity of the mercaptans, it is usually assumed that they are much more acid than the alcohols.[15] Lucas[16] gives $K_a = 3 \times 10^{-11}$ for ethyl mercaptan as compared with $K_a = 7.3 \times 10^{-20}$ for ethyl alcohol. It

seemed possible, therefore, that the mercaptans with their larger acidity constants might donate their proton to form complexes such as those formed with the alcohols.

Williams[17] has shown recently that the fundamental vibrational band of the SH group for benzyl, *n*-butyl and *n*-propyl mercaptans lies in the region 3.8–3.9 μ. For comparison we have repeated his results on benzyl and *n*-butyl mercaptans. Curves for these compounds, for thiophenol and for thioacetic acid are given in Fig. 1. The SH band is much more intense for the latter two compounds than for the former.

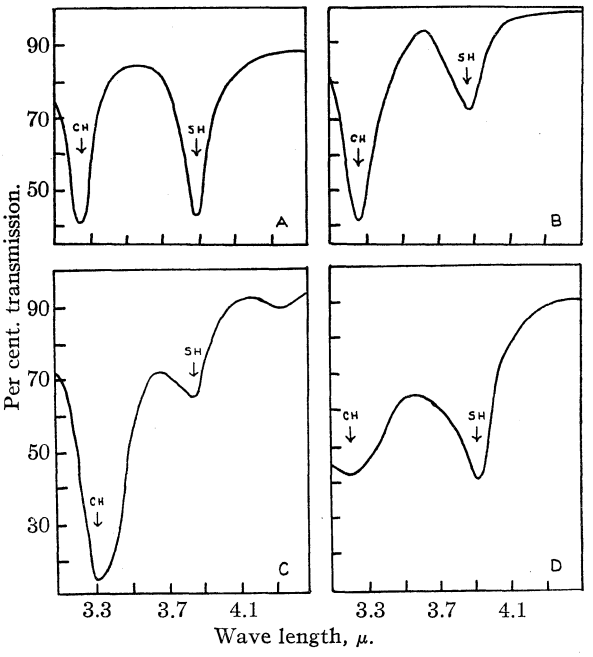

Fig. 1.—Transmission of: A, thiophenol, t = 0.005 cm.; B, benzyl mercaptan, t = 0.005 cm.; C, *n*-butyl mercaptan, t = 0.005 cm.; D, thioacetic acid, t = 0.002 cm.

A comparison of the intensities of the SH bonds of the compounds in Fig. 1 together with a comparison of their acidities leads to the conclusion that if any of these compounds are associated thiophenol would be. To ascertain whether polymerization occurs we measured the absorption of thiophenol in dilute solution in benzene. Figure 2 shows that the SH band does not shift to the shorter wave lengths upon dilution in an inert solvent as does the OH alcohol band,[18] thus confirming the evidence of molecular weights and other physical properties that the mercaptans are not associated in the liquid state.

To test for complex formation we studied, in the region of the SH band, mixtures of some mercaptans with several liquids which previously had been found to form complexes with heavy methyl alcohol through interaction with the OD group.[8b] Transmission curves for the different mixtures were observed and these were compared with theoretical transmission curves computed from Beer's law using the absorption coefficients obtained from the transmission curves of the pure liquids. The results for the thiophenol mixtures are shown in Fig. 3. The broken curves represent the transmission which would be expected of the mixtures if no interaction whatever occurred between the components; the solid

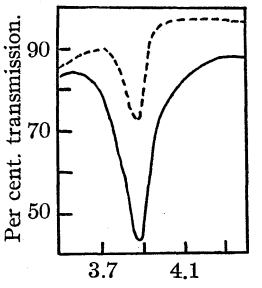

Fig. 2.—Broken line, 0.1 *M* thiophenol in benzene *versus* pure benzene, t = 0.361 cm.; solid line, pure thiophenol, t = 0.005 cm.

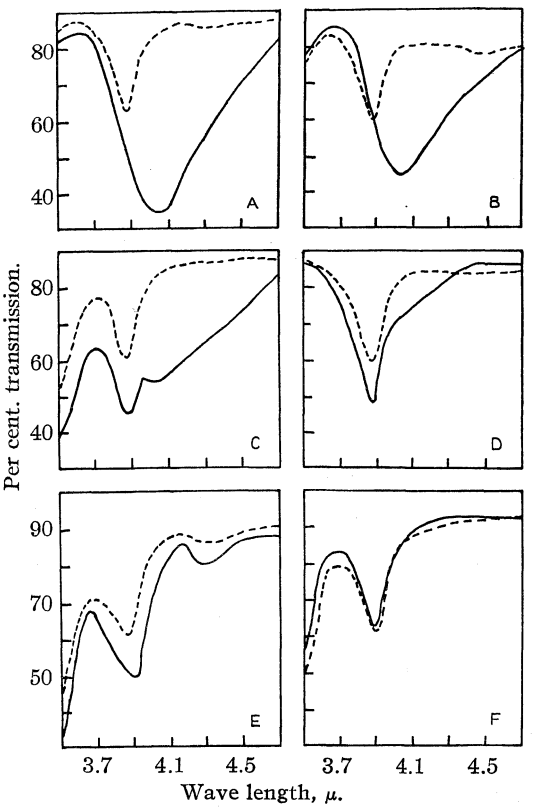

Fig. 3.—Theoretical (broken lines) and observed (solid lines) transmission of mixtures (1:1 vol., t = 0.005 cm.) of thiophenol with: A, pyridine; B, α-picoline; C, dibenzylamine; D, aniline; E, isopropyl ether; F, ethyl-*o*-toluidine.

curves represent the transmission which was actually observed.

The most pronounced variations observed were for thiophenol with pyridine and with α-picoline. For these mixtures the SH band is shifted to the longer wave lengths by about 0.18 μ or 114 wave numbers, and its intensity is increased several fold. We believe that these results give proof of the formation of SH → N bonds between the thiophenol and the amines.

The results indicate that thiophenol also forms a complex with dibenzylamine, but that the tendency to do so is slightly less than with pyridine or α-picoline. The position of the associational band is 4.04 μ for thiophenol–dibenzylamine as compared with 4.06 μ for thiophenol–pyridine. The rather strong band at 3.88 μ, the position of the SH band of pure thiophenol, indicates that a large percentage of the thiophenol is not linked to the dibenzylamine.

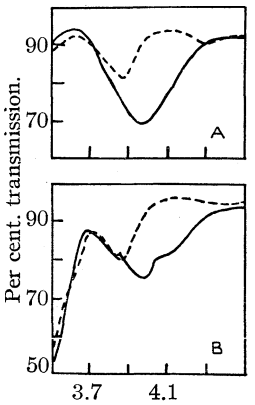

Fig. 4.—Theoretical (broken lines) and observed (solid lines) transmission of mixtures (1:1 vol., t = 0.005 cm.) of benzyl mercaptan with: A, pyridine; B, benzylamine.

Thiophenol tends to form a complex with aniline even less than it does with dibenzylamine. There is no minimum beyond 3.88 μ in the thiophenol–aniline curve although the departure of the experimental from the theoretical curve on the long wave length side of the band probably indicates some interaction. It may be that aniline (K_b = 4.6 × 10^{-10}) is too weakly basic to attract the proton from thiophenol sufficiently to form a hydrogen bridge. The existence of weak hydrogen bonds between the aniline molecules in the liquid state, for which there is evidence,[19] may also be a contributing factor in the non-formation of a complex. Hydrogen bonding between the aniline molecules could of course prevent the aniline nitrogen from accepting a proton from the mercaptan SH. In this connection Zellhoefer, Copley and Marvel[11d] have shown that aniline is a poor solvent for certain haloforms, and they attribute this to the association of the aniline.

Only one oxygenated solvent, isopropyl ether, was investigated for the formation of a complex with thiophenol. In the comparison of the proton-attracting power of liquids previously made,[8b] the ethers were found to form stronger hydrogen bonds with alcohols than did any of the other oxygenated solvents studied. Therefore, it was concluded that if isopropyl ether did not form bonds with the mercaptans, none of the oxygenated solvents would form them. As may be seen from a comparison of the experimental and theoretical curves for thiophenol–isopropyl ether, there is very little interaction. Thus it was not considered worth while to study mixtures of the mercaptans with other oxygenated solvents as there would probably be little complex formation between them.

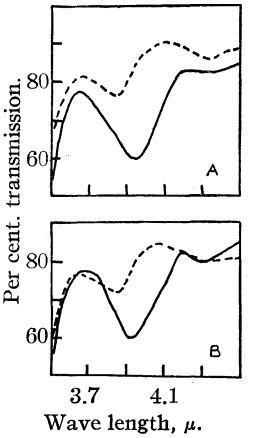

Fig. 5.—Theoretical (broken lines) and observed (solid lines) transmission of mixtures (1:1 vol., t = 0.005 cm.) of n-butyl mercaptan with: A, pyridine; B, α-picoline.

The experimental curve for the ethyl-o-toluidine–thiophenol mixture is almost identical with the theoretical curve computed from Beer's law. This result could be anticipated, for even if the nitrogen of the ethyl-o-toluidine strongly attracted the proton of the SH, steric hindrance would probably prevent association with the thiophenol.

Piperidine (K_b = 1.6 × 10^{-3}) formed a white crystalline solid immediately upon being mixed with thiophenol. Similar results were obtained with cyclohexylamine and with triamylamine. Apparently thiophenol forms hydrogen bonds with substances of a rather narrow range of basicities. For substances with basicity constants much lower than that of pyridine, no appreciable interaction occurs. For substances with basicities much higher than that of pyridine, the thiophenol

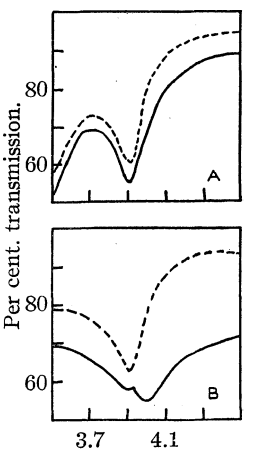

Fig. 6.—Theoretical (broken lines) and observed (solid lines) transmission of mixtures (1:1 vol., t = 0.002 cm.) of thioacetic acid with: A, isopropyl ether; B, pyridine.

(19) W. Gordy, *J. Chem. Phys.*, **7**, 167 (1939).

appears to be completely ionized by the base to form a salt.

Because the aliphatic mercaptans and benzyl mercaptan probably have lower acidity constants than thiophenol, they would be expected to show less tendency to share their proton in hydrogen bond formation. This was found to be true for the cases studied. Figure 4 gives the results obtained for benzyl mercaptan with pyridine and with benzylamine. Both of these liquids form hydrogen bonds with the benzyl mercaptan. The shift in the SH band of benzylamine caused by the pyridine is less than that caused by the pyridine on the SH band of thiophenol. Figure 5 shows the evidence secured for the interaction of *n*-butyl mercaptan with pyridine and α-picoline. A curve was obtained for piperidine which gave a minimum at 4.04 μ, but because of the intense CH absorption of piperidine and the weakness of the mercaptan band, the position of the associational band is probably not very accurate. Evidence was also found for weak hydrogen bonds between pyridine and thioacetic acid, Fig. 6. Isopropyl ether produced no shift in the thioacetic acid band.

[a] In each of these cases a weak band due to unmodified SH appeared.

The results for all the SH compounds are summarized in Table I.

NH and NH_2 Compounds.—Hydrogen bridges formed through an amine hydrogen probably play a significant role in the determination of protein structure.[6,11a,20] Attempts have been made to study directly hydrogen bonds in protein molecules.[21] Nevertheless the complexity of the protein molecules with their overlapping OH and NH_2 absorption makes the method difficult and the interpretation of the data somewhat uncertain. Thus it seems well to obtain all the data possible on the simpler NH and NH_2 compounds. This should be valuable in predicting behavior in the more complex cases.

Buswell, Rodebush and Roy[22] have made a significant contribution in their work on the acid amides. Although they succeeded in showing that association is present they could not tell whether it was due to NH → N or NH → O bonds, as both are possible. Even though there is some evidence for the very weak association of liquid ammonia,[3] physical data indicate that the aliphatic amines are not generally associated.[23] That the lack of association is not due to the weaker proton acceptor power of the amine nitrogen is evidenced by the marked perturbation produced by the amine nitrogen on the OD band of heavy alcohol[8] and is also evidenced by the basicity constants of these compounds.

Certain aromatic amines, nevertheless, are sufficiently acidic to share their proton to form hydrogen bridges. One of us has already shown that aniline is associated through NH → N bonds and that it will form complexes through NH → O bonds to certain oxygenated solvents.[19] The bonds are very weak, the shifts obtained being about one-fourth that found for methyl alcohol. Although Buswell, Rodebush and Roy[24] failed to find spectroscopic evidence for the association of aniline, their failure to observe the small shift may have been due to the low resolving power of their instrument, as other physical data[11d] agree

Rodebush (THIS JOURNAL **61**, 3252 (1939)) publish two curves for aniline in CCl_4: one 0.64 *M* and the other 0.01 *M*, showing the NH_2 absorption at the same position in both of these solutions. They offer these curves as evidence that aniline does not associate in the liquid state. That they did not detect the weak association of aniline was obviously due to their failure to study a sufficiently concentrated solution or the pure liquid.

with the interpretation that it is weakly associated. The work which has just appeared by Yeou Ta[25] on the third harmonic of the xylidines shows that they are associated except in the cases where steric hindrance prevents.

Wulf and Liddel[28] studied a number of amines by the infrared method. Their measurements were made in the region of the second harmonic of the NH band. As they made observations of only very dilute solutions in carbon tetrachloride, they could not study intermolecular association. They found that whenever a C=O group is adjacent to the NH_2 group, as in benzamide or methyl anthranilate, the NH band is appreciably perturbed. Hendricks, Wulf, Hilbert and Liddel[29] made similar studies of numerous compounds in which chelation was found to occur through OH → N bridges.

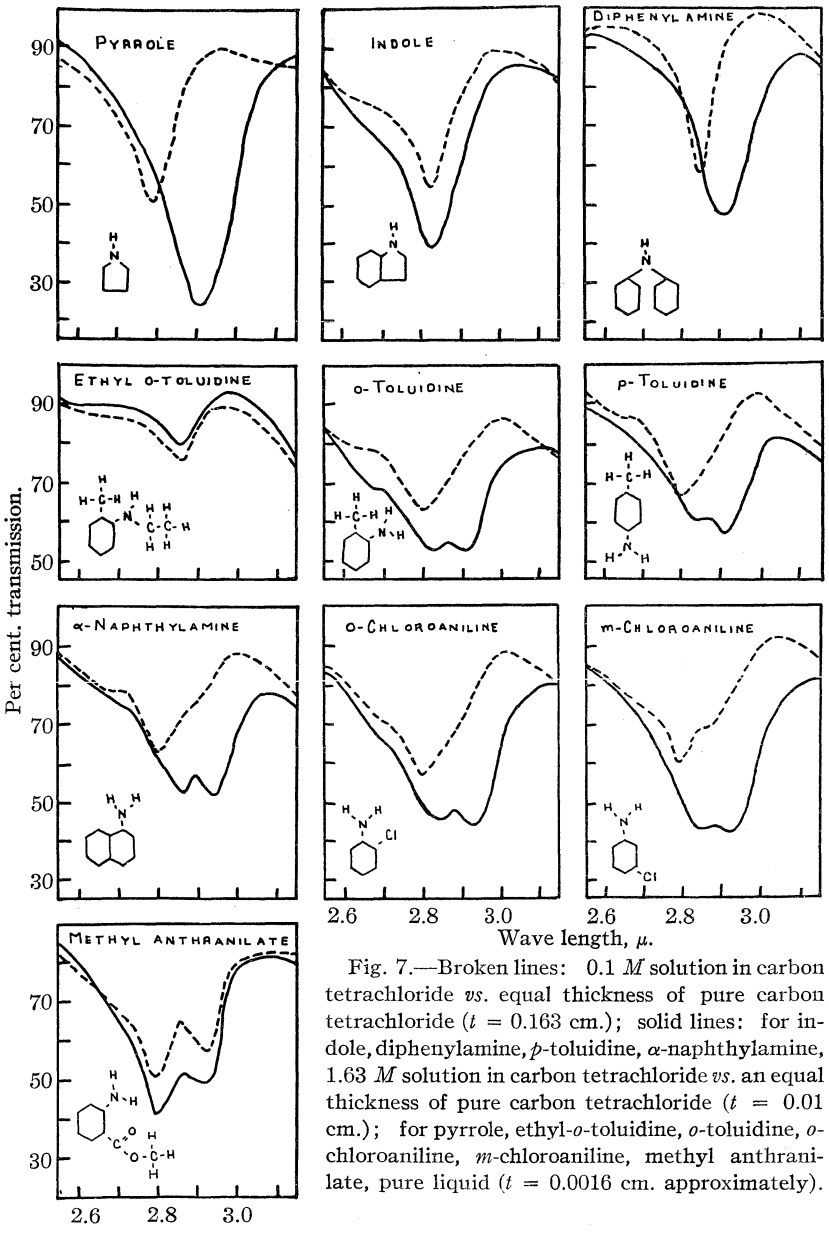

Fig. 7.—Broken lines: 0.1 *M* solution in carbon tetrachloride *vs.* equal thickness of pure carbon tetrachloride (t = 0.163 cm.); solid lines: for indole, diphenylamine, *p*-toluidine, α-naphthylamine, 1.63 *M* solution in carbon tetrachloride *vs.* an equal thickness of pure carbon tetrachloride (t = 0.01 cm.); for pyrrole, ethyl-*o*-toluidine, *o*-toluidine, *o*-chloroaniline, *m*-chloroaniline, methyl anthranilate, pure liquid (t = 0.0016 cm. approximately).

The present investigation included a number of amines having lower basicity constants than that of aniline, previously found to be weakly associated through hydrogen bonds. We obtained the absorption spectrum characteristic of the NH or NH_2 group of the unassociated amine in dilute solution of carbon tetrachloride and compared this with the absorption of the same group in the pure liquid or in concentrated solution when the compound was a solid. We also ran each of these compounds in an oxygenated solvent, *n*-butyl ether, in order to detect complex formation through NH → O bonds with the ether. In each case the cell thickness and concentration were arranged so that the different curves for the same substance represent approximately the same number of absorbers. Thus it is possible to observe the effects of association upon the intensity of the band as well as upon its position.

Figure 7 shows the study of the association of the pure substance. The dotted lines represent

Pyrrole is more acidic than the aliphatic amines, and there are reasons to believe that it is associated.[26] Freymann[27] has shown that the third harmonic shifts to the longer wave lengths and is broadened appreciably as the pyrrole is changed from the vapor to the liquid state.

the absorption of the dilute solution, 0.1 molar, and the solid lines represent that of the pure liquid or concentrated solution. The solution curves represent the ratio of the transmission of the solution to that of an equal thickness of the pure solvent. For the pure liquid the curves represent the ratio of the transmission of the cell containing the liquid to that of the empty cell. Because, for the reason discussed above, the associational bonds here are likely weaker than those for alcohol, we think that we are safe in assuming that the band which appears in the 0.1 molar solution is that of the monomeric form. The departure of the curve for the concentrated solution from that for the dilute solution may therefore be taken as a measure of the interaction which occurs.

For pyrrole, diphenylamine, *o*- and *p*-toluidine, α-naphthylamine, *o*- and *m*-chloroaniline, the shifts to the longer wave lengths and the increase of intensity in the band are evidence that hydrogen bonding occurs in the pure liquid or the concentrated solution. It is interesting to note that for indole, ethyl-*o*-toluidine and methyl anthranilate no shift nor marked intensity change occurs, an indication that these substances do not polymerize. From a consideration of the structural formula for ethyl-*o*-toluidine, which is given in the figure, it is rather obvious that steric hindrance may prevent polymerization of this compound. Intermolecular hydrogen bonds between the methyl anthranilate molecules are no doubt prevented by the formation of intramolecular bonds to the C=O group. That intramolecular bonds exist here is clear from a comparison of the curve for the dilute solution with those for the other NH_2 compounds given in the figure. This chelation is also evident from the experiments of Wulf and Liddel.[28] In view of the association of the similar compound, pyrrole, the failure of indole to polymerize is not so obvious. That it is not due to the fact that indole holds its proton too firmly to share it is shown by its donating it to form a complex with *n*-butyl ether. We are inclined toward the interpretation that steric hin-

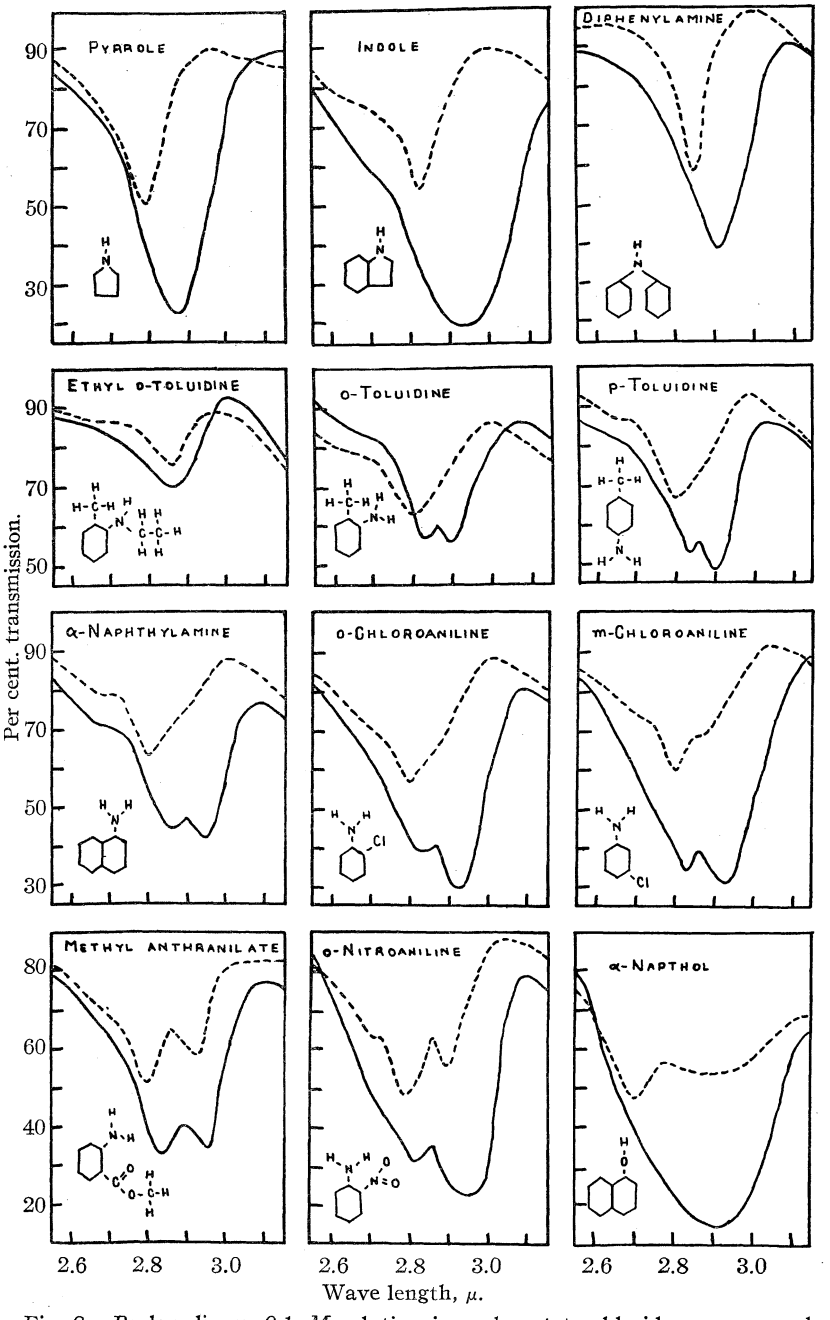

Fig. 8.—Broken lines: 0.1 *M* solution in carbon tetrachloride *vs.* an equal thickness of pure carbon tetrachloride (t = 0.16 cm.); solid lines: 0.1 *M* solution in *n*-butyl ether *vs.* an equal thickness of *n*-butyl ether (t = 0.163 cm.).

TABLE II

Substance	Minima in transmission curves, μ: 0.1 mol. sol. in CCl_4	1.63 mol. sol. in CCl_4	Pure liquid	0.1 mol. sol. in *n*-butyl ether	K_b

Methyl anthranilate	2.80 2.93		2.80 2.93	2.83 2.96	
o-Nitroaniline	2.79 2.89			2.82 2.95	1.5×10^{-14}
α-Naphthol	2.70 2.91			2.91	1.0×10^{-8}

drance prevents this polymerization. On the other hand, it may seem a little strange, though not impossible, that steric hindrance would prevent association between indole molecules and yet not prevent association between indole and ether.

The bands for the NH compounds are rather symmetrical and sharp. For the NH_2 compounds the association splits the band into a doublet with one component only slightly shifted from the position of maximum absorption of the monomeric band. This splitting may arise from the possibility that only one of the protons of the NH_2 group is involved in hydrogen bond formation. Even for the monomeric form of these compounds the bands are broader and more complex than those for the NH compounds. Wulf and Liddel[28] pointed out that in the region of the second harmonic the NH_2 absorption is complex as compared with that of NH and OH. Our curves, however, do not resemble closely those of these researchers. It is not to be expected that bands in the fundamental region should be similar to those of the second harmonic, as no simple relation exists between them.

Figure 8 shows a study of complex formation between *n*-butyl ether and the above-mentioned compounds. In addition, one other NH_2 compound, *o*-nitroaniline, is included, also an OH compound, α-naphthol. The curves for 0.1 molar solution in carbon tetrachloride are repeated here for comparison. All the curves given in this figure are for 0.1 molar solutions of the same thickness, 0.163 cm. Therefore any appreciable departure of the curves for the *n*-butyl ether solutions from those of the same substances in carbon tetrachloride is evidence for the interaction of the solute with *n*-butyl ether.

The same substances which were found to be polymerized through hydrogen bonds were also found to form complexes with the *n*-butyl ether. Yet indole, which, as was mentioned above, apparently does not polymerize, interacts strongly with the ether. The results indicate that ethyl-*o*-toluidine does not form a complex with the *n*-butyl ether. The curve for the methyl anthranilate in the *n*-butyl ether solution is somewhat more intense than the curve for the carbon tetrachloride solution of the same concentration, but the minima are only slightly shifted from the position of those for the carbon tetrachloride solution. Since the intermolecular bonds with the ether, if they are formed, would probably be of the same order of strength as the intramolecular bonds, which are already formed and which would probably be broken if a complex is formed, it is not possible to predict whether there is much interaction between the *n*-butyl ether and the methyl anthranilate. For *o*-nitroaniline the departure of the curve for the *n*-butyl ether solution from that for the solution in carbon tetrachloride is much more pronounced, an indication that the intramolecular hydrogen bonds to the NO_2 group do not prevent interaction with the ether. From previous measurements it is known that an ether oxygen attracts the proton of an hydroxyl group more strongly than does an oxygen of the nitro group of nitrobenzene or nitrotoluene.

The curves which are included for α-naphthol make possible a comparison of the strength of the bonds formed through an NH_2 group with those through an OH group. It is obvious that the effects of *n*-butyl ether on the OH band of the α-naphthol are much more pronounced than the effects of this solvent upon the absorption of the NH_2 group of the α-naphthylamine. The curve for the 0.1 molar solution of α-naphthol in carbon tetrachloride shows that the polymerization of the α-naphthol is not completely broken down at this

concentration, as there is still absorption in the region of 2.9 μ. The band appearing at 2.7 μ is the monomolecular band.

The positions of minima in the transmission curves for the pure liquids and different solutions are given in Table II.

In other reports[8] there is a comparison of the proton-attracting power of many different solvents, including *n*-butyl ether. By use of the data given there with the shifts in the NH or NH_2 bands caused by the *n*-butyl ether, it is possible to predict the interaction of these other solvents with the amines studied here.

The authors wish to thank Dr. Alpheus W. Smith and Dr. H. H. Nielsen for their constant interest and support, and Vida Miller Gordy for her assistance in the preparation of the manuscript. They also wish to acknowledge a very helpful discussion with Dr. G. B. B. M. Sutherland.

Summary

The association of the mercaptans with certain electron donor solvents has been investigated by means of infrared spectroscopy. The study included 1:1 volume mixtures of thiophenol with isopropyl ether, ethyl-*o*-toluidine, aniline, pyridine, α-picoline and dibenzylamine. For the ethyl-*o*-toluidine mixture the SH band of the thiophenol was virtually unaffected. For the mixtures with isopropyl ether, and with aniline, only a slight perturbation of the band occurred. For the mixtures with pyridine, α-picoline and dibenzylamine there was a shift of approximately 0.18 μ to the longer wave lengths, together with a broadening and a marked increase in intensity. These effects, we believe, indicate hydrogen bonding between the latter solvents and the thiophenol, with the SH group donating the proton. Similar but less pronounced effects were observed for *n*-butyl mercaptan, benzyl mercaptan and thioacetic acid with some of these solvents. A 0.1 *M* solution of thiophenol in benzene was studied, and the SH band was found to appear at the same position for the solution as for the pure liquid. This failure of the SH band to shift to shorter wave lengths upon dilution in an inert solvent is evidence that thiophenol is not polymerized in the liquid state.

The study included a number of amines having basicity constants about the same as or lower than that of aniline. All were found to be associated through hydrogen bonds except those for which steric hindrance would be expected to prevent the association. The absorption spectrum of the NH or NH_2 group of the unassociated amine in dilute solution in carbon tetrachloride was obtained and compared with the absorption of the same group of the pure liquid or of a concentrated solution when the compound was a solid. Each of the compounds was studied in an oxygenated solvent, *n*-butyl ether, in order to detect complex formation through NH $\rightarrow$ O bonds with the ether. The following compounds were found to be polymerized in the pure state, also to form complexes with the ether: pyrrole, diphenylamine, *o*- and *p*-toluidine, α-naphthylamine, *o*- and *m*-chloroaniline. Although the results indicate that indole does not polymerize, it appears to form a complex with *n*-butyl ether. Ethyl-*o*-toluidine apparently neither polymerizes nor forms complexes. Its lack of association can be ascribed to steric hindrance. Evidence was found for chelation in methyl anthranilate and *o*-nitroaniline. This chelation likely prevents appreciable polymerization or complex formation with these compounds. α-Naphthol, the one OH compound included, was found to be more strongly associated than the NH or NH_2 compounds of similar structure.

The Conductance of Some Salts in Chlorobenzene at 25°

BY ROBERT L. MCINTOSH AND DARWIN J. MEAD WITH RAYMOND M. FUOSS

I. Introduction

Specific interaction between solute and solvent is expected when an acid solute such as tributylammonium picrate is dissolved in a basic solvent. For example, in tricresyl phosphate[1] ($D = 6.92$ at 40°) this salt has a dissociation constant of 1.18×10^{-6}, which gives an ion size of 4.66×10^{-8} cm. But in ethylene chloride[2] ($D = 10.23$ at 25°), the dissociation constant is only 2.10×10^{-8}, which leads to an ion size of 2.4×10^{-8} cm. The ion sizes are calculated on the assumption that the interaction between ions can be represented as that between uniformly charged spheres in a homogeneous medium,[3] and if this model were correct, the ion size calculated from the dissociation constant of the solute and the dielectric constant of the solvent would be independent of solvent. Clearly tributylammonium picrate in tricresyl phosphate is electrolytically quite different from tributylammonium picrate in ethylene chloride, even after allowing for the difference in dielectric constant. A possible explanation can be found in an interaction between solute and solvent, which gives an effectively stronger electrolyte in the former solvent, which is equivalent to saying that the non-electrolytic dissociation[1] is suppressed in the basic solvent. Ethylene chloride is aprotonic and does not enter the equilibria.

But for completely substituted quaternary salts, independence of ion size on solvent has in general been found, so that it was possible to predict approximate values of dissociation constant from the dielectric constant of the solvent. In this paper, we shall present data showing that specific interaction between solute and solvent, as indicated by variation of ion size with solvent, is also possible for quaternary salts. The dissociation constants of tetrabutylammonium bromide and picrate in chlorobenzene ($D = 5.63$ at 25° and 60 cycles) are only about one-tenth as large as the values calculated from the ion sizes found for these salts in a number of other solvents.

II. Materials, Apparatus and Procedure

C. p. chlorobenzene was redistilled, and initial and final portions were discarded. It was then dried by two successive treatments with activated aluminum oxide. The solvent conductance was very sensitive to traces of moisture, as was the conductance of dilute solutions of the electrolytes. The best value obtained for the pure solvent was 2×10^{-12} mho. The solvent was stored over aluminum oxide, and filtered just before use directly into the dilutions flasks through a glass cotton plug by dry air pressure.

Tributyl and **tetrabutylammonium picrates** were those used by Elliott and Fuoss.[1] **Tetrabutylammonium bromide** was prepared by neutralizing a solution of tetrabutylammonium hydroxide (from tetrabutylammonium iodide and moist silver oxide in alcohol) with hydrogen bromide. It was recrystallized from ethyl acetate; m. p.[4] 103.1–103.3°. *Anal.* Subs., 0.3034, 0.2965: AgBr, 0.1760, 0.1722. Calcd. for Bu_4NBr: Br, 24.80. Found: Br, 24.69, 24.72.

Electrical Equipment and Cells.—Measurements were made at low voltage and 60 cycles, using the Schering or resistance bridge.[5] Solutions were made up by weight, and pumped by dry air pressure from the dilution flask into a platinum conductance cell,[6] which was then placed in an oil-filled thermostat at 25.00°. Several cell fillings were made with each solution in order to eliminate sorption errors.[4]

III. Results

The conductance data are summarized in Table I, and are shown as log Λ–log c plots in Fig. 1. Several dilution runs were made for each salt. In the case of the tributyl salt, three solu-

tions in the dilute range, marked with an asterisk in Table I, were also prepared directly, in order to be certain that solvent of low conductance was used. The point at 1.076×10^{-3} N looks high, as would be expected if the solutions absorbed a little moisture during preceding dilutions.

IV. Discussion

As is seen in Fig. 1, the conductance curves approach a straight line of slope $(-1/2)$ in the dilute region, indicating a simple binary equilibrium in this range. The curve for the bromide shows a broad minimum, similar to that shown by this salt in other solvents. As expected, the quaternary bromide is a weaker electrolyte than the quaternary picrate, while the tertiary picrate is much weaker than either. Quantitative comparison can be made by determining the constants of the curves.

From the viscosity[7] of chlorobenzene, $\eta_{25} = 0.00752$, and the limiting conductance of salts of this type in ethylene chloride[4,8] we estimate $\Lambda_0 = 60$. The $\Lambda\sqrt{cg}(c)$–c plots[9] are linear, and give the values found in Table II for the dissociation constants K and k corresponding to the ion pair and triple ion equilibria. In the last line are the a values calculated from K by the relationship[3]

TABLE II

CONSTANTS IN CHLOROBENZENE AT 25°

	Bu_4NPi	Bu_4NBr	Bu_3HNPi
K	1.88×10^{-8}	1.13×10^{-9}	2.10×10^{-13}
k	6.75×10^{-3}	0.42×10^{-3}	4.22×10^{-3}
a	4.75×10^{-8}	3.86×10^{-8}	2.98×10^{-8}

$$K^{-1} = \frac{4\pi N}{1000}\left(\frac{\epsilon^2}{DkT}\right)^3 Q\left(\frac{\epsilon^2}{aDkT}\right) \qquad (1)$$

where $Q(x)$ is the function

$$Q(x) = \int_2^x e^y y^{-4} dy \qquad (2)$$

The ratio of the dissociation constants of the quaternary picrate and bromide is 16.6, with an ion size *difference* of 0.89×10^{-8} cm. This is about the same as was found in anisole[4] (5.60 − 4.61 = 0.99) and in diphenyl ether[10] (5.33 − 4.60 = 0.73). In other words, the two salts have about the same *relative* strengths in these three solvents. But both have equivalent ion sizes nearly an ångström unit smaller in chlorobenzene than in the ethers; that is, they are much weaker electrolytes in chlorobenzene than their behavior in the other solvents would lead one to expect.

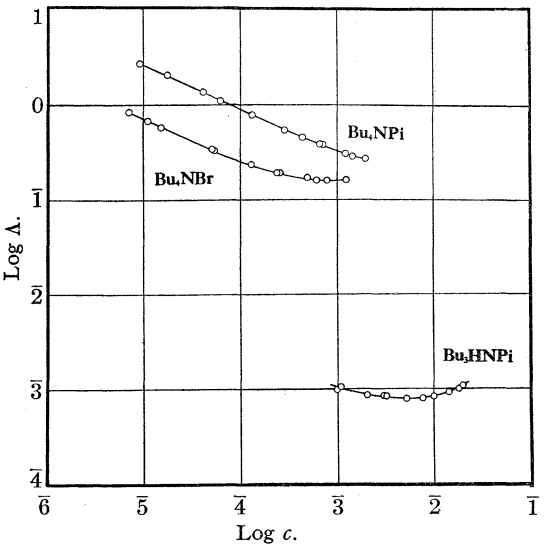

Fig. 1.—Conductance curves in chlorobenzene at 25°.

The following values for the parameter a for tetrabutylammonium picrate have been found: 5.83 in ethylene chloride[8] ($D_{25} = 10.23$), 5.80 in tricresyl phosphate[1] ($D_{40} = 6.92$), 5.60 in anisole[4] ($D_{25} = 4.27$), 5.33 in diphenyl ether[6] ($D_{50} = 3.53$) and 5.7 in benzene[11] ($D_{25} = 2.28$). A salt in chlorobenzene, for which $a = 5.6 \times 10^{-8}$, would have at 25° $K = 21.3 \times 10^{-8}$, which is 11.3 times as large as the dissociation constant found here for tetrabutylammonium picrate.

The tributyl salt is very weak in chlorobenzene, although relatively stronger than in ethylene chloride; the corresponding ion sizes are 2.98 and 2.40×10^{-8} cm.

The only conclusion to be reached at present is that other forces than coulomb interaction between ions must be considered in a general quantitative description of electrolytic behavior. Equation (1) gives the dependence of the ionic equilibrium on dielectric constant of solvent, but the variation of the parameter a from solvent to solvent for a given electrolyte shows that the present model is an over-simplification, and that even for strong electrolytes, specific interactions with solvent may be expected in some cases.

Summary

1. The conductances of tributylammonium picrate, tetrabutylammonium picrate and tetrabutylammonium bromide in chlorobenzene at 25° have been determined.

(11) Fuoss and Kraus, THIS JOURNAL, **55**, 3614 (1933).

2. The effective ion sizes of the quaternary bromide and picrate in chlorobenzene are about one ångström unit smaller than in a number of other solvents; this result indicates that specific interaction between solvent and solute can appear even in the case of strong electrolytes.

Relative Efficiency of Active Wave Lengths of Ultraviolet in Activation of 7-Dehydrocholesterol

BY JOHN W. M. BUNKER, ROBERT S. HARRIS AND L. MALCOLM MOSHER

The sterols which have received major attention in respect to their photochemical conversion into antirachitics are ergosterol and cholesterol, associated respectively with lower plants and with animal materials. Crystalline ergosterol may be regarded as the precursor of vitamin D_2 (Calciferol), the principal form of antirachitic vitamin now available from commercial activation; crystalline cholesterol, on the other hand, does not itself constitute a significant provitamin, but its derivative, 7-dehydrocholesterol, when irradiated with appropriate ultraviolet energy, is converted into vitamin D_3,[1,2] a form which has been found only in animal tissues.

In the present study the quantum efficiencies of certain wave lengths of ultraviolet in the activation of 7-dehydrocholesterol in ether have been measured and compared.

Irradiation Procedure.—Details of the irradiation procedure already have been published.[3] A cylindrical quartz vessel of 80 cc. capacity was filled with a 0.1% solution of 7-dehydrocholesterol[4] in anhydrous ether, C. P., and placed in the optical axis of the beam emerging from a quartz monochromator.[5] Exposure times were calculated from data on preliminary tests so that an approximation of 33 U. S. P. XI units (10 Steenbock units) would be produced with each batch. Since one batch would give sufficient active material for assay on only ten rats and since the protocol for this series called for groups of forty or fifty rats each, the irradiation procedure was repeated four or five times for each wave length. This was done over a period of five days during which time repetitive irradiations were scattered at random through the whole series, thereby distributing any undetected variations in the conditions of the irradiation. At each wave length each unit batch was subjected to 2475×10^{12} quanta of monochromatic ultraviolet energy.

Feeding of Activated Materials.—All batches of 7-dehydrocholesterol solution irradiated at a given wave length were pooled with three ether washings of the quartz vessel and with olive oil in the proportion of one gram of oil for each rat to be fed. The ether was removed under carbon dioxide in a moderate vacuum and the oil residue thoroughly incorporated into Steenbock #2965 ration in the proportion of 29 g. of diet to each gram of oil solution. The eight milligrams of treated 7-dehydrocholesterol which this oil contained had an expected potency of about 3.3 U. S. P. units of vitamin D.

These mixtures were then fed to groups of rats previously rendered rachitic in twenty-one days on the Steenbock #2965 ration. Group size was selected as follows (based on probability predictions from previous similar experiments involving a total of approximately three hundred rachitic rats): 40 rats each for the testing of materials irradiated with 2483 Å., 2537 Å., 2652 Å., and 3025 Å.; 50 rats each for testing 2804 Å., 2894 Å., and 2967 Å.; and 18 rats for testing 3130 Å., which previous tests had shown to be probably inactive.

During the six-day feeding period each animal consumed its quota of 30 g. of ration. Empty feeding jars were replenished with additional amounts of the #2965 diet, unfortified, until the end of the seventh day.

Observations.—A total of 328 rats entered the test period and all but two survived. At the end of this period these animals were killed, the left leg of each was X-rayed, then line tested, and the right legs were taken for ashing.

A summary of essential data including line test observations is presented in Table I. The whole bone ash values (on a fat-free dry basis) were between 31.7 and 33.6% for all active wave lengths; 28.8% for the inactive 3130 Å. line; and 27.3% for the rachitic controls.

In a previous communication we expressed the opinion that recorded differences between group responses must be greater than the quantities which by purely statistical computation are barely significant, if they are to be accepted as real. This restriction of the use of statistical methods applies to the evaluation of data derived from the usual sized bioassay groups but the restriction is lifted when the number of animals tested concurrently is sufficiently large.

Interpretation of Observations.—In respect to bone ash determinations, the group values for the active wave lengths varied within a small range

inconsistently with respect to X-ray and line test evaluations which are mutually confirmatory. This strengthens the opinion that bone ash determinations, because of variations inherent in the method or for some other undetected reason, fail to afford criteria sufficiently precise for detection of small differences in degrees of antirachitic response in rats. The line test or the roentgenogram procedures are more delicate.

[a] The computation of means to the fourth decimal is for subsequent mathematical treatment of these values.

In respect to line test observations, inspection of the arithmetic mean responses indicates a peak of response for 2967 Å. over all other wave lengths, and a suggestion that 2894 Å. may be slightly more active while 3025 Å. is slightly less active than the remaining four wave lengths.

This interpretation by inspection was tested by statistical analysis in which the significance of the differences among arithmetic mean responses was determined. That a real difference of means existed was shown when the variance within groups was proven significantly less than the variance among groups.

In order to determine which differences among means are real, the "*t*" test was applied, as an appropriate method in view of the numbers of observations available.

Let "*t*" represent the ratio of the difference between two means to the best estimate of a standard error of that difference. Then

$$t = \frac{\overline{X}_1 - \overline{X}_2}{s\sqrt{\frac{1}{N_1} + \frac{1}{N_2}}}$$

where $\overline{X}_1$, $\overline{X}_2$ = any two arithmetic mean response values, N_1, N_2 = the number of observations in the two groups, respectively, s = the best estimate of a standard deviation of a single group based on the data of the two groups considered, the value "*s*" being derived from the expression

$$s^2 = \frac{\Sigma(X_1 - \overline{X}_1)^2 + \Sigma(X_2 - \overline{X}_2)^2}{(N_1 - 1) + (N_2 - 1)}$$

where X_1, X_2 = each observation in the first or second group, respectively.

A "significant" value of "*t*" was taken to be 2.5, which gives approximately nineteen out of twenty chances that the differences found are real.

By the above test it appears that the response to 7-dehydrocholesterol activated by 2967 Å. is

TABLE II

SHOWING ESSENTIAL DATA USED IN THE "t" TEST

Wave lengths compared, Å.	Difference of arithmetic means	$s\sqrt{\frac{1}{N_1}+\frac{1}{N_2}}$	"t"	Interpretation

2967–3025	.4296	.14335	2.997	Significant

significantly greater than for any other wave length examined except for 2894 Å., which seems to have an effect intermediary between the effects of adjacent lines. There appears to be no significant difference between the activities of any other wave lengths tested.

The statistical analysis of results confirms the interpretation derived by inspection, and indicates that the lower efficiency of 3025 Å. may be regarded as not significant.

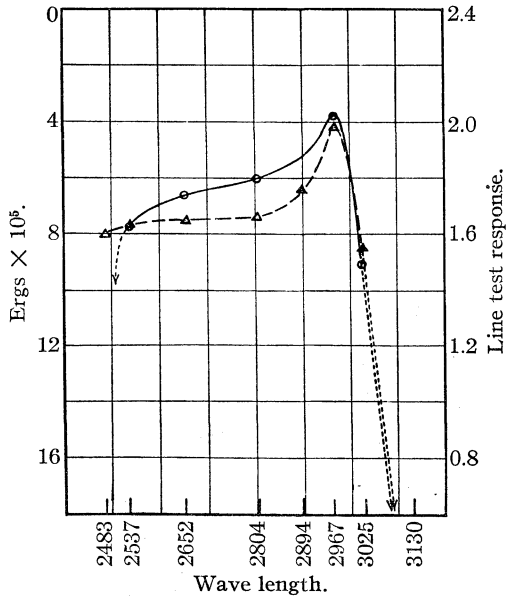

Fig. 1.—Relative antirachitic efficiencies of certain wave lengths of ultraviolet as determined by animal response: ○ = from direct irradiation of skin; △ = from feeding of activated 7-dehydrocholesterol.

Discussion.—When mammals are exposed to sources of ultraviolet of suitable wave length and energy, rickets can thereby be cured or prevented. It is assumed that there is produced in living tissues, by such activation of the skin, vitamin D of one of the major types. Although vitamin D_2 is absorbable from the intestinal tract of mammals and exerts in them an antirachitic therapeutic effect, its precursor, ergosterol, is not absorbed nor has it been identified in mammalian tissues. On the other hand, 7-dehydrocholesterol has been identified as the provitamin of animal tissues[1,2] and may be presumed to be the precursor of the vitamin D produced by irradiation of mammalian skin.

It has been shown[5,6] that rats whose skins have been irradiated with dominant mercury lines in the region bounded by 2537 and 3025 Å. exhibit an antirachitic response. The degrees of response to the various wave lengths tested are not equal per unit of applied energy, the potency of line 2967 Å., as determined by us,[5] being significantly greater than that of the other wave lengths. It also has been reported[3] that the photochemical activation of ergosterol (in ether) results in substantially equal production of antirachitic per quantum of ultraviolet energy applied over a similar range of wave lengths. This may be taken as an indication of a difference between ergosterol and the provitamin of the skin.

The results of this research are displayed in Fig. 1, together with those of a previous investigation of the activation of the skin of living rats. It is to be noted that there is a qualitative similarity between the activation curve of 7-dehydrocholesterol and of rat skin, whereas the activation of ergosterol[3] is dissimilar. This further strengthens the hypothesis that 7-dehydrocholesterol is the predominant provitamin D of the skin.

Summary

1. The photochemical activation of crystalline 7-dehydrocholesterol in ether by monochromatic ultraviolet of 2483, 2537, 2652, 2804 and 3025 Å. is substantially uniform per quantum of energy applied.

2. On a quantum basis, the activation by 2967 Å. is significantly greater than for any other

(6) Knudson and Benford, *J. Biol. Chem.*, **124**, 287 (1938).

wave length examined, with the possible exception of 2894 Å.

3. The activation by 2894 Å. appears to be intermediate between that of 2967 Å. and the other wave lengths tested.

4. No demonstrable antirachitic properties were produced by irradiation of 7-dehydrocholesterol in ether by ultraviolet of 3130 Å.

5. The superior effectiveness of 2967 Å. in antirachitic activation of 7-dehydrocholesterol parallels the significant superiority of this wave length in inducing healing upon direct irradiation of depilated rachitic rats, which supports the hypothesis that 7-dehydrocholesterol is a significant precursor of vitamin D in the skin.

Identification of Organic Compounds. I. Chlorosulfonic Acid as a Reagent for the Identification of Aryl Halides

BY ERNEST H. HUNTRESS AND FREDERICK H. CARTEN[1,2]

Although the action of chlorosulfonic acid has been studied upon many compounds, either as a means of introducing the sulfonic acid group or the chlorosulfonyl group, no systematic attempt to employ it as a reagent for the identification of organic compounds has been reported. The present paper reports the study of chlorosulfonic acid as applied to the identification of a considerable number of halogenated aromatic hydrocarbons.

The object of this work was to find a set of standard conditions such that treatment of the sample with chlorosulfonic acid would yield readily the corresponding arylsulfonyl chloride which in turn could be converted to the corresponding sulfonamide. The process of introducing the $-SO_2Cl$ group is hereafter designated as "chlorosulfonylation."

Two standard procedures (I and II) for effecting chlorosulfonylation have been devised and tested upon a large number of compounds. The first carries out the chlorosulfonylation in chloroform solution; the second uses no solvent. Both procedures employ a relatively large excess of chlorosulfonic acid in order to convert the intermediate sulfonic acid (to be expected from one mole of chlorosulfonic acid) as completely as possible to the corresponding sulfonyl chloride. The yields of arylsulfonyl chloride thus obtained are generally high (60–90%) and the process is extremely simple to execute.

(1) This paper is constructed from part of a dissertation submitted by Frederick H. Carten to the Faculty of the Massachusetts Institute of Technology in partial fulfillment of the requirements for the degree of Doctor of Philosophy in June, 1939.

(2) This work was assisted by a grant from the Warren Fund of the American Academy of Arts and Sciences for which grateful acknowledgment is hereby made.

Conversion of the arylsulfonyl chloride thus obtained to the corresponding arylsulfonamide was effected either by treatment with concentrated aqueous ammonium hydroxide, or by reaction with solid ammonium carbonate. The yields on this step were invariably nearly quantitative.

In a few cases the reaction with chlorosulfonic acid yielded abnormal products. Thus fluorobenzene, iodobenzene, *o*-dichlorobenzene and *o*-dibromobenzene at 50° with chlorosulfonic acid in the absence of any solvent, chloroform, yielded the corresponding sulfones. In a few other instances a small amount of the corresponding sulfones accompanied the usual sulfonyl chloride. From the point of view of identification, however, these sulfones serve just as well as the sulfonyl chlorides. Furthermore, in those cases where they accompany the sulfonyl chloride, they are readily separable from the final sulfonamide by their insolubility in alkali, the sulfonamides readily dissolving and being reprecipitable on acidification.

Another abnormal type of reaction occasionally observed was nuclear chlorination. This occurred notably with *p*-diiodobenzene and 1,2,4,5-tetrachlorobenzene but does not interfere with the identification of these compounds since the substitution products are readily obtained and have characteristic melting points.

Unsatisfactory results were obtained with the following compounds: *o*-chloroiodobenzene, *p*-chloroiodobenzene, *m*-chloroiodobenzene, *o*-bromoiodobenzene, *p*-bromoiodobenzene, *o*-iodotoluene, *m*-iodotoluene and *p*-iodotoluene. Treatment

of *o*- and of *p*-chlorobiphenyl by either procedure I or II gave only water soluble products.

Of the 28 sulfonamides reported in Table I six are new. The structures assigned in these six cases are, therefore, tentative and are based on analogies with other compounds actually studied. Of the four sulfones described two are previously unreported. The tentative structures assigned to these are, therefore, based only on analogies, and their complete establishment was not attempted in this research.

Since the three isomeric trichlorobenzenes yield sulfonamides which are not well adapted for their positive identification, we have studied the utility of nitration for this purpose. All of the mono- and dinitro derivatives of these three compounds have been reported but by such diversified procedures that we have devised a set of standard conditions for nitration. The dinitration products serve conveniently for characterization of the trichlorobenzenes, confirmatory evidence being supplied by their reaction with aniline.

Experimental Work

The melting points reported in this paper are uncorrected. They were determined on a standard rod form 360° melting point thermometer in a copper melting point block of the Berl and Kullmann type. Observation of the sample was assisted by means of a small 25 power microscope permanently attached to the apparatus.

The chlorosulfonic acid used in this work was obtained by distilling Eastman Kodak Co. practical grade in a stream of hydrogen chloride, retaining only the portion distilling between 153–157° (92% of the original material).

The organic compounds were carefully purified until their melting or boiling points checked closely with the values accepted in the literature.

Chlorosulfonylation with Chlorosulfonic Acid

Procedure I.—The compound (1.0 g.) was dissolved in chloroform (5 cc.), the solution placed in a six-inch (15 cm.) test-tube resting in an ice-bath at 0°, and treated dropwise with chlorosulfonic acid (5.0 g.). After the initial evolution of hydrogen chloride had subsided, the reaction mixture was brought to room temperature. After about twenty minutes the contents of the tube were poured into a 50-cc. beaker filled with crushed ice, the chloroform layer separated and washed with cold water, and the solvent evaporated. The residual crude arylsulfonyl chloride was then recrystallized from dry low boiling petroleum ether or from chloroform and dried in vacuum over concentrated sulfuric acid.

Procedure II.—This was exactly like Procedure I except that no solvent was employed. After pouring the sirupy reaction mixture onto crushed ice, the resultant arylsulfonyl chloride or sulfone was filtered with suction if a solid, or separated by means of a small separatory funnel if a liquid, washed with water and recrystallized from low boiling petroleum ether or benzene.

Some of the aryl halides used in this work react but slowly with chlorosulfonic acid at room temperature. Deviations from the above standard procedures found to result in improved yields are noted under the individual descriptions.

Every arylsulfonyl chloride described in this report when dissolved in alcohol and boiled with solid ammonium thiocyanate gives (on cooling) a yellow amorphous precipitate. The precise nature of the reaction is unknown but it serves as a qualitative means of detection of the sulfonyl chloride group. Our use of it represents an extension of the observations of Remsen and Turner,[3] on the reaction of benzenesulfonyl chloride.

Conversion of Arylsulfonyl Chlorides to Sulfonamides

Procedure A.—The arylsulfonyl chloride (0.5 g.) prepared according to Procedures I or II was boiled for ten minutes with concentrated (sp. gr. 0.90) ammonium hydroxide (5 cc.). After cooling to room temperature, and adding cold water (10 cc.), the resultant solid sulfonamide was filtered with suction and thoroughly washed. It was then recrystallized to constant melting point from dilute ethanol and dried at 105°.

Procedure B.—The product from either of the chlorosulfonylation procedures I or II (0.5 g.) was mixed with dry powdered ammonium carbonate (2.0 g.) and heated at 100° for thirty minutes. After washing with several 10-cc. portions of cold water, the residual solid was filtered off and recrystallized from dilute ethanol.

Remarks.—Any sulfone which may have been formed by the action of chlorosulfonic acid in Procedures I or II is of course entirely unaffected by either ammonium hydroxide or ammonium carbonate in Procedure A or B. It may be separated from the corresponding aryl sulfonamide by virtue of its insolubility in cold 6 *N* sodium hydroxide. The sulfonamides dissolve in the alkali and after filtration of the inert sulfone may be reprecipitated by addition of 6 *N* hydrochloric acid.

Sulfones Obtained with Chlorosulfonic Acid.—In four cases application of Procedure II to the original aryl halide gave only sulfones in 71–74% yield. Thus, fluorobenzene gave 4,4′-difluorodiphenylsulfone, white needles from benzene, m. p. 97–98 uncor. This product was obtained in 100% yield by heating the reaction mixture at 40° for one hour.

Anal. Calcd. for $C_{12}H_8F_2O_2S$: C, 56.70; H, 3.15. Found: C, 56.43, 56.82; H, 3.38, 3.54.

Iodobenzene by either Procedure I or II gave 4,4′-diiododiphenylsulfone, needles from benzene or glacial acetic acid, m. p. 201–202°.

Anal. Calcd. for $C_{12}H_8I_2O_2S$: S, 6.81; I, 53.99. Found: S, 6.92, 6.86; I, 53.93, 53.71.

The compound is undoubtedly identical with the so-called x,x-diiododiphenylsulfone of Beilstein VI-336.[4] From *o*-dichlorobenzene, Procedure II yielded 3,4,3′,4′-tetrachlorodiphenylsulfone, accompanied by a small pro-

1-Br	4-Br	81–83	191–193
2-Br	7-Br	142–143	207–208

[a] Except for those from fluorobenzene and chlorobenzene which were recrystallized from benzene and ether, respectively, all other sulfonyl chlorides were recrystallized from petroleum ether. [b] All sulfonamides were recrystallized from dilute alcohol. [c] All sulfonamides were analyzed for nitrogen (or halogen in two cases) and gave results in excellent accord with the theoretical values. [d] In order to save space references to m. p.'s previously reported are not included. [e] Accompanied by 8% of the corresponding sulfone. [f] Does not react at room temperature but gives 80% yield on refluxing for one hour. [g] The m. p. of a mixture of these two compounds was depressed to 168–171°. [h] Accompanied by 3% of the corresponding sulfone. [i] Followed by heating at 50° for ten minutes. [j] Followed by heating at 80° for one hour. [k] Followed by heating at 150° for one hour. [l] Followed by heating at 150° for thirty minutes.

portion (3–4%) of 3,4-dichlorobenzenesulfonamide. The sulfone crystallizes in plates from absolute alcohol or glacial acetic acid, m. p. 175–176° uncor.

Anal. Calcd. for $C_{12}H_6Cl_4O_2S$: S, 9.00; Cl, 39.85. Found: S, 8.76, 9.00; Cl, 39.65, 39.57.

It is undoubtedly identical with the so-called bis-[x,x'-dichlorophenyl]-sulfone (Beilstein VI-330).[5] From *o*-dibromobenzene Procedure II yielded 3,4,3',4'-tetrabromodiphenylsulfone, plates from hot alcohol, m. p. 176–177°.

Anal. Calcd. for $C_{12}H_6Br_4O_2S$: Br, 59.87. Found: Br, 60.66, 60.96.

(5) Friedel and Crafts, *Ann. chim.* (6) **10**, 415 (1887).

Chlorosulfonic acid gave "abnormal" results in three cases.

2,3,5,6-Tetrachloro-1,4-diiodobenzene: from *p*-diiodobenzene heated to 50° for five minutes with five parts of chlorosulfonic acid. Vigorous evolution of sulfur dioxide occurred and a pale brown solid precipitated. After pouring onto ice the crude product recrystallized from absolute alcohol or from glacial acetic acid in long white needles, m. p. 210–211° uncor.

Anal. Calcd. for $C_6Cl_4I_2$: Cl, 30.32; I, 54.27. Found: Cl, 30.42, 29.69; I, 52.12, 52.12.

Hexachlorobenzene: from 1,2,4,5-tetrachlorobenzene (5.0 g.) refluxed with chlorosulfonic acid (20.0 g.) for one hour. During this period, the reaction mixture turned dark green and a white solid appeared on its surface. As this solid gradually sublimed into the condenser its solution in the condensing chlorosulfonic acid was deep red, changing to green upon striking the mixture in the flask. After cooling, and pouring onto ice, the separating white solid (5.2 g., 78%) recrystallized from petroleum ether as needles, m. p. 218–219° uncor., and failed to depress the melting point of an authentic sample of hexachlorobenzene.

Anal. Calcd. for C_6Cl_6: Cl, 74.70. Found: Cl, 74.35, 74.29.

2-Bromo-5-chlorobenzenesulfonamide: from *p*-chlorobromobenzene by refluxing for one hour with five times its weight of chlorosulfonic acid, pouring onto ice and converting the resultant sulfonyl chloride (86% yield, m. p. 40–42°) to amide via Procedures A or B. The product showed m. p. 189–190° uncor.

Anal. Calcd. for $C_6H_5BrClNO_2S$: N, 5.18. Found: N, 5.23, 5.27.

The chlorosulfonylation of *p*-bromochlorobenzene could yield either 2-bromo-5-chlorobenzenesulfonyl chloride or 2-chloro-5-bromobenzenesulfonyl chloride or both. Armstrong and Briggs[6] report melting points of 46 and 66°, respectively, for these two isomers and melting points of 191 and 178° for the respective corresponding sulfonamides. Moreover, they report that the two sulfonamides are isomorphous and that their mixture showed no depression of melting point. This indicates that in our experiments both isomers may be formed but that our final product is mainly 2-bromo-5-chlorobenzenesulfonamide.

Nitration of the Trichlorobenzenes.—One gram of the compound was dissolved in five grams of fuming nitric acid (d = 1.49). 1,2,3-Trichloro- and 1,2,4-trichlorobenzene dissolved promptly with evolution of heat; 1,3,5-trichlorobenzene required warming for fifteen minutes on the water-bath. After complete solution had occurred, the mixture was poured onto crushed ice, the solid filtered and recrystallized from alcohol; yield quantitative. By this procedure 1,2,3-trichlorobenzene yielded 2,3,4-trichloro-1-nitrobenzene, m. p. 55–56°; 1,2,4-trichlorobenzene yielded 2,4,5-trichloro-1-nitrobenzene, m. p. 56°; and 1,3,5-trichlorobenzene gave 2,4,6-trichloro-1-nitrobenzene, m. p. 67–68°.

Dinitration.—To the nitric acid solution of mononitro compound obtained above was added 5 g. of concentrated sulfuric acid and the mixture refluxed for one hour. After cooling the mixture was poured into 100 cc. of water

(6) Armstrong and Briggs, *Chem. News*, **65**, 138–139 (1892).

and the precipitated dinitrotrichlorobenzene filtered, washed and recrystallized from alcohol; yields quantitative. By this procedure 1,2,3-trichlorobenzene yielded 4,5,6-trichloro-1,3-dinitrobenzene, m. p. 92–93°; 1,2,4-trichlorobenzene yielded 2,4,5-trichloro-1,3-dinitrobenzene, m. p. 102.5–103.5°; and 1,3,5-trichlorobenzene gave 2,4,6-trichloro-1,3-dinitrobenzene, m. p. 128.5°.

Reaction of the Dinitrotrichlorobenzenes with Aniline.—One gram of the dinitrotrichlorobenzene and five grams of pure aniline were heated on a water-bath for one hour. The mixture was then cooled and extracted with successive portions of 6 *N* hydrochloric acid to remove excess aniline. After filtering off the residual solid and washing with water, it was recrystallized from benzene or ethyl alcohol.

Application of this procedure to the dinitration product from 1,2,3-trichlorobenzene gave 4,6-dianilino-5-chloro-1,3-dinitrobenzene, m. p. 136–138°.

Anal. Calcd. for $C_{18}H_{13}ClN_4O_4$: N, 14.56. Found: N, 14.88, 14.91.

From the dinitration product of 1,2,4-trichlorobenzene there resulted 2,6-dianilino-5-chloro-1,3-dinitrobenzene, m. p. 182°.

Anal. Calcd. N, 14.56; Cl, 9.21. Found: N, 14.79, 14.86; Cl, 9.20, 9.28.

From the dinitration product of 1,3,5-trichlorobenzene there was obtained the previously reported 2,4,6-trianilino-1,3-dinitrobenzene, m. p. 179–180°.

Summary

1. A method for the identification of aryl halides by means of chlorosulfonylation with chlorosulfonic acid has been shown to yield excellent results.

2. Of thirty-two aryl halides studied, thirty yield characteristic arylsulfonyl chlorides readily converted to the corresponding arylsulfonamides and the other two yield reaction products characteristic of the original compound.

3. Three trichlorobenzenes have been characterized by mono-, di- and tri-nitration and the reaction products of the dinitrotrichlorobenzenes with aniline have been found useful derivatives.

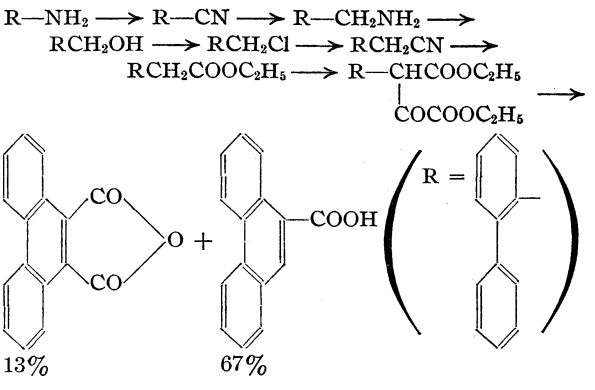
A New Synthesis of Phenanthrene Derivatives. I. Phenanthrene-9,10-dicarboxylic Anhydride and Phenanthrene-9-carboxylic Acid

BY T. A. GEISSMAN AND ROY W. TESS

In an attempt to develop a convenient method for the synthesis of phenanthrene-9,10-dicarboxylic anhydride, a modification of the Bougault method of ring closure[1] applied to the biphenyl ring system has been studied. While the results obtained are encouraging, those described in this paper are of a preliminary nature, and are published at this time because of the necessity for temporarily suspending work on the problem.

A new approach to the synthesis was sought for two reasons: the method used appeared to offer (1) a cheaper procedure and one more readily adapted to the preparation of large amounts than those of Jeanes and Adams[2] or of Weizmann, Bergmann and Berlin,[3] and (2) a synthesis which could be generalized more readily than either of those mentioned[4] to the preparation of analogous compounds containing other substituents in the rings.

The steps in the synthesis are



The synthesis proceeds smoothly in the manner shown, and although suspension of the study has made it impossible to work out conditions for a quantitative ring-closure without decarboxylation, the total yield of phenanthrene derivatives is good.

The synthesis of 2-biphenylacetic acid by von Braun and Manz[5] has been accomplished by the

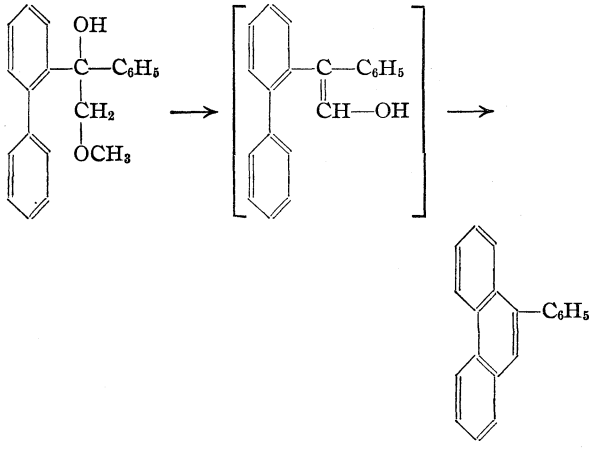
(4) The synthesis of Weizmann, *et al.*[3] is based upon the preparation by Gruber and Adams [THIS JOURNAL, **57**, 2555 (1935)] of the adduct of dicyclohexenyl and maleic anhydride.

(5) Von Braun and Manz, *Ann.*, **468**, 273 (1929).

same series of reactions up to the formation of 2-biphenylacetonitrile. The step involving the reduction of the nitrile to the methylamine has been improved in the present work with the elimination of the side-reaction leading to unwanted secondary amine.

The suggestion of Bradsher[6] that ring closure of compounds such as 1-phenyl-1-(2-biphenyl)-2-methoxyethanol-1 proceeds through an intermediate carbonyl compound (or its enol form)



finds support in the present work. The alkali-solubility and violet color with ferric chloride shown by ethyl 2-biphenyloxalylacetate indicate that it exists completely as the enol and lead to the belief that 2-biphenylacetaldehydes or acetones are cyclized through their respective enols.

Experimental

The synthesis of 2-biphenylacetonitrile is described by von Braun and Manz[5] but since numerous details are lacking in this article, a more detailed description of several of the steps involved seems desirable.

o-Phenylbenzylamine.—A mixture of 122.5 g. of *o*-cyanobiphenyl (distilled from Raney nickel), one teaspoonful of Raney nickel, 150 cc. of liquid ammonia and 50 cc. of ether was placed in a bomb under a pressure of 3350 lb. (223 atm.) of hydrogen. Upon heating to 120° the pressure rose to 4500 lb. (300 atm.), then gradually fell to 1670 lb. (111 atm.) in about four hours. After the bomb was cooled and the pressure released, the ammonia was allowed to evaporate and the residue dissolved in ether and filtered. The filtrate was extracted with dilute hydrochloric acid and the product recovered by ether extraction of the neutralized solution and distilled. The product boiled almost entirely at 163–168° (15 mm.) and practically no higher-boiling residue remained in the distillation flask (von Braun and Manz[5] give b. p. 163° (12 mm.)).

o-Phenylbenzyl Alcohol.—A solution of 17.9 g. of sodium nitrite in 25 cc. of water was added over ten minutes to a cooled solution of 12.0 g. of *o*-phenylbenzylamine in 50 cc. of acetic acid. When all the nitrite had been added the solution was stirred for ten minutes at room temperature and poured into water. The solution was neutralized with solid sodium carbonate and extracted with ether. Unchanged amine was removed by washing the ether solution with dilute acid and after removal of the ether the product was distilled. The fraction boiling at 177–184° (15 mm.) weighed 11.5 g. (v. Braun and Manz[5] give b. p. 174° (13 mm.)).

o-Phenylbenzyl Chloride and o-Phenylbenzyl Cyanide.—These were prepared by methods too well known to require detailed description. The chloride boiled at 161–168° (16 mm.) (v. Braun and Manz[5] give 154° (12 mm.)). The cyanide boiled at 181–190° (15–16 mm.) (v. Braun and Manz[5] give 182° (12 mm.)).

Ethyl 2-Biphenylacetate.—To a solution of 55 g. of 95% alcohol and 45 g. of concentrated sulfuric acid was added 43.3 g. of 2-biphenylacetonitrile. The solution was gently refluxed for thirteen hours and poured into water. The ester was extracted with ether and distilled. There was obtained 55.2 g. of ester, b. p. 180–185° (15 mm.). The identity of the ester was established by saponifying a sample of it to the known[5] 2-biphenylacetic acid.

Phenanthrene-9,10-dicarboxylic Anhydride and Phenanthrene-9-carboxylic Acid.—The oxalylation of ethyl 2-biphenylacetate by means of dry potassium ethoxide was found to be superior to the method in which metallic sodium is used; the latter method was found to give good results when applied to the oxalylation of ethyl phenylacetate by Rising and Stieglitz.[7]

Potassium ethoxide was prepared by allowing 2.0 g. of powdered potassium covered with 50 cc. of dry ether to react with 2.5 g. of absolute ethanol. To the ice-cooled suspension of the resulting potassium salt was added a mixture of 7.5 g. of ethyl oxalate and 12.0 g. of ethyl 2-biphenylacetate. The potassium ethoxide dissolved and a greenish-brown solution resulted, which in the course of two days turned a yellow-red in color. The solution was decomposed with cracked ice and the aqueous layer separated. The ether layer was washed well with small portions of ice water and the combined aqueous extracts acidified with ice-cold, dilute sulfuric acid. The product was extracted with ether, the ether solution dried and evaporated. The oxalyl derivative was obtained as a pale yellow oil which gave a deep violet coloration with alcoholic ferric chloride. Attempts to crystallize it were fruitless; it showed a tendency to decompose upon prolonged exposure to air.

To the oily oxalyl ester was added a mixture of 50 cc. of glacial acetic acid and 30 cc. of 48% hydrobromic acid and the mixture refluxed for three hours. After fifteen to twenty minutes of refluxing, yellow needles began to form and a heavy precipitate soon filled the solution. The mixture was cooled and the product collected. It was pale yellow, crystalline and weighed 7.95 g.

The ether layer containing the non-acidic material from the oxalylation reaction yielded 2.7 g. of unchanged ethyl 2-biphenylacetate.

(6) Bradsher, THIS JOURNAL, **61**, 3131 (1939).

(7) Rising and Stieglitz, THIS JOURNAL, **40**, 723 (1918).

The crude material melted poorly and proved to be a mixture. Recrystallized from acetic anhydride, it yielded 1.25 g. of yellow needles of the anhydride melting at 310–315° (literature, 312°[3] and 322°[2]), and 6.0 g. of colorless needles of the acid, melting at 249–250° (literature[8] 250°). The acid was converted to methyl phenanthrene-9-carboxylate, white needles from methanol, m. p. 115–116° (literature[9] 116°).

(8) Werner and Kunz, *Ann.*, **321**, 327 (1902).
(9) Mosettig and van de Kamp, THIS JOURNAL, **52**, 3704 (1930).

Summary

1. The synthesis of phenanthrene-9,10-dicarboxylic anhydride and phenanthrene-9-carboxylic acid by ring closure of ethyl 2-biphenyloxalylacetate is described.

2. The method described constitutes a new synthesis of phenanthrene derivatives.

Sterols. LXXXVII. Cholesterol and Sitosterol Derivatives

BY RUSSELL E. MARKER AND EWALD ROHRMANN

Inasmuch as most of the oxidation studies on the sterols have been made with chromic anhydride in acetic acid, it seemed of interest to study the action of potassium permanganate in acetic acid on some of these substances. It is well known that potassium permanganate in alkaline medium oxidizes cholesterol to a cholestanetriol-3,5,6,[1,2,3] the reagent under these conditions apparently having no tendency to oxidize the secondary alcohols to ketones. The resulting triol differs from that obtained by the hydroxylation of cholesterol with hydrogen peroxide. That this difference is due to the configuration of the tertiary hydroxyl group at C-5 is indicated by the fact that the two triols on oxidation with chromic anhydride yield different cholestanol-5-diones-3,6.

In acetic acid solution cholesterol with potassium permanganate yields a cholestanol-5-dione-3,6 which is very probably identical with that obtained by oxidizing with chromic anhydride the alkaline permanganate oxidation product of cholesterol. With cholesteryl acetate a 3-acetoxy-5-hydroxy-6-ketocholestane was obtained. Similar results were obtained with sitosterol and sitosteryl acetate. The same products were obtained when the oxidations were conducted at room temperature or at 55°, there apparently being little tendency for ring B to open between C-5 and C-6.

The oxidation of cholestanol-3(β) with potassium permanganate in acetic acid solution at room temperature gave a good yield of cholestanone. At a temperature of 55° both cholestanone and 2,3-cholestane dicarboxylic acid were obtained. The oxidation of neocholestene at room temperature gave largely 2,3-cholestane dicarboxylic acid.

The preparation of 7-ketositosteryl chloride has been carried out by the chromic anhydride oxidation of sitosteryl chloride.[4] The substance undergoes reactions analogous to those of 7-ketocholesteryl chlorides.[4,5]

We wish to thank Parke, Davis and Company for their generous help and assistance during the various phases of this work.

Experimental Part

Oxidation of Cholesterol and Sitosterol Derivatives with Potassium Permanganate.—(a) **Cholesterol.**—To a solution of 2 g. of cholesterol in 150 cc. of acetic acid was added 75 cc. of 1 *N* aqueous potassium permanganate and 75 cc. of acetic acid. After standing for six hours at room temperature the mixture was diluted with water and the solid taken up with ether. The ethereal extract was washed with water and dilute sodium carbonate solution and the ether evaporated to yield approximately 1.6 g. of crystalline residue. This was crystallized from acetone to give compact white crystals, m. p. 248–251°.

Anal. Calcd. for $C_{27}H_{44}O_3$: C, 77.8; H, 10.65. Found: C, 78.0; H, 10.7.

(b) **Cholesteryl Acetate.**—To a solution of 2 g. of cholesteryl acetate in 210 cc. of acetic acid heated at 45–50° was added 50 cc. of 1 *N* aqueous potassium permanganate over a period of thirty minutes and the mixture was heated at 50° for an additional thirty minutes. The product was worked up and crystallized from acetone as described above to give white plates, m. p. 231–233°.

Anal. Calcd. for $C_{29}H_{48}O_4$: C, 75.6; H, 10.5. Found: C, 75.8; H, 10.7.

Similar results were obtained when the oxidation was conducted at room temperature.

(1) Windaus, *Ber.*, **40**, 257 (1907).
(2) Pickard and Yates, *J. Chem. Soc.*, **93**, 1678 (1908).
(3) Pimone, *Gazz. chim. ital.*, **62**, 1101 (1932).
(4) Marker, *et al.*, THIS JOURNAL, **59**, 619 (1937).
(5) Marker and Rohrmann, *ibid.*, **61**, 3022 (1939).

With hydroxylamine acetate the product yielded an *oxime* which was crystallized from aqueous methanol, m. p. 204–206°.

Anal. Calcd. for $C_{29}H_{49}O_4N$: C, 73.2; H, 10.4. Found: C, 73.5; H, 10.4.

(c) **Neocholestene.**—A suspension of 2 g. of neocholestene in 250 cc. of acetic acid was mixed with a solution of 1.5 g. of potassium permanganate in 200 cc. of 90% acetic acid. After standing at room temperature for seven hours the mixture was worked up as described previously. There was very little neutral material. The acidic fraction from the sodium carbonate washing was crystallized from aqueous acetic acid to yield white crystals, m. p. 193–195°. This gave no depression with an authentic sample of the 2,3-cholestane dicarboxylic acid, m. p. 193.5–195°.

(d) **Cholestanol.**—Oxidation of β-cholestanol at room temperature under the above conditions gave a product which crystallized from aqueous acetone as white needles, m. p. 126–128°. This gave no depression with a sample of cholestanone, m. p. 126.5–128°. There was no appreciable acid fraction.

When the oxidation was carried out at 55° for three hours using twice as much permanganate as in the room temperature oxidation approximately equal amounts of cholestanone and of the 2,3-diacid of cholestane were obtained.

(e) **Sitosterol.**—Sitosterol was oxidized as described for cholesterol. The neutral fraction was crystallized from acetone as compact white crystals, m. p. 240°.

Anal. Calcd. for $C_{29}H_{48}O_3$: C, 78.3; H, 10.9. Found: C, 78.3; H, 11.2.

(f) **Sitosteryl Acetate.**—This was oxidized as described for cholesterol. The product was crystallized from acetone as white needles, m. p. 251°.

Anal. Calcd. for $C_{31}H_{52}O_4$: C, 76.15; H, 10.75. Found: C, 76.1; H, 10.8.

$\Delta^{4,5}$-Cholestenedione-3,6 from Cholestanol-5-dione-3,6.—A mixture of 600 mg. of cholestanol-5-dione-3,6 and 12 g. of powdered potassium bisulfate was heated in high vacuum at 150–180°. The sublimate was crystallized from aqueous acetone as white plates, m. p. 121–123°.

Anal. Calcd. for $C_{27}H_{42}O_2$: C, 81.3; H, 10.6. Found: C, 81.3; H, 10.6.

7-Ketositosteryl Chloride.—To a well-stirred solution of 25 g. of sitosteryl chloride in 500 cc. of glacial acetic acid heated at 55° on a water-bath was added a solution of 20 g. of chromic anhydride in 30 cc. of 50% acetic acid during one hour. A small amount of ethanol was then added, the mixture evaporated *in vacuo* to a volume of 250 cc. and 20 cc. of water added to the residual solution. The solution was cooled at 0° for twenty hours. The product was washed with 75% acetic acid and 95% ethanol, and crystallized from acetone to give white plates, m. p. 155–156°.

Anal. Calcd. for $C_{29}H_{47}OCl$: C, 77.85; H, 10.6. Found: C, 77.7; H, 10.5.

7-Hydroxysitosteryl Chloride.—A solution of 1 g. of 7-ketositosteryl chloride and 1 g. of aluminum isopropylate in 45 cc. of dry isopropyl alcohol was refluxed for twelve hours. The residual material was diluted with water and extracted with ether. Evaporation of the ether gave a crystalline residue which was recrystallized from methanol–acetone to give white plates, m. p. 138–139°.

Anal. Calcd. for $C_{29}H_{49}OCl$: C, 77.5; H, 11.0. Found: C, 77.7; H, 10.8.

7-Ketositosterylene.—A mixture of 200 mg. of 7-ketositosteryl chloride, 9 cc. of 95% ethanol, 0.5 cc. of water and 300 mg. of potassium hydroxide was refluxed for ninety minutes. The solution was diluted with water and the precipitated solid extracted with ether. Evaporation of the ether gave a residue which was crystallized from acetone–ethanol as pale yellow plates, m. p. 106–107°.

Anal. Calcd. for $C_{29}H_{46}O$: C, 84.8; H, 11.3. Found: C, 84.7; H, 11.2.

7-Ketositostyl Chloride.—A mixture of 2 g. of 7-ketositosteryl chloride, 700 mg. of Adams catalyst and 100 cc. of ether was shaken with hydrogen at 3 atm. pressure at room temperature for six hours. The mixture was filtered and the filtrate evaporated. The residue was crystallized from acetone–ethanol as white plates, m. p. 128–129°.

Anal. Calcd. for $C_{29}H_{49}OCl$: C, 77.5; H, 11.0. Found: C, 77.7, 77.4; H, 10.9, 11.0.

This product was recovered unchanged after heating for two hours at 60° with chromic anhydride.

A mixture of 150 mg. of 7-ketositostyl chloride, 300 mg. of Adams catalyst and 100 cc. of glacial acetic acid was shaken with hydrogen at 3 atmospheres pressure for five hours at room temperature. The product was crystallized from acetone–methanol to give white needles, m. p. 107–109°. This gave no depression with a sample of sitostyl chloride, m. p. 107–109°.

Anal. Calcd. for $C_{29}H_{51}Cl$: C, 80.0; H, 11.8. Found: C, 79.7; H, 11.8.

Summary

A short study has been made of the action of potassium permanganate in acetic acid on cholesterol and sitosterol compounds.

The preparation and some reactions of 7-ketositosteryl chloride are reported.

STATE COLLEGE, PENNA. RECEIVED NOVEMBER 13, 1939

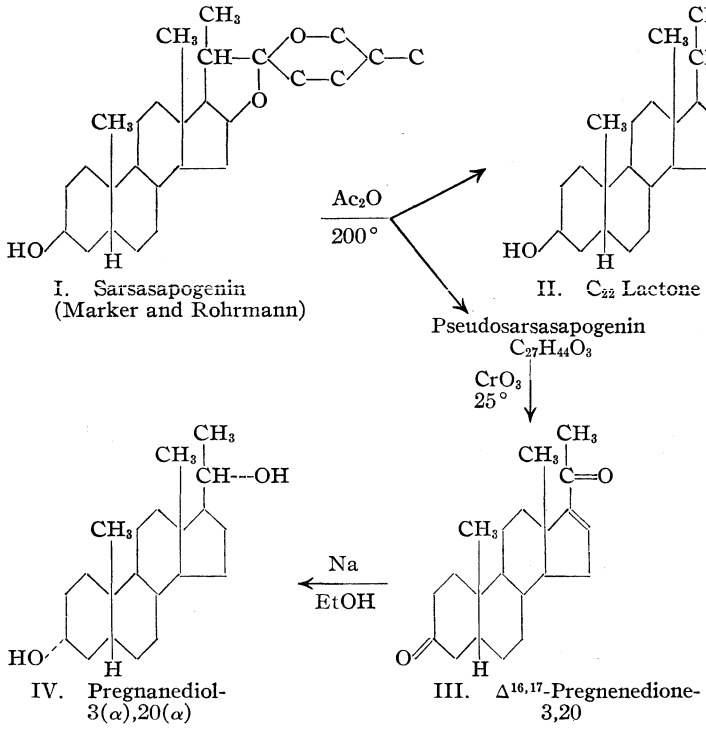
[CONTRIBUTION FROM THE SCHOOL OF CHEMISTRY AND PHYSICS OF THE PENNSYLVANIA STATE COLLEGE]

Sterols. LXXXVIII. Pregnanediols from Sarsasapogenin

BY RUSSELL E. MARKER AND EWALD ROHRMANN

In a recent communication[1] we reported the successful conversion of sarsasapogenin to pregnanediol-3(α),20(α). The fact that this transformation can be accomplished by simple reactions in good yields makes sarsasapogenin one of the cheapest and most practical sources of pregnane derivatives from which it is possible to prepare progesterone, testosterone and desoxycorticosterone.

Sarsasapogenin (I) reacts with acetic anhydride at 200° to yield an isomeric substance, which because of its superficial resemblance to the sapogenins has been designated as pseudosarsasapogenin. While this substance undergoes many interesting reactions, the work herein reported is concerned with the preparation of the product, its oxidation to $\Delta^{16,17}$-pregnenedione-3,20 and a study of the reduction products of this latter substance.



I. Sarsasapogenin (Marker and Rohrmann)

II. C_{22} Lactone

IV. Pregnanediol-3(α),20(α)

III. $\Delta^{16,17}$-Pregnenedione-3,20

The isomerization of sarsasapogenin to pseudosarsasapogenin is also effected by acid anhydrides other than acetic anhydride. Propionic anhydride is quite effective while succinic anhydride is less effective and with phthalic anhydride no crystalline products were isolated. In the case of *n*-butyric anhydride (b. p. 198°) the isomerization was effected by simple refluxing. It is of interest that acidic products were encountered in all of these isomerization reactions. These were investigated in the acetic anhydride reaction and found to consist largely of the C_{22} hydroxy lactone (II) of sarsasapogenin.[2,3] Pseudosarsasapogenin forms a di-*p*-nitrobenzoate, indicating the presence of two hydroxyl groups.

In attempting to convert pseudosarsasapogenin to pseudosarsasapogenone by mild oxidation with chromic anhydride, an unsaturated diketone of the composition $C_{21}H_{30}O_2$, m. p. 202°, was obtained in good yields. This substance is unquestionably $\Delta^{16,17}$-pregnenedione-3,20 (III), a substance first reported by Masch[4] and referred to briefly by Butenandt, *et al.*,[5] in a recent publication concerning $\Delta^{16,17}$-*allo*-pregnenedione-3,20. The product was reported to melt at 196° and was obtained in a study of 17-bromopregnanol-3-one-20.

That our product is $\Delta^{16,17}$-pregnenedione-3,20 is shown by the fact that on reduction with sodium and ethanol it yields pregnanediol-3(α),20-(α) (IV) identical with that isolated from various urines. This reduction indicates that the ethylenic bond is conjugated with a carbonyl group. Reduction of $\Delta^{16,17}$-pregnenedione-3,20 with palladium catalyst gave pregnanedione-3,20 as would be anticipated. Catalytic hydrogenation of the unsaturated diketone with Adams catalyst in neutral medium gave pregnanediol-3(β),20(β),[6]

(6) Marker, Kamm and Jones, THIS JOURNAL, **59**, 1595 (1937).

pregnanediol-3(β),20(α)[7] and pregnanediol-3(α), 20(β). There appear to be appreciable amounts of other products formed in these reductions but we have not yet succeeded in isolating any product other than those of the regular pregnane series. One might expect to obtain some isopregnane compounds (*i. e.*, isomerized at C-17)[8] in these reactions.

The transformation of sarsasapogenin to $\Delta^{16,17}$-pregnenedione-3,20 definitely clears up several important points regarding the nuclear structure of sarsasapogenin, namely, the presence of a C-21 methyl group and the presence of an hydroxyl group at C-3. Inasmuch as the sarsasapogenin lactone (II) has been converted into tigogenin lactone,[9] it follows that the nuclear structure of tigogenin differs only in the configuration at C-5.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part[10]

Reaction of Sarsasapogenin Acetate with Acid Anhydrides. (a) **Acetic and Propionic Anhydrides.**—A mixture of 8 g. of sarsasapogenin acetate and 30 cc. of acetic anhydride was heated in a bomb tube at 195–200° for ten hours. The acetic anhydride was evaporated *in vacuo* and the residual sirup hydrolyzed with ethanolic potassium hydroxide. The alkaline solution was diluted with water and the precipitated solid taken up in ether. The ether was evaporated to a small volume and the white crystals collected, washed with ether and recrystallized from ethyl acetate to give white needles, m. p. 171–173°; yield 70%.

Anal. Calcd. for $C_{27}H_{44}O_3$: C, 77.8; H, 10.6; mol. wt., 416. Found: C, 77.8, 77.9; H, 10.6, 10.5; mol. wt. (Rast), 440.

The product gave a **di-*p*-nitrobenzoate** which crystallized rather poorly from acetone as pale yellow crystals, m. p. 156.5–159°.

Anal. Calcd. for $C_{41}H_{50}O_9N_2$: C, 68.9; H, 7.1. Found: C, 68.7, 68.9; H, 6.9, 7.0.

Attempts to prepare a crystalline acetate with boiling acetic anhydride were unsuccessful.

The aqueous alkaline layer from the above hydrolysis was acidified with hydrochloric acid and the mixture extracted with ether. The ethereal extract was washed with water, the ether evaporated and the residual material sublimed in high vacuum at 150–200°. The sublimate was crystallized from ether–pentane to give white needles, m. p. 199–201°. This gave no depression in melting point with an authentic sample of sarsasapogenin lactone, m. p. 199–200°.

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.25; H, 9.9. Found: C, 76.4; H, 9.9.

With boiling acetic anhydride this yielded an **acetate** which was crystallized from ether–pentane as white needles, m. p. 184–185°. This gave no depression in melting point with an authentic sample of sarsasapogenin lactone acetate, m. p. 184.5–185.5°.

Anal. Calcd. for $C_{24}H_{36}O_4$: C, 74.15; H, 9.3. Found: C, 74.3; H, 9.4.

When sarsasapogenin acetate was treated with propionic anhydride as described for acetic anhydride, a good yield of pseudosarsasapogenin, m. p. 169–171°, was obtained.

When sarsasapogenin acetate (2 g.) was heated in a bomb tube with glacial acetic acid (20 cc.) at 210° for seven hours the only product which could be isolated crystalline was a small amount of sarsasapogenin (after hydrolysis).

(b) **Succinic Anhydride.**—A mixture of 2 g. of sarsasapogenin acetate and 12 g. of succinic anhydride was heated in a bomb tube at 195–200° for ten hours. The brown colored solid reaction mixture was refluxed for thirty minutes with an excess of ethanolic potassium hydroxide. The mixture was diluted with water and the precipitated solid taken up in ether. The ether was evaporated and the residual crystalline solid was treated with Norite and crystallized from ethyl acetate–acetone to give white needles, m. p. 169–172°. This gave no depression with the product obtained above, m. p. 171–173° obtained with acetic anhydride. A similar reaction using phthalic anhydride gave only non-crystalline products.

(c) **With *n*-Butyric Anhydride.**—A solution of 4 g. of sarsasapogenin acetate and 30 cc. of *n*-butyric anhydride was refluxed for eight hours. The *n*-butyric anhydride was evaporated *in vacuo* and the residual sirup hydrolyzed with ethanolic potassium hydroxide. The product was crystallized from ether–acetone as white needles, m. p. 170–173°. This gave no depression with a sample of pseudosarsasapogenin prepared above, m. p. 171–173°.

$\Delta^{16,17}$-Pregnenedione-3,20 from Pseudosarsasapogenin.—To a solution of 1 g. of pseudosarsasapogenin in 30 cc. of acetic acid was added a solution of 1.0 g. of chromic anhydride in 10 cc. of 80% acetic acid. After standing at room temperature for one hour the solution was diluted with water and the precipitate taken up in ether. The ethereal solution was washed with water and 3% sodium hydroxide solution. Evaporation of the ether gave a solid which was crystallized from acetone as large white plates, m. p. 200–202°. This substance is $\Delta^{16,17}$-pregnenedione-3,20. The yield varied from 50 to 70% in different preparations.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6. Found: C, 80.0, 80.1; H, 9.4, 9.6.

With semicarbazide acetate this gave a **semicarbazone** which crystallized from ethanol as white crystals, m. p. 310° dec.

Anal. Calcd. for $C_{23}H_{36}O_2N_6$: C, 64.4; H, 8.5. Found: C, 64.2; H, 8.6.

The acidic fraction from the oxidation gave a product which crystallized from ether–pentane as small white crystals, m. p. 234–237°. This gave no depression with a sample of 3-keto-*etio*-bilianic acid, m. p. 235–238°.

(7) Marker, Kamm, Wittle, Oakwood, Lawson and Laucius, THIS JOURNAL, **59**, 2291 (1937).

(10) Microanalyses by Dr. John R. Adams, Jr., of this Laboratory.

Anal. Calcd. for $C_{19}H_{28}O_5$: C, 67.8; H, 8.4. Found: C, 67.5; H, 8.5.

Reduction of $\Delta^{16,17}$-Pregnenedione-3,20. (a) With Sodium and Ethanol.—To a boiling solution of 300 mg. of $\Delta^{16,17}$-pregnenedione-3,20 in 100 cc. of absolute ethanol was added 7 g. of sodium over a period of seventy-five minutes. The solution was diluted with water and the precipitated solid taken up with ether. The ethereal extract was washed well with water and the ether evaporated until crystals began to separate. These were collected, washed with ether and crystallized from acetone as small white crystals, m. p. 236–239°. This gave no depression with an authentic sample of pregnanediol-3(α),20(α), m. p. 237–239°. The yield was 250 mg.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.7; H, 11.3.

With boiling acetic anhydride this gave a **diacetate** which crystallized from methanol as small white plates, m. p. 177–179°. This gave no depression with a sample of the diacetate of pregnanediol-3(α),20(α), m. p. 177–179°.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.2; H, 10.0. Found: C, 74.2; H, 10.0.

(b) With Adams Catalyst.—A mixture of 700 mg. of $\Delta^{16,17}$-pregnenedione-3,20, 120 cc. of absolute ethanol and 400 mg. of Adams catalyst was shaken with hydrogen at 3 atm. pressure at room temperature for fifteen hours. The catalyst was removed and the filtrate evaporated to a volume of about 20 cc. To this hot solution was added a hot solution of 1 g. of digitonin in 50 cc. of 90% ethanol. After standing for two hours at room temperature the digitonide was filtered, washed and dried.

The filtrate containing the *epi*-fraction was evaporated *in vacuo* to a volume of about 10 cc. After the addition of 150 cc. of ether the mixture was filtered and the filtrate evaporated. The residue was crystallized from ethanol to give small, compact, white crystals, m. p. 232–234°. The mixture with a sample of pregnanediol-3(α),20(β), m. p. 231°, melted at 231–234°.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.7; H, 11.3.

With hot acetic anhydride the product yielded a diacetate which crystallized from aqueous ethanol as white needles, m. p. 108–109.5°. This gave no depression with a sample of the diacetate of pregnanediol-3(α),20(β), m. p. 109–110°.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.2; H, 10.0. Found: C, 75.4; H, 9.9.

The digitonide (750 mg.) was dissolved in 10 cc. of pyridine and heated at 90° for one hour. The solution was diluted with ether and the turbid mixture filtered. The pyridine was removed from the filtrate with dilute hydrochloric acid and the ether evaporated. After treatment with Norite the product was crystallized from aqueous ethanol as compact white crystals, m. p. 173–175°. This gave no depression with an authentic sample of pregnanediol-3(β),20(β), m. p. 174–176°.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.5; H, 11.2.

The first mother liquor from the beta-sterol fraction was freed from solvent and acetylated with boiling acetic anhydride. After repeated crystallization from aqueous ethanol a product was obtained as white needles, m. p 138–140°. This gave no depression with a sample of the diacetate of pregnanediol-3(β),20(α), m. p. 141°.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.2; H, 10.0. Found: C, 74.4; H, 9.9.

(c) With Palladium.—A mixture of 250 mg. of $\Delta^{16,17}$-pregnenedione-3,20, 120 cc. of absolute ethanol and 1 g. of palladium–barium sulfate catalyst was shaken with hydrogen at 1 atm. pressure at room temperature for ninety minutes. The catalyst was removed and the solvent distilled *in vacuo*. The residue was crystallized from aqueous ethanol to give compact white crystals, m. p. 117–119°. This gave no depression with an authentic sample of pregnanedione-3,20, m. p. 117.5–119°.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.5; H, 10.1.

With semicarbazide acetate in the usual manner the substance gave a **di-semicarbazone** which crystallized from aqueous ethanol as white crystals, m. p. 244° dec.

Anal. Calcd. for $C_{23}H_{40}O_2N_6$: C, 63.8; H, 9.3. Found: C, 63.6; H, 9.2.

Summary

The isomerization of sarsasapogenin to pseudosarsasapogenin with acid anhydrides is described.

Pseudosarsasapogenin on mild oxidation with chromic anhydride is converted into $\Delta^{16,17}$-pregnenedione-3,20.

The reduction products of $\Delta^{16,17}$-pregnenedione-3,20 have been studied.

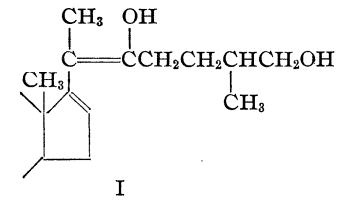
Sterols. LXXXIX. Reactions of Pseudosarsasapogenin

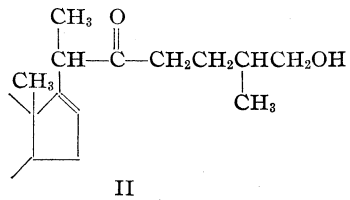
BY RUSSELL E. MARKER AND EWALD ROHRMANN

Of the many reactions which are peculiar to sarsasapogenin,[1] probably the most interesting and certainly the most significant from the standpoint of elucidating the relationship existing between this sapogenin and the sterols is the isomerization by acid anhydrides[2] to yield pseudosarsasapogenin. This isomeric substance is of great significance because of the ease with which it is converted into $\Delta^{16,17}$-pregnenedione-3,20 by mild oxidation with chromic anhydride.

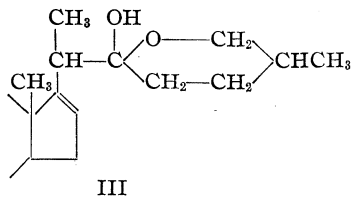
All of our evidence, which is derived largely from oxidation and reduction studies seems to indicate that pseudosarsasapogenin is best represented by structure I or possibly by one of its equivalents, II or III.



I



II



III

Pseudosarsasapogenin (suggested formulations)

As discussed in previous work,[2] pseudosarsasapogenin upon mild oxidation with chromic anhydride yields $\Delta^{16,17}$-pregnenedione-3,20 (VII) and 3-keto-*etio*-bilianic acid. Pseudosarsasapogenin upon acetylation with hot acetic anhydride gives a non-crystalline product which upon mild oxidation with chromic anhydride yields $\Delta^{16,17}$-pregnenol-3(β)-one-20 acetate (VI) and 3(β)-hydroxy-*etio*-bilianic acid (V).[3] Further oxidation of $\Delta^{16,17}$-pregnenol-3(β)-one-20 acetate yielded 3(β)-hydroxy-*etio*-bilianic acid. The oxidation of acetylated pseudosarsasapogenin at elevated temperatures gives largely the bilianic acid. Neither pseudosarsasapogenin nor the acetylated product reacts with semicarbazide acetate under the usual conditions.

Pseudosarsasapogenin upon hydrogenation with Adams catalyst in acetic acid, ethanol or acidic ethanol yields dihydropseudosarsasapogenin. This substance yields a diacetate and a di-*p*-nitrobenzoate. It is of interest that acetylated pseudosarsasapogenin upon hydrogenation with Adams catalyst yields a substance identical with the diacetate of dihydropseudosarsasapogenin. This fact does not appear to be in accordance with structure III for pseudosarsasapogenin.

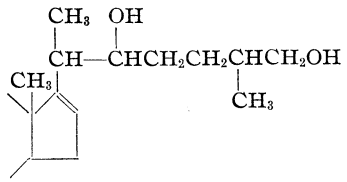
Dihydropseudosarsasapogenin upon oxidation at 15° with chromic anhydride readily yields $\Delta^{16,17}$-pregnenedione-3,20 and a diketo acid (VIII) of the composition $C_{27}H_{42}O_4$. This acid forms a disemicarbazone and a methyl ester and on further oxidation with chromic anhydride yields $\Delta^{16,17}$-pregnenedione-3,20. The fact that this acid readily forms a disemicarbazone while pseudosarsasapogenin does not react with semicarbazide acetate does not seem to be in accordance with structure II for pseudosarsasapogenin.

Dihydropseudosarsasapogenin diacetate upon oxidation with chromic anhydride at 90° gives a good yield of 3-(β)-hydroxy-*etio*-bilianic acid. No neutral product was obtained. Oxidation of the diacetate at 25–30° yields 3-(β)-hydroxy-*etio*-bilianic acid and a neutral fraction consisting of $\Delta^{16,17}$-pregnenol-3(β)-one-20 acetate and a mixture of neutral products which were not separated. When the diacetate was oxidized at 15° it was recovered largely unchanged which is in contrast to the analogous oxidation of the free dihydro compound. Evidently the presence of an acetoxy group at C-27 hinders the oxidation of a reactive group at C-22.

The ease of formation of $\Delta^{16,17}$-pregnenedione-3,20 from both pseudosarsasapogenin and dihydropseudosarsasapogenin suggests that both of these substances contain a non-reducible ethylenic linkage at C-16, C-17 and a reactive group at C-22.

(1) Marker and Rohrmann, THIS JOURNAL, **61**, 846 (1939).
(2) Marker and Rohrmann, *ibid.*, **62**, 518 (1940).
(3) Marker and Rohrmann, *ibid.*, **61**, 2722 (1939).

The occurrence of non-reducible ethylenic linkages in sterol compounds is of course not unusual, apocholic acid[4] being a notable example. Inspection of the three suggested formulations (I, II, and III) for pseudosarsasapogenin indicates that all of these should yield the same dihydro compound on reduction and that dihydropseudosarsasapogenin is probably best represented by structure IV.

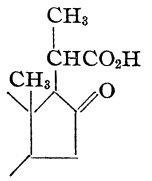


IV. Dihydropseudosarsasapogenin (suggested)

It seems peculiar that pseudosarsasapogenin and dihydropseudosarsasapogenin form *bis* rather than the expected *tris* derivatives. This is possibly due to hindrance at the C-22 position.

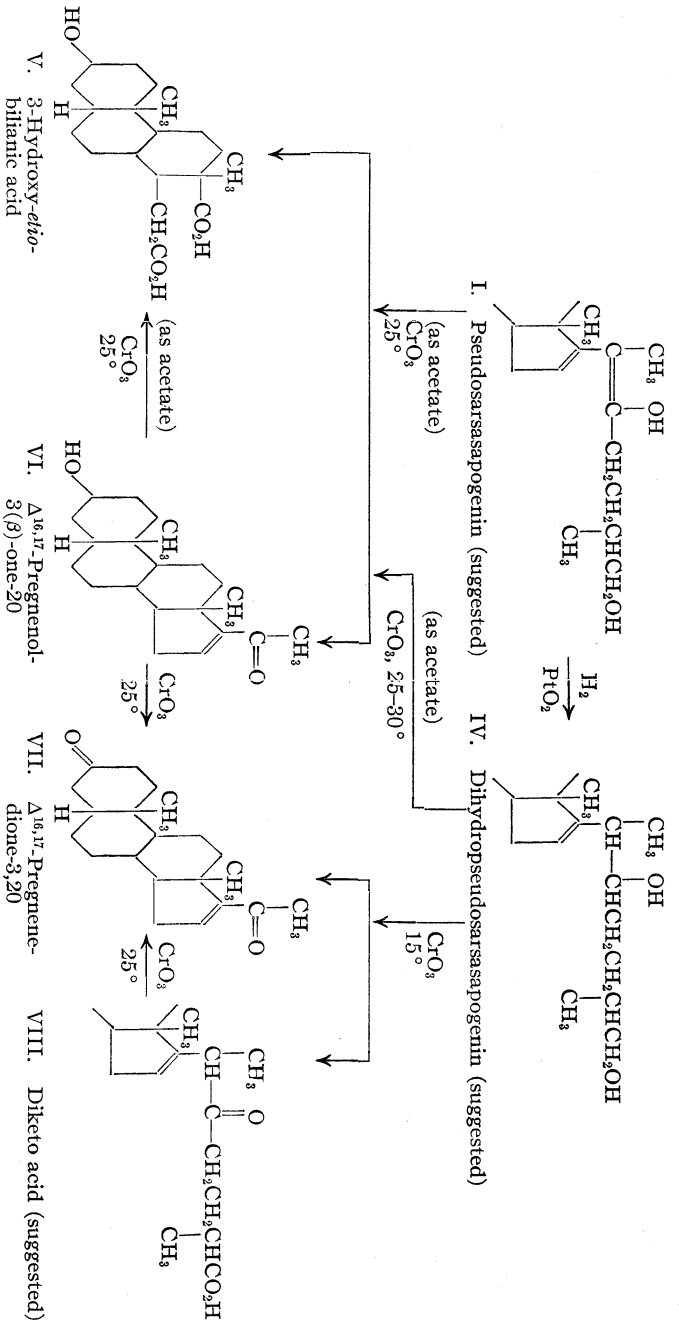
It is of interest that in the oxidation of the diacetates of pseudosarsasapogenin and dihydropseudosarsasapogenin an appreciable amount of the 3-(β)-hydroxy-*etio*-bilianic acid apparently is formed as the anhydride and occurs as such in the neutral fraction of the oxidations. This is in accordance with observations on the analogous oxidation of *allo*-pregnanetriol-3,16,20 to 3-keto-*etio-allo*-bilianic acid.[5]

In all of the oxidation studies of the pseudo and dihydropseudo diacetates it is significant that none of the C_{22} keto acid[6] (IX) was encountered. This is in accordance with suggested structures of the pseudo and dihydropseudo compounds.



IX. C_{22} Keto Acid

The $\Delta^{16,17}$-pregnenol-3(β)-one-20 acetate obtained in the oxidation of acetylated pseudosarsasapogenin and dihydropseudosarsasapogenin was characterized by a study of its reduction products. With sodium and ethanol it yields pregnanediol-3-(β),20(α). Hydrogenation with Adams catalyst and subsequent oxidation with chromic anhydride yielded the acetate of pregnanol-3(β)-one-20. These transformations are in accordance with previous postulations concerning



the configuration of the C-3 hydroxyl group in sarsasapogenin.[7,8] $\Delta^{16,17}$-Pregnenol-3(β)-one-20 acetate on alkaline hydrolysis and subsequent mild oxidation with chromic anhydride readily yields $\Delta^{16,17}$-pregnenedione-3,20.

Experimental Part[9]

Pseudosarsasapogenin.—This was prepared as described in previous work. Pseudosarsasapogenin is very readily oxidized by selenium dioxide, a reaction which we have not investigated further as yet. It reacts readily with bromine but at present we have not isolated any definite crystalline products from this reaction. Pseudosarsasapogenin does not react with semicarbazide acetate under the usual conditions. The acetylated product is likewise unreactive.

Oxidation of Acetylated Pseudosarsasapogenin. (a) at 90°.—Pseudosarsasapogenin (2.5 g.) was refluxed for thirty minutes with 15 cc. of acetic anhydride. The acetic anhydride was evaporated *in vacuo* and the residual sirup dissolved in 60 cc. of acetic acid. The solution was heated on a steam-bath while 5 g. of chromic anhydride in 50 cc. of 80% acetic acid was added over a period of one hour. Ethanol (10 cc.) was then added and the solution evaporated *in vacuo* to a volume of about 50 cc. Water was added and the precipitated solid taken up in ether and the ethereal extract washed with 3% sodium hydroxide solution and water. The sodium hydroxide washing was heated on the steam-bath for twenty minutes to complete hydrolysis. The solution was then cooled, acidified with hydrochloric acid and the precipitated solid was taken up in ether and crystallized from chloroform to give 600 mg. of white crystals, m. p. 221–223°. This gave no depression with a sample of 3-hydroxy-*etio*-bilianic acid, m. p. 220–222°.

Anal. Calcd. for $C_{19}H_{30}O_5$: C, 67.4; H, 8.9. Found: C, 67.3; H, 8.9.

With hot acetic anhydride the acid gave an *acetate anhydride* which crystallized from aqueous acetone as flat white needles, m. p. 204.5–206.5°. This gave no depression with a sample of the acetate anhydride of 3-hydroxy-*etio*-bilianic acid, m. p. 205–207°.

Anal. Calcd. for $C_{21}H_{30}O_5$: C, 69.6; H, 8.3. Found: C, 69.5; H, 8.3.

The ethereal solution containing the material not extracted with alkali was evaporated and the residual sirup hydrolyzed with ethanolic potassium hydroxide. Water and dilute hydrochloric acid were added and the precipitate taken up in ether and crystallized from ether to give 30 mg. of small white crystals, m. p. 284–287°. This product has not been investigated further.

Anal. Calcd. for $C_{22}H_{34}O_4$: C, 72.9; H, 9.5; neut. equiv., 362. Found: C, 73.1, 73.1; H, 9.3, 9.5; neut. equiv., 358.

The filtrate from this acid was evaporated and crystallized from chloroform to give white crystals, m. p. 220–222°. This gave no depression with a sample of 3-hydroxy-*etio*-bilianic acid, m. p. 220–222°.

(b) At Room Temperature.—Pseudosarsasapogenin (3 g.) was treated with acetic anhydride as before and the residual sirup dissolved in 100 cc. of acetic acid. To this solution was added 3 g. of chromic anhydride in 30 cc. of 80% acetic acid. The mixture was allowed to stand at room temperature for one hour. Water was added and the precipitated solid taken up in ether. The ethereal extract was washed with water and 3% sodium hydroxide solution.

The alkaline water layer was acidified with hydrochloric acid and the precipitated acid was taken up in ether and crystallized from chloroform to give white crystals, m. p. 220–222°. This gave no depression with a sample of 3-hydroxy-*etio*-bilianic acid, m. p. 220–222°.

Anal. Calcd. for $C_{19}H_{30}O_5$: C, 67.4; H, 8.9. Found: C, 67.0; H, 8.8.

The neutral fraction was crystallized from aqueous methanol to give white plates, m. p. 144–146°. This product is the *acetate* of $\Delta^{16,17}$-pregnenol-3(β)-one-20.

Anal. Calcd. for $C_{23}H_{34}O_3$: C, 77.0; H, 9.6. Found: C, 76.8, 77.0; H, 9.5, 9.4.

When treated with semicarbazide acetate under the usual conditions the product gave a *semicarbazone* which crystallized from aqueous ethanol, m. p. 250–252°.

Anal. Calcd. for $C_{24}H_{37}O_3N_3$: C, 69.35; H, 9.0. Found: C, 69.2; H, 8.8.

The filtrate remaining after removal of most of the $\Delta^{16,17}$-pregnenol-3(β)-one-20 acetate upon hydrolysis with ethanolic potassium hydroxide yielded an acid which crystallized from chloroform as white crystals, m. p. 219–222°. This gave no depression with a sample of 3-hydroxy-*etio*-bilianic acid, m. p. 220–222°. This indicates that some of the 3-hydroxy-*etio*-bilianic acid is present in the oxidation mixture as the anhydride.

3-(β)-Hydroxy-*etio*-bilianic Acid from $\Delta^{16,17}$-Pregnenol-3(β)-one-20 Acetate.—The acetate of $\Delta^{16,17}$-pregnenol-3(β)-one-20 was oxidized in acetic acid solution with chromic anhydride for sixteen hours at room temperature. The acid fraction after alkaline hydrolysis was crystallized from chloroform to give small white plates, m. p. 221–223°. This gave no depression with a sample of 3(β)-hydroxy-*etio*-bilianic acid, m. p. 220–222°.

Anal. Calcd. for $C_{19}H_{30}O_5$: C, 67.4; H, 8.9. Found: C, 67.3; H, 8.9.

$\Delta^{16,17}$-Pregnenedione-3,20 from $\Delta^{16,17}$-Pregnenol-3(β)-one-20 Acetate.—The acetate of $\Delta^{16,17}$-pregnenol-3(β)-one-20 was hydrolyzed by refluxing for ten minutes with ethanolic potassium hydroxide solution. The product was crystallized from ethanol as white needles, m. p. 207–209°. The product evidently contains a molecule of ethanol, as indicated by the analysis.

Anal. Calcd. for $C_{23}H_{38}O_3$: C, 76.2; H, 10.6. Found: C, 76.2, 76.2; H, 10.6, 10.6.

When treated with semicarbazide acetate under the usual conditions the product gave a *semicarbazone* which crystallized from ethanol, m. p. 240° dec.

Anal. Calcd. for $C_{22}H_{35}O_2N_3$: C, 70.7; H, 9.5. Found: C, 70.6; H, 9.5.

Treatment with boiling acetic anhydride gave the acetate, m. p. 143–145°, which gave no depression with the original acetate, m. p. 144–146°.

To a solution of 150 mg. of the hydrolyzed product in 10 cc. of acetic acid was added 100 mg. of chromic an-

(9) Microanalyses by Dr. John R. Adams, Jr., of this Laboratory.

hydride in 5 cc. of 80% acetic acid. After standing for twenty minutes at room temperature, water was added and the products taken up in ether, and washed free from acid with sodium hydroxide. The neutral material was crystallized from acetone to give white plates, m. p. 199–201°. This gave no depression with a sample of $\Delta^{16,17}$-pregnenedione-3,20, m. p. 200–202°.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6. Found: C, 80.3; H, 9.5.

Reduction of $\Delta^{16,17}$-Pregnenol-3(β)-one-20 Acetate. (a) With Sodium and Ethanol.—To a boiling solution of 500 mg. of the acetate of $\Delta^{16,17}$-pregnenol-3(β)-one-20 in 100 cc. of absolute ethanol was added 6 g. of sodium over a period of one hour. The solution was diluted with water and extracted with ether. The product was crystallized from ether and finally from acetone to give compact white crystals, m. p. 180–183°. This gave no depression with a sample of pregnanediol-3(β),20(α), m. p. 182–184°.

Acetylation with hot acetic anhydride yielded an acetate which crystallized from aqueous ethanol as white needles, m. p. 138–140°. This gave no depression with a sample of the diacetate of pregnanediol-3(β),20(α), m. p. 139–141°.

(b) **With Adams Catalyst.**—A mixture of 300 mg. of $\Delta^{16,17}$-pregnenol-3(β)-one-20 acetate, 300 mg. of Adams catalyst and 120 cc. of absolute ethanol was shaken with hydrogen at 3 atm. at room temperature for three hours. No definite crystalline product was isolated. The entire product was oxidized in acetic acid (20 cc.) at room temperature with 300 mg. of chromic anhydride for one hour. The product was crystallized from aqueous ethanol as compact white crystals, m. p. 118–119.5°. This gave no depression with a sample of pregnanedione-3,20, m. p. 118–120°.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.6; H, 10.2.

In another experiment the acetate of $\Delta^{16,17}$-pregnenol-3-(β)-one-20 (800 mg.) was reduced as above. The catalyst and solvent were removed and the residue dissolved in 25 cc. of acetic acid. To this solution was added a solution of 500 mg. of chromic anhydride in 10 cc. of 80% acetic acid. After standing for thirty minutes at room temperature, water was added and the precipitated solid taken up in ether and freed from acids by washing with water and sodium carbonate solution. The product was crystallized from aqueous ethanol as thick white needles, m. p. 116–118°. This gave no depression with a sample of pregnanol-3(β)-one-20 acetate, m. p. 118–120°.

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.6; H, 10.1. Found: C, 76.6; H, 10.1.

Dihydropseudosarsasapogenin.—A mixture of 1 g. of pseudosarsasapogenin, 500 mg. of Adams catalyst and 120 cc. of acetic acid was shaken with hydrogen at 3 atm. at room temperature for fifteen hours. The catalyst was filtered and the filtrate evaporated *in vacuo*. The residual sirup was hydrolyzed with ethanolic potassium hydroxide and crystallized from acetone as small white plates, m. p. 168–170°. The mixture with the original pseudosarsasapogenin (m. p. 171–173°) melted at 150–155° and that with dihydrosarsasapogenin (m. p. 165–166°) at 154–162°. Similar results were obtained when the reduction was carried out in ethanol or in ethanol acidified with hydrochloric acid.

Anal. Calcd. for $C_{27}H_{46}O_3$: C, 77.4; H, 11.1. Found: C, 77.3; H, 10.9.

With boiling acetic anhydride the substance gave a **diacetate** which crystallized from pentane as white needles, m. p. 95–97°.

Anal. Calcd. for $C_{31}H_{50}O_5$: C, 74.1; H, 10.0. Found: C, 74.0, 74.1; H, 9.9, 10.0.

With *p*-nitrobenzoyl chloride in pyridine at 60° a **di-*p*-nitrobenzoate** was formed which crystallized from ethyl acetate as white needles, m. p. 196–197.5°.

Anal. Calcd. for $C_{41}H_{52}O_9N_2$: C, 68.7; H, 7.3. Found: C, 68.7; H, 7.1.

Dihydropseudosarsasapogenin does not react noticeably with selenium dioxide. It absorbs bromine slowly in acetic acid solution.

Reduction of Acetylated Pseudosarsasapogenin.—Pseudosarsasapogenin (2 g.) was refluxed with an excess of acetic anhydride and the anhydride evaporated *in vacuo*. The residual sirup was reëvaporated several times with acetic acid and finally dissolved in a mixture of 50 cc. of acetic acid and 75 cc. of absolute ethanol. The solution was shaken with 1 g. of Adams catalyst and hydrogen at 3 atm. pressure at room temperature for twelve hours. The catalyst was removed and the acetic acid evaporated *in vacuo*. The residue was crystallized from pentane as white needles, m. p. 95–97°. This gave no depression with a sample of the diacetate of dihydropseudosarsasapogenin, m. p. 95–97°.

Anal. Calcd. for $C_{31}H_{50}O_5$: C, 74.1; H, 10.0. Found: C, 74.2; H, 9.9.

Oxidation of Dihydropseudosarsasapogenin.—To a solution of 4 g. of dihydropseudosarsasapogenin in 200 cc. of acetic acid was added 6 g. of chromic anhydride in 50 cc. of 80% acetic acid. After standing at 15–18° for ninety minutes a large volume of water was added and the mixture shaken with ether. The ethereal solution was washed with water and 3% sodium hydroxide solution. The aqueous alkaline layer was acidified with hydrochloric acid and the precipitated acid taken up with ether and crystallized from acetone as small white needles, m. p. 233–236°. This is a diketo acid (VIII).

Anal. Calcd. for $C_{27}H_{42}O_4$: C, 75.3; H, 9.6. Found: C, 75.3, 75.1; H, 9.4, 9.6.

With semicarbazide acetate in the usual manner, the acid gave a **disemicarbazone** which crystallized from ethanol as small white crystals, m. p. 209° dec.

Anal. Calcd. for $C_{29}H_{48}O_4N_6$: C, 63.9; H, 8.9. Found: C, 63.7; H, 8.5.

With diazomethane in ether–methanol solution the acid gave a **methyl ester** which crystallized from pentane as white needles, m. p. 85–87°.

Anal. Calcd. for $C_{28}H_{44}O_4$: C, 75.6; H, 10.0. Found: C, 75.4; H, 9.8.

The ethereal extract containing the neutral fraction was evaporated and the residue crystallized from acetone to give $\Delta^{16,17}$-pregnenedione-3,20 as white plates, m. p. 199–201°. This gave no depression with an authentic sample of $\Delta^{16,17}$-pregnenedione-3,20, m. p. 200–202°.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6. Found: C, 80.3; H, 9.6.

$\Delta^{16,17}$-Pregnenedione-3,20 from Diketo Acid (VIII).—To a solution of 250 mg. of diketo acid in 20 cc. of acetic acid was added a solution of 250 mg. of chromic anhydride in 5 cc. of 80% acetic acid. After standing at 25° for seventy-five minutes water was added and the precipitated solid taken up in ether and washed with water and potassium hydroxide solution. Evaporation of the ether gave a product which crystallized from acetone as white plates, m. p. 199–201°. This gave no depression with a sample of $\Delta^{16,17}$-pregnenedione-3,20, m. p. 200–202°.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6. Found: C, 80.1; H, 9.5.

The acidic fraction yielded some unchanged diketo acid.

Oxidation of Diacetate of Dihydropseudosarsasapogenin. (a) **At 90°.**—To a solution of 4 g. of dihydropseudosarsasapogenin diacetate in 100 cc. of acetic acid heated at 90° was added with stirring over a course of one hour 8 g. of chromic anhydride in 40 cc. of 80% acetic acid. The mixture was heated for an additional hour after which ethanol was added and the mixture evaporated *in vacuo* to a volume of about 75 cc. Water was added and the precipitated solids taken up in ether. The ethereal solution was washed with water and 3% sodium hydroxide. The aqueous alkaline layer was heated on the steam-bath for twenty minutes and the acids precipitated with hydrochloric acid. The acidic product was crystallized from chloroform as white crystals, m. p. 220–223°. This gave no depression with an authentic sample of 3-hydroxy-*etio*-bilianic acid, m. p. 220–222°. The yield was 1.4 g.

Anal. Calcd. for $C_{19}H_{30}O_5$: C, 67.4; H, 8.9. Found: C, 67.3; H, 8.8.

Hydrolysis of the "neutral fraction" gave only additional amounts of the above bilianic acid. There was no noticeable neutral material.

(b) **At Room Temperature.**—To a solution of 2 g. of dihydropseudosarsasapogenin diacetate in 100 cc. of acetic acid was added 2 g. of chromic anhydride in 20 cc. of 80% acetic acid. After standing at 25–28° for two hours, water was added and the precipitated solid taken up in ether. The ethereal solution was washed with water and 3% sodium hydroxide solution. The acidic fraction was hydrolyzed and worked up as under (a). The product crystallized from chloroform as small white crystals, m. p. 219–222°. This gave no depression with a sample of 3-hydroxy-*etio*-bilianic acid, m. p. 220–222°.

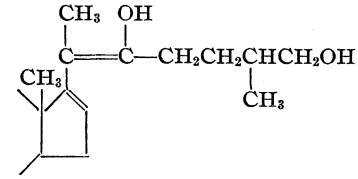
The neutral fraction was crystallized from aqueous methanol to give white plates, m. p. 143–145°. This gave no depression with a sample of pregnenol-3-(β)-one-20 acetate, m. p. 144–146°.

Anal. Calcd. for $C_{23}H_{34}O_3$: C, 77.0; H, 9.6. Found: C, 76.7; H, 9.4.

When the reaction was carried out below 20° the only neutral product which could be isolated (after alkaline hydrolysis) was dihydropseudosarsasapogenin.

Summary

Evidence has been presented indicating that pseudosarsasapogenin probably has the structure (or one of its equivalents)



STATE COLLEGE, PENNA. RECEIVED DECEMBER 26, 1939

Sterols. XC. Oxidation Products of Sarsasapogenin. Pregnanetriol-3,16,20

BY RUSSELL E. MARKER, EWALD ROHRMANN, HARRY M. CROOKS, EUGENE L. WITTLE, ELDON M. JONES AND D. L. TURNER

In a recent publication the conversion of sarsasapogenin to pregnane derivatives was described.[1] This degradation involved the isomerization of sarsasapogenin to pseudosarsasapogenin, the oxidation of this substance to $\Delta^{16,17}$-pregnenedione-3,20 and the subsequent reduction of this to pregnanedione-3,20 and the various pregnanediols.

The fact that sarsasapogenin (III) appears to have a potential ketone group which is very reactive in the presence of acids[2] suggested a method of directly converting the substance to a pregnane derivative in one step, namely, by a persulfate oxidation. It is well known that persulfates in the presence of sulfuric acid readily react with polycyclic ketones to yield lactones. A typical example of this type of oxidation is the conversion of camphor (I) to α-campholide (II).[3] Ruzicka and Stoll[4] carried out similar oxidations in a lig-

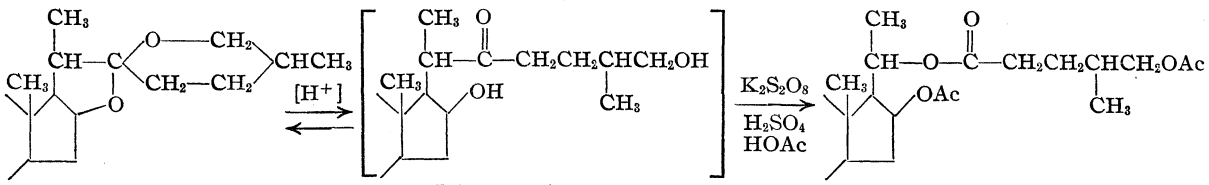
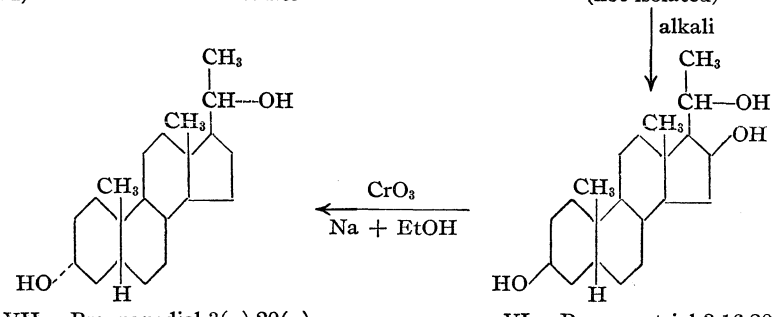
roin medium to obtain good yields of lactones. Rollett and Bratke[5] carried out the oxidations in an aqueous acetic acid medium in the presence of a small amount of sulfuric acid.



III. Sarsasapogenin (Marker and Rohrmann)

IV. Postulated intermediate

V. Ester (not isolated)



VII. Pregnanediol-3(α),20(α)

VI. Pregnanetriol-3,16,20

Using this latter procedure we have carried out the oxidation of sarsasapogenin acetate with potassium persulfate and have obtained a substance after alkaline hydrolysis of the composition $C_{21}H_{36}O_3$ (VI). This substance forms an acetate and a benzoate which appear to be *tris* derivatives. The substance contains no ketonic groups. Mild oxidation of the substance with chromic anhydride followed by removal of the acidic products with alkali and subsequent reduction of the neutral fraction with sodium and ethanol gave pregnanediol-3(α),20(α) (VII). This indicates that the original substance was pregnanetriol-3,16,20 (VI) since by a similar procedure *allo*-pregnanetriol-3,16,20 has been converted to *allo*-pregnanedione-3,20.[6,7] When the neutral fraction from the persulfate oxidation was oxidized with chromic anhydride (without prior alkaline hydrolysis), the only product which was obtained on subsequent hydrolysis was pregnanetriol-3,16,20. This indicates that all of the hydroxyl groups are esterified in the course of the oxidation.

The ease with which this conversion of sarsasapogenin to pregnanetriol-3,16,20 takes place raises many interesting questions in regards to the mechanism of the cleavage. It appears that all of the facts are in complete accordance with the ketone spiro acetal structure of the sapogenin side chain as is indicated in the suggested mechanism given in the accompanying chart. The postulated intermediates IV and V were not isolated.

epi-Sarsasapogenin acetate on oxidation with persulfate yielded a triol having the *epi* configuration at C-3. The persulfate oxidation of sarsasapogenin acetate yields an appreciable acidic fraction which we have not investigated as yet.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part[8]

Pregnanetriol-3(β),16,20 from Sarsasapogenin Acetate.—A mixture of 1 g. of sarsasapogenin acetate, 4 g. of potassium persulfate, 150 cc. of 90% acetic acid and 1 cc. of concentrated sulfuric acid was refluxed for two hours. Water was added and the precipitated solid taken up in ether and washed with water and 3% sodium hydroxide. The ether was evaporated and the residual material was hydrolyzed with ethanolic potassium hydroxide. Water was added to the alkaline solution and the precipitated solid taken up in ether and crystallized from ether–pentane as small white crystals, m. p. 223–226°. The yields varied from 20 to 40% in different runs.

Anal. Calcd. for $C_{21}H_{36}O_3$: C, 74.9; H, 10.8. Found: C, 75.0, 74.8; H, 10.6, 11.0.

With benzoyl chloride in pyridine the product gave a **benzoate** which was crystallized from methanol as white prisms, m. p. 185–187°.

Anal. Calcd. for $C_{42}H_{48}O_6$: C, 77.7; H, 7.5. Found: C, 77.9; H, 7.5.

With boiling acetic anhydride the substance gave a **triacetate** which crystallized from dilute ethanol as white crystals, m. p. 108–111°.

(5) Rollett and Bratke, *Monatsh.*, **43**, 685 (1922).

(6) Marker, Kamm, Wittle, Oakwood and Lawson, THIS JOURNAL, **60**, 1067 (1938).

(7) Marker and Wittle, *ibid.*, **61**, 855 (1939).

(8) Microanalyses by Dr. John R. Adams, Jr., of this Laboratory.

Anal. Calcd. for $C_{27}H_{42}O_6$: C, 70.1; H, 9.2. Found: C, 69.8; H, 9.1.

Pregnanetriol-3(α),16,20 from *epi*-Sarsasapogenin.—*epi*-Sarsasapogenin acetate was treated with potassium persulfate as described above. After hydrolysis with ethanolic potassium hydroxide the neutral fraction yielded a substance which crystallized from ether to give white crystals, m. p. 206–207°.

Anal. Calcd. for $C_{21}H_{36}O_3$: C, 74.9; H, 10.8. Found: C, 74.9; H, 10.7.

With benzoyl chloride in pyridine the product gave a **benzoate** which crystallized from aqueous acetone as small white needles, m. p. 153–155°.

Anal. Calcd. for $C_{42}H_{48}O_6$: C, 77.7; H, 7.5. Found: C, 77.3; H, 7.4.

Conversion of Pregnanetriol-3(β),16,20 to Pregnanediol-3(α),20(α).—To a solution of 900 mg. of pregnanetriol in 35 cc. of acetic acid was added slowly a solution of 400 mg. of chromic anhydride in 5 cc. of water and 15 cc. of acetic acid. The solution was allowed to stand at room temperature for twenty minutes and then diluted with water and the product taken up in ether. The ether solution was washed with sodium hydroxide solution and water and evaporated to dryness to give a colorless neutral oil which was dissolved in 200 cc. of boiling absolute ethanol and reduced with 10 g. of sodium. Water was then added and the neutral fraction extracted with ether. The ether solution was washed with water and evaporated to leave a yellow oily residue which was dissolved in 10 cc. of acetone and allowed to stand overnight. The product which crystallized from the solution was purified by further recrystallization from acetone to give pregnanediol-3(α),-20(α), m. p. 235–238°. It gave no depression with a sample of pregnanediol-3(α),20(α), m. p. 236–239°. It gave a depression of 20° with the original pregnanetriol.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.7; H, 11.3. Found: C, 78.7; H, 11.2.

Treatment with acetic anhydride gave the **diacetate of pregnanediol-3(α),20(α)**, m. p. 177–179°, which gave no depression of the melting point with the known diacetate, m. p. 178–180°.

Summary

Sarsasapogenin has been converted to pregnanetriol-3,16,20 by persulfate oxidation.

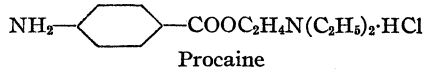
Heterocyclic Local Anesthetics. Carbazole, Dibenzofuran and Dibenzothiophene Derivatives[1]

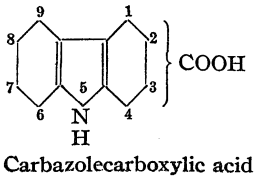
BY ROBERT R. BURTNER AND GERHARD LEHMANN

In any study of local anesthetics of the procaine type one is impressed by the fact that most of the structural variations have been focused upon the amino alcohol portion of the molecule. The effect of alkylation of the nuclear amino group has been studied, and in a few instances useful drugs have resulted, whereas the introduction of an aryl group in this position has received little or no attention.

The carbazole carboxylic acids offered a readily available group of starting materials of the latter type with the interesting variation involving the carbon–carbon bond between the two benzene nuclei.



Procaine

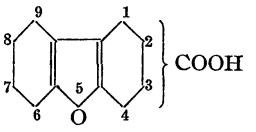


Carbazolecarboxylic acid

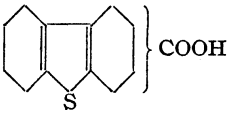
(1) Presented before the Medicinal Section of the American Chemical Society at the Baltimore Meeting, April, 1939.

Previous investigation of a series of esters of carbazole-N-(or 5)-carboxylic acid by Knoefel[2] led to some rather active compounds of low toxicity. In the present study a series of dialkylaminoalkyl esters of the isomeric carbazolecarboxylic acids was prepared with suitable variations involving the alcohol portion of the molecule as well as nuclear substituents.

Seeking to determine the effect of replacement of the heterocyclic element by oxygen and sulfur an analogous series of esters of dibenzofuran and dibenzothiophenecarboxylic acids was investigated.



Dibenzofurancarboxylic acid



Dibenzothiophenecarboxylic acid

In order to study the effect of the carbon–carbon bond between the two benzene nuclei on the activity of compounds of this type, the correspond-

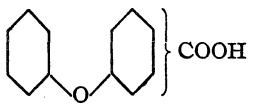
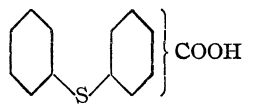
[a] 0 = none, − = weak, + = full, ++ = deep. A 1% cocaine solution gave deep anesthesia lasting fifteen minutes. [b] A 5% solution of this compound gave weak anesthesia for three minutes. [c] Dose at which 50% of animals died. The fatal dose of cocaine is 0.08 g./kg. [d] Intravenous M. L. D. in rabbits = 20 mg./kg. [e] The duration of anesthesia for 5% solutions of compounds 1, 6, 8 and procaine applied intracutaneously in man is 69 min., 34 min., 24 hr. and 70 min., respectively.

ing derivatives of diphenyl ether and diphenyl sulfide also were prepared.



Phenoxybenzoic acid



Thiophenoxybenzoic acid

Experimental Part

Carbazole Derivatives.—The unsubstituted carbazolecarboxylic acids were prepared either by carbonation of the N-potassium derivative followed by pyrolytic rearrangement, or by alkali fusion of the corresponding methyl ketones according to known methods.[3,4] 5-Ethylcarbazole-2-carboxylic acid was obtained in good yield by alkylation of the acid with ethyl sulfate followed by saponification.[5]

5-*n*-Butylcarbazole-2-carboxylic Acid.—A mixture of 21 g. of carbazole-2-carboxylic acid, 47 g. of *n*-butyl sulfate, 42 g. of sodium hydroxide (dissolved in 28 cc. of water) and 146 cc. of acetone was shaken vigorously with intermittent cooling for ten minutes. The solid mass was poured into one liter of water containing 50 g. of sodium hydroxide and concentrated to a volume of 500 cc. The resulting solution was chilled, filtered and acidified. The crude product, which became granular on standing overnight, was filtered out, dried and crystallized from petroleum ether. The yield of white needles melting at 157° was 15 g.

Anal. Calcd. for $C_{17}H_{17}O_2N$: N, 5.24. Found: N, 5.36.

5-Ethylcarbazole-3-carboxylic Acid.—Repeated attempts to alkylate carbazole-3-carboxylic acid using ethyl sulfate or ethyl iodide were unsuccessful. The desired product, however, was obtained easily by alkali fusion of 5-ethyl-3-acetylcarbazole described below.

Fifteen grams of 3-acetylcarbazole, 15 cc. of ethyl sulfate, 15 g. of sodium hydroxide (dissolved in 10 cc. of water) and 100 cc. of acetone were shaken for fifteen minutes. Dilution with water gave the crude product, which was crystallized from petroleum ether to yield 15 g. of 5-ethyl-3-acetylcarbazole melting at 97°.

Anal. Calcd. for $C_{16}H_{15}ON$: N, 5.9. Found: N, 5.6.

Potassium hydroxide fusion gave a 40% yield of the desired acid melting at 248° after crystallization from toluene.

Anal. Calcd. for $C_{15}H_{13}O_2N$: N, 5.82. Found: N, 5.92.

5-*n*-Butylcarbazole-3-carboxylic Acid.—As with the ethyl derivative described above, this acid could not be prepared by direct alkylation but was obtained by alkali fusion of 5-*n*-butyl-3-acetylcarbazole.

A mixture of 28 g. of 3-acetylcarbazole, 70 g. of *n*-butyl iodide, 30 cc. of 66% potassium hydroxide and 140 cc. of acetone was refluxed for twenty-four hours. After dilution with water the acetone and excess butyl iodide were boiled off, the chilled mixture filtered and the crude product crystallized from petroleum ether to yield 28 g. of 5-*n*-butyl-3-acetylcarbazole melting at 74.5–75°.

Anal. Calcd. for $C_{18}H_{19}ON$: N, 5.28. Found: N, 5.41.

Fusion with potassium hydroxide gave an 8% yield of

(3) German Patent 442,609; British Patent 27,051.

(4) Meitzner, THIS JOURNAL, **57**, 2327 (1935); Plant and Williams, *J. Chem. Soc.*, 1142 (1934); Borsche and Fiese, *Ber.*, **40**, 378 (1907).

the desired acid which was crystallized from benzene and melted at 198°.

Anal. Calcd. for $C_{17}H_{17}O_2N$: N, 5.24. Found: N, 5.6.

8-Nitrocarbazole-3-carboxylic Acid.—Two grams of sodium nitrite was added in portions, with stirring, to a solution of 5.5 g. of carbazole-3-carboxylic acid in 80 cc. of acetic acid at 90°. A solution of 4.5 cc. of acetic acid and 4.5 cc. of concentrated nitric acid was then added dropwise with stirring at 80–85°. Stirring was continued for one hour at 85°, the resulting mixture chilled and the yellow product filtered out and washed with 50 cc. of alcohol. Refluxing with 100 cc. of alcohol and 40 cc. of 40% sodium hydroxide for thirty minutes gave, after dilution with water and acidification, 6 g. of a yellow amorphous powder, m. p. 335° (dec.). Crystallization from nitrobenzene raised the melting point to 338°.

Anal. Calcd. for $C_{13}H_8O_4N_2$: N, 10.95. Found: N, 11.1.

Decarboxylation with copper bronze in the high boiling fraction (b. p. 300–350°) of technical pyridine gave 2-nitrocarbazole.

6,7,8,9-Tetrahydrocarbazole-2-carboxylic Acid.—Thirty-eight grams of *p*-hydrazinobenzoic acid[6] and 38 cc. of cyclohexanone were heated on a steam-bath for fifteen minutes and then refluxed gently with stirring for fifteen minutes with 400 cc. of 10% (by volume) sulfuric acid. The chilled mixture was filtered, the crude product dissolved in dilute alkali, decolorized with Darco and acidified. The yield of pure product melting at 279° was 40 g.

Anal. Calcd. for $C_{13}H_{13}O_2N$: N, 6.51. Found: N, 6.46.

The dialkylaminoalkyl esters were prepared by conversion to their respective acid chlorides (by means of phosphorus trichloride) followed by treatment with the desired alcohol (method A) or by way of the ω-chloroalkyl ester which was then treated with the appropriate amine (method B).

β-Chloroethyl Carbazole-2-carboxylate.—A slow stream of dry hydrogen chloride was passed into a refluxing solution of 10 g. of carbazole-2-carboxylic acid in 50 cc. of ethylene chlorohydrin for a period of six hours. After standing overnight at laboratory temperature the mixture was poured into 400 cc. of ice water, the crystalline product filtered out, washed with sodium bicarbonate solution and crystallized from benzene to yield 8 g. of the ester melting at 141°.

Anal. Calcd. for $C_{15}H_{12}O_2NCl$: Cl, 12.95. Found: Cl, 13.0.

γ-Chloropropyl Carbazole-2-carboxylate.—A procedure similar to that above starting with 20 g. of the acid and 80 cc. of trimethylene chlorohydrin gave 18 g. of pure product, m. p. 129°.

Anal. Calcd. for $C_{16}H_{14}O_2NCl$: Cl, 12.32. Found: Cl, 12.26.

β-Diethylaminoethyl 5-Ethylcarbazole-2-carboxylate (Method A).—Ten grams of 5-ethylcarbazole-2-carboxylic acid and 40 cc. of phosphorus trichloride were heated on a steam-bath for one and one-half hours. The excess phosphorus trichloride was distilled off under reduced pressure and the acid chloride cautiously treated with 50 cc. of β-diethylaminoethanol. When the initial reaction had subsided, the mixture was heated on a steam-bath for fifteen minutes and then let stand overnight at laboratory temperature. After dilution with 500 cc. of water containing 50 cc. of 10% sodium hydroxide the oily base was extracted with ether, the ethereal extract washed with water and dried over sodium sulfate. The solvent was removed and the excess amino-alcohol distilled off under reduced pressure. The crude base was dissolved in 300 cc. of dry ether, treated with Darco and the filtrate saturated with dry hydrogen chloride. The viscous hydrochloride was taken up in 150 cc. of warm acetone from which it soon precipitated in crystalline form. The acetone filtrate was concentrated to 50 cc. to yield an additional amount of material. Crystallization of the combined products from methanol gave 7 g. of the hydrochloride melting at 204°.

γ-Diethylaminopropyl Carbazole-2-carboxylate (Method B).—Seventeen grams of γ-chloropropyl carbazole-2-carboxylate and 11 g. of diethylamine were heated in a sealed tube at 110° for thirty-six hours. The base was isolated and converted to its hydrochloride in the same manner as described in method A to give 8 g. of the desired compound melting at 169°.

β-Diethylaminoethyl 8-Aminocarbazole-3-carboxylate.—Using the procedure described under method A, β-diethylaminoethyl 8-nitrocarbazole-3-carboxylate hydrochloride was obtained, melting at 225–227°, after crystallization from ethanol.

Anal. Calcd. for $C_{19}H_{22}O_4N_2Cl$: N, 11.8. Found: N, 11.5.

Reduction was effected by means of iron filings and acetic acid in the customary manner. When the reaction was complete, the mixture was poured into water, made alkaline and filtered. The precipitate was extracted with acetone, the extract treated with Darco and the solvent removed. The crude base was then dissolved in ether and precipitated as the hydrochloride. Addition of alkali to an aqueous solution of the salt precipitated the base in crystalline form, which was filtered out and recrystallized from petroleum ether to give yellow plates, m. p. 146–147°.

Dibenzofuran and Dibenzothiophene Derivatives. β-(*p*-Phenoxy)-acrylic Acid.—Thirty-five grams of *p*-phenoxybenzaldehyde,[7] 175 cc. of acetic anhydride and 28 g. of twice fused sodium acetate were refluxed for eight hours and then diluted with 1400 cc. of warm water to destroy excess acetic anhydride. The mixture was made alkaline to phenolphthalein and extracted with ether to remove any oily precipitate. Acidification precipitated the crude acid which was crystallized from petroleum ether to yield 10 g. of acid melting at 135°.

Anal. Calcd. for $C_{15}H_{12}O_3$: C, 75.0; H, 5.0. Found: C, 75.18; H, 4.89. The acid chloride was obtained by treatment with thionyl chloride in benzene solution and boiled at 225° (18 mm.).

Since this paper was presented, *bis*-(β-diethylaminoethyl)-dibenzofuran-2,8-dicarboxylate dihydrochloride, m. p. 251–253°, has been prepared and found to be only faintly active at a concentration of 5%.

[a] See (*a*) Table I. [b] See (*c*) Table I. [c] Intravenous M. L. D. in rabbits = 30 mg./kg. [d] The concentration and duration of anesthesia for solutions of compounds 12, 22 and procaine applied intracutaneously in man are, respectively: 0.5%, 60 min.; 0.2%, 53 min.; 0.5%, 70 min.

The other acids used in the preparation of the esters listed in Table II were prepared by known methods.[8,9] Although Courtot prepared dibenzothiophene-2-carboxylic acid by carbonation of the corresponding Grignard reagent,[8d] it also may be obtained by diazotizing the recently accessible 2-aminodibenzothiophene,[10] converting the diazonium halide to the nitrile and hydrolyzing according to the customary procedure.

The esters of the above acids were prepared by either of the two methods described in the case of the carbazolecarboxylic acids.

γ-Chloropropyl Dibenzofuran-2-carboxylate.—Twenty-three grams of dibenzofuran-2-carboxylic acid chloride and 50 cc. of trimethylene chlorohydrin were heated at 150° (bath temp.) for five hours, the excess trimethylene chlorohydrin distilled off under reduced pressure and the residual material poured into water. The crude product was washed with water and crystallized from petroleum ether to give 20 g. of ester melting at 85°.

Anal. Calcd. for $C_{16}H_{13}O_3Cl$: Cl, 12.27. Found: Cl, 12.25.

β-Diethylaminoethyl 7-Aminodibenzofuran-2-carboxylate.—7-Nitrodibenzofuran-2-carboxylic acid chloride, prepared by refluxing the nitro acid with thionyl chloride for ten hours, melted at 225° after crystallization from toluene. The acid chloride was treated in the usual manner with diethylaminoethanol to give an 85% yield of the nitro ester, m. p. 161°. Reduction of the nitro group was effected with iron filings and acetic acid in the usual manner. The crude oily product was dissolved in absolute ethanol and treated with one equivalent of alcoholic hydrogen chloride. Crystallization from ethanol gave the monohydrochloride, m. p. 255°.

β-Isobutylaminoethyl Dibenzofuran-2-carboxylate.—The β-isobutylaminoethanol is most conveniently prepared by the interaction of isobutyl bromide and ethanolamine.[11] The formation of the ester is best carried out in the manner of a Schotten–Baumann reaction according to the procedure of Goldberg and Whitmore.[12] The hydrochloride of this ester as well as the amyl derivative are somewhat unusual in that their aqueous solutions are slightly alkaline to litmus.

The β-*n*-amylaminoethanol and its ester are prepared in the same manner as described above.

Pharmacological Results

Anesthetic potency was determined on rabbits' cornea by applying the solutions for one minute and testing the reflex at each minute thereafter. At least six experiments were carried out for

(8) See the following references for preparation of these acids: (a) Borsche and Bothe, *Ber.*, **41**, 1940 (1908); (b) Kirkpatrick and Parker, THIS JOURNAL, **57**, 1126 (1935); (c) Hinkel, Ayling and Beynon, *J. each concentration and compared with a 1% solution of cocaine. In most instances the induction period varied from one to three minutes.

Toxicity was determined by subcutaneous injections in white mice. In the carbazole series lethal doses resulted in convulsions preceded by excitement, whereas with the sulfur compounds and no. 22 the symptoms were weakness and depression even in fatal doses. The dibenzofuran derivatives in small doses cause depression, while larger amounts give rise to convulsions. The lethal intravenous dose in rabbits for compounds no. 1, 8 and 12 is 20, 20 and 30 mg./kg., respectively, death being preceded in each instance by clonic-tonic convulsions and dyspnea. Death occurred in all cases through respiratory failure.

Discussion

Of the simple unsubstituted carbazole esters the 2- and 3-isomers (nos. 1 and 2) exhibit about the same degree of anesthetic potency, with the 4-isomer falling considerably behind. Among the analogous dibenzofuran derivatives the 3-isomer (no. 13) possesses the greatest anesthetic potency, while the 2- and 4-isomers follow in order of decreasing activity. This was rather unexpected, since in compounds of the procaine type the para position (corresponding to the 2-position in carbazole) of the carboxyl group with respect to the amino group has been regarded as the most favorable combination, the meta and ortho isomers following in order of decreasing activity. Furthermore, in the case of the dibenzofuran compounds the observed order is likewise at variance with the predictions one might make from a study of the alkoxybenzoic acid esters in which the compounds bearing the side chain para to the ether linkage are the most active. It is possible that the abnormally high activity of the 3-isomer in either series may be due to the fact that the side chain occupies a position para to the *carbon–carbon* bridge and that this position combination exerts a more profound influence than that resulting from the para relationship between the imino group or the ethereal oxygen and the carboxyl group. With the analogous dibenzothiophene derivatives it is evident that these compounds possess a much weaker anesthetic action, exhibiting not only a shorter duration of corneal anesthesia but also a much less profound effect.

In the carbazole series the order of toxicity is quite definitely 2>3>4-isomer, while among the dibenzofuran isomers there is little difference in toxicity, whereas with the dibenzothiophene derivatives the order is reversed, the 4-isomer being the most toxic.

Extending the carbon chain between the carbonyl group and the terminal nitrogen atom in the carbazole or the dibenzofuran series practically doubles the toxicity with a much less significant increase in anesthetic potency. Substitution of *n*-butyl groups for ethyl in the alcohol of the carbazole esters results in a proportional decrease in activity and toxicity. The effect of replacing hydrogen by an alkyl group on the ring nitrogen varies with the position of the side chain. With the carboxyl group in the 3-position the introduction of the N-ethyl group nearly doubles the anesthetic potency without increasing the toxicity. It is interesting to note that this compound (no. 8) is at least three times as potent as cocaine and only one-fifth as toxic. When the carboxyl group is in the 2-position both toxicity and activity are reduced by the introduction of the N-ethyl group and practically lost with the substitution of an N-butyl group. Partial hydrogenation of the carbazole nucleus increases the toxicity by more than two-fold without affecting the potency.

The β-mono-isobutylaminoethyl dibenzofuran-2-carboxylate (no. 16) offers no advantage over the diethylaminoethyl ester (no. 12) and does not exhibit any measurable degree of pressor action. This is somewhat surprising, since the corresponding derivative of the procaine type recently described by Goldberg and Abramson[13] is considerably more active than procaine and possesses definite pressor activity. The mono-*n*-amyl ester (no. 17) is somewhat better than no. 12, since it has a slightly lower toxicity and greater duration of corneal anesthesia. The introduction of an ethylenic linkage between the dibenzofuran nucleus and the carbonyl group as in compound no. 19 results in a slight decrease in toxicity but a much greater drop in activity. This also is at variance with the expected result, since the introduction of an ethylenic linkage at such a point generally enhances the efficacy of the parent compound.

In considering the effect of opening the carbon–carbon bond between the two benzene nuclei as in compounds nos. 22 and 24, it is evident that such a transition in the oxygen derivative results pri-

(13) Goldberg and Abramson, *J. Pharmacol.*, **62**, 69 (1938).

marily in a marked increase in toxicity with only a minor increase in activity. In the case of the diphenyl sulfide ester the toxicity is likewise greater than that of its dibenzothiophene analog, although in this instance the anesthetic potency is substantially enhanced both as to duration and quality.

None of these compounds had a mydriatic action in the concentrations used, whereas they all caused more or less irritation of the cornea and conjunctiva, the extent of the damage depending on the concentration. The pathological changes were conjunctivitis, chemosis, opacity of the cornea and intense secretion with consequent ectropion.

Effect on Blood Pressure and Respiration.—The action on blood pressure and respiration was determined for compounds no. 1, 8 and 12 by intravenous injection of 5 mg./kg. in dogs anesthetized with ether or without anesthesia. All three drugs caused depression of respiration and a sharp fall in blood pressure, the latter effect being only slightly diminished by the addition of epinephrine.

Action on Human Skin.—The anesthetic action of five of these compounds was further examined by means of wheal experiments on human skin under aseptic conditions. The solutions were prepared so as to contain 0.9% sodium chloride and a concentration of epinephrine of 1:250,000. Two-tenths cc. of this solution was used for intracutaneous injection. The duration, quality of anesthesia and side effects were observed and compared with procaine.

The same relative order of activity as was observed in the corneal studies is maintained in this instance. The unusual duration of compound 8 is worthy of note. As might have been predicted from the experiments on the rabbit cornea each of the compounds thus examined was more or less irritating and painful on injection.

The irritating effects of the entire group of compounds appear to be inherent to the nucleus involved, since meticulous purification, variation of the substituent groups and changing the method of synthesis does not materially alter the situation.

Acknowledgment.—The authors wish to express their appreciation to Mr. John W. Cusic for assistance with some of the experimental work.

Summary

The investigation of a series of alkylaminoalkyl esters of carbazole-, dibenzofuran- and dibenzothiophenecarboxylic acids led to some powerful local anesthetics. The best one of the series is β-diethylaminoethyl 5-ethylcarbazole-3-carboxylate hydrochloride (no. 8), which is more than thrice as potent as cocaine and only one-fifth as toxic. The activity of these compounds appears to be predominantly a function of the position of the carboxyl group rather than other structural variations. Opening of the carbon–carbon bridge in the dibenzofuran and dibenzothiophene derivatives does not improve the therapeutic efficiency. All of these compounds were more or less irritating to the rabbit's eye and to human skin, so that they cannot be regarded as useful anesthetics.

Sulfanilamide Derivatives. VI. Substituted N^1-Aliphatic Sulfanilamides[1]

BY M. L. CROSSLEY, E. H. NORTHEY AND M. E. HULTQUIST

A number of N^1-alkyl and hydroxyalkylsulfanilamides have been prepared by Kharasch, Mietzsch, Fourneau, Bauer and others.[2,3,4,5] As part of our program on N^1-substituted sulfanilamides, we have independently synthesized many of the derivatives reported by these authors, as well as a number of others which have not hitherto been published to our knowledge. The latter are sulfanilyl derivatives of aliphatic amines, amino-alcohols, diamino-alcohols, and amino-acids. Closely allied derivatives of morpholine and difurfurylamine are included.

The syntheses of these derivatives followed the

general procedure used previously[6] except in the case of the amino-acid ester derivatives. The N-sulfanilylamino acids were first prepared.[7] These were then esterified by boiling with the corresponding alcohol in the presence of hydrogen chloride. Di-*n*-butyl-N-sulfanilylglutamate was difficult to crystallize, so was isolated and recrystallized as the hydrochloride.

Pharmacology.—The long chain N^1-alkylsulfanilamides were prepared with the object of obtaining lipoid solubility. The promising pharmacological properties of N^1-dodecanoylsulfanilamide[8] made the investigation of other lipoid soluble derivatives of particular interest. The available results indicate that the long chain N^1-alkylsulfanilamides are decidedly inferior to the corresponding N^1-acylsulfanilamides on experimental streptococcal infections in mice.

The derivatives of amino-alcohols, amino-acid esters and morpholine appeared to be almost inactive while the difurfurylamine derivative was toxic. The esters were also inactive.

The pharmacological work was done under the direction of D. R. Climenko and will be reported elsewhere.

Experimental

2-Sulfanilamidoethyl Dodecanoate.—4-Nitrobenzenesulfonyl chloride was heated with excess aqueous 2-hydroxyethylamine and the product recrystallized from 50% alcohol giving N-2-hydroxyethyl-4-nitrobenzenesulfonamide, m. p. 126–127°; 41 g. (0.166 mole) of this was dissolved in 40 cc. of pyridine at 80° and 40 g. of dodecanoyl chloride was added gradually at 90–100°. The temperature was maintained for twenty min., then the hot mixture was poured into 500 cc. of water. The product was recrystallized from 80% alcohol, giving 78.4 g. of yellow crystals of 4-nitrobenzenesulfonamidoethyl dodecanoate, m. p. 72.0–73.5°. The nitro group was reduced by adding a solution of the compound in 100 cc. of toluene to a hot mixture of 60 g. of iron powder, 200 cc. of water, and 4 cc. of hydrochloric acid, then boiling for fifteen hours under agitation. The mixture was neutralized to *p*H 8, filtered, and the cake washed with hot toluene. The toluene layer was dried over calcium chloride and distilled under reduced pressure. The residue was taken up in 60% alcohol and recrystallized three times, using activated charcoal.

Intermediates for this series were obtained as follows: "Lorolamine" from E. I. du Pont de Nemours & Company was fractionated giving *n*-octylamine, b. p. 183–188° (770 mm.), and *n*-dodecylamine, 135.5–138.5° (15 mm.), setting point 26.5°. *n*-Octadecylamine and 9-octadecenylamine were obtained from Armour & Company, and were used without purification. β-Hydroxyethylamine, ethylenediamine, diethylenetriamine and N-(β-hydroxyethyl)-ethylenediamine were obtained from Carbide & Carbon Chemical Corp. and were used without purification. Difurfurylamine was obtained from the B. F. Goodrich Tire & Rubber Company. 2-Methyl-2-amino-1-propanol and 2-methyl-2-amino-1,3-propanediol were obtained from Commercial Solvents Corp. 1,3-Diamino-2-propanol was obtained from Eastman Kodak Company. 4′-(2′-Aminoethyl)-morpholine was synthesized from ethylenediamine and *bis*-β-chloroethyl ether.[9]

Summary

1. Eighteen new sulfanilamide derivatives are reported. These are sulfanilyl derivatives of aliphatic amines, polyamines, amino alcohols, diamino alcohols and aminoacid esters. Closely allied derivatives of morpholine and difurfurylamine are included.

2. The available pharmacological results in-

The Electrolysis of Some Higher Aliphatic Organomagnesium Halides in Ethyl Ether

BY WARD V. EVANS, DAVID BRAITHWAITE AND EDMUND FIELD

The electrolysis studies of the simple organomagnesium halides have been completed.[1] These studies indicated that the main course of the reaction was the liberation of the organic free radical, which then reacted by disproportionation to give the corresponding saturated and unsaturated hydrocarbons. In the electrolysis of *n*-propylmagnesium halide in ethyl ether[1d] it was found, however, that there was a marked tendency for the liberated free radical to combine to give the coupled product *n*-hexane. The isopropylmagnesium halide, on the other hand, showed very little or no tendency to couple upon electrolysis.

The present work is a continuation of this problem, electrolyzing some higher organomagnesium halides in ethyl ether, and attempting thereby to further our knowledge of the coupling tendency. To accomplish this the four isomeric butyl compounds were studied, as well as the *n*-hexyl compound.

Experimental

The same apparatus that has previously been described was used,[1b] and platinum electrodes were employed throughout the investigation.

***n*-Butylmagnesium Bromide.**—In this electrolysis the solution conducted the electric current so readily that even at 0.4 to 0.5 ampere there was not sufficient heat generated to cause the solvent to reflux. Since refluxing was the sole means of agitation, there was no great amount of disturbance in this electrolysis, and consequently the magnesium plated out and often bridged the gap between the electrodes. For the most part this was avoided by shaking the cell, but it undoubtedly accounts for the low efficiency found.

It was noted, however, that gas was liberated when the gap between the electrodes had nearly been closed, whereas otherwise no gas was liberated. Samples of this gas at different current densities were taken, and the analyses, made by the absorption method, are shown in Table I. Change in current density had no effect on the composition of the gas over a small range.

A quantity of 0.72 mole of Grignard reagent was decomposed during the electrolysis, and the efficiency was approximately 65% based on the number of coulombs passed through the solution. On the basis of the amount of octane isolated experimentally, approximately 85% of the butyl radicals liberated coupled. Because of loss in isolating and purifying the octane, the actual amount of coupling must be approximately 100%.

Isobutylmagnesium Bromide.—As in the case of *n*-butylmagnesium bromide, no gas was liberated except when magnesium nearly bridged the gap between the electrodes. There was not sufficient gas to fractionate, and all that could be done with this small amount of gas was to determine that the saturated hydrocarbon gas in the mixture was essentially C_4.

A 500-cc. sample of the original organomagnesium halide (1.36 *N*) was hydrolyzed and analyzed. About 5 cc. of diisobutyl was found, indicating a slight coupling during the formation of the Grignard reagent.

The efficiency of this electrolysis was found to be about 83% based on the number of coulombs passed through the solution. After electrolysis, 500 cc. (0.6 *N*) was hydrolyzed and analyzed. No alcohols were found, but approximately 35 cc. of diisobutyl was present. During the electrolysis 0.78 equivalent of Grignard compound was decomposed. Therefore, on the basis of the amount of diisobutyl found, approximately 96% of the liberated isobutyl free radical coupled.

***s*-Butylmagnesium Bromide.**—No gas was liberated during this electrolysis.

A 500-cc. sample (1.35 *N*) of the original Grignard was hydrolyzed and analyzed before electrolysis. A 2-cc. portion of this solution was identified as the coupled product, 3,4-dimethylhexane.

On the basis of the amount of 3,4-dimethylhexane found on analyzing the solution after electrolysis, about 43% of the liberated free radical coupled. This would appear to be a poor yield of the coupled product, but considerable difficulty was encountered in the isolation of the product.

No alcohols were found.

On a second electrolysis of *s*-butylmagnesium bromide, the solution was prepared 0.588 *N* and 825 cc. electrolyzed until 0.165 equivalent had been decomposed. On the basis of the amount of coupled product isolated from the original solution and the electrolyzed solution, coupling took place to about 49%. In this experiment an external heater was used to keep the solution in the vicinity of the electrodes refluxing vigorously. This heater accomplished two things. It stopped the magnesium from bridging

TABLE I

ANALYSIS OF GAS LIBERATED BY THE ELECTROLYSIS OF *n*-BUTYLMAGNESIUM BROMIDE

Amp./sq. dm.	CO_2	Other unsatd. hydrocarbons	O_2	H_2	CO	Unsatd. hydrocarbon (butylene)	Hydrocarbons	*n*
1.0	2.0	1.2	2.0	2.5	1.2	42	50	3.7
1.6	...	2.1	1.5	2.2	...	43	52	3.6
0.4 to 2.0 (range)	0.8	1.1	1.9	0.3	0.3	40	55	3.7

the gap between the electrodes, and also decreased the solubility of any gases formed during the electrolysis and aided them to escape by means of the refluxing. Gas was not liberated to the extent that it could be collected.

Two possible conclusions can be drawn from these results. First, the free radical liberated on electrolysis may be considered to couple 100% since no gas was given off. The explanation for the poor yield of the isolated coupled product could be offered on the basis that some of the product was lost in separating it from the large volume of ether used as a solvent. Second, the coupling can be considered to take place only to the extent indicated by the amount of coupled product isolated. The remainder of the products of the electrolysis, supposedly butane and butylene, could be thought of as dissolving in the ether solution and consequently being lost on analysis.

The first interpretation seems more plausible because of the ease of liberation of small amounts of butane and butylene in the *n*-butylmagnesium bromide electrolysis, and because of the unfavorable conditions for solution of the gases when the solution was in a state of reflux. On this basis, then, the *s*-butyl free radical takes its assigned place in Table II.

***t*-Butylmagnesium Bromide.**—In the electrolysis of this compound the gas liberated could not be analyzed by the absorption method due to the presence of ethyl ether vapors. Also, the coupled product, di-tertiary-butyl, is a very volatile hydrocarbon. Only approximations, therefore, could be made as to amounts present.

A 550-cc. sample (0.506 *N*) of the solution was analyzed before electrolysis, and about 1 g. of the coupled hydrocarbon estimated to be present. After electrolysis, upon hydrolyzing and analyzing the same quantity of solution (0.278 *N*), from 3 to 4 g. of di-tertiary-butyl was found.

No alcohols were found.

During this electrolysis gas was given off freely but, as has been stated, samples at different current densities could not be analyzed because of the nature of the mixture. Therefore, after the run was completed, a Podbielniak distillation was made on the gas collected. The fractionation was not very efficient, and the main result was merely the separation of the gaseous products from the ethyl ether vapors. With the elimination of the ethyl ether vapors, however, it was then possible to analyze the hydrocarbon mixture by means of absorption and combustion. The mixture was found to be essentially isobutylene and C_4 saturated hydrocarbon, probably isobutane.

***n*-Hexylmagnesium Bromide.**—No gas was given off during this electrolysis.

On analysis of 500 cc. of original solution (0.916 *N*) 4 to 5 cc. of dodecane was found. During the electrolysis 0.364 equivalent of Grignard compound was decomposed. From 500 cc. of the final solution (0.507 *N*) 23 cc. of dodecane was isolated. The yield of the coupled product then, on the basis of the material isolated, was 82.5%. Since no other products were found, it can be assumed that the coupling reaction is the only one, and the obvious discrepancy between 82.5 and 100% is due to experimental methods of isolation.

Discussion

From all the data obtained thus far on the electrolysis of various aliphatic organomagnesium halides, we are able to draw certain conclusions.

1.—In all cases studied the ionization of the Grignard reagent and the liberation of the organic free radical at the anode may be represented as follows

$$R_2MgMgX_2 \rightleftharpoons \left[R{:}\ddot{\underset{\cdot\cdot}{Mg}}{:}\ddot{\underset{\cdot\cdot}{X}}{:} \right]^- + [Mg{:}R]^+$$

$$\downarrow -e \qquad\qquad \downarrow +e$$

$$R + MgX_2 \qquad {}^1/_2Mg + {}^1/_2MgR_2$$

2.—The reactions of the free radical with the solvent as represented in earlier papers[1b,d] seem to disappear, or at least become negligible as higher molecular weight organomagnesium halides are used for electrolytes.

TABLE II

GRADATION OF TENDENCY TO COUPLE WITH CHANGE OF STRUCTURE

Free radical		Coupling tendency
Ethyl		Trace
Isopropyl (mono-methyl substitution on C 1 of ethyl radical)		Trace
t-Butyl (dimethyl substitution on C 1 of ethyl radical)		Slight
n-Propyl (mono-methyl substitution on C 2 of ethyl radical)		Approximately 50%
s-Butyl (dimethyl substitution on C 1 and 2 of ethyl radical)		Approximately 100%
Isobutyl (dimethyl substitution on C 2 of ethyl radical)		Approximately 100%

3.—As higher molecular weight compounds are electrolyzed the main reaction seems to be one of coupling.

Certain generalizations can be made regarding structures necessary for nearly complete coupling.

A.—Straight chain free radicals of four carbon atoms or more will have approximately a 100% tendency to couple.

B.—Substituted *n*-propyl free radicals will have nearly a 100% tendency to couple.

It is interesting to consider the free radicals as substituted ethyl radicals, and it can be shown that there is a gradual increase in the tendency to couple as the ethyl radical becomes substituted with methyl groups. This is shown in Table II.

If we consider isopropyl and *t*-butyl as monomethyl and dimethyl substituted ethyl radicals, respectively, the effect of substitution on carbon number one is comparatively slight. If we consider *n*-propyl and isobutyl as mono-methyl and dimethyl substituted ethyl radicals, the effect on carbon number two is very marked. This analogy cannot be carried further, because, as has been stated, the higher molecular weight aliphatic radicals tend toward 100% coupling.

Summary

The products of electrolysis of the four butylmagnesium halides have been reported.

The products of the electrolysis of *n*-hexylmagnesium bromide in ethyl ether have been reported.

The relation between the structure of the free aliphatic radical liberated upon electrolysis and its tendency to couple has been presented.

Surface Conditions of Silver Halides and Rate of Reaction. I. Rate of Reduction of Precipitated Silver Chloride

BY T. H. JAMES

The effects of adsorption during and subsequent to the preparation of silver halide precipitates and sols are clearly shown, in both the physical and in the chemical behavior of the resulting product. The very important role played by adsorption of sensitizing dyes and gelatin in the photochemistry of the silver halides has been demonstrated by the work of several investigators.[1] The effects of adsorption on the chemical reduction of silver halide are less well understood, and the problem is clouded by lack of concrete evidence on the mechanism of the reduction process. The fact that gelatin markedly retards the reduction of unexposed silver halide by developing agents has been known since the early days of the gelatin dry plate, but the manner in which the gelatin acts has been the subject of conflicting views. Reinders and van Nieuwenburg[2] found that the reduction of silver chloride by ferrous citrate was definitely retarded by as little as 0.0012% gelatin in the solution, and an increase in the gelatin concentration resulted in a further decrease in the reaction rate. They assumed that three steps were involved in the over-all process: (1) solution of the silver chloride, (2) reduction of the silver ions in solution; and (3) crystallization of the silver. They attributed the effect of gelatin to a retardation of the crystallization process. Sheppard, however, viewed the protective action of gelatin as an adsorption effect, and showed that a layer of gelatin of approximately molecular thickness is tenaciously held to silver bromide grains which have been prepared in the presence of gelatin.

A decision between the conflicting points of view evidently rests upon a knowledge of the mechanism of the reduction process. Hydroxylamine is a reducing agent well adapted to an experimental investigation of the problem. The reaction between hydroxylamine and silver ions has been studied.[3] Reduction of silver chloride proceeds with quantitative formation of nitrogen, and this allows a convenient method of following the reaction. In addition, hydroxylamine is a photographic developing agent and results ob-

tained with it should be directly applicable to the theory of the development process.

Materials and Procedure

Silver chloride was prepared by precipitation. Purified samples of silver nitrate and potassium chloride were employed in the preparation of the primary solutions. In the precipitation, 5.00 ml. of 0.20 *M* potassium chloride was added from a buret to a solution of 5.00 ml. of 0.10 *M* silver nitrate plus 10.00 ml. of water. The tip of the buret dipped beneath the surface of the silver nitrate solution, and stirring was maintained by a glass paddle rotated at the rate of 600 r. p. m. The time of delivery of the potassium chloride solution was twenty seconds. By this procedure, results reproducible within 5% could be obtained from day to day.

The reaction between the silver chloride and hydroxylamine was carried out in the apparatus previously described.[3] The silver chloride precipitates were, in general, allowed to age for eighteen to twenty-two hours before use, and when additions such as gelatin, dye, or excess chloride were made, sufficient time was allowed for equilibrium before addition of the hydroxylamine. The time required varied from a few minutes to several hours, depending upon the addition in question. The solutions were buffered at *p*H 7.25, and a total volume of 60.0 ml. was employed in the rate measurements. The temperature was 20.0 ± 0.03°. All operations were carried out in a photographic dark room. When sensitizing dyes were employed, a no. 3 Wratten safelight was used. For all other cases, a no. 1 safelight sufficed.

The specific surface of the silver chloride precipitates was determined by the amount of dye IVa (3,3'-diethyl-9-methylthiocarbocyanine chloride) adsorbed. The dye solution was added in slight excess, and, after equilibrium had been attained, the excess dye in solution was determined by comparison with a series of standards. The dye adsorption is irreversible.[4]

Experimental Results

The general form of the reaction curve is given in Fig. 1. The shape of the curve suggests a strongly autocatalytic reaction, and this is confirmed by the fact that the introduction of colloidal silver into the silver chloride precipitate at the time of preparation markedly increases the rate of reduction. The shape of the reaction curve of the un-nucleated silver chloride is similar to that obtained for the reduction of silver ions by hydroxylamine in the presence of gold nuclei,[3] and, just as in that case, a plot of the cube root of the nitrogen volume against the time yields a straight line over one-fourth to one-third of the reaction course. This is illustrated by curve 2 of Fig. 1. In general, the points representing volumes of less than 0.3 fell definitely away from the straight line, and the line cut the "*t*" axis at finite values. Accordingly, the time, *T*, at which a nitrogen volume of 0.30 was obtained (representing 5% of the reaction course) was taken as a representation of the rate of formation of silver nuclei. In the following, the rate itself is expressed as the reciprocal, $1/T$. However, the relative results do not vary appreciably if any other sufficiently small value of the nitrogen volume is chosen for the determination of the rate. A measure of the rate of the silver-catalyzed reaction is given by the slope of the straight-line plot, and the values obtained are included in the subsequent tables. However, we are concerned here chiefly with the rate of the preliminary reaction. Discussion of the silver-catalyzed reaction will be reserved for a later paper in which results of an investigation of nucleated silver chloride precipitates will be presented.

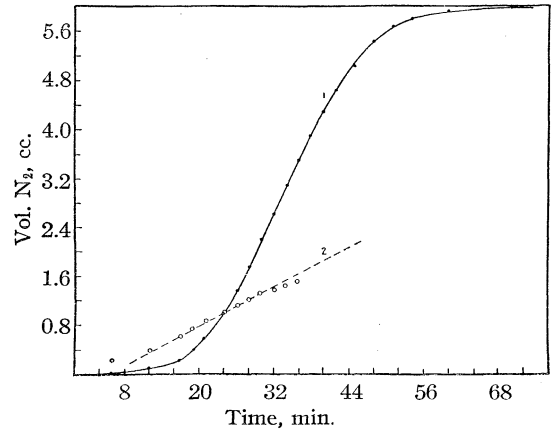

Fig. 1.—Reduction of AgCl by NH_2OH: Curve 1, *V*–*t* plot; Curve 2, $V^{1/3}$–*t* plot.

Effect of Age of the Precipitate on the Reaction Rate.—If a freshly prepared silver chloride precipitate is allowed to stand in contact with the mother liquor, the specific surface, as determined by dye adsorption, decreases at first and eventually attains a minimum value.[5] In the presence of excess chloride, the minimum is attained within a few hours. In the present investigation,

the aging of the precipitate is very well represented by the change in the rate of the initial reaction with hydroxylamine. The rate data are given in Table I. In Fig. 2, the curve represents the specific surface in arbitrary units as a function of age, and the crosses represent the reaction rates. The agreement is almost too good.

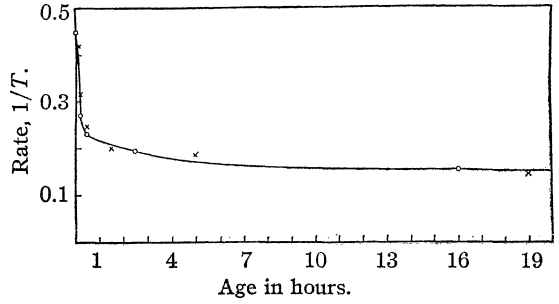

Fig. 2.—Effect of age of precipitate on rate of reaction: —○—○—, specific surface; × ×, reaction rate.

Variation of Rate with the Amount of Free Surface.—The well-aged silver chloride precipitate employed adsorbed 0.105 mg. of dye IVa at saturation, and the covered precipitate was attacked by hydroxylamine at a very low rate. An investigation was therefore carried out on a series of precipitates in which varying amounts of the surface were covered with the dye. The results are given in Table II. The calculated rates given in the last column are based upon the assumption that the rate of reaction is directly proportional to the available surface, and a small correction has been made for the finite "minimum" rate. The agreement between the experimental and calculated rates is quite good.

TABLE II

VARIATION OF RATE WITH AVAILABLE SURFACE

Fraction of surface covered by dye	T, min.	Slope	$1/T$	Calcd. rate
0	6.8	0.112	0.147	0.147
0.078	7.2	.110	.139	.136

3.00	37	.043	.027
5.00	37	.038	.027
10.00	40	.038	.025

When a portion of the silver chloride surface was covered with dye IVa, the minimum reaction rate in the presence of gelatin was decreased by approximately the amount calculated on the basis of strict proportionality. The time required to attain equilibrium between the silver chloride and gelatin was increased, however. This is indicated by the data in Table IV. The time required for equilibrium in the absence of dye was, in general, not greater than one hour.

TABLE IV

EFFECT OF GELATIN ON THE REACTION OF SILVER CHLORIDE PARTLY COVERED BY DYE IVa

Fraction of surface covered by dye	Gelatin, mg./10	Time of agitation with gelatin	T, min.	$1/T$
0	0.50	2 hr.	37.0	0.027
0.33	.10	1 hr.	46.4	.0216
.33	.10	5 hr.	49.0	.0204
.33	.50	2 hr.	53.0	.0189

3.00	3.50	66	.010	.105	.0525
5.00	5.50	110	.006	.009	.050

Discussion

The surface conditions of the silver chloride precipitate are of major importance in determining the rate of the initial stage of reduction by hydroxylamine. This is clearly shown by the close correlation between the specific surface and the reaction rate, both in the aging experiments and in the effect of an irreversibly adsorbed dye.

The effect of gelatin upon the reaction rate is of special interest. The curve representing rate as a function of the amount of gelatin breaks quite sharply, and additions of gelatin in excess of 0.5 mg. have little effect upon the reaction rate. The specific surface of the silver chloride, calculated from the adsorption of dye IVa (0.105 mg. per 0.50 mmole of AgCl) is approximately 9×10^2 sq. cm. The gelatin layer, therefore, exceeds molecular thickness.[6] Since gelatin in solution is not molecularly dispersed at the temperature employed in the present investigation (20°), it appears quite possible that the amount of gelatin required to produce the maximum effect upon the reaction rate will be smaller at higher temperatures. This point will be investigated later.

The failure of Reinders and Nieuwenburg[2] to obtain a minimum reaction rate at low gelatin concentrations might suggest a fundamental difference in the mechanism of the reaction which they studied. However, in their experiments, the gelatin was added to the reducing solution (Eder's ferrous citrate) preceding the addition of the silver chloride. Under these conditions, equilibrium between the gelatin and the silver chloride would not be obtained. Hence, rates of adsorption are involved in their experiments, and their results cannot be compared with those herein presented.

The form of the curve representing the effect of gelatin suggests that the gelatin is tenaciously held by the silver chloride and is probably irreversibly adsorbed. The decrease in reaction rate is to be attributed to this surface effect. These results do not support Reinders' suggestion that the effect is upon the rate of crystallization of silver from solution. In the present case, moreover, it is possible to measure the effect of gelatin on the reaction between hydroxylamine and silver ions in the presence of sodium sulfite,[3] and these measurements show a much smaller effect of gelatin than that encountered in the present work. The sharp minimum is not obtained. Thus, in one set of experiments in which silver ion was supplied by ionization of the silver sulfite complex, the rate, in the absence of gelatin, was 0.115. The addition of 1.0 mg. of gelatin reduced it to 0.071; of 5.0 mg. of gelatin to 0.051; and of 20 mg. of gelatin to 0.043.

The effect of gum arabic upon the reduction of silver chloride is much smaller than that of gelatin, and the form of the curve is different. The adsorption of gum arabic is probably reversible, and, in fact, the reaction rate data fit fairly well the expression derived from the Langmuir isotherm.

The adsorption of bromide ion[7] and iodide ion[8] by their respective silver salts does not follow the

(8) I. M. Kolthoff and J. J. Lingane, THIS JOURNAL, **58**, 1528 (1936).

Langmuir isotherm for small ion concentrations, and Kolthoff employs the equation

$$\Delta x = k\Delta \log a$$

for the adsorption of iodide ion to silver iodide. Such an expression obviously cannot hold for high ion concentrations where the surface is almost completely covered. Direct study of the adsorption in this region is beyond the power of ordinary analytical methods. It is of interest to note, therefore, that the reaction rate law suggested by the data in Table VII may be obtained directly from the Langmuir isotherm. The concentrations of chloride employed are such that the surface of the precipitate should be almost completely covered by the adsorbed monolayer, but the concentrations have not yet reached the values at which serious effects might be expected as the result of $AgCl_2^-$ formation.

The free surface, according to the Langmuir expression, is given by the equation

$$l - \alpha = \frac{l}{l + \beta c}$$

If c is relatively large, l may be neglected in comparison with βc, and the free surface will vary inversely as the chloride-ion concentration. Therefore, the rate, which varies as the free surface, varies inversely as the chloride-ion concentration.

The picture of the mechanism of the initial reaction suggested by the results of the present investigation is as follows. Hydroxylamine, in ionized form,[3] attacks those silver ions at the silver chloride surface which are not protected by adsorbed chloride ion or agents such as gelatin and adsorbed dye. It appears further that gelatin and possibly even the strongly held dye IV do not afford complete protection, but merely decrease the frequency of suitable contact between silver ions and hydroxylamine. Reduction of silver ions from solution may be definitely ruled out for the experimental conditions employed. At the end of the reaction, the silver is found in a white, spongy form which closely resembles the original chloride, whereas reduction of silver ions from solution yields silver powder or plating on the vessel walls. If reduction took place from solution, the effect of the gelatin and the dye could be explained only as an effect upon the rate at which the silver chloride dissolved. Solution, as the rate-controlling process, is not compatible with the catalytic action of silver and the direct proportionality between the rate and the hydroxylamine concentration.

Acknowledgment.—The author is indebted to R. H. Lambert and R. D. Walker of these Laboratories for information concerning the dye used in this investigation and for the calculation of the specific surface of the silver chloride precipitate.

Summary

1. The reduction of precipitated silver chloride by hydroxylamine has been studied with particular reference to the effects of aging of the precipitate, dye adsorption, gelatin adsorption and chloride-ion concentration upon the initial reaction rate.

2. The reaction rate closely parallels the change in specific surface with aging. The reaction is strongly inhibited by adsorption of the sensitizing dye, 3,3′-diethyl-9-methylthiocarbocyanine, to the silver chloride, and the reaction rate is approximately proportional to the free surface when the precipitate is only partly covered with the dye.

3. Gelatin markedly inhibits the reaction, and a minimum rate is obtained.

4. The kinetics of the process suggest that the initial reaction involves unprotected silver ions at the silver chloride surface. Under the conditions of this investigation, the silver ions do not pass into solution prior to reduction.

5. The effect of excess chloride-ion concentration upon the reaction rate suggests that, when the silver chloride surface is largely covered with chloride ions, further adsorption follows the Langmuir isotherm.

Inner Complex Salts of the 8-Hydroxyquinoline-5-sulfonic Acid

BY JACOB MOLLAND

When a solution of ferric sulfate is added to an aqueous solution of 8-hydroxyquinoline-5-sulfonic acid, the mixture is colored a deep green. If increasing amounts of copper sulfate are added to this mixture, the color gradually fades. If copper sulfate is added to a solution of the pure 8-hydroxyquinoline-5-sulfonic acid, no appreciable change of color occurs. The color reaction of iron has a considerable interest for analytical chemistry, as will be shown in papers which are to be published in the near future. The reaction is due to the formation of an inner complex iron salt, and the fading caused by the addition of copper must be explained by the formation of an equilibrium between the green iron salt and a colorless copper salt. The scope of this paper is to study the composition of these salts by means of a spectrophotometric investigation.

Supposing that the color reaction of iron is due to the formation of z molecules of an inner complex salt from x molecules of the 8-hydroxyquinoline-5-sulfonic acid and y ferric ions, the reaction can be represented by the equation

$$xR + yFe^{+++} = zRFe + sH^+$$

R denoting the 8-hydroxyquinoline-5-sulfonic acid and RFe the iron compound. Analogously the formation of the copper compound, RCu, can be represented by the equation

$$\xi R + \eta Cu^{++} = \zeta RCu + \sigma H^+$$

If the initial hydrogen-ion concentration is sufficiently large, the alteration caused by the reaction may be neglected, and the equilibrium condition for an aqueous solution of the 8-hydroxyquinoline-5-sulfonic acid containing iron and copper will be

$$\frac{[Fe^{+++}]^{y\xi}\ [RCu]^{x\zeta}}{[Cu^{++}]^{x\eta}\ [RFe]^{z\xi}} = \text{const.} \qquad (1)$$

Let the initial concentrations be $[R]_0 = a$, $[Fe^{+++}]_0 = b$, $[Cu^{++}]_0 = c$, $[RFe]_0 = 0$, $[RCu]_0 = 0$. In order to simplify the calculation, the concentrations of iron and copper are also kept so large that they may be considered as constant during the reaction. After establishment of the equilibrium, the concentration of the complex iron salt is measured by means of an extinction estimation. Let the observed Bunsen–Roscoe extinction coefficient be d. Further, let the extinction coefficient D be observed when a great excess of iron is added to a solution of the pure 8-hydroxyquinoline-5-sulfonic acid of the concentration A. In this case the 8-hydroxyquinoline-5-sulfonic acid is practically completely transformed to the complex iron salt, giving a concentration Az/x. The salt concentration corresponding to the extinction coefficient, d, is then $[RFe] = dzA/xD$.

On account of the great excess of iron and of copper, the concentration of the 8-hydroxyquinoline-5-sulfonic acid is vanishing. The amount of the acid which is not used for the formation of the iron salt, is used for the formation of the copper salt. This amount is

$$a - \frac{x}{z} \cdot [RFe] = a - \frac{A}{D} d$$

and the quantity of the copper salt formed is

$$[RCu] = \frac{\zeta}{\xi}\left(a - \frac{A}{D} d\right)$$

Finally, the concentrations of iron and of copper will remain practically constant, $[Fe^{+++}] = b$ and $[Cu^{++}] = c$. Introducing these values into equation (1), we obtain

$$\frac{b^{y\xi}\left(a - \frac{A}{D} d\right)^{x\zeta}}{c^{x\eta} d^{z\xi}} = \text{const.} \qquad (2)$$

The ratio x/y can be determined by the following experiment. The maximum concentration of the iron compound obtainable from a concentration p of the 8-hydroxyquinoline-5-sulfonic acid will be pz/x. This concentration can be obtained approximately if a great excess of iron is used. Let the extinction coefficient in this case be d_p. Further, the maximum concentration of the iron salt obtainable from a concentration q of iron will be qz/y, and this concentration is approximately reached if a great excess of 8-hydroxyquinoline-5-sulfonic acid is used. Let the extinction coefficient in this case be d_q. If now the same iron compound is formed in both cases, the molecular extinction coefficient ϵ must be the same in the two experiments, and we obtain the equation

$$\epsilon = \frac{d_p}{\frac{z}{x} p} = \frac{d_q}{\frac{z}{y} q}$$

giving $x/y = pd_q/qd_p$. An experiment gave the figures $p = 3.10^{-5}$, $q = 2.10^{-5}$, $d_p = 0.314$, $d_q = 0.630$. Substituting these figures, we obtain $x/y = 3.01$. The simplest formula giving this result is $(C_9H_6O_4NS)_3Fe$. If we accept this formula, we obtain $x = 3$, $y = 1$, $z = 1$.

If b and c are kept large and constant, and the extinction coefficient is measured for different values of a, equation (2) then can be written in the form

$$\left(a - \frac{A}{D}d\right)^{3\zeta/\xi} \Big/ d = \text{const.} \qquad (3)$$

allowing the determination of the ratio ζ/ξ. Let the extinction coefficient d_m correspond to the concentration a_m and d_n correspond to a_n. Then ζ/ξ is determined by the equation

$$\frac{\zeta}{\xi} = \frac{1}{3}\frac{\log d_m - \log d_n}{\log\left(a_m - \frac{A}{D}d_m\right) - \log\left(a_n - \frac{A}{D}d_n\right)} \qquad (4)$$

In order to determine ζ/ξ by means of equation (4), an experiment was carried out with a series of solutions containing 0.003 g. molecule of ferric sulfate, 0.01 g. molecule of copper sulfate, and increasing amounts from 0.00002 to 0.00014 g. molecule of 8-hydroxyquinoline-5-sulfonic acid per liter. The constant A/D for the wave length in question was determined to 0.0000685 by means of the observations given in Table I. The results are seen in Table I. These data should be combined two by two in equation (4). Generally q numbers can be combined in couples in $\frac{1}{2}q(q-1)$ different ways. In the present case with $q = 9$ we get 36 possible combinations. A mathematical investigation[1] will, however, show that a great part of these combinations will give a poor determination of ζ/ξ, as the mean square error of the extinction estimation in some cases will be greatly magnified by insertion into equation (4). Therefore we select ten combinations giving small mean square errors (Table II). The mean value of ζ/ξ is 0.509, showing that one molecule of the copper compound contains two molecules of 8-hydroxyquinoline-5-sulfonic acid.

12	3	.497
12	4	.488
10	2	.537
10	3	.559
8	2	.476

If a and b are kept constant, we are now able to write equation (2) in the form

$$\frac{\left(a - \frac{A}{D}d\right)^3}{c^{3\eta/\zeta}d^2} = \text{const.}$$

allowing the determination of η/ζ. Let the extinction coefficients d_m and d_n correspond to the concentrations c_m and c_n. Then

$$\frac{\eta}{\zeta} = \frac{\left(\log\left(a - \frac{A}{D}d_m\right) - \frac{2}{3}\log d_m\right) - \left(\log\left(a - \frac{A}{D}d_n\right) - \frac{2}{3}\log d_n\right)}{\log c_m - \log c_n} \qquad (5)$$

An experiment for the determination of η/ζ by means of equation (5) was carried out with a series of solutions containing 0.0025 g. molecule of ferric sulfate, 0.00013 g. molecule of 8-hydroxyquinoline-5-sulfonic acid, and increasing amounts of copper sulfate, from 0.01 to 0.1 g. molecule per liter. The extinction coefficients seen in Table III were observed (corrected for the extinction of the ferric sulfate and the copper sulfate). For the wave length used, A/D was determined to 0.0000786 by means of the data of Table III. Also in this case ten combinations with small mean square errors are collected (Table IV).

The copper compound thus contains one atom of copper and two molecules of 8-hydroxyquinoline-5-sulfonic acid.

Summary

The inner complex iron and copper salts of the 8-hydroxyquinoline-5-sulfonic acid were studied by means of extinction measurements, and the composition of the salts is found to correspond to the formulas $(C_9H_6O_4NS)_3Fe$ and $(C_9H_6O_4NS)_2Cu$.

Reaction between Ammonia and $SeO_2 \cdot 2HCl$ and $SeO_2 \cdot 2HBr$

BY JULIUS JACKSON[1] AND G. B. L. SMITH

The materials formed when selenium dioxide reacts with hydrogen chloride and bromide have been studied by several investigators.[2] Muehlberger and Lenher[2c] have shown that $SeOCl_2 \cdot H_2O$ is identical with $SeO_2 \cdot 2HCl$ of Ditte[2a] and that $SeO_2 \cdot 2HCl$ will give selenium oxychloride on dehydration. Latimer and Hildebrand[3] have listed this material as $H_2SeO_2Cl_2$. This paper presents a study of the reaction between ammonia and $SeO_2 \cdot 2HCl$ and $SeO_2 \cdot 2HBr$. The data obtained are in harmony with the postulation that these materials are mixtures of $2H^{++}(SeO_2X_2)^{--}$ and $(SeOXH_2O)^{+}X^{-}$.[4]

Experimental

Five g. of either $SeO_2 \cdot 2HCl$ or $SeO_2 \cdot 2HBr$, prepared by treating selenium dioxide with two equivalents of the respective halogen hydride, was dissolved in 100 ml. of the anhydrous solvent and ammonia passed into the solution for a period of two hours. The resulting precipitate was separated by filtration, washed with the solvent, dried in a vacuum desiccator, and analyzed for selenium, ammonia and the respective halogen. The data obtained are summarized in Table I.

TABLE I

[a] Analyses represent mean values of two to four determinations. [b] Solvent was anhydrous ethyl acetate. [c] Solvent was anhydrous acetic acid and ammonia added as ammonium acetate. [d] Ammonia added for thirty minutes.

Discussion

Since the analyses indicated that the reaction products were mixtures, the composition of which varied with conditions, a number of arbitrary hypotheses were tested by computing the composition by the method of "indirect analysis." Reasonable material balances were obtained by assuming that the products were ammonium halide, ammonium selenite and ammonium dihalogenoselenite. These conclusions were confirmed by microscopic examination and X-ray diffraction measurements of several of the materials.

The formation of the ammonium salts of dichloroselenious acid and dibromoselenious acid shows that these acids are present in $SeO_2 \cdot 2HCl$ and $SeO_2 \cdot 2HBr$. However, the formation of the ammonium salts of selenious acid and of hydrogen halide indicates that no single structure can be assigned to $SeO_22 \cdot HCl$ or $SeO_2 \cdot 2HBr$. Accordingly, the authors suggest that these materials comprise an equilibrium (dynamic isomers) mixture as follows

$$H_2SeO_2X_2 \rightleftharpoons SeOXH_2O \cdot X$$

The water in the $SeOXH_2O \cdot X$ is replaced by ammonia forming $SeOXNH_3 \cdot X$ and this liberated water causes hydrolysis of the $SeO_2X^{=}_2$ ion yielding HX and H_2SeO_3. Further work is necessary, however, to establish definitely the presence of $SeOXNH_3 \cdot X$.

Summary

1. The products of the reaction of $SeO_2 \cdot 2HCl$ or $SeO_2 \cdot 2HBr$ with ammonia are ammonium selenite and the corresponding ammonium halide and ammonium di-halogeno-selenite.

2. $SeO_2 \cdot 2HCl$ or $SeO_2 \cdot 2HBr$ comprises an

Selenium Oxychloro Compounds of Pyridine, Pyridinium Chloride and Related Substances

BY JULIUS JACKSON[1] AND G. B. L. SMITH

Introduction

The basic properties of pyridine and compounds of the same type have been demonstrated not only through the formation of salts, as pyridinium chloride, but also by the formation of series of pyridinates and analogous substances. It is to be expected, therefore, that pyridine and related substances will form definite compounds with selenium oxychloride which may be regarded as bases of the selenium oxychloro system.[2]

This paper presents a summary of the investigations into the nature of the reactions of pyridine, quinoline and isoquinoline in selenium oxychloride. Gordon[3] and Heimerzheim[4] have studied metathetical reactions in selenium oxychloride by conductometric and potentiometric titrations. Solutions of pyridine in selenium oxychloride (base[5]) have been allowed to react with solutions of stannic chloride, ferric chloride, sulfur trioxide and arsenic trichloride in selenium oxychloride (acids). The curves obtained when relative conductances or voltages were plotted against volume of reagent added showed that the acids and bases had reacted in definite stoichiometric ratios. Edgington and Firth[6] have demonstrated the formation of a dipyridinate of selenium oxychloride and found that the compound decomposes to $(C_5H_5N)_2SeCl_4$ and $(C_5H_5N)_2SeCl_2$ at temperatures above 145°.

The present studies have demonstrated the formation of well-defined compounds of selenium oxychloride with pyridine, quinoline and isoquinoline which may be characterized by the general formulas: $RSeOCl_2$; $(R)_2SeOCl_2$. The substances formed are very finely crystalline, or possibly amorphous, white to creamy white solids. The compounds in which two moles of the bases are combined with one mole of selenium oxychloride are not decomposed at 61° in the case of quinoline and isoquinoline but in the case of pyridine this compound loses the base and decomposes to the "monopyridinate" at 61° in 167 hours. Isoquinoline appears to have the greatest tendency to combine in 2-1 ratio and pyridine the least. The compounds of the type $RSeOCl_2$ are all stable at 61°. Attempts to recrystallize these materials from selenium oxychloride yield gelatinous products which cannot be separated from the excess solvent. An attempt to recrystallize the "monopyridinate" $C_5H_5N\cdot SeOCl_2$ from glacial acetic acid yielded a substance which gave the atomic ratios 1:3:1 for Se:Cl:N and for which the formula $C_5H_5NH\cdot SeOCl_3$ is suggested. Definitely crystalline compounds also were obtained by adding pyridinium, quinolinium and isoquinolinium chlorides to $SeOCl_2$. In the case of pyridinium chloride the product appears as beautiful cubical crystals. They all may be characterized by the general formula $(RHCl)\cdot(SeOCl_2)_2$, except in the case of isoquinoline which appears to be a mixture of $RHCl\cdot SeOCl_2$ and $(RHCl)(SeOCl_2)_2$.

Experimental

Materials.—Commercial carbon tetrachloride was purified by fractionation. C. p. pyridine, quinoline and isoquinoline were dried with potassium hydroxide, distilled and preserved in glass ampules. The corresponding chlorides were prepared by precipitation in benzene solution with hydrogen chloride.

Analyses.—Selenium was weighed as elementary selenium, which was precipitated by sulfurous acid from a solution containing 20% hydrochloric acid. Chlorine was weighed as silver chloride. Pyridine, quinoline and isoquinoline were separated by distilling from a solution containing 25% sodium hydroxide and then were absorbed in an approximately 0.1 *N* solution of hydrochloric acid.

Isoquinolinium chloride	Crystallized from $SeOCl_2$	2.974	7.080	2.000	Probably mixtures of	29.39	31.42	32.33	Probably mixtures		
		2.910	7.678	2.000	the monosolvate	28.63	33.91	32.18			
		2.235	4.986	1.000	and disolvate	31.11	31.17	22.78			

[a] Atomic ratios are for the moist material for the first six compounds and are for the crystalline material for the chlorides. These values are all based on at least two determinations. [b] Analyses reported are based on two to four determinations.

The excess hydrochloric acid was titrated with standard sodium hydroxide using methyl orange as indicator, followed by a determination of the combined hydrochloric acid using phenolphthalein as indicator.

Reaction between Selenium Oxychloride and Pyridine Bases.—A weighed sample of selenium oxychloride was dissolved in 50 ml. of carbon tetrachloride. Either a one or two molar equivalent quantity of pyridine or other base was dissolved in 50 ml. of the same solvent and the two solutions were added dropwise to 50 ml. of carbon tetrachloride contained in a 500-ml. Wolf flask. The white solid which formed was separated by filtration and washed three times with fresh carbon tetrachloride. One portion of the material was analyzed immediately for selenium, chlorine and base. Another portion was freed of carbon tetrachloride by drying in an Abderhalden oven at 61° and 17 mm. pressure. The experimental details and analytical data obtained are presented in Table I.

Reaction between Selenium Oxychloride and the Chlorides of Pyridine Bases.—Ten ml. of selenium oxychloride was saturated with the respective chloride at a temperature of 70–80° and the resulting solution chilled to 0° or slightly lower and allowed to remain at this temperature for one hour. The resulting crystals were separated by filtration after adding 25 ml. of carbon tetrachloride, washed with the same liquid and dried in a vacuum desiccator. Table I presents the analytical data obtained.

Discussion

The experimental findings presented in this paper are in agreement with the thesis that selenium oxychloride is the parent solvent of a system of compounds.[2] The formation of $C_5H_5N \cdot SeOCl_2$ and $(C_5H_5N)_2SeOCl_2$ and the analogous compounds of quinoline and isoquinoline is suggestive of ammonium hydroxide and ammonium oxide. It is suggested that the pyridine type compounds act as bases, "electron pair donors" toward the solvent cation, $SeOCl^+$. This is a verification of the postulation that pyridine when dissolved in selenium oxychloride forms selenium oxychloro–pyridinium cation, $C_5H_5NSeOCl^+$, and chloride ion.

The isolation of definite selenium oxychloro compounds of pyridinium chloride and the other two chlorides, which we may term "solvates," indicates something about the solvation of the chloride ion in selenium oxychloride. Julien[7] found that hydrogen chloride is soluble in selenium oxychloride and that the resulting solution has a high electrical conductivity. Wise[8] isolated the mono-solvates of potassium chloride and believed that rubidium and cesium chlorides also formed "mono-solvates." Since potassium, rubidium and cesium ions are not likely to be solvated, it is probable that the molecule of selenium oxychloride is associated with the chloride ion and $KCl \cdot SeOCl_2$ is potassium trichloroselenite, $K^+(SeOCl_3)^-$. The data presented in this paper, however, for pyridinium chloride and related chlorides are indicative of a disolvated chloride ion, *i. e.*, $Se_2O_2Cl_5^-$. In each case selenium would have a covalent number of four.

Summary

1. Selenium oxychloride forms two series of compounds with pyridine, quinoline, and isoquinoline in which one and two moles of the base are combined with one mole of selenium oxychloride. These facts substantiate the view that pyridine and related substances act as bases in selenium oxychloride.

(7) Julien, THIS JOURNAL, **47**, 1799 (1925).
(8) Wise, *ibid.*, **45**, 1233 (1923).

2. Pyridinium chloride and quinolinium chloride crystallize from solutions in selenium oxychloride with two molecules of the solvent. Isoquinolinium chloride probably forms a mixture of the mono-solvate and the di-solvate. These facts indicate the possibility of disolvation of the chloride ion in selenium oxychloride.

Chlorogermanic Acid and the Chlorogermanates. Properties and Crystal Structure of Cesium Hexachlorogermanate

BY A. W. LAUBENGAYER, O. B. BILLINGS AND A. E. NEWKIRK

The tendency of the elements of Group IV, exclusive of carbon and thorium, to form complex ions with the halogens is well recognized. Germanium is known[1] to form hexafluogermanates but no other halogen complexes of germanium have been studied. Pauling[2] has shown that it is possible to predict the type of aggregate which two ions can form by considering the ratio of the ionic radii. Using his values for the radii, the ratios of the univalent ionic radius of germanium to those of fluorine, chlorine, bromine, and iodine are 0.54, 0.42, 0.39, and 0.35, respectively. Since 0.41 is the minimum radius ratio which will permit hexacoördination it is evident that germanium should form hexahalogen complex ions with fluorine and chlorine but can only have a coördination number of four toward bromine or iodine. Because the ratio in the case of chlorine is so close to the limit between hexa- and tetra-coördination, it is to be anticipated that the hexachlorogermanate ion will not form except under the most favorable conditions.

In the present investigation the formation of chlorogermanic acid and its salts has been studied.

Experimental

Formation of Chlorogermanic Acid.—Germanium tetrachloride is slightly soluble in concentrated hydrochloric acid.[3] This indicates that chlorogermanic acid may be formed, but that it is not very stable in solution since its formation to any great extent would give rise to high solubility of the tetrachloride.

Chlorostannic acid crystallizes as the hexahydrate when a solution of stannic chloride in concentrated hydrochloric acid is chilled. A similar procedure was tried in an effort to isolate chlorogermanic acid. Germanium tetrachloride was added to an equal volume of 12 *N* hydrochloric acid to give a two liquid layer system and the mixture was chilled to −49°. No crystals appeared. When gaseous hydrogen chloride was bubbled through cold anhydrous germanium tetrachloride no solid formed above −49°, the freezing point of germanium tetrachloride. If chlorogermanic acid is formed under such conditions it is present in such small amounts that it will not crystallize out.

Migration studies of solutions of various concentrations of germanium tetrachloride in 6 *N* hydrochloric acid gave evidence that the small amount of germanium in solution is present in complex ions. The solutions were electrolyzed in a migration cell which had a capacity of 60 cc. The concentration of germanium in anolyte and catholyte was determined before and after electrolysis with a given current for a definite period of time. These experiments are summarized in Table I.

TABLE I

MIGRATION OF GERMANIUM DURING ELECTROLYSIS OF SOLUTIONS OF $GeCl_4$ IN 6 *N* HCl

Expt.	Time, min.	Current, m. amp.	Grams Ge per 1000 g. solution: Original	Anolyte finally	Catholyte finally
1	70	86	2.001	2.072	1.903
2	60	87	4.681	4.734	4.627

Both of these experiments show a small but significant migration of germanium toward the anode, indicating the presence of an anion of this element, presumably $GeCl_6^{=}$. The solutions contained such large concentrations of other ions that the concentration of chlorogermanate ions could not be calculated from the data.

Formation of Chlorogermanates.—The direct addition of ammonia to 12 *N* hydrochloric acid saturated with germanium tetrachloride gave only a precipitate of ammonium chloride with no evidence of chlorogermanate formation.

The reactions of the alkali chlorides with germanium tetrachloride were studied under a variety of conditions.

Anhydrous germanium tetrachloride was refluxed with a weighed amount of sodium chloride for several days, the mixture being protected from atmospheric moisture. No evidence of any reaction could be observed. Similarly the chlorides of lithium, potassium, cesium and calcium did not react when refluxed with anhydrous germanium tetrachloride.

The low solubility of germanium tetrachloride in concentrated hydrochloric acid makes it impossible to achieve any large concentration of germanium tetrachloride in an

(2) Pauling, THIS JOURNAL, **49**, 765 (1927).

(3) Allison and Müller, THIS JOURNAL, **54**, 2833 (1932).

aqueous solution containing sufficient acid to prevent hydrolysis. Also the alkali chlorides are all rather insoluble in concentrated hydrochloric acid. It is impossible, therefore, to prepare the aqueous solution presumably the most ideal for the formation of chlorogermanates, namely, one high in concentration of chloride ion, germanium tetrachloride, and alkali ion. All attempts to obtain chlorogermanates from such systems failed.

Cesium chloride, however, is quite soluble in a mixture of one volume of ethyl alcohol and two volumes of 12 *N* hydrochloric acid. When germanium tetrachloride was added to such a solution a flocculent yellowish-white precipitate was formed. This was filtered off, washed with 12 *N* hydrochloric acid, and dried in air to a light yellow powder. It was found advisable to use less than the equivalent amount of germanium tetrachloride for the precipitation to avoid contamination of the precipitate by the tetrachloride. Analysis of the dry powder showed it to be cesium hexachlorogermanate, Cs_2GeCl_6. In the analysis the chlorine was determined as silver chloride and the germanium by precipitation as the sulfide and conversion to the oxide.[4] Cesium was determined by heating the cesium chlorogermanate with a low flame. The compound decomposes into cesium chloride and germanium tetrachloride and the latter volatilizes. The residual cesium chloride was finally heated to its melting point, 646°, and then cooled and weighed. It was found to retain only very slight traces of germanium.

Anal. Calcd. for Cs_2GeCl_6: Cs, 48.21; Ge, 13.18; Cl, 38.62. Found: Cs, 48.77; Ge, 12.54; Cl, 38.62.

Properties of Cesium Hexachlorogermanate.—Cesium hexachlorogermanate dissolves readily in water, undergoing rapid hydrolysis. It is insoluble in 12 *N* hydrochloric acid and in absolute ethyl alcohol, but 100 cc. of a 1:2 mixture dissolves 1.5 g. at 0° and 4.3 g. at 75°. It may readily be recrystallized from this mixed solvent.

Cesium chlorogermanate is stable in dry air at room temperature. Passage of a slow stream of nitrogen over it at various temperatures and then through a dilute solution of silver nitrate showed that decomposition, without melting, to cesium chloride and germanium tetrachloride became appreciable at 160° and was very rapid and in some hours complete at 200°.

The density of the compound at 25° was found to be 3.45 ± 0.01 by the pycnometric method, using toluene as the immersion liquid.

The crystals are well formed and are isotropic and, for the most part, octahedral. Their refractive index is 1.68.

Crystal Structure of Cesium Hexachlorogermanate.—A powder X-ray diffraction pattern for the compound was obtained, using Cu Kα radiation. The data fitted a face-centered cubic lattice, since only lines having all odd or all even indices appeared. The structure is probably of the ammonium chloroplatinate type, and the intensity calculations have been made on this basis. This type of structure is also shown by cesium fluogermanate.[5]

A value of a_0 was calculated for each line. The values for the last 20 lines were plotted against $\cos^2\theta$, and the best straight line through the points was extrapolated to $\cos^2\theta = 0$ to obtain $a_0 = 10.21$ Å. In this manner, correction was

made for incorrect centering of the specimen and for absorption in the powder rod.[6]

The density of cesium chlorogermanate as determined pycnometrically was 3.45. From this figure and the value of a_0 the number of molecules in the unit cell was calculated to be 3.96. The number of molecules in the unit cell is therefore four, and the density calculated from X-ray data is 3.48.

The values for the intensities of the powder lines were calculated from the formula

$$I = \text{constant}\left(\frac{1+\cos^2 2\theta}{\sin 2\theta \sin\theta}\right) jS^2 \text{ where}$$

$$S = f_{Ge} + 2f_{Cs}\cos 2\pi\left(\frac{h+k+l}{4}\right) + 2f_{Cl}(\cos 2\pi hx + \cos 2\pi kx + \cos 2\pi lx)$$

The atomic f-values of Pauling and Sherman[7] were used throughout these calculations. In order to determine the chlorine parameter, values of 0.22, 0.23 and 0.24 were used to calculate the intensities for the first ten lines. The value $x = 0.23$ gave the best agreement with the observed and was therefore used in the calculation of the remaining intensities. The observed intensities were corrected for absorption in the powder rod in the usual manner. The values for the observed and calculated intensities are given in Table II. The agreement is reasonable.

From the chlorine parameter of 0.23, the germanium–chlorine distance was calculated to be 2.35 Å. This is in good agreement with the value 2.34 Å. calculated from the ionic radii of Pauling.[2]

The authors wish to acknowledge the assistance of Professor J. L. Hoard who made available X-ray equipment and helped with the interpretation of the X-ray data.

Summary

1. The formation of chlorogermanic acid and its salts has been studied under a variety of conditions.

2. Evidence for the formation of negatively charged complex ions, presumably $GeCl_6^=$, when germanium tetrachloride is dissolved in concentrated hydrochloric acid has been obtained by migration experiments.

3. Cesium hexachlorogermanate has been prepared and its properties and crystal structure have been studied. It has a face-centered cubic lattice.

The Dielectric Constants of Some Pairs of Diastereomers

BY SAUL WINSTEIN AND REUBEN E. WOOD

Pairs of diastereomeric substances show no very characteristic differences in physical properties such as boiling point, polarizability, etc.[1] However, owing to the lack of free rotation about carbon–carbon single bonds[2] there is the possibility that the dipole moments and thus the dielectric constants of *meso* and *dl* compounds or *erythro* and *threo* compounds may differ sufficiently to be useful analytically. Also, there is the possibility that there may be enough regularity in these differences to allow the formulation of rules for the assignment of configuration to diastereomers on the basis of dielectric constant measurements. To study these possibilities and in some cases to obtain data immediately useful in analysis and identification we have determined the dielectric constants of some pairs of diastereomers available to us.

Materials

***meso-* and *dl*-2,3-Diacetoxybutanes.**—The *meso* isomer, m. p. 2.5°, b. p. (13 mm.) 83.6°, was prepared[3] from *meso*-2,3-butanediol, m. p. 34.0°, and distilled through a 40-cm. Weston column.[4] The *dl* isomer, m. p. 42.1°, was prepared[3] from the *dl*-2,3-butanediol from pure *cis*-2,3-epoxybutane.[5]

***dl-erythro-* and *dl-threo*-2,3-Diacetoxypentanes.**—These materials were kindly furnished us by Professor H. J. Lucas and Mr. M. J. Schlatter of these Laboratories.

(4) Weston, *Ind. Eng. Chem., Anal. Ed.*, **5**, 179 (1933).

(5) Winstein and Lucas, THIS JOURNAL, **61**, 1576 (1939).

Distillation through the Weston column yielded constant boiling materials; *erythro* isomer, b. p. (12 mm.) 90.4°; *threo* isomer, b. p. (12 mm.) 94.3°.

***dl-erythro-* and *dl-threo*-3,4-Diacetoxyheptanes.**—These materials were generously loaned us by Dr. W. G. Young of the University of California at Los Angeles. The *threo* isomer was pure while the *erythro* material needed redistillation. Distillation through the Weston column yielded constant boiling material, b. p. 114.2° (10 mm.).

***meso-* and *dl*-2,3-Dibromobutanes.**—These compounds were obtained as constant boiling materials from *meso*-2,3-diacetoxybutane and *trans*-2,3-epoxybutane[5,6] or the bromohydrin or 2-acetoxy-3-bromobutane derived from it. k_2 for the reaction of these dibromides with potassium iodide[7] in 99.00% methanol at 74.93° using synthetic methanol was 0.0553 for the *meso* preparation and 0.0298 for the *dl* compound.

***dl-erythro-* and *dl-threo*-2,3-Dibromopentanes.**—Very pure materials were generously made available by Mr. M. J. Schlatter.

***meso-* and *dl*-3,4-Dibromohexanes.**—These compounds were kindly supplied by Dr. W. G. Young.

***dl-erythro-* and *dl-threo*-2-Acetoxy-3-bromobutanes.**—These compounds were prepared as previously described[5,6] starting with pure *cis-* and *trans*-2,3-epoxybutanes.

Apparatus and Method

The dielectric constant measuring apparatus has been referred to in another paper.[8] As mentioned there the cell used was of the type described by Doborzynski.[9] For a cell of this type there may be derived an expression which relates approximately the cell's capacitance to the dielectric constant of the filling fluid. This will be of the form

$$\epsilon = \frac{l(C - m)}{1 - n(C - m)}$$

in which ϵ is the dielectric constant of the fluid, C the capacitance of the cell and l, m and n are constants characteristic of the cell. Such an equation was used to calculate the dielectric constants here reported. The values of l, m and n for the cell used were determined from measurements with fluids of known dielectric constant, *viz.*, air and the carefully purified liquids carbon tetrachloride, benzene, chlorobenzene, ethyl bromide, and ethylene dichloride. It was found possible to select values for l, m and n so that when the resulting equation was used to calculate the dielectric constants of the standard fluids ϵ's resulted which were on the average within 0.2% of the literature values we chose, namely, 1.001,[10a] 2.227,[10b] 2.272,[10c] 5.612,[10c] 9.21,[10d] 10.36.[10c]

Data and Discussion

Table I summarizes the dielectric constants, ϵ, we have obtained for the substances investigated. In the case of the *dl*-2,3-diacetoxybutane and *meso*-3,4-dibromohexane the values recorded are those obtained by linear extrapolation from the value for a mixture and the value for one pure diastereomer. These values are thus not as accurate as the others.

The values, in general, are listed to four significant figures to show the differences between the isomeric samples. The differences between the dielectric constant of the members of a pair of diastereomers are accurate enough to require so many figures even though the accuracy of the absolute values is only about 0.2%.

From a practical standpoint it is interesting to notice in Table I the very appreciable differences that exist in most cases between the dielectric constants of the isomeric substances. The dielectric constant is thus an excellent property for identification and even analysis in these cases that are usually otherwise quite difficult. An identification or analysis on the basis of a dielectric constant measurement is especially accurate if one or both of the pure isomers are available so that high accuracy for the absolute value of the dielectric constant is not necessary. Already the dielectric constants of the 2,3-dibromobutanes[5,6] and the 2,3-dibromopentanes[11] have proved very useful in these Laboratories.

TABLE I

PROPERTIES OF SOME PAIRS OF DIASTEREOMERS

Substance	Isomer	d^{25}_4	$n^{25}D$	ϵ at 25°
2,3-Diacetoxybutane	*meso*	1.0213	1.4121	6.644
	dl	1.0235[a]	1.4133[a]	5.10[a]
2,3-Diacetoxypentane	*dl-erythro*	1.0022	1.4147	6.734
	dl-threo	1.0073	1.4175	5.228
3,4-Diacetoxyheptane	*dl-erythro*	0.9758 (20°)	1.4207	6.684
	dl-threo	0.9829 (20°)	1.4241	5.029
2,3-Dibromobutane	*meso*	1.7747	1.5091	6.245
	dl	1.7836	1.5125	5.758
2,3-Dibromopentane	*dl-erythro*	1.6724	1.5062	5.430
	dl-threo	1.6745	1.5064	6.507
3,4-Dibromohexane	*meso*	1.5940	1.5049	4.67[b]
	dl	1.5896	1.5031	6.732
2-Acetoxy-3-bromobutane	*dl-erythro*	1.3327	1.4489	7.268
	dl-threo	1.3320	1.4490	7.414

[a] Obtained by linear extrapolation using the values for one pure isomer and for a mixture of *meso* and *dl* isomers. Mixtures were measured either due to lack of material or to be able to perform the measurement at 25°. Mixture of 58.5% *dl* and 41.5% *meso* exhibited dielectric constant of 5.740. [b] See *a*. Mixture of 60.7% *dl* and 39.3% *meso* exhibited a dielectric constant of 5.922.

(11) Lucas and Schlatter, unpublished work.

Dielectric constants have been reported previously for several of the compounds we have investigated. Sherrill and co-workers[12] have reported the dielectric constant of 2,3-dibromopentane prepared from 2-pentene obtained presumably by Boord's[13] synthesis as 5.43. This agrees with our value for *dl-erythro*-2,3-dibromopentane and indicates that the 2-pentene was pure *trans*-2-pentene. It is very interesting that the Boord synthesis gives essentially pure *trans*-2-pentene.

The 2,3-dibromobutanes have been previously investigated by Trieschmann,[14] but the materials employed by him were of doubtful purity. The dielectric constants 8.96 for the *meso* isomer and 8.72 for the *dl* compound reported by Trieschmann are about 50% larger than the values reported in this paper. In view of the values for the dielectric constants generally reported for substances of the type of the dibromobutanes it seems very unlikely that the dibromobutanes have dielectric constants as high as 8.96 and 8.72 and the finding of Trieschmann that *meso*- and *dl*-2,3-dibromobutane possess the same dipole moment possibly is incorrect also.

We had hoped that in a series of pairs of compounds such as the 2,3-diacetoxybutanes, 2,3-dibromobutanes, and 2-acetoxy-3-bromobutanes, there would be a regularity in the relative dielectric constants of the isomers. However, values obtained do not indicate a simple correspondence between relative dielectric constant and configuration. Since the *meso* isomer displays the higher dielectric constant in the case of both the dibromobutanes and the diacetoxybutanes, one might expect the *erythro*-2-acetoxy-3-bromobutane to exhibit a larger dielectric constant than the *threo* compound. Instead the last two compounds have nearly the same dielectric constant and that of the *threo* isomer is slightly larger.

In the case of the dibromobutanes, dibromopentanes, and dibromohexanes the situation is similar. The order of relative dielectric constants in the case of the dibromobutanes is different from the order obtaining for the other two pairs of dibromides. The greatest regularity observed was in the diacetoxyalkane series. For each of the three pairs of these compounds examined the *meso* or *erythro* isomer has the larger dielectric constant. In fact, the dielectric constants are nearly the same for corresponding members of the three different pairs of isomers.

Several expressions[15,16,17] relating the dielectric constant of liquids to the dipole moments of their molecules have been proposed. Using Onsager's equation

$$\mu^2 = \frac{(n^2 + 2\epsilon)(\epsilon - n^2)}{\epsilon(n^2 + 2)^2} \frac{M}{D}$$

Böttcher[18] calculated μ for a number of liquids and obtained values agreeing reasonably well on the whole with those reported for the gaseous molecules. It seemed worth while to subject our data to a similar treatment to estimate the dipole moments, and in particular the relative dipole moments, of the diastereomeric pairs we studied.

Since between the members of each pair of these isomers ϵ differs much more than the other parameters appearing in Onsager's equation, the difference in the calculated μ's between isomers is in the same direction as the difference between ϵ's. We used $n^{25}D$ for n; the dipole moment values thus calculated are tabulated below.

Compound	Dipole moment of the *meso* or *dl-erythro* isomer		Dipole moment of the *dl* or *dl-threo* isomer
2,3-Diacetoxybutane	2.35	>	1.95
2,3-Diacetoxypentane	2.48	>	2.07
3,4-Diacetoxyheptane	2.68	>	2.18
2,3-Dibromobutane	1.73	>	1.62
2,3-Dibromopentane	1.67	<	1.90
3,4-Dibromohexane	1.57	<	2.06
2-Acetoxy-3-bromobutane	2.23	≈	2.26

It has been pointed out by Dr. V. Schomaker that the dipole moment of ethylene dichloride calculated by means of Onsager's theory from the dielectric constant of the liquid is considerably greater than the dipole moment of a molecule in the gas at the same temperature, and that this fact probably indicates that the relative abundance of the *cis* and *trans* forms of ethylene dichloride in the liquid is quite different from the relative abundance in the gas. The same effect may be expected to occur in the liquids discussed in the present paper; the dipole moments which we have calculated may, for this reason, differ appreciably from those of the corresponding free molecules.

Moreover, it is conceivable, but not probable, that molecular association[17] in some of the liquids affects the dielectric constants of the members of

a diastereomeric pair enough differently to lead to an erroneous conclusion as to which member has the higher dipole moment. Pertinent to this question are Stewart's findings[19] that in the cases of diethyl tartrate, pinene and camphene the *dl* mixtures possess the same dielectric constants as the corresponding *d* or *l* compounds.

Despite the uncertainties and approximations involved in computing dipole moments from the dielectric constants of pure liquids it seems probable that the values tabulated above indicate correctly both the approximate dipole moments of the diastereomers and the sense of the difference between the dipole moments of the members of a pair of isomers.

While any extended discussion of the significance of the relative dipole moments of the pairs of diastereomers we have investigated should await actual quantitative work on the dipole moments, several things may be pointed out at this time. It would seem that the order *meso* > *dl* and the analogous one *erythro* > *threo* are much more prevalent than has been indicated by the previous literature. The dipole moments of the diethyl tartrates, the dimethyl α,α'-dimethoxysuccinates, the dimethyl α,α'-dichlorosuccinates, the hydrobenzoins, and the stilbene chlorides have been reported previously.[20,21] In these cases only the diethyl tartrates exhibit the order of dipole moments *meso* > *dl*, and the difference in dipole moments is very large only for the stilbene chlorides. Judging from dielectric constants it would appear that in the cases investigated by us the differences between dipole moments of isomers are not very large. Except for the dibromobutanes, the compounds which exhibit the order *meso* > *dl* seem to be the ones with angular polar groups.[2]

The relative dipole moments of diastereomers such as the 2,3-dibromobutanes depend on both the equilibrium configurations about the central carbon–carbon bond and the vibrations or rotations about this bond. Thus, the customary expectation that the *meso* isomer will have the lower dipole moment seems difficult to justify. For example, in the case of the 2,3-dibromobutanes, electron diffraction studies[22] have shown that the equilibrium configuration for both the *meso* and *dl* isomers is that with the bromine atoms *trans* to each other. Thus, the equilibrium *meso* molecule has zero moment and the equilibrium *d* or *l* molecule has a small moment. The rather large moment of this type of molecule then arises chiefly from vibrations about the mean configuration. The shape of the potential curve is different for the *meso* and *dl* compounds because different interactions are involved in the vibration about the mean position. Thus, it is conceivable that either order, *meso* > *dl* or *dl* > *meso* is possible for diastereomeric pairs.

Acknowledgment.—We wish to acknowledge our gratitude to those already mentioned as having furnished chemicals, and also to Professor Linus Pauling and particularly to Dr. J. Norton Wilson for criticisms and suggestions.

Summary

The dielectric constants of seven pairs of diastereomers, namely, the 2,3-diacetoxybutanes, 2,3-diacetoxypentanes, 3,4-diacetoxyheptanes, 2,3-dibromobutanes, 2,3-dibromopentanes, 3,4-dibromohexanes, and 2-acetoxy-3-bromobutanes, have been measured. In general, the members of a pair of diastereomers differ sufficiently in their dielectric constants for the dielectric constant to be useful for analytical purposes.

From these dielectric constants dipole moments have been estimated using Onsager's equation. The ϵ's and μ's for *meso* and *erythro* compounds are compared with those for the corresponding *dl* and *threo* isomers.

The Dehydration of Some Tertiary Alcohols Containing the Cyclohexane Ring

BY WILLIAM A. MOSHER

Although many tertiary alcohols containing the cyclohexane ring have been prepared, especially by Sabatier and Mailhe,[1] it appears that none has been subjected to a careful study of its dehydration products. In dehydration only one of the expected products has been reported. The properties of the olefins formed are such as to make physical separation extremely difficult, if not impossible, when only small amounts of materials are used.

In order to obtain data on the manner of dehydration of certain of these alcohols, as well as to gain some insight into the process as applied to the group as a whole, we have prepared and dehydrated 1-methylcyclohexanol, 1-ethylcyclohexanol, 1-isopropylcyclohexanol, and dimethylcyclohexylcarbinol. The alcohols were prepared by means of the Grignard reaction. The dehydration was effected by heating with iodine under a column so that the olefins and water distilled out of the mixture as formed. The use of ozonolysis offers a simple and satisfactory approach to the problem as it makes physical separation of the isomers unnecessary. If we assume that no shifting of the double bonds occurs after dehydration, one of the products of each dehydration will give rise to formaldehyde, acetaldehyde, or acetone; in the case of dimethylcyclohexylcarbinol both acetone and formaldehyde may be formed. These facts greatly simplify the problem as it is only necessary to ozonize the olefin mixture obtained by dehydration and analyze, both qualitatively and quantitatively, for the appropriate carbonyl compounds. From the analyses the ratios of the isomers in the dehydration products may be determined. The accuracy of such a method is approximately 10%. A very complete discussion of the technique of ozonolysis is given by Church, Whitmore and McGrew.[2]

The absence of isomerization concomitant with, or subsequent to, dehydration is indicated by the following facts. In the case of dimethylcyclohexylcarbinol the summation of acetone and formaldehyde was within 5% of the theoretical. In the case of 1-methylcyclohexanol, analysis for methyl ketone in the ozonolysis product gave a value of 93% of the theoretical. Finally, the method of dehydration used minimizes secondary reactions by removing the dehydrated product from the action of the dehydrating agent. The absence of polymerization is indicated by the recovery of yields of olefin always better than 97% having the properties of the monomer.

We may look upon dehydration as a competitive reaction indicating the relative affinities of structurally different carbon atoms for a proton. According to the concept of Whitmore[3] the hydroxyl group is removed leaving a carbon atom with only six electrons. To stabilize this organic fragment a proton may be lost from an adjacent carbon atom. The determination of the ratio in which different carbon atoms lose protons measures the affinities of the groups in question and gives a relative indication of the bond strengths.

In the dehydration of 1-methylcyclohexanol no formaldehyde was detected in the products of ozonolysis indicating that no methylenecyclohexane was formed and that only 1-methylcyclohexene was formed by the dehydration. In the case of 1-ethylcyclohexanol only a trace of acetaldehyde was found, indicating that less than 1% of ethylidenecyclohexane was formed. Presumably the other 99% was present as 1-ethylcyclohexene. An amount of acetone corresponding to approximately 5% of the theoretical was found in the products from 1-isopropylcyclohexanol, indicating this percentage of isopropylidenecyclohexane in the olefin mixture. The analysis of the products from dimethylcyclohexylcarbinol gave values of approximately 50% each for acetone and formaldehyde indicating equal amounts of isopropylidenecyclohexane and isopropenylcyclohexane in the mixture.

Dehydration apparently will take place in such a manner that the double bond occurs principally in the ring when this is possible. In other words the hydrogen atoms attached to the ring are less firmly bound than those of a more aliphatic nature. In the case of 1-isopropylcyclohexanol a cyclic hydrogen is lost in preference to the tertiary

hydrogen of the isopropyl group. At first sight the case of dimethylcyclohexylcarbinol seems more unusual in that a primary hydrogen from a methyl group is lost in equality with a tertiary hydrogen from the ring. It must be remembered, however, that there are six primary hydrogens on adjacent carbons while only one adjacently attached tertiary hydrogen. On this basis the tertiary hydrogen is lost relatively more readily than a primary hydrogen.

Experimental

Apparatus and Methods.—The column under which the dehydrations were carried out was of the type described by Whitmore and Lux.[4] It was packed with single turn glass helices and had an efficiency equivalent to 12 theoretical plates. Its nichrome resistance windings were connected in series with a "variac" for temperature control of the column jackets.

The ozone was generated by passing dry oxygen through a generator obtained from the U. S. Ozone Co., Scottdale, Pa. The generator was calibrated so that a measured amount of ozone could be delivered by controlling the rate and time of oxygen flow. The ozonolyses of the olefin mixtures were conducted as described by Whitmore and Church.[5] In all cases the theoretical amount of ozone just saturated the olefin.

Preparation of Materials.—The cyclohexanol derivatives were prepared by the usual Grignard procedure; their boiling points, refractive indices ($n^{20}D$), and yields based upon the halides used were, respectively, as follows: 1-methyl- 70° at 25 mm., 1.4546, 60%; 1-ethyl- 78° at 20 mm., 1.4642; 1-isopropyl- 80° at 18 mm., 1.4579, 35%; dimethylcyclohexylcarbinol 96–98° at 18 mm., 1.4700, 40%. In the reaction of isopropylmagnesium bromide and cyclohexanone a 7% yield of cyclohexanol, α-naphthyl urethan m. p. 128°, was obtained. Cyclohexylidenecyclohexanone[6] amounting to 34% of the original cyclohexanone was isolated and identified through its semicarbazone, m. p. and mixed m. p. 177°.

Dehydration of the Alcohols.—In all cases the dehydrations were carried out by heating 0.15 to 0.20 mole of the alcohol with 0.05 to 0.1 g. of iodine. The jackets of the column under which the dehydrations were performed were set at a temperature which would allow water and olefin to distil out of the mixture but which prevented loss of undehydrated alcohol. In all cases dehydration was rapid and complete. Both the water and olefin obtained were weighed; the yields of water from all four alcohols were 95–95.5% and the yields of olefin were 97.5–99%. The olefin mixtures were dried over anhydrous sodium sulfate at 10°. The olefins were treated in no other way before ozonolysis.

Analysis.—The ozonolyses were conducted by the method referred to above.[5] Formaldehyde was detected by the resorcinol–sulfuric acid test; methyl ketone by the iodoform reaction; sodium nitroprusside was used to indicate acetone. In cases where acetone was expected it was isolated as such by distilling it out of the aqueous solution and identified by preparing the 2,4-dinitrophenylhydrazone. Formaldehyde was determined by iodimetric titration when no acetone or other methyl ketone was present. When acetone was present with formaldehyde the two were determined together by titration with iodine in basic solution and the formaldehyde determined separately on an aliquot part with hydrogen peroxide and standard base.[2] Acetone was determined by Messinger's method,[7] as was the methyl ketone from 1-methylcyclohexanol.

The aqueous distillate from the decomposition of the ozonide from 1-methylcyclohexanol gave no test for formaldehyde, nor methyl ketone. The solution failed to give a positive Schiff test. After removing the zinc from the residue in the decomposition flask iodimetric titration showed the presence of methyl ketone, 93% calculated as 6-ketoheptaldehyde.

In the case of 1-ethylcyclohexanol the aqueous distillate gave no test for aldehyde or methyl ketone. The contents of the dry-ice trap attached to the condenser outlet gave a positive test for aldehyde with Schiff reagent. Alcohol was added to the trap contents and then 2,4-dinitrophenylhydrazone and concd. hydrochloric acid. After refluxing, evaporating most of the low boiling solvent, water was added to effect a complete separation of the hydrazone. The dried product corresponded to a 0.5% yield of acetaldehyde. On recrystallizing twice from alcohol, the derivative melted at 163° and showed no depression when mixed with an authentic specimen of the 2,4-dinitrophenylhydrazone of acetaldehyde.

In the case of 1-isopropylcyclohexanol the distillate gave a positive iodoform test. Analysis showed a 2.5% yield of acetone. The distillate gave no test for aldehyde; the residue in the decomposition flask gave no iodoform reaction.

The presence of both formaldehyde and acetone was demonstrated in the products from dimethylcyclohexylcarbinol. Analysis showed yields of 53% formaldehyde and 42.5% acetone. Methyl cyclohexyl ketone, one of the products, would interfere with the acetone analysis. However, it was not allowed to distil over; water was allowed to distil out but the ketone, being an insoluble oil, was returned to the decomposition flask by proper adjustment of the take off stopcock on the decomposition apparatus. Acetone was distilled out of the aqueous solution using the 12-plate column; a 35% yield was obtained in this way, 2,4-dinitrophenylhydrazone m. p. and mixed m. p. 126°.

The author wishes to acknowledge the valuable assistance and advice of his colleagues, Dr. Paul H. Scrutchfield and Dr. Richard F. Cox.

Summary

1. 1-Methylcyclohexanol, 1-ethylcyclohexanol, 1-isopropylcyclohexanol, and dimethylcyclohexylcarbinol have been dehydrated with iodine and the resulting olefin mixtures ozonized. From the analysis of the ozonolysis products

(4) Whitmore and Lux, THIS JOURNAL, **54**, 3448 (1932).
(5) Whitmore and Church, *ibid.*, **54**, 3710 (1932).

the ratios of dehydration have been determined.

2. Dehydration tends to take place in such a manner that the double bond formed enters the ring when this is possible.

3. It is noted that a proton is lost from the cyclohexane ring more readily than from a methyl, ethyl or isopropyl group.

Lupine Studies. XV.[1] The Alkaloids of *Lupinus sericeus* Pursh

BY JAMES FITTON COUCH

The silky lupine, *Lupinus sericeus*, occurs in the plains and canyons of the pinyon and yellow pine belts from Saskatchewan to South Dakota, Wyoming, Oregon, and Washington.[2]

A collection made by the late A. B. Clawson has been examined and found to contain two alkaloids, spathulatine previously isolated[3] and a new alkaloid now named nonalupine, $C_{15}H_{24}ON_2$, isomeric with lupanine and differing from it in important respects.

The discovery of spathulatine in another lupine presented an opportunity for a revision of the chemistry of the alkaloid, particularly in the light of new developments in our knowledge of the lupine alkaloids since spathulatine was first described. The formula then assigned to the alkaloid on the basis of analyses of the base and the mercuric iodide compound as well as the molecular weight determination is $C_{33}H_{64}O_5N_4$. This formula cannot easily be harmonized with the series of sparteine derivatives now known. The molecular weight is more than twice that of lupanine but is supported by the high melting point reported, 227° (uncor.). Moreover, the large content of hydrogen precludes a combination of structures with a sparteine skeleton and requires a largely aliphatic structure with not more than two 6-membered rings.

Analyses of both the anhydrous and the hydrated alkaloid for carbon, hydrogen, and nitrogen gave figures that agree with the previously assigned formula. The newly prepared compound with potassium iodide which is analogous to the mercuric iodide compound previously described also furnishes analytical evidence consistent with the previously assigned formula. In this study no evidence has been obtained to indicate that the formula requires revision.

The behavior of spathulatine suggests the presence of amine-oxide groups, possibly adjacent to a carbonyl group, for three of the nitrogen atoms, the function of the fourth being undetermined. This view is supported by the slight basicity of spathulatine and the inability to prepare crystalline salts with the usual acids and by its sparing solubility in acetone and ether. The formation of a compound with three molecules of potassium iodide also supports this view since compounds with one molecule of potassium iodide to each amine-oxide group are readily formed. When treated with sulfur dioxide spathulatine is converted into an unidentified base probably as a result of reduction of the amine-oxide groups.

When boiled with hydrochloric acid spathulatine is converted into an isomer of spartyrine, $C_{15}H_{24}N_2$, which is positive to the modified Grant's test.[4] This behavior indicates the probability of hydrolysis with subsequent ring closure to form the sparteine skeleton. This relates spathulatine to the other lupine alkaloids.

The other alkaloid in the plant, nonalupine, is of interest because of its non-basic character. When a solution of nonalupine and camphor-sulfonic acid is evaporated to dryness the free alkaloid may be dissolved out of the residue by ether. No salts with mineral acids have been obtained. This behavior is difficult to explain. Since the alkaloid contains two nitrogen atoms and but one oxygen atom it cannot have lost its basicity because of amine-oxide formation or because of ad-

(1) Paper XIV, THIS JOURNAL, **61**, 3327 (1939).

(2) W. W. Eggleston in I. Tidestrom, "Flora of Utah and Nevada," *Contr. U. S. Nat. Herbarium*, **25**, 297 (1925).

(3) J. F. Couch, THIS JOURNAL, **46**, 2507 (1924). The alkaloid was isolated from a lupine collected by the writer and identified by W. W. Eggleston as *L. spathulatus* Rydb. whence the name spathulatine given to the new base. Since that time there has arisen a difference in opinion among botanists as to the proper name of the species used, I. Tidestrom (personal communication) referring it to *L. marianus* Rydb. and being confirmed by C. P. Smith. Eggleston considered *marianus* a synonym of *spathulatus* and recombined the species. Material of a species identified by C. P. Smith as *L. spathulatus* collected near Puffer's Lake, Utah, has been examined and found free from spathulatine. The alkaloid has, it appears, been misnamed since, unless there is a reversal of botanical opinion, it does not occur in *L. spathulatus*.

(4) J. F. Couch, *Am. J. Pharm.*, **97**, 36 (1925).

jacent carbonyl groups. The possibility of an oxygen bridge between the nitrogen atoms involves assumptions of structure which are unacceptable. The alkaloid is unaffected by warming with sulfur dioxide in water. It reduces potassium permanganate in neutral solution forming a crystalline compound containing two atoms of oxygen more than the parent substance. This compound which may be an amine-oxide is also unaffected by hot sulfur dioxide in water.

These alkaloids differ from octalupine found in *L. sericeus* var. *flexuosus*[5] which is considered by botanists to be only a variety of *L. sericeus*. It appears that the dissimilarities between the two forms extend to the physiological processes and are deeper than mere varietal differences.

Experimental Part

Material Used.—The plant material used was collected by A. B. Clawson in the neighborhood of Meeker, Colo., on August 24, 1934, and was identified by C. P. Smith. The plant was air-dried and shipped to Washington, D. C., for examination. It then contained 11.36% of moisture.

Isolation of the Alkaloids.—The finely ground plant (5.55 kg.) was extracted with alcohol and the alkaloids were recovered by the process previously described.[6] The yield of crude alkaloids freed of solvent was 181 g. or 3.68% of the moisture-free plant. The sirupy mass was dissolved in acetone plus 10% of alcohol, filtered from a little resin, and the solvent was distilled off. The residue solidified to a mass of prismatic crystals embedded in a thick brownish sirup. The mass was negative to the modified Grant's test for sparteine.[7] It was only slightly soluble in ether.

Isolation of Spathulatine.—The alkaloidal mixture was treated with cold acetone which dissolved the sirup, leaving most of the crystals undissolved. These were recrystallized several times from hot acetone plus a little norit and then melted constantly at 233–234°.[8] Mixture with spathulatine from *Lupinus marianus* caused no change in the melting point. A sample was dried at 110° to constant weight.

Anal. Calcd. for $C_{33}H_{64}O_5N_4$: C, 66.39; H, 10.82; N, 9.39. Found: C, 66.11, 66.65; H, 11.14, 10.64; N, 9.54, 9.48. Undried sample: calcd. for $C_{33}H_{64}O_5N_4 \cdot 4^1/_2H_2O$: C, 58.45; H, 10.85; H_2O, 11.96. Found: C, 58.65; H, 10.91, averages of 6 analyses; H_2O, 12.01.

The picrate forms yellow needles, quite soluble in water and melting at 182–184°. A methiodide was obtained in scanty yield as diamond-shaped crystals melting at 250–252°. It did not depress the melting point of authentic spathulatine methiodide. Spathulatine decomposed when an attempt was made to distill it under reduced pressure.

Spathulatine Potassium Iodide.—Spathulatine (3 g.) in 5 cc. of water was mixed with 2.1 g. of potassium iodide in 2 cc. of water. There was an immediate precipitation of small crystals in good yield. These were recrystallized from hot water as large prisms of m. p. 260–261°. A test portion was moistened with sulfuric acid and ashed. It evolved iodine vapor and left a residue of potassium sulfate.

Anal. Calcd. for base·3KI: I, 34.81. Found: I, 34.85, 34.82.

Spathulatine and Sulfur Dioxide.—A stream of sulfur dioxide was passed through a solution of 2 g. of spathulatine in 10 cc. of water for two days. The product was alkalized with sodium hydroxide and the milky precipitate extracted with chloroform which on evaporation left a brownish oil from which nothing crystalline could be isolated. It has not yet been identified but it has been shown not to contain spathulatine.

Spathulatine and Hydrochloric Acid.—Spathulatine (3 g.) and 10 cc. of concd. hydrochloric acid and 25 cc. of water was maintained at the boiling point for six hours until fumes of hydrogen chloride were given off. The mixture turned dark brown. On cooling nothing crystallized. The mixture was alkalized with sodium hydroxide and extracted with chloroform. The chloroform extract was a yellow oil which was strongly positive to the modified Grant's test. It formed a crystalline perchlorate of m. p. 216–217°. When mixed with *d*-lupanine perchlorate (m. p. 214–216°) the mixture melted at 194–207° like a mixture.

Anal. Calcd. for $C_{15}H_{24}N_2HClO_4$: C, 53.98; H, 7.5; N, 8.42. Found: C, 54.15, 53.85; H, 7.51, 7.80; N, 8.61, 8.34.[9] The base was very slightly levorotatory.

The new base gave a precipitate with mercuric chloride like that given by sparteine and formed a picrate which was recrystallized from hot water, m. p. 214–216°. Mixed with spartyrine picrate (m. p. 206–207°) the mixture melted at 192–202°.

Isolation of a New Lupine Alkaloid, Nonalupine.—The acetone solution containing the sirup dissolved from the original alkaloidal residue was allowed to evaporate. It solidified to a mass of crystals. It was dissolved in hot acetone and filtered from the crystals that formed on cooling. The solution was evaporated and the brownish crystalline residue was recrystallized several times from methyl isobutyl ketone plus a little norit as colorless leaflets of m. p. 91.5–92.5°, b. p. 260–270° (18 mm.). Mixed with 16-keto sparteine (m. p. 85–86°) the mixture melted from 80 to 97°. Dried to constant weight at 110° the substance softened at 219° and was completely melted at 235°. On recrystallizing from water the substance took up solvent and then melted at 90–91°, regenerating the original hydrated base.

Anal. Calcd. for $C_{15}H_{24}ON_2 \cdot 2H_2O$: C, 63.34; H, 9.97; N, 9.85; H_2O, 12.68. Found: C, 63.11, 63.23; H, 9.39, 9.88; N, 9.71, 9.68; H_2O, 12.51.[9] In alcohol, $[\alpha]^{25}D$ $-21.3°$, $c = 5.15$, $l = 1$, $a = 2.19°$.

Nonalupine Gold Chloride.—The gold chloride double salt was recrystallized from hot water as small yellow needles, m. p. 177.5–178° decompn. It decomposed when heated to 110°.

(5) J. F. Couch, THIS JOURNAL, **61**, 1523 (1939).
(6) J. F. Couch, *ibid.*, **56**, 2434 (1934).
(7) J. F. Couch, *Am. J. Pharm.*, **97**, 36 (1925).
(8) Melting points are corrected.
(9) The analyses were made by the Arlington Laboratories, Vera A. Conard, Director.

Anal. Calcd. for base·2HAuCl$_4$·5H$_2$O: Au, 38.72. Found: Au, 38.71.

Nonalupine picrate recrystallized from 50% alcohol melted at 185–186°.

Oxidation of Nonalupine.—Nonalupine (5 g.) in 600 cc. of water was treated with a saturated solution of potassium permanganate in the cold until the pink color persisted for twenty-four hours. The filtrate was extracted with chloroform, which took out an oil (2.5 g.) that slowly crystallized. Recrystallized from a mixture of chloroform and petroleum ether the substance formed long flat crystals, m. p. 168.5–170.5°. On drying in the oven it slowly volatilized, losing 28% of its weight in fifteen days at 110°. A further crop (2 g.) of the substance was obtained by extracting the precipitated manganese dioxide with alcohol.

Anal. Calcd. for $C_{15}H_{24}O_3N_2$: C, 64.24; H, 8.63; N, 9.99. Found: C, 63.99, 64.18; H, 8.45, 8.58; N, 9.84, 9.94.

The substance was recovered unchanged after warming with sulfur dioxide in water. It is readily soluble in water and the solution is neutral to test papers.

Oxynonalupine Gold Chloride.—This compound is quite soluble in water. On slow evaporation it forms small yellow needles, m. p. 238–239°. Analysis indicated a partial reduction of the base on combination with gold chloride.

Anal. Calcd. for $C_{15}H_{24}O_2N_2$·HAuCl$_4$: Au, 32.61. For $C_{15}H_{22}O_2N_2$·HAuCl$_4$: Au, 32.72. Found: Au, 32.82.

Summary

Lupinus sericeus Pursh. collected in Colorado contained when dried 3.68% of alkaloids consisting of spathulatine, previously described, and nonalupine, a new lupine alkaloid. A reinvestigation of the chemistry of spathulatine has confirmed the empirical formula previously assigned to this base. Nonalupine is not basic enough to form salts with strong acids.

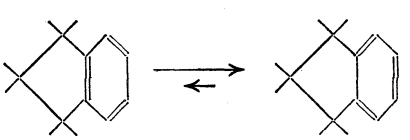
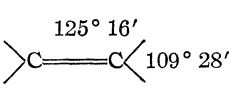
Aromatic Stabilized Double Bonds. Mills–Nixon Problem

BY RICHARD T. ARNOLD AND ROBERT L. EVANS

The fundamental stereochemical problem proposed by Mills and Nixon[1] can be summarized by the equilibrium



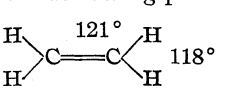
The assumptions in this interesting and clever proposal are: (a) that the structure of the olefinic double bond is represented by



and (b) that there exists a simple relation between bond types and bond angles.

Many experimental and theoretical approaches have been made toward a solution,[2,3,4] but the evidence submitted is most contradictory and leaves the problem completely unsolved. Objections have been raised to practically all of the experimental evidence thus far produced.[5]

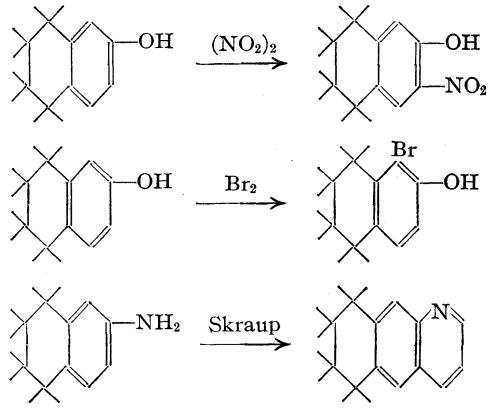
The structure of ethylene recently has been determined, apparently with some degree of accuracy, and gives the following picture:[6,7]



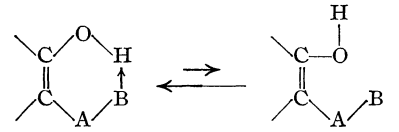
Pauling and Brockway[8] have shown however that the angles in tetramethylethylene are nearly tetrahedral. These models, if true, question the validity of a simple correlation between bond angles and bond types. The foremost use of this assumption lies at the basis of the Sidgwick–Springall experiments. The structural work just completed on formaldehyde again raises a serious objection to this correlation.[9]

The wave mechanical treatment of the Mills–Nixon problem leads to the conclusion that substitution reactions (with high activation energies) cannot be used to locate stabilized aromatic double bonds. That this conclusion is in accordance with the experimental evidence is shown by the following

(1) Mills and Nixon, *J. Chem. Soc.*, 2510 (1930).
(2) Sidgwick and Springall, *J. Chem. Soc.*, 1532 (1936).
(3) McLeish and Campbell, *ibid.*, 1103 (1937).
(4) Sutton and Pauling, *Trans. Faraday Soc.*, **31**, 939 (1935).
(5) Brockway and Taylor, *Brit. Ann. Reports*, **34**, 219 (1937).
(6) H. W. Thompson, *Trans. Faraday Soc.*, **35**, 697 (1939).
(7) Private communication from Professor Verner Schomaker of the California Institute of Technology.
(8) Pauling and Brockway, THIS JOURNAL, **59**, 1223 (1937).
(9) Stevenson, LuValle and Schomaker, *ibid.*, **61**, 2508 (1939).

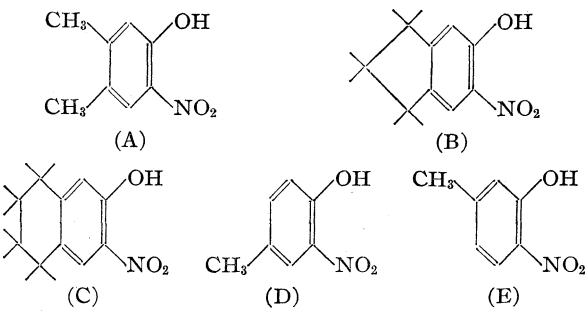


It is seen that the double bond can be placed in either of the two possible positions depending on the reaction chosen. During the past two years, an attempt has been made in this Laboratory to develop a physical method for locating double bonds which is free from objections. Using the naphthalene nucleus, the structure of which is well accepted, it has been shown[12] that if a hydroxyl and negative (electron attracting) group are placed around a stabilized double bond, an abnormally strong acid results. It has been proved[13] that chelate ring structures involving stabilized double bonds are unusually strong. In connection with correlations between the acidity of the hydroxy group and chelate rings involving stabilized double bonds, one must recognize two effects. This can be described by making use of a general equation



The inductive effect of (AB) is easily passed across the stabilized double bond. However, around this stabilized double bond the hydrogen bond is abnormally strong and, thermodynamically, results in a higher concentration of (1). Since it is easy for the proton to dissociate from (2) the overall effect of hydrogen bond formation is a slight diminution in the acidity. It must be recognized however that the inductive effect is usually the more important. This method has been extended, with a full realization of its limitations, to the Mills–Nixon problem by a careful study of the following molecules

(10) Thoms and Kross, *Archiv. Pharm.*, **265**, 336–347 (1927).
(11) Von Braun and Gruber, *Ber.*, **55**, 1710 (1922).
(12) Arnold and Sprung, THIS JOURNAL, **60**, 1163 (1938).
(13) Arnold and Sprung, *ibid.*, **61**, 2475 (1939).



The acidity of the hydroxyl group here has been found to depend on four factors: namely, (a) the type of activating group present; (b) the strength of the chelate ring; (c) the inductive effect of all the dipoles present; and (d) the carbon–carbon bond type between the hydroxyl and activating group. As far as possible the first three factors have been held constant in A, B and C. Differences in dissociation constants for these substances must then indicate a dissimilarity in bond type. Actually the acidities of A, B and C are almost identical. A study of any interaction (*ortho*-effect) between the two methyl groups in A has been made by determinations on D and E. Such interactions seem to be active but appear to be constant in A, B and C. This has been recognized in dipole moment studies.

The possibility of stabilization in hetero rings containing one or more oxygen atoms, which according to our calculations is more probable than in hydrindene, is being investigated intently. Table I summarizes the data upon which the above mentioned statements are based.

TABLE I

Solvent: Ethanol–Water (50% by weight)

Compound	*T*, °C.	*p*K
2-Nitrophenol	29	8.20
4,5-Dimethyl-2-nitrophenol	28	8.81
4,5-Dimethyl-2-nitrophenol	37	8.90
5-Hydroxy-6-nitrohydrindene	37	8.96
6-Hydroxy-7-nitrotetralin	37	9.05
4-Methyl-2-nitrophenol	28	8.57
5-Methyl-2-nitrophenol	28	8.43

Experimental

5-Hydroxyhydrindene.—Thirty-five grams of 5-acetamidohydrindene was hydrolyzed with concentrated hydrochloric acid in several treatments to give 31 g. of the amine. To this sample in 45 cc. of concentrated hydrochloric acid and 70 cc. of water was added 21 g. of sodium nitrite in a saturated solution. To the clear solution was added 50 cc. of borofluoric acid (40%), and the white crystals which formed were filtered immediately. Decomposition of the crystals and filtrate (separately) using 44 cc. of sulfuric acid in 177 cc. of water gave after

steam distillation 12.5 g. of the phenol; b. p. 148–152° (30 mm.).[14,15]

5-Hydroxy-6-nitrohydrindene.—(a) The above 5-aminohydrindene was diazotized and nitrated in one step according to Neunhoffer[16] but on steam distillation an impurity accompanied the product. This unknown material melted at 82–83°.

(b) Following Diepolder's general method,[17] 5-hydroxyhydrindene was nitrated directly. The impurity (m. p. 82–83°) was again obtained but it was found that the high solubility of the desired compound in petroleum ether (b. p. 60–68°) allowed it to be decanted away from the more insoluble impurity and then crystallized; m. p. 63.5–64.5°.

6-Hydroxy-7-nitrotetralin.—Raney nickel catalytic hydrogenation of β-naphthol gave 50–60% yields of 6-hydroxytetralin at 190° and 500 lb. pressure (33.3 atm.). This phenol was nitrated with nitrogen dioxide and after steam distillation gave a 21% yield of the product which was recrystallized from ethanol; m. p. 88.5–89°. The acetate prepared from acetyl chloride in pyridine melted at 100°.[10]

6-Methoxy-7-nitrotetralin.—Using two equivalents each of 2.0 *N* sodium hydroxide and methyl sulfate, we obtained from 3.05 g. of the phenol, 1.37 g. of the ether. The substance was pale yellow and melted at 50–51.5°.

Anal. Calcd. for $C_{11}H_{13}O_3N$: C, 63.73; H, 6.32. Found: C, 63.74; H, 6.54.

4,5-Dimethyl-2-nitrophenol.—This compound was prepared by the direct nitration of the phenol using Diepolder's method; m. p. 85–86°.[14]

5-Methyl-2-nitrophenol.—Technical *m*-cresol was nitrated in cooled glacial acetic acid with a small excess of nitric acid dissolved in glacial acetic acid. After steam distillation and recrystallization, it melted at 54.5–55°.[18]

4-Methyl-2-nitrophenol.—This substance was prepared in the usual manner from *p*-cresol.

MINNEAPOLIS, MINNESOTA RECEIVED OCTOBER 23, 1939

Summary

1. In the light of recent structural studies on ethylene and tetramethylethylene, some of the original assumptions of the Mills–Nixon postulate are questionable.

2. A set of physical measurements on nitrophenols indicates no appreciable stabilization of double bonds caused by ring structures.

3. It has been pointed out that substitution reactions do not offer an acceptable method for locating double bonds.

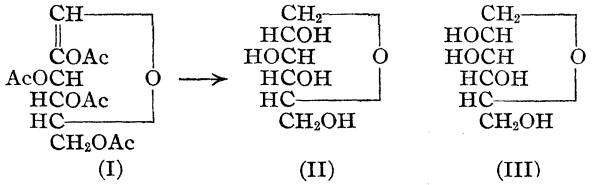
The Chemistry of Naturally Occurring Monoanhydrohexitols. II. Synthetic Tetramethylstyracitol[1]

BY WERNER FREUDENBERG AND JOHN T. SHEEHAN

In 1930 Zervas[2] reported the synthesis of styracitol, the naturally occurring monoanhydrohexitol in *styrax obassia*. Tetraacetyl oxyglucal (I) was hydrogenated and subsequently deacetylated to 1,5-anhydro-*d*-sorbitol (II) or 1,5-anhydro-*d*-mannitol (III) depending on whether a *cis* or a *trans* addition occurred at the double bond.



(I) (II) (III)

The synthetic material was identical with the natural product. The question, however, if styracitol should be classified as a sorbitol or a mannitol derivative was not answered.

In a recent publication from this Laboratory we[3] attempted to ascertain the configuration of styracitol by a comparison of the rates of oxidation with lead tetraacetate and by an application of the isorotation rules to styracitol and its isomer polygalitol. These two substances were assumed to be epimeric since they formed on oxidation the same anhydrofructosazone[4] and glucosazone.[5] On the basis of this assumption the experimental results favored the mannitol structure for styracitol and the sorbitol structure for polygalitol.

To establish definitely the configuration of styracitol as a sorbitol or mannitol derivative, it was deemed necessary to devise a synthesis of a derivative of styracitol starting with glucose or mannose wherein all asymmetric centers are protected and remain unaltered throughout the series

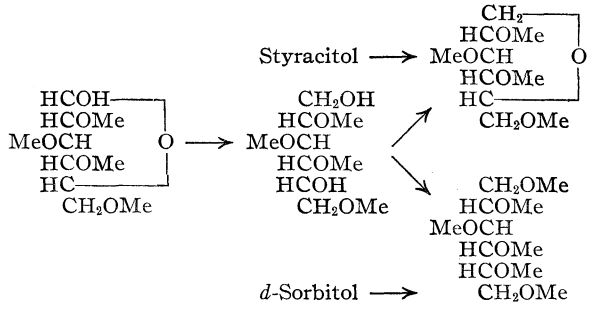
of reactions. The tetramethyl ether of styracitol was the derivative chosen. It was synthesized from tetramethyl-*d*-glucopyranose by reducing the latter and then dehydrating the 2,3,4,5-tetramethylsorbitol obtained. The dehydrated product agreed in every respect with that obtained by methylating the natural styracitol isolated from the shells of *styrax obassia*. Styracitol therefore has the configuration of 1,5-anhydro-*d*-sorbitol as originally announced by Zervas.

To exclude the possibility of tetramethylmannitol being formed in the hydrogenation of tetramethylglucopyranose, the reduction was carried out in a neutral medium at high pressure. Furthermore a portion of the product obtained was completely methylated and its properties compared with an authentic sample of hexamethylsorbitol. The two compounds were found to agree completely, indicating that the hydrogenation and methylation had no racemizing or epimerizing effects.



When tetramethyl-*d*-mannopyranose was used as a starting material and methylated and dehydrated as described for the glucose derivative with the hope of synthesizing tetramethylpolygalitol, which as mentioned above was thought to be the epimer of tetramethylstyracitol, the resulting synthetic tetramethyl ether was not identical with that obtained from the natural product but differed considerably in physical properties. The configuration of 1,5-anhydro-*d*-mannitol therefore is excluded for polygalitol, and the two naturally occurring anhydro polyhydric alcohols are not epimeric.

The methylated derivatives herein described, while useful as reference compounds in establishing the presence of furanose and pyranose rings, may find other uses as they are high boiling limpid liquids quite soluble both in organic and inorganic solvents.

Experimental

Styracitol.—This compound was isolated from *styrax obassia* according to the method described by Asahina,[6] melting at 155°, $[\alpha]^{23}D$ −49.4° (H_2O, c = 1.6).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.89; H, 7.37. Found: C, 43.90; H, 7.32.

Tetramethylstyracitol.—Ten grams of styracitol was methylated according to the method of West and Holden.[7] The product obtained was a limpid, colorless sirup which distilled at a bath temperature of 110° under 1.5 mm. pressure; $[\alpha]^{23}D$ −36.5° (no solvent), n^{25} 1.4520, d. 1.0849.

Anal. Calcd. for $C_{10}H_{20}O_5$: C, 54.54; H, 9.13; CH_3O, 56.31. Found: C, 54.62; H, 9.14; CH_3O, 56.72.

Tetramethylsorbitol.—A solution of 30 g. of tetramethylglucose in 75 cc. of water and 15 cc. of alcohol was reduced for seven hours at 135° under a pressure of 1300 pounds (85 atm.) of hydrogen in the presence of Raney nickel. The filtered solution was evaporated *in vacuo* to a clear sirup which did not reduce Fehling's solution. The sirup was purified by distillation at a bath temperature of 145° under 2 mm. pressure; $[\alpha]^{23}D$ +10.3° (EtOH, c = 6.3), $[\alpha]^{23}D$ +4.7° ($CHCl_3$, c = 10.5), n^{20} 1.4612.

Anal. Calcd. for $C_{10}H_{22}O_6$: C, 50.40; H, 9.32; CH_3O, 52.03. Found: C, 50.36; H, 9.36; CH_3O, 52.35.

Tetramethyl-1,5-anhydrosorbitol.—Fifteen grams of tetramethylsorbitol and 2 cc. of 13% sulfuric acid solution were heated *in vacuo* for half an hour at 140°. The solution was neutralized with 0.4 g. of anhydrous sodium carbonate after which a small amount of decolorizing charcoal and 50 cc. of ether were added. The solution was filtered and dried over anhydrous sodium sulfate. After filtering, the ether was removed leaving a sirup which distilled colorless at a bath temperature of 115° under 2 mm. pressure; $[\alpha]^{23}D$ −36.2° (no solvent), n^{25} 1.4518, d. 1.0876.

Anal. Calcd. for $C_{10}H_{20}O_5$: C, 54.54; H, 9.13; CH_3O, 56.31. Found: C, 54.29; H, 9.08; CH_3O, 56.58.

Hexamethylsorbitol.—Ten grams of tetramethylsorbitol was methylated according to the method of West and Holden. The product obtained was a colorless sirup which distilled at a bath temperature of 100° under 1.5 mm. pressure; $[\alpha]^{23.5}D$ 1.93° (no solvent), n^{22} 1.4370, d. 1.0476. For comparison 10 g. of sorbitol was methylated in the above fashion. The resulting product was found to distil at 100° under 1.5 mm. pressure; $[\alpha]^{24}D$ 1.97° (no solvent), n^{22} 1.4367, d. 1.0334.

Anal. Calcd. for $C_{12}H_{26}O_6$: C, 54.14; H, 9.77; CH_3O, 69.92. Found: C, 54.17; H, 9.75; CH_3O, 70.02 (product from tetramethylsorbitol); C, 54.07; H, 9.94; CH_3O, 69.80 (product from sorbitol).

Polygalitol.—This compound was isolated from *polygala amara*, according to the method described by Shinoda.[5] Briefly, the pulverized drug was repeatedly extracted with methyl alcohol and the extract, after the addition of water, neutralized with magnesia, filtered and the filtrate then taken to dryness in the air. The residue of dark brown gum was extracted with absolute methyl alcohol and the combined extract concentrated. Through the careful ad-

(6) Asahina, *Ber.*, **45**, 2365 (1912).
(7) West and Holden, THIS JOURNAL, **56**, 930 (1934).

dition of ether the bulk of the saponin present in the extract was removed. The filtrate was concentrated with removal of ether and, after standing a few days in the ice-box, crystals appeared. These were filtered off and recrystallized from methyl alcohol, forming colorless plates, melting at 142–143°; $[\alpha]^{21}D$ +42.0° (H_2O, c = 1.8).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.89; H, 7.37. Found: C, 43.95; H, 7.44.

Tetramethylpolygalitol.—Ten grams of polygalitol was methylated according to the method of West and Holden. The product obtained was a limpid, colorless sirup which distilled at a bath temperature of 80° under 2 mm. pressure; $[\alpha]^{23}D$ +67.67° (no solvent); n^{22} 1.4444, d. 1.0571.

Anal. Calcd. for $C_{10}H_{20}O_5$: C, 54.54; H, 9.13; CH_3O, 56.31. Found: C, 54.54; H, 9.10; CH_3O, 56.55.

Tetramethylmannitol.—A solution of 30 g. of tetramethylmannose in 75 cc. of water and 15 cc. of alcohol was reduced for seven hours at 135° under a pressure of 1300 pounds (85 atm.) of hydrogen in the presence of Raney nickel. The filtered solution was evaporated *in vacuo* to a clear, thick sirup which did not reduce Fehling's solution. The sirup was purified by distillation at a bath temperature of 150° under 2 mm. pressure; $[\alpha]^{21}D$ +20.7° (EtOH, c = 10.15), $[\alpha]^{21}D$ +17.5° ($CHCl_3$, c = 10.6), n^{24} 1.4605.

Anal. Calcd. for $C_{10}H_{22}O_6$: C, 50.40; H, 9.32; CH_3O, 52.03. Found: C, 50.34; H, 9.27; CH_3O, 52.38.

Tetramethyl-1,5-anhydromannitol.—Fifteen grams of tetramethylsorbitol and 2 cc. of 13% sulfuric acid solution were heated *in vacuo* for a half hour at 140°. The solution was neutralized with 0.4 g. of anhydrous sodium carbonate, after which a small amount of decolorizing charcoal and 50 cc. of ether were added. The solution was filtered and dried over anhydrous sodium sulfate. After filtering off the sodium sulfate, the ether was removed leaving a limpid sirup which distilled colorless at a bath temperature of 95° under 2 mm. pressure; $[\alpha]^{22}D$ +30.6° (no solvent), n^{22} 1.4479, density 1.0435.

Anal. Calcd. for $C_{10}H_{20}O_5$: C, 54.54; H, 9.13; CH_3O, 56.31. Found: C, 54.21; H, 9.03; CH_3O, 56.24.

Hexamethylmannitol.—Ten grams of tetramethylmannitol was methylated according to the method of West and Holden. The product obtained was a colorless sirup which distilled at a bath temperature of 95° under 2 mm. pressure; $[\alpha]^{22}D$ +12.53° (no solvent), $n^{21}D$ 1.4403, density 1.0458. For comparison 10 g. of isolated mannitol was methylated in the above fashion. The resulting product was found to distil at 97° under 2 mm. pressure; $[\alpha]^{22}D$ +12.46° (no solvent), $n^{21}D$ 1.4400, d. 1.0410.

Anal. Calcd. for $C_{12}H_{26}O_6$: C, 54.14; H, 9.77; CH_3O, 69.92. Found: C, 54.28; H, 9.58; CH_3O, 69.90 (product from tetramethylmannitol); C, 54.28; H, 9.79; CH_3O, 70.07 (product from mannitol).

Acknowledgments.—The authors wish to express their thanks to Dr. P. A. Levene for permission to carry out the high pressure reductions in his laboratory, to Prof. S. Takei for the styrax used, and to the Atlas Powder Co. for a sample of natural mannitol. The microanalyses were made by J. F. Alicino of this Laboratory.

Summary

Styracitol has been proved to be 1,5-anhydro-*d*-sorbitol by the synthesis of its tetramethyl derivative.

Polygalitol has been shown not to be 1,5-anhydro-*d*-mannitol.

A new method is described for establishing the presence of furanose and pyranose rings by preparing the corresponding methylated anhydro sugar alcohols.

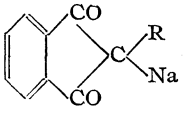
A Synthesis of Substituted α-Naphthoquinones

BY C. F. KOELSCH AND D. J. BYERS

The recent discovery that vitamin K is a substituted α-naphthoquinone adds importance to all reactions leading to substances of this class. The research described in the present paper is an investigation of a series of reactions by means of which 2-alkyl, 2-alkyl-3-hydroxy-, and 2-alkyl-3-carbalkoxy-α-naphthoquinones and hydroquinones can be prepared. The reactions may be formulated as

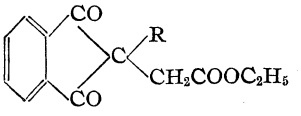
$$o\text{-}C_6H_4(COOC_2H_5)_2 + RCH_2COOC_2H_5 \xrightarrow{Na}$$



(1)

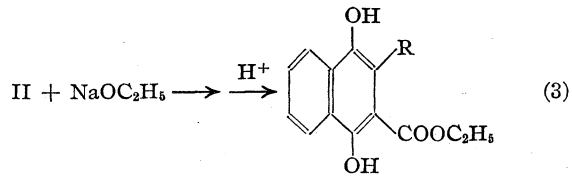
I

$$I + BrCH_2COO_2H_5 \longrightarrow$$



(2)

II



(3)

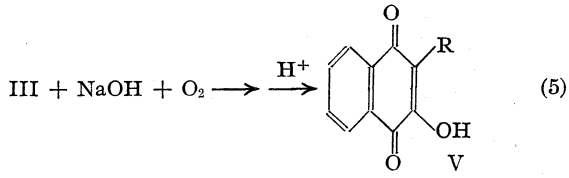
IV



(5)

V

Reaction (1) has been carried out previously by Wislicenus and Kötzle[1] for the case where R was methyl. In the present investigation it was carried out for the cases where R was methyl, ethyl, *n*-propyl and *n*-butyl.

Reaction (2) has been studied by Nathanson,[2] by Radulescu and Gheorgiu[3] and by Gheorgiu[4] for the cases where R was phenyl and methyl. In the present investigation the reaction was carried out for the cases where R was methyl, ethyl, *n*-propyl and *n*-butyl; the products in the latter two cases were not purified, but were used directly in reaction (3).

Reaction (3) was found to take place when R was phenyl by Radulescu and Gheorgiu,[3] and was later studied for the case where R was methyl by Gheorgiu.[5] The yield and the quality of the methyl quinone so obtained were reported to be inferior to those of the phenyl quinone prepared previously by the analogous method. The reaction was applied in the present research to the cases where R was methyl, ethyl, *n*-propyl and *n*-butyl, the expected hydroquinones being formed in fair yields.

The combination of reactions represented in (4) was believed feasible by analogy with the results of Nef[6] who showed that quinone acids lose carbon dioxide readily. It was carried out only in the case where R was ethyl, and yielded 77% of the theoretical amount of 2-ethylnaphthoquinone.

(5) Gheorgiu, *Compt. rend.*, **198**, 755 (1934).
(6) Nef, *Ber.*, **18**, 3496 (1885).

The reactions formulated in (5) were carried out in the cases where R was ethyl and *n*-butyl. They find an analogy in the work of Radulescu and Gheorgiu,[3] who discovered that when air was not excluded in the rearrangement of II (R = phenyl) to III, the product contained some 2-phenyl-3-hydroxynaphthoquinone.

Experimental

Since corresponding experiments involving compounds differing only in the size of the alkyl group R were quite similar, details are given for those only in which R was ethyl. Analytical data, yields, and melting points are given in Table I.

2-Ethylindanedione-1,3.—To a hot (115°) mixture of ethyl phthalate (55 g.) and sodium wire (10.5 g.) was added 30 g. of ethyl butyrate. Heating was continued for four hours; the mixture was then cooled and triturated with moist ether. The acidic products were removed by solution in dilute aqueous alkali. The quantity of dilute sulfuric acid necessary to precipitate all of the organic material was added in three portions, the mixture being extracted with ether after each addition. The third extract contained phthalic acid, while the diketone was in the first two. It distilled at 135–140° (7 mm.), and was recrystallized from benzene.

Ethyl 2-Ethylindanedionyl-2-acetate.—To a solution of the above diketone (13.6 g.) in absolute alcohol (25 ml.) was added a solution of potassium hydroxide (4.4 g.) in absolute alcohol (50 ml.) and then 13.0 g. of ethyl bromoacetate. The resulting mixture was boiled for two and one-half hours, distilled to a volume of 40 ml. and poured into water. The precipitated oil soon solidified and was then recrystallized from alcohol.

2 - Ethyl - 3 - carbethoxy - 1,4 - naphthohydroquinone.—The above diketo-ester (13.8 g.) was added to a solution of sodium (3 g.) in absolute alcohol (40 ml.) under a hydrogen atmosphere. The resulting reddish-brown solution was boiled for two hours, and then air-free water (50 ml.) was added through the condenser. The whole was poured into 600 ml. of air-free cold dilute sulfuric acid, and the precipitated pale yellow product was crystallized from alcohol.

2 - Ethyl - 3 - carbethoxy - 1,4 - naphthoquinone.—2-Ethyl-3-carbethoxynaphthohydroquinone was oxidized with chromic acid in cold acetic acid. The resulting yellow quinone was crystallized from a mixture of ether and petroleum ether.

2-Ethyl-3-hydroxy-1,4-naphthoquinone.—Sodium hydroxide (20 ml. of 1%) was added to 2-ethyl-3-carbethoxynaphthohydroquinone (1 g.) in warm alcohol (5 ml.). Air was bubbled through the solution at 50° for ten minutes, and then heating was continued for ten minutes without the air stream. The water solution was decanted from the yellow oil into cold dilute acetic acid, and the yellow product which separated was crystallized twice from alcohol.

2-Ethylnaphthoquinone.—A solution of 2-ethyl-3-carbethoxynaphthohydroquinone (1 g.) in 12 ml. of 5% sodium hydroxide containing 5 drops of alcohol was boiled under hydrogen for two hours. Acidification under hydrogen

p-Cymene Studies. IV. Mononitration of 2-Amino-*p*-cymene. Preparation of 3-Amino-*p*-cymene and *o*- and *p*-Cymylenediamine

BY THOMAS F. DOUMANI AND KENNETH A. KOBE

Of the three possible nitro-2-amino-*p*-cymenes, only one has been reported formed in the nitration of 2-amino-*p*-cymene liquid isomer obtained by Wheeler and Brooks.[1,2] We now find that the large amount of tarry by-product in this reaction consists almost exclusively of a solid isomer. Wheeler and Brooks claimed their liquid product to be 2-amino-5-nitro-*p*-cymene, which would make the solid product the 2-amino-3-nitro-*p*-cymene. In our investigation of these compounds the following proof is given that the liquid isomer (I) is 2-amino-3-nitro-*p*-cymene and the solid isomer (II) is 2-amino-5-nitro-*p*-cymene. Product I on reduction gave an unknown diamine in which the *ortho* position of the amino groups is proved by their ready condensation with benzil and phenanthraquinone, and by its conversion to a benzimidazole on heating with glacial acetic acid or atmospheric distillation of its diacetyl derivative. Product II when reduced to the diamine could be oxidized to thymoquinone.

The 2-acetamino-*p*-cymene is extremely diffi-

(1) Wheeler and Brooks, THIS JOURNAL, **49**, 2832–2834 (1927).
(2) Wheeler and Cutlar, *ibid.*, **49**, 2819–2822 (1927).

cult to purify for nitration purposes. Nitration of this acetyl derivative gave 52% 2-amino-3-nitro-*p*-cymene and 48% 2-amino-5-nitro-*p*-cymene. The nitration of 2-amino-*p*-cymene sulfate gave approximately 60% 2-amino-3-nitro-*p*-cymene and 40% 2-amino-5-nitro-*p*-cymene.

In this work 2-formylamino-*p*-cymene was used instead of the corresponding acetyl derivative, because of its ease of purification and subsequent ease of hydrolysis of the formyl groups from the isomeric nitroamines. Further, it gave the isomeric nitroamines in a practically pure state after fractionation, thus eliminating any purification through acyl derivatives. Nitration gave 70% of 2-amino-3-nitro-*p*-cymene and 30% of 2-amino-5-nitro-*p*-cymene.

Reduction of the nitroamines with zinc dust and sodium hydroxide gave the corresponding cymylenediamines in excellent yield. Statements as to the instability of *p*-cymylenediamine were found to be somewhat misleading. This compound was isolated in the pure state and found to deteriorate only very slowly in the presence of light. In aqueous ethanol solution this compound is more rapidly destroyed. The elaborate vacuum distillation apparatus employed by Wheeler and Bost[3] for the isolation of this diamine was found to be unnecessary.

Experimental[4,5]

2-Formylamino-*p*-cymene (I).—Nitration and reduction were carried out according to our published methods.[6] All *p*-toluidine was removed from the crude 2-amino-*p*-cymene by repeated fractionation *in vacuo*. A solution of 149 g. (1.0 mole) of 2-amino-*p*-cymene and 90 g. (1.76 moles) of formic acid (90%) was refluxed for two hours. (The excess of formic acid was used to prevent violent bumping.) The product after shaking with 300 ml. of water and cooling gave the formyl derivative as an oil which rapidly solidified. It was crystallized twice from ethanol, forming colorless needles of m. p. 108.8–109.4°. It is very soluble in cold concentrated sulfuric acid or chloroform, quite soluble in ether or acetone, slightly soluble in hot water, and practically insoluble in cold water.

Anal. Calcd. for $C_{11}H_{15}NO$: N, 7.90. Found: N, 7.95.

Nitration.—100 g. of I (0.565 mole) of m. p. 108.8–109.4° was dissolved in 400 g. of sulfuric acid (sp. gr. 1.84). To this solution at 0° was added drop by drop with stirring a previously cooled nitrating acid consisting of 56 g. (0.613 mole) of nitric acid (sp. gr. 1.42) and 100 g. of sulfuric acid (sp. gr. 1.84). After the addition of all the nitrating acid stirring was continued for ten minutes. The mixture was poured with efficient stirring into about 0.5 kg. of crushed ice in 0.5 kg. of water. The product was a yellow, sticky, amorphous mass which became hard and crystalline after several hours. It was filtered, washed with cold water and air dried. The filtrate was extracted with 50 ml. of chloroform and the latter evaporated; total yield, 113 g. (90%).

Hydrolysis.—The crude formyl-nitroamines (113 g.) were refluxed for one hour with 150 ml. of 30% sodium hydroxide solution. The red nitroamine layer was washed with water; the sodium hydroxide layer extracted with benzene (25 ml.), and the latter evaporated off; total yield, 98.2 g. (99%).

Separation of Isomeric Nitroamines.—The nitroamines (98.2 g.) were fractionated very slowly three times in a 150 ml. well-lagged Vigreux flask of 16-cm. column resulting in the following fractions: (1) 0.8 g. of a light yellow liquid of b. p. 65–67° (1 mm.); (2) 64.5 g. of an orange-red liquid of b. p. 114–116° (1 mm.); and (3) 26.6 g. of a yellow solid b. p. 144–148° (1 mm.), m. p. 57–60°. The residue in the flask was 4.5 g. At this low pressure superheating very easily occurs; consequently, to avoid this, fractionation must be executed slowly; approximately eight hours was used.

Fraction (1) was acetylated by refluxing with 5 ml. of acetic anhydride for one hour. The resulting product (after washing with water and refrigerating at 0°) remained liquid. It was boiled for one hour with 20 ml. of concentrated hydrochloric acid made alkaline with sodium hydroxide solution, and extracted with benzene. The free base was refluxed with 5 ml. of formic acid (90%) for one hour; it was crystallized once from ethanol and boiled with Norite in ethanol; m. p. 108.8–109.4° (mixed m. p. with authentic 2-formylamino-*p*-cymene was the same).

2-Amino-3-nitro-*p*-cymene (II).—Fraction (2), 64.5 g., was acetylated by refluxing with equivalent acetic anhydride for three hours. The product consisted of only one **acetylderivative,** as colorless needles of m. p. 167.6–167.8° from ethanol–ether mixture. It was crystallized by dissolving in ethanol, diluting with ether and cooling to 0°. A total of 65 g. of this acetyl derivative was isolated; the residue of crystallization amounted to 0.6 g. Thus the II taken for acetylation was practically pure.

Anal. Calcd. for $C_{12}H_{16}N_2O_3$: N, 11.86. Found: N, 11.82.

This acetyl derivative was hydrolyzed by refluxing with 100 ml. of concentrated hydrochloric acid for two hours. The mixture was made alkaline with sodium hydroxide solution and after washing with water was distilled. II is an orange-red liquid of sweet taste and of b. p. 142.9° (5 mm.), 158.8° (10 mm.), 175.6° (20 mm.) and at atmospheric pressure it is decomposed. The salts formed with hydrochloric, nitric, or sulfuric acid are all hydrolyzed by cold water.

Its **formyl derivative** was prepared by refluxing 5 g. of II with 10 g. of formic acid (90%) for five hours. (After

(3) Wheeler and Bost, THIS JOURNAL, **50**, 2000 (1928).

(4) All melting points are corrected and were determined using Brothcom total immersion thermometers graduated in 0.2° (immediately after crystallization and air drying); this was found to be necessary since many of the compounds, such as the acyl derivatives of the nitroamines, were found to be transformed upon standing into modifications which for some of the compounds have different melting points.

(5) Analyses for nitrogen by micro-Dumas using dry-ice as a source of pure carbon dioxide.

(6) Kobe and Doumani, *Ind. Eng. Chem.*, **31**, 257 (1939); Doumani and Kobe, *ibid.*, **31**, 264 (1939).

two hours refluxing there still remained unreacted amine.) It was crystallized from ethanol in colorless needles which soften at 128.0° and melt at 139.6–140.0°.

Anal. Calcd. for $C_{11}H_{14}N_2O_3$: N, 12.61. Found: N, 12.60.

Its **benzoyl derivative** was prepared by heating 5 g. of 2-amino-3-nitro-*p*-cymene with 10 g. of benzoyl chloride for five minutes at 90°. It crystallizes from ethanol as colorless needles of m. p. 193.4–193.8°.

Anal. Calcd. for $C_{17}H_{18}N_2O_3$: N, 9.39. Found: N. 9.33.

***o*-Cymylenediamine (III).**—Thirty-five grams of II, 35 ml. of ethanol, and 30 ml. of 30% sodium hydroxide solution was shaken with the addition of 50 g. of zinc dust in such portions that the solution gently refluxed. After the addition of all the zinc dust it was further refluxed for one hour giving a light brown solution. The excess zinc dust was filtered off in the hot, and the filtrate rapidly cooled, causing the diamine to crystallize out. (In alkaline solution upon standing in the presence of air this compound is slightly oxidized to a reddish dye very soluble in ethyl ether.) This *o*-diamine forms hard, well-defined, colorless, rhombic crystals from ethanol of m. p. 95.0–95.8°. It remains practically colorless on long standing in the presence of light. It is very soluble in acetone, ethyl ether, chloroform, or benzene, and practically insoluble in petroleum ether; yield 26 g. (88%).

Anal. Calcd. for $C_{10}H_{16}N_2$: N, 17.06. Found: N, 17.04.

***o*-Diacetylcymylenediamine (IV).**—Fifteen grams of III was dissolved in 30 ml. of acetic anhydride. The diacetyl derivative crystallized out upon cooling; colorless needles of constant m. p. 235.1–235.3° were obtained after one crystallization from ethanol. Refluxing 5 g. of III with 10 ml. of acetic anhydride for one hour gave a mixture of IV and the anhydro base (V).

Anal. Calcd. for $C_{14}H_{20}N_2O_2$: N, 11.28. Found: N, 11.23.

2,7-Dimethyl-4-isopropyl-benzimidazole (V). A.—Ten grams of IV was distilled at atmospheric pressure, b. p. 326–327° (uncor.). The distillate was crystallized by dissolving in the minimum volume of warm benzene and diluting with two volumes of warm petroleum ether. Upon cooling colorless crystals of m. p. 179.5–179.9° were obtained. This benzimidazole is very soluble in ethanol, ethyl ether, chloroform, or benzene, slightly soluble in hot water or petroleum ether, and practically insoluble in cold water. It readily forms salts with dilute hydrochloric, nitric, sulfuric, or acetic acid.

Anal. Calcd. for $C_{12}H_{16}N_2$: N, 14.88. Found: N, 14.81.

B.—2.5 g. of III was refluxed for one hour with 10 g. of glacial acetic acid. It was made alkaline with dilute sodium hydroxide solution, clarified by boiling with Norite in benzene, and recrystallized as in A, above. A mixed m. p. with the above compound in A was not depressed.

2,3-Diphenyl-5-isopropyl-8-methylquinoxaline.—3.3 g. of III, 4.2 g. of benzil, and 30 ml. of ethanol were refluxed together for fifteen minutes. The quinoxaline separated out and was recrystallized from benzene–ethanol mixture (1:2); colorless crystals, m. p. 136.7–137.3°. This compound gives a blood red coloration when treated with a drop of concentrated sulfuric acid; upon dilution, the color becomes yellow. Concentrated hydrochloric acid gives a yellow coloration.

Anal. Calcd. for $C_{24}H_{22}N_2$: N, 8.27. Found: N, 8.14.

10-Isopropyl-13-methyldibenzophenazine.—0.8 g. of III, 1 g. of phenanthraquinone, and 20 ml. of glacial acetic acid were refluxed for fifteen minutes. The product was insoluble and was crystallized from benzene as light yellow needles of m. p. 181.2–181.4°. This compound gives a purplish-red coloration when treated with a drop of concentrated sulfuric acid. Concentrated hydrochloric acid gives a yellow coloration.

Anal. Calcd. for $C_{24}H_{20}N_2$: N, 8.33. Found: N, 8.26.

2-Amino-5-nitro-*p*-cymene (VI).—Fraction (3), 26.6 g., was recrystallized from ethanol as canary yellow needles of m. p. 66.6–67.6°. A total of 24.8 g. of VI was isolated; only 1.1 g. of impure amine could not be purified in this manner; however, upon acetylation with acetic anhydride it proved to be the 2-acetamino-5-nitro-*p*-cymene. Thus, the 26.6 g. of nitroamine taken for crystallization was practically pure. Like II its salts with hydrochloric, nitric, or sulfuric acid are all hydrolyzed by cold water; unlike it, however, it is tasteless.

Anal. Calcd. for $C_{10}H_{14}N_2O_2$: N, 14.42. Found: N, 14.48.

The **acetyl derivative,** prepared by refluxing with equivalent acetic anhydride for three hours, was crystallized once from ethanol and boiled with Norite in ethanol, giving colorless needles of m. p. 142.8–143.2°.

Anal. Calcd. for $C_{12}H_{16}N_2O_3$: N, 11.86. Found: N, 11.81.

Its **formyl derivative** was prepared by refluxing 5 g. of the amine with 20 ml. of formic acid (90%) for four hours; yellow crystals from ethanol, m. p. 101.6–102.2°.

Anal. Calcd. for $C_{11}H_{14}N_2O_3$: N, 12.61. Found: N, 12.59.

Its **benzoyl derivative,** prepared by heating the amine with a 20% excess of benzoyl chloride at 90° for fifteen minutes, crystallized from ethanol as light yellow, monoclinic crystals of m. p. 139.0–139.4°.

Anal. Calcd. for $C_{17}H_{18}N_2O_3$: N, 9.39. Found: N, 9.42.

***p*-Cymylenediamine (VII).**—19.4 g. (0.1 mole) of VI dissolved in 50 ml. of ethanol was mixed with 25 ml. of 40% sodium hydroxide solution and treated with 30 g. of zinc dust in such portions that the solution gently refluxed when shaken. Refluxing was continued for one hour after the addition of all the zinc dust; the excess zinc dust was filtered off, the ethanol evaporated off, the brown amine layer separated from the caustic layer and the amine distilled, b. p. 120–125° (1 mm.) uncor. The colorless amine rapidly turned yellow. It was recrystallized by dissolving in the minimum benzene (1 vol.) in the hot, diluting with warm petroleum ether (2 vols.), and cooling, giving large yellow coarse crystals that rapidly turned brown; m. p. 50.0–50.5°; yield 14.1 g. (86%).

Anal. Calcd. for $C_{10}H_{16}N_2$: N, 17.06. Found: N, 17.01.

p-**Diacetylcymylenediamine.**—Two grams of VII was heated with 10 ml. of acetic anhydride at 90° for five minutes. Crystallization from benzene gave m. p. 262.0–262.2°.

Anal. Calcd. for $C_{14}H_{20}N_2O_2$: N, 11.28. Found: N, 11.27.

Thymoquinone.—Half a gram of finely crushed VII was shaken for five minutes with 50 ml. of 50% ferric chloride solution at room temperature. The thymoquinone was insoluble; it was filtered off and crystallized from petroleum ether; m. p. 45.6–46.0° mixed m. p. with thymoquinone[7] prepared from thymol was the same.

3-Nitro-*p*-cymene (**VIII**). A.—From II: 8 g. of powdered sodium nitrite was dissolved in 160 g. of sulfuric acid (sp. gr. 1.84) below 40°. Very slowly at 35–40° was added 20 g. of II to avoid the precipitation of the insoluble amine sulfate. Stirring was continued for fifteen minutes after which a drop when poured in water gave none of the colored nitroamine. To this mixture was slowly added 300 ml. of absolute ethanol with vigorous shaking; the resulting mixture was refluxed for one hour. Steam distillation gave some phenolic substance (removed by washing with dilute sodium hydroxide solution) and VIII; yield 9.7 g. (52%). VIII is a light yellow liquid of b. p. 116.7 (10 mm.), b. p. 133.5 (20 mm.), and at atmospheric pressure it is decomposed.

B.—From VI: 20 g. of VI was dissolved in 20 ml. of glacial acetic acid and diazotized exactly as in A. The product consisted mostly of a phenolic residue in the steam distillation flask. The yield of VIII was 2.3 g.

C.—Twenty grams of the mixture of isomeric nitroamines in the proportion as formed by the nitration of I was diazotized and treated as in A, with the further addition of 5 g. of freshly reduced copper as a suspension in the absolute ethanol; yield 9.8 g. (53%).

3-Amino-*p*-cymene (**IX**).—The VIII in A and B above, were separately reduced with iron powder and hydrochloric acid.[6] Both amines gave the same formyl derivative by refluxing with twice the volume of formic acid (90%) for two hours. **3-Formylamino-*p*-cymene** forms colorless needles from ethanol of m. p. 106.2–106.6°. There was a depression of the melting point when admixed with I.

Anal. Calcd. for $C_{11}H_{15}NO$: N, 7.90. Found: N, 7.83.

3-Amino-*p*-cymene is a colorless liquid of b. p. 105.7° (10 mm.), 122.1° (20 mm.), 240.2° (760 mm.).

Thymol.—Five grams of IX was dissolved in 50 ml. of 5% sulfuric acid and diazotized with the exact equivalent of sodium nitrite dissolved in 10 ml. of water. It was steam distilled, extracted with dilute sodium hydroxide, and acidified, giving thymol of m. p. 47–49° from petroleum ether. The m. p. was raised when mixed with synthetic thymol from *m*-cresol and isopropyl alcohol.

(7) Kremers, Wakeman, and Hixon, *Org. Syntheses*, **6**, 92 (1926).

Summary

1. Nitration of 2-formylamino-*p*-cymene gives 70% of 2-amino-3-nitro-*p*-cymene and 30% of 2-amino-5-nitro-*p*-cymene. Nitration of 2-acetylamino-*p*-cymene gives 52 and 48%, respectively, of the above nitroamines.

2. Quantitative separation of the isomeric nitroamines can be effected by fractionation *in vacuo*.

3. The isomeric cymylenediamines can be obtained in excellent yield from the nitroamines by reduction with zinc dust and sodium hydroxide solution.

4. The nitroamine that has previously been described as 2-amino-5-nitro-*p*-cymene has been proved to be 2-amino-3-nitro-*p*-cymene.

Alkaline Hydrolysis of Condensation Products of Hydantoin with Aldehydes[1]

BY HENRY R. HENZE, WILLIAM B. WHITNEY AND MARGARET A. EPPRIGHT

The condensation of aldehydes with the methylene hydrogens in —X—CH_2—CO— has been a valuable reaction for synthetic purposes following Perkin's[2] condensation of salicylic aldehyde and sodium acetate in the presence of acetic anhydride. This reaction has since been modified and widely applied. Plöchl and Wolfrum[3] were the first to employ it in connection with condensations involving the —NH—CH_2—CO— grouping. Initially, Plöchl used glycine but later he found that hippuric acid, the benzoyl derivative of glycine, gave much better results. Erlenmeyer[4] studied the chemical behavior of these condensation products of hippuric acid and obtained alpha amino acids by their reduction and *subsequent* hydrolysis.

Wheeler and Hoffman[5] further modified the

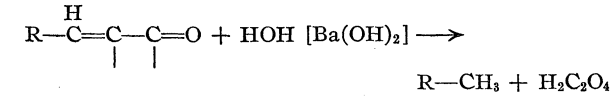
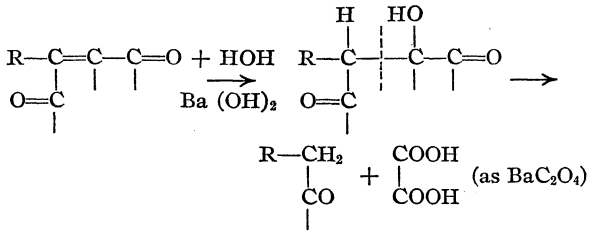
method by replacing hippuric acid with hydantoin, which contains the —NH—CH_2—CO— structure in a heterocycle. In only one instance, namely, that of anisalhydantoin, was the initial condensation product hydrolyzed by alkali *prior* to reduction, and Wheeler and Hoffman reported that "when it is boiled with alkali it gives *p*-methoxyphenylpyruvic acid." No details were recorded as to the yield and proof of identity of the latter, of the formation of by-products, or concerning the concentration and specific identity of the alkali used. Since either sodium hydroxide or barium hydroxide was utilized in hydrolyzing the reduced reaction products, it seems probable that one or the other of these bases was used in cleaving anisalhydantoin.

We have studied the effect of aqueous solutions of both sodium and barium hydroxide upon anisalhydantoin and believe that Wheeler and Hoffman utilized a dilute solution of barium hydroxide, for a 5% solution of sodium hydroxide liberates ammonia and forms some *p*-methoxyphenylpyruvic acid. However, some oxalic acid and *p*-methoxytoluene are formed, also. Concentrated solutions of either sodium or barium hydroxide when boiled with anisalhydantoin yield no *p*-methoxyphenylpyruvic acid; indeed, with barium hydroxide *p*-methoxytoluene and oxalate are the chief products although small amounts of anisaldehyde, anisyl alcohol and anisic acid are formed, too. It is of interest to note that concentrated solutions of either of these alkalies convert *p*-methoxyphenylpyruvic acid into oxalate and *p*-methoxytoluene.

The hydrolytic effect of barium hydroxide solution on *o*-chlorobenzalhydantoin, on *m*-nitrobenzalhydantoin, and on furfuralhydantoin has been studied. In each instance no substituted pyruvic acid was isolated; instead, the chief result was to convert the —CH= grouping into methyl.



The alkaline hydrolysis of these hydantoin condensation products is strictly analogous to the cleavage of the condensation products of hydantoin with isatin and 5-methylisatin reported by Henze and Blair[6] and for which the following mechanism had been proposed:



The essential steps in the mechanism of alkaline hydrolysis are: (a) the addition of a molecule of water to the ethylenic linkage in such a way that the HO— adds to the C atom of the hydantoin nucleus and the H— to the other C atom of the C=C linkage; (b) the double bond being saturated, the linkage between the two carbons breaks, either because of migration of a hydrogen atom in the reversal of enolization, or because of intermolecular change (bimolecular rather than monomolecular process).

Nicolet and Campbell,[7] as a result of a study of alkaline hydrolysis of benzalcreatinine (benzal-2-imino-1-methylhydantoin) and related compounds concluded that "It seems, however, to be well established that it is a matter of somewhat extreme difficulty to open the ring in any of the unreduced aldehyde condensation products of hydantoins by the action of alkali." That this statement is too broad is shown by the results of the present investigation.

Since *o*-chlorobenzalhydantoin and *m*-nitrobenzalhydantoin had not been synthesized previously, it was deemed desirable to reduce and hydrolyze the compounds in order to convert them into α-amino acids. By this process *o*-chlorophenylalanine and *m*-aminophenylalanine were obtained.

Experimental

Action of Sodium Hydroxide on Anisalhydantoin.—One gram of anisalhydantoin[5] was digested in 100 cc. of 5% sodium hydroxide solution for five hours at 80–90°; during this period ammonia was evolved and, in addition, the odor characteristic of *p*-methoxytoluene was detected in the reaction flask. The reaction mixture was neutralized with dilute hydrochloric acid causing the separation of a small amount of yellow solid. The latter did not contain nitrogen, and its solution in ethyl alcohol developed a fleeting blue-green color when treated with dilute, aqueous ferric chloride solution. A positive test for oxalate was obtained in the acid filtrate.

Action of Barium Hydroxide on Anisalhydantoin.—Thirty-five grams of anisalhydantoin, 300 g. of crystalline barium hydroxide and 400 cc. of water were digested under reflux in an oil-bath at 120–135° for one hundred hours.

(6) Henze and Blair, THIS JOURNAL, **55**, 4621 (1933).

(7) Nicolet and Campbell, THIS JOURNAL, **50**, 1155 (1928).

At intervals during the hydrolysis the cooling water was withdrawn from the condenser and distillation was permitted until a total volume of 150 cc. of distillate had been collected. The distillate was saturated with potassium carbonate and the oily layer was separated and dried. Upon distillation the product (7.5 cc.) proved to be a mixture, the chief constituent being *p*-methoxytoluene, b. p. 177.5–178°; d^{20}_4 0.9735; $n^{20}D$ 1.5140; M_R calcd. 37.19; M_R found, 37.73; a trace of anisic aldehyde was identified.

The mixture remaining after hydrolysis was cooled and filtered, the residue and filtrate being examined independently. The residue consisted largely of barium hydroxide and carbonate, but contained oxalate, also. The filtrate was treated with ether which served to extract 1 cc. of anisyl alcohol, b. p. 259° (cor.). From the filtrate upon acidification there separated 9 g. of curdy solid which was shown to be anisic acid, m. p. 184°; neutral equivalent 149 (in alcohol), 151 (in water); m. p. of mixture with authentic sample of anisic acid 184.5°; m. p. of mixture with *p*-methoxyphenylpyruvic acid showed a depression of twenty degrees.

Anal. Calcd. for $C_8H_8O_3$: C, 63.13; H, 5.30. Found: C, 63.50; H, 5.30.

Further confirmation of the identity of anisic acid was obtained by its conversion into the ethyl ester,[8] m. p. 7° (cor.); b. p. 264.5°; $n^{20}D$ 1.5238.

Converson of "Anisal-azlactone" [2-Phenyl-4-(*p*-methoxyphenyl)-oxazolone] into *p*-Methoxyphenylpyruvic Acid.—Following Dakin's[9] procedure, anisaldehyde was condensed with hippuric acid to form "anisal-azlactone," m. p. 158°. Fifty grams of the "azlactone" was heated for one hour with 750 cc. of 40% sodium hydroxide solution in an oil-bath at 110–115° following the directions of Wakeman and Dakin.[10] At the close of thirty minutes it was noticed that an oil, as well as water, was refluxing in the condenser; hence, during the next half hour distillation was permitted in order to collect the oily liquid. The reaction mixture was cooled and extracted with ether, the extract being combined with that of the distillate. After drying the extract over anhydrous potassium carbonate, and removing the ether, the residual liquid boiled at 177°; d^{20}_4 0.9702; $n^{20}D$ 1.5120; M_R calcd. for *p*-methoxytoluene, 37.19; M_R found, 37.74.

Continuing with the procedure 13 g. of *p*-methoxyphenylpyruvic acid,[11] melting at 185°, was obtained.

Action of Barium Hydroxide on *p*-Methoxyphenylpyruvic Acid.—Four grams of *p*-methoxyphenylpyruvic acid, 13 g. of crystalline barium hydroxide and 15 cc. of water were heated in an oil-bath for fifteen hours at 115–120°. The reaction mixture was subjected to steam distillation at intervals during the period of digestion. From the distillate there was isolated 0.8 cc. of an oil sparingly soluble in water. After drying over anhydrous potassium carbonate, the oil had b. p. 176.5°; d^{20}_4 0.9705; $n^{20}D$ 1.5130; hence, this product was *p*-methoxytoluene. Moreover, the presence of oxalate in the reaction mixture was established.

Action of Barium Hydroxide on Furfurylhydantoin.—Thirty grams of furfuralhydantoin, 320 g. of crystalline barium hydroxide and 350 cc. of water were digested under reflux in an oil-bath at 110–120° for sixty hours. After ten hours an oil, as well as water, was noticed in the condenser; therefore, the reaction mixture was subjected intermittently to steam distillation. From a total distillate of 500 cc. there separated 8 cc. of a yellow-green colored oil, sparingly soluble in and less dense than water, and of an aromatic odor strongly suggestive of the xylenes. After drying the oil was distilled and identified as being 2-methylfuran;[12] b. p. 63.2° (cor.); d^{20}_4 0.9032; $n^{20}D$ 1.4310; M_R calcd., 23.71; M_R found, 23.50. No organic matter other than oxalate was identified in the material remaining after hydrolysis.

Preparation of *o*-Chlorobenzalhydantoin.—*o*-Chlorobenzaldehyde (10 g.), hydantoin (10 g.), fused sodium acetate (8.2 g.) and glacial acetic acid (59 cc. to which 1 cc. of acetic anhydride had been added) were refluxed together for one hour in an oil-bath at 145°. Upon cooling some *o*-chlorobenzalhydantoin crystallized and additional material was obtained by dilution of the solution. The total yield of crude product was 10 g. (66%). After recrystallization from acetone and ethanol the silky needles melted at 275° (cor.). This derivative is soluble in glacial acetic acid, acetone and ethanol, but is nearly insoluble in water, ether and benzene.

Anal. Calcd. for $C_{10}H_7ClN_2O$: C, 53.94; H, 3.17; Cl, 15.92; N, 12.59. Found: C, 54.21; H, 3.36; Cl, 16.15; N, 12.87.

Action of Barium Hydroxide on *o*-Chlorobenzalhydantoin.—Ten grams of *o*-chlorobenzalhydantoin was refluxed with a mixture of 50 g. of barium hydroxide (octahydrate) and 50 cc. of water for fifty hours. The liquid refluxing in the condenser contained oily droplets; hence, the reaction mixture was steam distilled and the distillate extracted with ether. After drying and removal of the solvent, the residual liquid, by reason of the following data, was identified as being *o*-chlorotoluene: b. p. 155° (cor.); d^{20}_4 1.0890; $n^{20}D$ 1.5250; M_R calcd., 36.09; M_R found, 35.62.

Anal. Calcd. for C_7H_7Cl: Cl, 28.02. Found: Cl, 27.80.

Reduction of *o*-Chlorobenzalhydantoin.—Ten grams of *o*-chlorobenzalhydantoin, 45 g. of hydriodic acid (sp. gr. 1.7) and 10 cc. of glacial acetic acid were refluxed for two hours in an oil-bath at 120°. The solution was steam distilled until free from acid and cooled, thus causing the separation of 7.5 g. of white, crystalline solid material. The **5-(*o*-chlorobenzyl)-hydantoin** was recrystallized from glacial acetic acid in the form of white, glistening platelets melting at 240° (cor.).

Anal. Calcd. for $C_{10}H_9ClN_2O_2$: C, 53.45; H, 4.03; Cl, 15.79; N, 12.48. Found: C, 52.64; H, 3.77; Cl, 15.78; N, 12.09.

Hydrolysis of 5-(*o*-Chlorobenzyl)-hydantoin.—Ten grams of 5-(*o*-chlorobenzyl)-hydantoin, 50 g. of barium hydroxide (octahydrate) and 50 cc. of water were refluxed for about fifty hours. Most of the barium was removed

(8) Radcliffe and Brindley, *Perfumery Essentl. Oil Record*, **13**, 414 (1922), report m. p. 7–8°; b. p. 263°; $n^{18.5}D$ 1.5245.

(11) Wakeman and Dakin, ref. 10, report m. p. 190–192°, but Erlenmeyer and Wittenberg, *Ann.*, **337**, 294 (1904), report m. p. 186°.

(12) Paul, *Compt. rend.*, **200**, 1118 (1935).

from the solution by saturation with carbon dioxide, the remainder by exact neutralization with sulfuric acid. After filtration and concentration of the filtrate, 7.4 g. (88% yield) of white solid separated. After recrystallization from water and alcohol, **o-chlorophenylalanine** melts at 260–261° (cor.).

Anal. Calcd. for $C_9H_{10}ClNO_2$: C, 54.13; H, 5.05; Cl, 17.77; N, 7.02. Found: C, 55.14; H, 5.04; Cl, 17.30; N, 7.68.

Anhydrous hydrogen chloride was passed into an ethanol solution of *o*-chlorophenylalanine causing the separation of solid material. The latter was filtered, washed with a cold, saturated solution of hydrogen chloride in ethanol, and dried in a vacuum desiccator. The melting point of **o-chlorophenylalanine hydrochloride** is 255–256° (cor.).

Anal. Calcd. for $C_9H_{11}Cl_2N_2O_2$: Cl, 30.01. Found: Cl, 29.87.

Preparation of *m*-Nitrobenzalhydantoin.—Ten grams of hydantoin, 15 g. of *m*-nitrobenzaldehyde, 8.2 g. of fused sodium acetate, 60 cc. of glacial acetic acid and 2 cc. of acetic anhydride were heated together in an oil-bath at 145°; yellow solid material began to separate from solution after about three hours, but heating was continued for a total of eleven hours. Upon cooling and filtering, 14.5 g. (58% yield) of solid, with m. p. 250°, was obtained. After recrystallization from glacial acetic acid the bright yellow crystals of *m*-nitrobenzalhydantoin melted at 277° (cor.). This compound is quite sparingly soluble in all common solvents, the largest solubility being that (1.75–2 g./100 cc.) in boiling glacial acetic acid.

Anal. Calcd. for $C_{10}H_7N_3O_4$: C, 51.49; H, 3.03; N, 18.07. Found: C, 51.48; H, 3.18; N, 18.02.

Action of Barium Hydroxide on *m*-Nitrobenzalhydantoin.—Twenty grams of *m*-nitrobenzalhydantoin, 100 g. of barium hydroxide (octahydrate) and 100 cc. of water were placed in a distilling flask and heated in an oil-bath at 120° for about thirty hours. During this time a slow distillation occurred and oily droplets were collected in the receiver. After drying, the oil was identified as being *m*-nitrotoluene by its boiling point and refractive index.

The residue in the flask, to which water was added to replace that removed through distillation, was heated for an additional period of thirty hours before being examined for oxalate; the latter was present.

Reduction of *m*-Nitrobenzalhydantoin.—To 23.3 g. of *m*-nitrobenzalhydantoin were added 100 g. of tin and 500 cc. of concd. hydrochloric acid and the mixture was heated in an oil-bath for six hours at 120° while hydrogen chloride was passed into the well-stirred solution. The bright yellow crystals quickly changed to a flocculent light gray colored solid which dissolved after about five hours. The solution was concentrated, to remove much of the excess acid, diluted with water to adjust the *p*H, and saturated with hydrogen sulfide. After filtration and decolorization of the filtrate with Norite, further concentration in a vacuum desiccator over sulfuric acid caused separation of a crystalline solid. The latter was recrystallized from dilute hydrochloric acid and yielded the **hydrochloride of 5-(*m*-aminobenzyl)-hydantoin,** m. p. 270° (cor.). This salt is extremely soluble in water and alcohol, but is insoluble in acetone and ether.

Anal. Calcd. for $C_{10}H_{12}ClN_3O_2$: C, 49.68; H, 5.01; Cl, 14.67; N, 17.39. Found: C, 49.71; H, 5.27; Cl, 14.55; N, 17.11.

Action of Barium Hydroxide on 5-(*m*-Aminobenzyl)-hydantoin Hydrochloride.—The hydrolysis was accomplished in the usual manner with 17.5 g. of *m*-aminobenzylhydantoin, 87.5 g. of crystalline barium hydroxide and 87.5 cc. of water. The **dihydrochloride of *m*-aminophenylalanine,** m. p. 225° (cor.), was recrystallized from hydrochloric acid.

Anal. Calcd. for $C_9H_{14}Cl_2N_2O_2$: C, 42.69; H, 5.58; N, 11.06. Found: C, 43.02; H, 5.97; N, 11.29.

Summary

The behavior on alkaline hydrolysis of anisal-, furfural-, *o*-chlorobenzal-, and *m*-nitrobenzalhydantoin has been studied. The results are to be predicted on the basis of a mechanism advanced previously by Henze and Blair.

The Preparation and Degradation of Lithocholic Acid

BY WILLARD M. HOEHN AND HAROLD L. MASON

The importance of desoxycorticosterone as the most active of the crystalline substances thus far isolated from the adrenal gland makes it desirable to develop methods for its preparation. Stigmasterol[1] and cholesterol[2] have been used as raw materials for its preparation by several procedures. It is the purpose of this note to describe some improved procedures for the conversion of bile acids into materials suitable for the preparation of desoxycorticosterone and related substances.

The first step was the conversion of cholic and desoxycholic acids to lithocholic acid. This conversion has been accomplished by a number of procedures[3] but the over-all yields have not been encouraging. By the action of benzoyl chloride and pyridine on methyl desoxycholate at 15° the 3-monobenzoate was obtained in good yield. Oxidation to methyl 3-benzoxy-12-ketocholanate with chromic acid proceeded smoothly as did the subsequent preparation of the semicarbazone. The over-all yield of semicarbazone from methyl desoxycholate was more than 80%. Reduction of the semicarbazone by the Wolff–Kishner method yielded an average of 60% of recrystallized lithocholic acid.

The degradation of lithocholic acid by the Wieland–Barbier method was performed as previously described for desoxycholic acid.[4] Reindel and Niederlander[5] and Sawlewicz and Reichstein[6] have described similar degradations. The melting points and specific rotations of the compounds so obtained are given in Table I since some of these values are not recorded in the literature. Oxidation of the acetylated diphenylethylenes was performed at 45–50° because of their insolubility in acetic acid at 15°. The other procedures require no comment.

TABLE I

DEGRADATION PRODUCTS OF LITHOCHOLIC ACID

Compound	M. p. °C.	$[\alpha]^{25}_{5461}$	Formula	Calcd., % C	Calcd., % H	Found, % C	Found, % H
3-Acetoxy-*bis-nor*-cholanyldiphenylethylene	158–160	+75.5 (in $CHCl_3$)	$C_{38}H_{50}O_2$	84.71	9.36		
3-Acetoxypregnanyldiphenylethylene	150–152	+140 ± 3° (in $CHCl_3$)	$C_{37}H_{48}O_2$	84.61	9.22		
1,1-Diphenyl-methyl-(3-acetoxy-*etio*-cholanyl)-ethylene	158–160	+398 ± 2° (in $CHCl_3$)	$C_{36}H_{46}O_2$	84.65	9.08	84.73	9.31
Pregnanol-3(α)-one-20	148–149	+129 ± 3° (in alcohol)	$C_{21}H_{34}O_2$	79.19	10.76	78.85	10.74
21-Benzalpregnanolone	228–230	+181 ± 3° (in alcohol)	$C_{28}H_{38}O_2$	82.71	9.42	82.34	9.51
3-Acetoxy-*etio*-cholanic acid	226–229	+86.4 ± 3° (in alcohol)	$C_{22}H_{34}O_4$	72.87	9.46	72.70	9.33
etio-Lithocholic acid	270–272		$C_{20}H_{32}O_3$	74.96	10.07	74.51	10.06

Ozonolysis of 1,1-diphenyl-methyl-(3-acetoxy-*etio*-cholanyl)-ethylene[7] followed by hydrolysis gave pregnanol-3(α)-one-20.[8] Further degradation proceeded as with the corresponding ketone derived from desoxycholic acid. The benzal ketone was isolated and its properties were found to agree with those given by Marker and Wittle[9] who have recently used this procedure for the preparation of *etio*-cholanic acids from the pregnanolones. The preparation of dehydro-*etio*-lithocholic acid and 4-bromo-3-keto-*etio*-cholanic acid by the usual methods offered no difficulties.

Experimental Part

Methyl 3-Benzoxy-12-hydroxycholanate.—A solution of 32 g. (0.08 mole) of methyl desoxycholate in 150 cc. of dry benzene was cooled to 5°, 10 cc. of dry pyridine was added, and then 9.3 cc. (0.081 mole) of benzoyl chloride in 20 cc.

(1) Steiger and Reichstein, *Helv. Chim. Acta*, **20**, 1164 (1937).

(2) Serini, Logemann and Hildebrand, *Ber.*, **72**, 391 (1939).

(3) Recent papers are (a) Bergström and Haslewood, *J. Chem. Soc. London*, 540 (1939); (b) Dutcher and Wintersteiner, THIS JOURNAL, **61**, 1992 (1939).

(5) Reindel and Niederlander, *Ber.*, **68**, 1969 (1935).

(6) Sawlewicz and Reichstein, *Helv. Chim. Acta*, **20**, 949 (1937).

(7) The Referee has pointed out that we have fallen into error in our previous paper[4] in naming the diphenylethylenes derived from desoxycholic and homologous acids. *3,12-Diacetoxy-bis-nor-cholanyldiphenylethylene* is correct for the compound called 3,12-diacetoxy-*nor*-cholanyldiphenylethylene; *3,12-diacetoxypregnanyl*diphenylethylene (or *3,12-diacetoxy-ter-nor-cholanyldiphenylethylene*) instead of 3,12-diacetoxy-*bis-nor*-cholanyldiphenylethylene; and *1,1-diphenyl-methyl-(3,12-diacetoxy-etio-cholanyl)*-ethylene instead of 3,12-diacetoxy-*ter-nor*-cholanyldiphenylethylene. The names previously applied included one carbon atom in both the ethylene group and the cholanyl radical.

of dry benzene was added at such a rate that no rise in temperature occurred. The mixture was allowed to come to room temperature and to stand for three hours. The benzene solution was washed with three 100 cc. portions of 0.5 *N* hydrochloric acid, then with 0.2 *N* sodium hydroxide and finally with water. After removal of water with anhydrous sodium sulfate, the benzene was distilled in a vacuum. The glassy residue was dissolved by warming with 200 cc. of dry ether. The etherate of methyl 3-benzoxy-12-hydroxycholanate crystallized from the solution on standing. It was air-dried and then melted at 78–80° with frothing; yield, 87–89%.

Anal. Calcd. for $C_{32}H_{46}O_5 \cdot {}^1/_2C_4H_{10}O$: C, 74.55; H, 9.39. Found: C, 74.35; H, 9.36.

When two molar equivalents of benzoyl chloride and pyridine were used, the dibenzoate of methyl desoxycholate was obtained, m. p. 145–146°.

Methyl 3-Benzoxy-12-ketocholanate.—A solution of 44 g. (0.08 mole) of methyl 3-benzoxy-12-hydroxycholanate etherate in 70 cc. of acetic acid was evaporated in a vacuum to remove the ether, and the residue was dissolved in 400 cc. of glacial acetic acid. To this solution, cooled to 15°, was added 8 g. of chromic acid in 100 cc. of 90% acetic acid. The mixture stood overnight in the refrigerator and was worked up in the usual manner for the neutral product. This substance usually was not isolated. It can be crystallized in the icebox from a large volume of absolute alcohol and then melts at 94–95°.

Semicarbazone.—The crude keto ester was dissolved in 250 cc. of alcohol and a solution of 19 g. (0.17 mole) of semicarbazide hydrochloride and 15 g. of sodium acetate in 100 cc. of 80% alcohol was added. This mixture was refluxed for fourteen hours. The bulk of the semicarbazone separated during the refluxing and was removed by filtration of the hot solution. A second crop, obtained by cooling, was purified by boiling with water. The total yield, after drying at 110° for eight hours, was 43 g. (95% based on the etherate). It melted at 160–162° after recrystallization from alcohol.

Lithocholic Acid (1).—A mixture containing 45 g. of sodium and 43 g. (0.076 mole) of the semicarbazone in 400 cc. of absolute alcohol was heated in an autoclave at about 200° for seven hours. The reaction product was dissolved in hot water and acidified to congo red with dilute hydrochloric acid. The precipitated acid was washed on the filter with hot water, dried and crystallized from acetone. The yield of lithocholic acid (m. p. 183–185°; $[\alpha]^{25}D$ +34°; $[\alpha]^{25}_{5461}$ +39°) was 18.4 g. (64.6%).

Anal. Calcd. for $C_{24}H_{40}O_3$: C, 76.55; H, 10.71. Found: C, 76.36; H, 10.68.

Lithocholic Acid (2).—Seventy grams (0.110 mole) of the disemicarbazone of methyl 3-benzoxy-7,12-diketocholanate (prepared by procedures similar to those used for the preparation of the semicarbazone of methyl 3-benzoxy-12-ketocholanate) was added to a solution of 70 g. of sodium in 700 cc. of methyl alcohol and heated in an autoclave at 174 ± 5° for six hours. After solution of the reaction products in warm water the methyl alcohol was removed in a vacuum. The aqueous fraction was warmed until all solids were dissolved and was then poured with stirring into an excess of dilute hydrochloric acid. The precipitated acid, which was often somewhat gummy, was suspended in 0.8 *N* sodium hydroxide solution and heated to 40–50° on the water-bath. The sodium lithocholate which separated under these conditions was filtered out, resuspended in 1 *N* sodium hydroxide and again isolated. It was then dissolved in hot water and the solution was poured into a slight excess of dilute hydrochloric acid. The lithocholic acid was filtered off and washed well with water. Dried at 110° and crystallized from dry acetone, the yield was 25.9 g. (62.5%) of lithocholic acid (m. p. 183.5–185°).

Dehydro-*etio*-lithocholic Acid.—A solution of 390 mg. (0.00124 mole) of *etio*-lithocholic acid in 20 cc. of glacial acetic acid was cooled to 15° and 100 mg. of chromic acid in 1 cc. of 90% acetic acid was added. After one hour the excess of chromic acid was reduced with alcohol. The solvents were removed in a vacuum and the residue was extracted with 200 cc. of ether and 100 cc. of water. The ether layer was separated, washed with water until colorless and dried over anhydrous sodium sulfate. The acid, after crystallization from acetone, weighed 330 mg. (84%). Crystallization from benzene gave a product which melted at 246–248°. Marker and Wittle[9] report a melting point of 246–249° but no analytical figures are given.

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.49. Found: C, 75.46; H, 9.70.

4-Bromo-dehydro-*etio*-lithocholic Acid.—To a solution of 784 mg. (0.00246 mole) of dehydro-*etio*-lithocholic acid in 30 cc. of glacial acetic acid at 18° was added 6.3 cc. of 0.82 *N* bromine in glacial acetic acid solution. After standing ten minutes the solvents were removed in a vacuum. The residue was taken up in ethyl acetate from which crystallized 620 mg. (63.5%); m. p. 190–192°.

Anal. Calcd. for $C_{20}H_{29}O_3Br$: C, 60.45; H, 7.19. Found: C, 60.30; H, 7.40.

Summary

Lithocholic acid has been prepared from cholic and desoxycholic acids with an over-all yield of 50%. Some of the intermediate compounds of the Wolff–Kishner degradation of lithocholic acid have been described.

The Synthesis of the Sodium Salt of Tetradecamethylene Disulfonic Acid

BY GILBERT C. H. STONE

In a previous paper by the author,[1] a method for the synthesis of the sodium salts of alkane-α,ω-disulfonic acids by means of the Strecker reaction[2] was described. In each run the reaction had been followed by means of an argentometric titration of aliquot portions of the reaction mixture. And in each case the reaction was found to go to completion if given sufficient time. Table I gives the number of carbons in the alkane-α,ω-disulfonate and a rough estimate of the time for complete conversion.

TABLE I

Carbons	Time for complete conversion, hrs.
2	12
3	18
4	24
5	36
6	60
10	168

It can be inferred that for the preparation of higher members of this series, by means of the same method, an unduly long period of heating would be required. Reactions of this nature have been carried out successfully in short periods of time by using an autoclave to obtain high temperatures.[3,4,5] In order to obviate the use of the autoclave, which is inconvenient in the preparation of large quantities of material, other methods were sought.

A solvent in which both the initial materials are soluble was employed. The dibromide reacted with various simple sulfur-containing compounds yielding terminal carbon–sulfur linkages. In most cases such substances can be oxidized to the sulfonic acid stage. Because of the possibility of forming sulfides, which would yield sulfones upon oxidation, the synthesis of mercaptans was avoided. Preparation of a dithiocyanate met with no success. A dixanthate, however, could be made and oxidized to the sulfonic acid. The following synthesis of the sodium salt of tetradecamethylene disulfonic acid serves as an example of the method whereby the higher homologs of this series may be prepared.

Experimental Part

Tetradecamethylene Glycol.—This was prepared by means of the Grignard reaction from decamethylene dibromide[1] and ethylene oxide, by an adaptation of the method of Dreger.[6] After washing, drying and then vacuum distilling the crude glycol, the properties checked fairly well with those reported by P. Chuit.[7] The yield was 40% of the theoretical amount.

Tetradecamethylene Dibromide.—290 g. (1.26 moles) of the above glycol was treated with gaseous anhydrous hydrogen bromide according to the method of Ruhoff, Burnett and Reid.[8] The resulting dibromide, dissolved in twice its weight of ethylene chloride, was washed and then dried over calcium chloride. After decolorizing with Norite and then removing the solvent, the residue was distilled *in vacuo* and the fraction coming over at 172–175° under 2–3 mm. pressure was collected. The yield was 65% of the theoretical.

Anal. Calcd. for $C_{14}H_{28}Br_2$: C, 47.18; H, 7.93. Found: C, 47.60; H, 7.78.

Sodium Tetradecamethylene Disulfonate.—A solution of 402 g. (one mole) of tetradecamethylene dibromide in 2 liters of hot ethyl alcohol was added slowly to a solution of 480 g. (3 moles) of potassium ethylxanthate in 2 liters of ethanol. The mixture was refluxed with stirring for twenty-four hours. After completely removing the alcohol by distillation, the residual yellow liquid was dissolved in a minimum quantity of ether, well washed with water, and dried with calcium chloride. After removal of the ether, the residual yellow liquid was taken up in redistilled dioxane, and water added until a slight turbidity resulted; 2720 g. (17 moles) of bromine and 1000 ml. of water were added in alternate small portions with shaking. After several hours, excess bromine was removed on a steam-bath, and finally hydrogen bromide and other volatile substances were driven off under reduced pressure by repeated distillations. The liquid remaining was diluted with water and an aqueous solution of silver nitrate added until no more silver salts precipitated. The suspension was brought to a boil and filtered hot. In order to remove any of the silver disulfonate, which is soluble in hot water, from the silver bromide, the precipitate on the Buchner funnel was extracted repeatedly with boiling water. After combining the filtrates and evaporating down to incipient precipitation, the solution was allowed to cool. The silver salt was filtered off and washed with cold water. Further evaporation of the resulting filtrate gave another crop of crystals.

(6) Dreger, "Organic Syntheses," Coll. Vol. I, p. 299.
(7) Chuit, *Helv. Chim. Acta*, **9**, 264 (1926).
(8) Ruhoff, Burnett and Reid, THIS JOURNAL, **56**, 2784 (1934).

The silver disulfonate was suspended in water, and the silver removed as the sulfide. The yellowish brown filtrate was evaporated down to 2000 ml., exactly neutralized with sodium hydroxide, and concentrated to incipient crystallization. The sodium salt of tetradecamethylene disulfonic acid crystallized out in the ice-box overnight. Several crops of the salt were so obtained. The crystals were purified by dissolving them in a minimum of hot water and adding twice the volume of redistilled acetone. This process of purification was repeated five times. The resulting crystals were white with a slight grayish cast and were not very soluble in water. A solution of the salt was neutral to alizarin. Like the other sodium disulfonates,[1] it showed no tendency to hydrolyze. The yield was 54% of the theoretical.

Anal. Calcd. for $NaO_3S(CH_2)_{14}SO_3Na$: C, 41.76; H, 7.01; Na, 11.43. Found: C, 41.74; H, 6.99; Na, 11.48.

The author wishes to express his thanks to Prof. H. T. Clarke of Columbia University for his kind advice and help during the course of this work; and to Mr. W. Saschek for performing the analyses.

Summary

A method for the preparation and purification of the sodium salts of the higher members of the series of the alkane-α,ω-disulfonic acids has been described. Details were given in regard to the synthesis and properties of the sodium salt of tetradecamethylene disulfonic acid.

The Activity Coefficient of Thallous Iodate in Solutions of Alkane-α,ω-disulfonates

BY GILBERT C. H. STONE

The alkane-α,ω-dicarboxylic acids have been studied extensively by Gane and Ingold,[1] Greenspan,[2] and others, with the view of ascertaining the fine structure and dimensions of the aliphatic chain in such molecules. Their results, which indicate that the chain has a rigidly extended zigzag configuration, check well with X-ray data.[3,4,5] These compounds are weak acids, not completely dissociated in aqueous solution. They do not lend themselves to studies, such as activity coefficient measurements from solubility data, which are made on the basis of theories developed on the assumption of complete dissociation. Strong dibasic acids of similar structure would be necessary. With this in mind, a series of alkane-α,ω-disulfonic acids with from one to fourteen carbons were prepared by the author.[6,7] Titration curves of these acids indicated that they are at least as strong as sulfuric acid.

It was desired to determine the qualitative and, if possible, the quantitative effect which would be obtained by increasing the distance between the two strongly polar groups; and the saturated straight aliphatic chain seemed ideal as a separating medium, especially since its normal length and diameter are known. It was hoped that by increasing the distance of separation of these polar groups a point might be found where the molecule ceased to behave as bivalent or dibasic and perhaps functioned as two univalent ions. A study of this nature might throw some light on the structure of large-sized multicharged ions, such as the proteins, which behave as multivalent ions despite the relatively large distances which separate the charged groups.[8]

By taking advantage of the Debye–Hückel relationship

$$-\log \gamma_{\pm} = \frac{0.5056\sqrt{\mu}}{1 + a \times 0.3286 \times 10^{8}\sqrt{\mu}} \text{ at } 25°$$

and that $\log S/S_0 = -\log \gamma_{\pm}$, solubility measurements seemed one way of attacking the problem. The "a" value gives an estimate of the *average* ion parameter. While the *average* distance of closest approach might not be expected to check with the actual size of the alkane-α,ω-disulfonate ion, as other ions are present in the solution, nevertheless, since these other ions remain the same, qualitatively and quantitatively, throughout the series of measurements, the a value should increase as the chain length increases.

In the calculations of the ionic strength

$$\mu = \frac{1}{2}\Sigma m_i z_i^2$$

(1) Gane and Ingold, *J. Chem. Soc.*, 1594 (1928); 2267 (1928); 1691 (1929); 1375 (1930).

(2) Greenspan, *Chem. Rev.*, **12**, 339 (1933).

if the valence of the disulfonate ion is two, then for a molar solution, μ would be 3. On the other hand, if the ion were so long that it functioned as two moles of a univalent substance, μ would be 2. In other words, the tangent of the limiting law in the former case would be 0.5056, and in the latter case it would be 0.6193. With a decrease in the effective valency due to an increase in chain length, or increase in the separation of the charged groups, the tangents of the curves should be expected to increase. On the other hand, if the effective valency does not decrease and an effect is obtained due only to the increasing size of the molecule, the limiting tangent of the curve should remain the same, 0.5056, but the curves should diverge from this tangent to a greater and greater extent as the size of the ion increases.

Unfortunately, the solubility of the sodium salt of the alkane-α,ω-disulfonates reaches a maximum at the fourth or fifth carbon stage and then decreases rapidly. The salt of the fourteen carbon member of the series is just sufficiently soluble that these measurements could be made on it. To continue lengthening the chain in an attempt to achieve the above-mentioned effect seemed fruitless.

Experimental

The sodium salt of methanedisulfonic acid was prepared according to Schroeter.[9] The salt was recrystallized several times and the analysis checked with the theoretical values.

The synthesis and purification of the other sodium salts of the alkane-α,ω-disulfonic acids, as well as their titration curves, have been described.[6,7]

TABLE I

SOLUBILITY OF $TlIO_3$ IN THE PRESENCE OF SODIUM ALKANE α,ω-DISULFONATES

Soly. of $TlIO_3$ in water = S_0 = 1836 × 10^{-6} mole per liter at 25°

$$-\log \gamma_0 = \frac{0.5056\sqrt{0.001836}}{1 + 3 \times 10^{-8} \times 0.3286 \times 10^{8}\sqrt{0.001836}} = 0.0208^{b} \quad -\log \gamma_{\pm} = 0.0208 + \log S/S_0$$

[a] In the cases of the one carbon and the fourteen carbon sodium disulfonate solutions, a different sample of the saturating salt was used. An average of 30 solubility determinations on this thallous iodate resulted in S_0 = 1831 × 10^{-6} mole per liter. [b] An a value of 3 Å. was assumed for $TlIO_3$.

(9) Schroeter, *Ann.*, **418**, 246 (1918).

The preparation of thallous iodate and the method of analysis were those of La Mer and Goldman.[10]

Solutions of the sodium salts of the disulfonic acids were made up with conductivity water and of the strengths shown in Table I. These solutions were rotated with the solid thallous iodate in glass-stoppered Pyrex bottles in a water-bath for twenty-four hours at a temperature of 25.00 ± 0.01°. The solid was allowed to settle and the supernatant solution filtered at 25.0° and then analyzed.

Discussion

From Curve I, which is a plot of the data given in Table I, it can be seen that despite the lengthening of the aliphatic chain or the greater separation of the sulfonate groups, all the curves approach the same theoretical limiting tangent of 0.5056. However, these curves deviate from the limiting tangent more and more as the chain length increases. This would indicate that the sodium salts of the alkane-α,ω-disulfonic acids behaved in solution as bivalent compounds, there being no indication in these experiments that even with a separation of fourteen carbons the two terminal negative groups ceased to have an effect upon each other.

(10) La Mer and Goldman, THIS JOURNAL, **51**, 2632 (1929).

The continuous deviation of the curves from the theoretical limiting tangent with increasing chain lengths may be attributed to the increasing size of the ion involved. As can be seen from the table of data, the average distance of closest approach becomes greater as the chain becomes longer. These values of a were calculated by means of the La Mer, Gronwall and Greiff extended formula of the Debye–Hückel relationship.[11] The calculated values of a for any one series of measurements on any one disulfonate do not vary very much. As might be expected, the values obtained for a on the most dilute solutions showed the greatest deviation from the average; in these cases the accuracy of the measurements was at its lowest.

An attempt was made to correlate the average values of a with an increase in one CH_2 group. Approximately 0.25 Å. corresponded to the size of the methylene group. This value is far from that obtained by measurements of other kinds. However, the a values calculated on the basis of the Debye–Hückel equation do not check well with, for example, the size of the ion found by X-ray measurements. The value of a is not the absolute size of the ion, but the distance of nearest approach. Hydration, the presence of other ions, etc., will affect this value greatly.

Notwithstanding all this, the effect of separating the two charged groups of the ion is not as great as one might have expected. However, the long disulfonate ion, with a negative charge at either end, in all likelihood would bend around in the presence of an ion of opposite charge, both negative groups being attracted by the positive ion. Such a bending would greatly decrease the effective size of the disulfonate ion and account for the results obtained. This bending would not take place in the solid state nor in the case of the corresponding dicarboxylic acids, which are not greatly dissociated. Such a distortion would also explain why, even with a distance equivalent to fourteen carbon atoms between two charged groups, the bivalent disulfonate ion shows no unusual effect and behaves like a small ion of equal charge.

The author wishes to express his gratitude to Professor H. T. Clarke of Columbia University for his kind help and coöperation in the work on this problem.

(11) La Mer, Gronwall and Greiff, *J. Phys. Chem.*, **35**, 2245 (1931).

Summary

The solubility of thallous iodate was measured at 25° in aqueous solutions of the sodium salt of alkane-α,ω-disulfonic acids with from one to fourteen carbons in the separating chain. The results were considered on the basis of the Debye–Hückel equation.

All of the above-mentioned salts functioned as bivalent compounds, despite the great separation of the sulfonate groups in the case of the latter members of the series.

The values for the mean effective ionic diameters were calculated for each salt of the series of the alkane-α,ω-disulfonates. These values increased with increasing chain length. However, this increase in effective size was equivalent to only 0.25 Å. for each additional CH_2 group in the chain.

The small increment in effective size due to the addition of a methylene group to the aliphatic chain, as well as the bivalency of the disulfonate ion, was accounted for on the assumption that the molecule bent in the presence of a positive ion, both negative groups of the disulfonate ion being attracted to the oppositely charged particle.

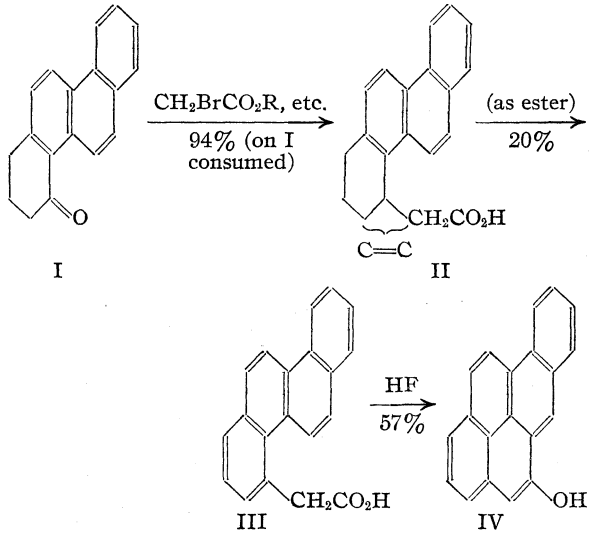
Synthesis of 6-Hydroxy-3,4-benzpyrene and 8-Isopropyl-1,2-benzanthracene from 9,10-Dihydrophenanthrene

BY LOUIS F. FIESER AND WILLIAM S. JOHNSON

In extension of previous work[1] in which a satisfactory method was developed for obtaining 4-keto-1,2,3,4-tetrahydrochrysene (I) starting with 9,10-dihydrophenanthrene,[1b] this ketone has been utilized for the synthesis of the hitherto undescribed 6-hydroxy-3,4-benzpyrene (IV) by the process outlined.



I II III IV

The Reformatsky reaction at first seemed unpromising because of the separation of an insoluble complex which stopped the reaction. While no way was found for pushing the reaction to completion, it proved quite satisfactory to operate under mild conditions permitting the easy recovery of the unchanged starting material in a pure form after saponification of the ester. After dehydration with formic acid, the crude acidic product, possibly consisting of a mixture of isomers, was esterified and the ester dehydrogenated with sulfur, which gave better results than palladium charcoal. The product was contaminated with a small amount of high melting material which appeared to be a hydrocarbon, but this was separated easily after saponification of the ester.

Cyclization of 4-chryseneacetic acid (III) proceeded well under the influence of anhydrous hydrogen fluoride[2] giving pure 6-hydroxy-3,4-benzpyrene (IV) in good yield. It seemed interesting to determine whether an intermediate ketone could be detected, for in the formation of anthrones by cyclization, the use of hydrogen fluoride provides a particularly advantageous means of isolating the material in the ketonic condition and avoiding enolization. Even with highly sensitive anthrones which have not been isolated as such, it has been possible to effect a Grignard addition by adding the reagent directly to the crude residue remaining after evaporation of the hydrogen fluoride.[2b,3] This technique was applied in the present case and the mixture examined care-

(1) Fieser and Johnson, (a) THIS JOURNAL, **61**, 168 (1939); (b) *ibid.*, **61**, 1647 (1939).

fully for the presence of a carbinol or hydrocarbon. Aside from a trace of fluorescent material, no such product was found and it is concluded that the intermediate has no appreciable stability in the ketonic form.

Another series of synthetic experiments afforded 8-isopropyl-1,2-benzanthracene, desired as a further member of the series described[1] and for comparison with the carcinogenic 6-isopropyl compound[4] and with the 7[4]-(inactive) and 5[5]-isomers. The 8-keto-3,4,5,6,7,8-hexahydro-1,2-benzanthracene required as starting material was obtained from γ-(9,10-dihydro-2-phenanthryl)-butyric acid by cyclization with hydrogen fluoride in 89.5% yield (pure). A careful investigation of other cyclization methods was previously reported[1a] and the yields of pure ketone may be summarized for comparison: 85% sulfuric acid, 22%; zinc chloride and acetic acid-anhydride, 45%; phosphorus pentachloride-aluminum chloride, 63.5%. The ketone reacted satisfactorily with isopropylmagnesium bromide, giving after dehydration a hydrocarbon mixture which was dehydrogenated successfully with sulfur at 250°. Pure 8-isopropyl-1,2-benzanthracene was isolated through the picrate in 35% yield in the dehydrogenation step. It has been observed that an isopropyl group is eliminated from the 5[6]- and 10[7]-positions in dehydrogenations conducted with selenium but that a 10-isopropyl[7] or a 4-methyl[8] group can be retained at least in part by the use of sulfur.

Experimental Part[9]

4-Chryseneacetic Acid (III).—The Reformatsky condensation of methyl bromoacetate with 4-keto-1,2,3,4-tetrahydrochrysene[1b] (I) under a variety of conditions was subject to the difficulty that a sparingly soluble zinc complex separated as an oil which coated the zinc and stopped the reaction. Expedients tried with little success included vigorous stirring, the use of various special solvents, and suspension of the zinc in a basket to keep it away from the walls of the vessel. After numerous trials it was found most satisfactory to allow the reaction to proceed to a stopping point under moderate conditions and work up the mixture in such a way as to recover unchanged starting material in a pure condition.

Highly active metal for the reaction was prepared by immersing 30-mesh zinc in hot (100°) concentrated sulfuric acid containing a few drops of concentrated nitric acid. There was little evident reaction except that after about fifteen minutes the zinc surface became very bright. The acid was largely decanted and water added; a vigorous reaction with the dilute acid was allowed to proceed for a few minutes and the metal was then collected, washed thoroughly with water and then with acetone, and dried.

In a typical run 4 g. of activated zinc was added to a solution of 2 g. of the ketone (I) and 1.2 cc. of methyl bromoacetate in 40 cc. of dry benzene. The mixture was heated in a water-bath almost to boiling and a crystal of iodine was introduced, when the reaction promptly started and soon became vigorous. After heating for one hour the zinc had become completely coated over with oily complex, the mixture was cooled, enough methanol was added to dissolve the oil, and the solution was decanted from the metal, shaken with 10% hydrochloric acid, water, and saturated salt solution, and filtered through sodium sulfate. After removal of the solvent, the residual oil was boiled for fifteen minutes with excess 1 *N* alcoholic potassium hydroxide; water was added to the hot solution to the point of incipient cloudiness and on cooling 1.0 g. of unchanged ketone of good quality crystallized. Acidification of the alkaline liquor brought down a dark amorphous product which lost no weight when heated with anhydrous formic acid and which therefore was already in a dehydrated condition; yield 1.1 g. (94%, based on ketone consumed).

A solution of 1.7 g. of the crude acid in 250 cc. of methanol was saturated in the cold with hydrogen chloride, refluxed for twelve hours, diluted and extracted with ether. Vacuum distillation gave 1.44 g. of the ester as a yellow oil; this was heated with 0.18 g. of sulfur for two hours at 210°, and after heating with a pinch of zinc dust for five minutes, the product was distilled in vacuum. The distillate was dissolved in hot acetone–methanol and the solution filtered from about 80 mg. of high melting, unsaponifiable material (chrysene?). On cooling, 0.59 g. of product separated as glistening prisms (m. p. 109–111°) consisting of methyl 4-chryseneacetate contaminated with some of the above by-product. This was readily removed after saponification with 0.22 g. of potassium hydroxide in 7 cc. of boiling alcohol. The potassium salt of the chryseneacetic acid separated on cooling as glistening blades and was obtained colorless by washing with acetone. The salt dissolved readily in water and after filtration from a trace of the high-melting solid 4-chryseneacetic acid was precipitated in a high state of purity, m. p. 206.5–207.5°; yield 0.34 g. (20.1%, based on the crude unsaturated acid). A sample, crystallized once from benzene–acetone, formed colorless needles, m. p. 207–208°.

Anal.[10] Calcd. for $C_{20}H_{14}O_2$: C, 83.89; H, 4.93. Found: C, 84.12; H, 5.00.

From a number of variations tried in the dehydrogenation step it appeared that the reaction with sulfur proceeded better at the temperature specified than at higher or lower temperatures. With palladium charcoal the higher temperature required seemed to favor the formation of the high melting by-product and the yield was lower.

6-Hydroxy-3,4-benzpyrene (IV).—The following experiment was designed to detect any ketonic material

resulting from the cyclization of 4-chryseneacetic acid. Three-tenths gram of the acid was treated with 20 g. of chilled liquid hydrogen fluoride in a platinum cylinder and after thirty minutes the excess reagent was removed in a stream of air and the chilled residue was treated with the Grignard reagent from 1.5 g. of magnesium and excess methyl chloride. After three hours the mixture was worked up as usual, giving a yellow, highly fluorescent ethereal solution. Evaporation left a solid residue which was sublimed at 150–155° and 0.001 mm. Sublimation occurred rapidly at first and then stopped, apparently because of encrustation of the residual solid, but after dissolving this in ether and evaporating to dryness, a further sublimate was obtained. The operation was repeated once more and the combined sublimate was crystallized from toluene, giving 0.16 g. (57%) of light yellow needles, m. p. 193–194°, decompn. Recrystallization raised the m. p. to 195–196°, decompn.

Anal.[10] Calcd. for $C_{20}H_{12}O$: C, 89.53; H, 4.51. Found: C, 89.12; H, 4.56.

The substance couples readily with diazotized *p*-nitroaniline to give a sparingly soluble, red azo compound. Like 4'-hydroxy-3,4-benzpyrene,[11] the phenol gives a red color in concentrated sulfuric acid and on adding a drop of concentrated nitric acid the solution acquires a transient green color changing to deep blue.

In search of a possible hydrocarbon the mother liquors were combined with the residue from the sublimation and submitted to chromatographic adsorption, but only a trace of fluorescent material could be washed through the tower with benzene and this was not identified.

8-Keto-3,4,5,6,7,8-hexahydro-1,2-benzanthracene.—γ-(9,10-Dihydro-2-phenanthryl)-butyric acid (7.1 g.) was treated with hydrogen fluoride (100 g.) at room temperature for two hours, the reagent was largely removed with a stream of air and the residue neutralized with sodium carbonate solution and extracted with benzene. No unchanged acid was detected and distillation in vacuum gave 6.2 g. (94%) of nearly colorless ketone. One crystallization from ligroin yielded 5.92 g. (89.5%) of colorless prisms, m. p. 89.5–90.5°, remelting at 96.5–97.5° (see ref. 1a).

8-Isopropyl-1,2-benzanthracene.—A benzene solution of 3 g. of the above ketone was added to a stirred solution of the Grignard reagent from 3 g. of magnesium and 15 g. of isopropyl bromide (transient red color). After refluxing for two hours and standing overnight, the product was worked up in the usual way and heated at 220° for several minutes to effect dehydration and distilled in vacuum from a small amount of high boiling residue. The pale yellow distillate (2.56 g.) when treated with petroleum ether gave 0.73 g. of crystallizate, consisting of pure starting ketone. The hydrocarbon fraction recovered from the mother liquor was an oil amounting to 1.83 g. (73.5%, based on ketone consumed). A mixture of 1.47 g. of the crude material and 0.34 g. of sulfur was heated at 205–250° for forty-five minutes, when the evolution of hydrogen sulfide had practically ceased, heated with a pinch of zinc dust, and distilled. The distillate, which partially solidified, was clarified by passage through an alumina tower in benzene solution and treated with 1.5 g. of picric acid in alcohol solution. One recrystallization from alcohol gave 0.94 g. (35%) of the **picrate** as shiny red blades, m. p. 151–153°. After three recrystallizations, a sample melted at 155.5–156.5°.

Anal.[12] Calcd. for $C_{21}H_{18}\cdot C_6H_3O_7N_3$: N, 8.41. Found: N, 8.38.

Filtration of a benzene solution of 0.6 g. of the picrate through an alumina tower gave a yellow solution fluorescent in ultraviolet light. Crystallization of the hydrocarbon from alcohol gave 0.27 g. (83.5%) of glistening yellow prisms, m. p. 95–97.5°. Recrystallized from petroleum ether, the compound melted at 97–98°.

Anal.[12] Calcd. for $C_{21}H_{18}$: C, 93.29; H, 6.71. Found: C, 93.32; H, 6.74.

Summary

4-Keto-1,2,3,4-tetrahydrochrysene has been converted by Reformatsky reaction and dehydrogenation into 4-chryseneacetic acid and the latter cyclized with hydrogen fluoride to 6-hydroxy-3,4-benzpyrene.

8-Isopropyl-1,2-benzanthracene was synthesized by a process requiring a dehydrogenation in the last step; this was accomplished successfully with sulfur without loss of the alkyl group.

Aryl Isothiocyanates and Ethyl Acetonedicarboxylate

BY DAVID E. WORRALL

It has been shown[1] that a piperidone is obtained by the action of *p*-tolyl isothiocyanate on ethyl acetonedicarboxylate. The product, which is readily methylated, may be converted into a benzothiazole derivative through the action of bromine. These reactions have been studied with phenyl isothiocyanate itself and some of the more common derivatives.

Experimental

To 0.1 g. mole of pulverized sodium suspended in ether was added 0.05 g. mole of the ester and then a similar amount of the isothiocyanate. After several hours the mixture, dissolved in water containing crushed ice, was carefully decomposed by addition to cold dilute hydrochloric acid. The pasty product using hot alcohol or alcohol–benzene mixture yielded yellow plates and prismatic needles varying in amount from 3–8 g. All melted with decomposition. Tars were obtained with *o*-tolyl and *β*-naphthyl isothiocyanates. Prepared by short heating with methyl iodide in alcohol solution the sulfomethoxy derivatives separated as bright yellow slender needles. The benzothiazoles, yellow crystalline powders precipitated from glacial acetic acid solution by the action of bromine, were thoroughly washed with alcohol and used directly for analysis. They may be crystallized from aniline. The melting points were too high to be recorded with a sulfuric acid-bath.

Summary

Several piperidones have been prepared by the interaction of representative aryl isothiocyanates with ethyl acetonedicarboxylate. The corresponding sulfomethoxy and benzothiazole derivatives were synthesized.

The Ternary System: Isopropyl Alcohol, Toluene and Water at 25°

BY E. ROGER WASHBURN AND ALBERT E. BEGUIN[1]

Continuing a series of previously described investigations[2] of similar systems, solubility and distribution studies have been carried out with the system isopropyl alcohol, toluene and water at 25.0°.

Materials.—Carefully purified water was used. It was prepared by the partial condensation of steam from an alkaline permanganate solution.

The toluene was the better of the two grades obtainable from the Eastman Kodak Company. As efforts to purify this material further failed to alter its physical constants it was used as received. The specific gravity d^{25}_4 was 1.4938.

The isopropyl alcohol, from Eastman Kodak Company, was refluxed for many hours with fresh lime. It was then distilled into a carefully dried all glass still from which it was fractionally distilled. The middle portion of the distillate, boiling from 81.7 to 81.9° was used. It had a specific gravity d^{25}_4 of 0.78087 and a refractive index n^{25}_D of 1.3748.

Procedure and Results.—The details of the experimental work which seem to different workers to be most suitable for different ternary systems differ so that it is hardly possible to state that one system was studied by a previously described procedure and give an entirely truthful impression. The procedure followed in this investigation was like that described previously[3] with the following modifications. The titrations were carried out at 25.0° in small Erlenmeyer flasks which were shaken mechanically in the constant temperature bath except when additions of water or toluene were made from weight pipets. The values obtained with toluene as a titrant agreed with those obtained with water as the added liquid as closely as the water titrations agreed with each other. Preliminary titrations were carried out with materials not of the highest purity so that in the final titrations dropwise addition of all but the last few tenths of a gram of titrant was avoided.

The appearance of the end-point varied with different proportions of alcohol and toluene in the liquid titrated. At the lower end of the water rich part of the binodal curve relatively large droplets of the second phase appeared at the end-point; both phases appeared perfectly clear even after separation. As points further up on the curve were determined the droplets of the toluene rich phase separating out at the end-point became smaller and smaller until at an alcohol concentration of about 35% the mixture had the appearance of a fine mist. Above about 43% alcohol across the top of the curve and down to about 42% alcohol on the toluene rich side a still finer state of subdivision, a "milkiness," appeared at the end-point. In this region the first indication that the end-point was being approached was an opalescence, probably like that noted on cooling certain two component systems just before they separate into two liquid phases at the critical temperature. The remainder of the toluene rich side presented end-points similar to those on the lower part of the water rich side.

The end-points consisting of droplets and mists were easily observed by looking through the solution at a light bulb behind the bath. The "milky appearing" end-points were studied by light reflected from smooth black background suspended back of the titration flask. It was necessary to have the water-bath filled with very clear water when these titrations were carried out.

A special technique was developed in order to obtain reproducible results for the extreme lower ends of the solubility curve or more particularly for the important first and last parts of the refractive index–concentration curves used for the analysis. Flasks presenting a very small air space were employed since the amount of titrant used to saturate the air was important. The amounts of the first two liquids added to the small flasks were determined by weight, and the third liquid was added drop by drop from a fine pipet. The weight was determined from the number of drops added. The flask was carefully stoppered and if after about an hour the third liquid had all dissolved the process was repeated with one more drop of titrant.

The refractive indices of these saturated solu-

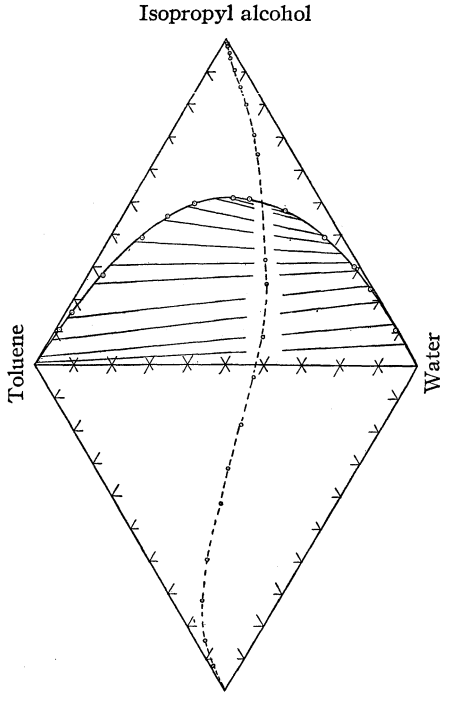

Fig. 1.

The tie lines were determined by adding varying amounts of alcohol to two liquid phase water–toluene mixtures. The amounts of alcohol were kept below that necessary to bring about complete miscibility. The mixtures were shaken from time to time during the twenty-four hours they were kept in the constant temperature bath. The deep but narrow flasks used for this work were constructed from 25-mm. test-tubes and 6-mm. glass tubes fitted with glass stoppers. The refractive index of each of the layers in the equilibrum mixture was determined. The concentration of these solutions was then read from large curves obtained by plotting refractive index against concentration for each of the three components in the saturated solutions. The fact that the sum of the percentages of the three components in each of the layers equaled 100.0 ± 0.1 indicates something of the precision of the analysis. Similar precision by these methods is not possible in several of the ternary systems that we have studied. Typical values are given in Table II and the marked values are used in locating the tie lines and the conjugation curve in Fig. 1. The intersection of the conjugation curve with the solubility curve locates the plait point.

If the solubility curve for this system is compared with those for the systems containing methyl alcohol[4] and ethyl alcohol[2] in place of isopropyl alcohol, certain interesting differences will be observed. The isopropyl alcohol is the most efficient and the methyl alcohol is least efficient in bringing about miscibility in toluene–water systems. The maximum amounts (wt. %) of the alcohols necessary to bring about homogeneity are isopropyl 51, ethyl 57, methyl 67.5. When the curves are plotted with mole % instead of wt. % the differences become even greater, isopropyl 41, ethyl 47, methyl 68.

(4) L. S. Mason and E. Roger Washburn, THIS JOURNAL, **59**, 2076 (1937).

Beech and Glasstone[5] came to the same conclusion in regard to the relative efficiency of these alcohols in bringing about miscibility of ethyl acetate and water although a simple study of their binodal curves alone does not indicate the relation.

Methyl alcohol has the highest values for internal pressure, dielectric constant and dipole moment, and isopropyl alcohol has the lowest values for these constants among these alcohols. Since water has very high values and toluene very low values we may consider that the above solubility studies support the idea that liquids of high internal pressure and polarity tend to "squeeze out" relatively non-polar liquids.

A comparison of the tie lines is also interesting. The alcohols dissolve chiefly in the water layer, especially when they are present in relatively small proportions. As the amounts of the alcohols increase, increasing proportions are found in the toluene layer. The proportion of ethyl alcohol in the toluene layer increases more rapidly with increasing proportions of alcohol than is noted with methyl alcohol, but the proportion of isopropyl alcohol increases most rapidly of all.

This increase in the case of isopropyl alcohol continues to such an extent that a horizontal tie line finally results, after which more alcohol is found in the toluene layer than in the water layer.

Inasmuch as the alcohols have values of internal pressure, etc., nearer to the values for toluene than to the values for water, we might expect more alcohol to be found in the toluene layer. The isopropyl alcohol, however, is most like toluene, and the relatively greater tendency which it has to enter the toluene is what would be expected.

Summary

The solubility relationships for the ternary system toluene, isopropyl alcohol and water have been determined at 25.0°.

The refractive indices of these saturated solutions have been determined and used to study the distribution of isopropyl alcohol between toluene and water at 25.0°.

This system has been briefly compared with similar systems containing methyl and ethyl alcohols in place of isopropyl alcohol.

The Vapor Pressures, Heats of Vaporization and Melting Points of N^{14} and N^{15} Ammonias

BY HARRY G. THODE*

It has been observed previously[1,2] that the nitrogen isotopes are concentrated to a slight extent by the distillation of liquid ammonia, indicating that the N^{14} ammonia has the higher vapor pressure. However, the vapor pressure difference between N^{14} and N^{15} ammonia can now be measured directly since high concentrations of N^{15} have been obtained.[3] In this paper a simple apparatus is described for measuring the vapor pressure difference between two isotopic samples of liquid ammonia. With this apparatus the vapor pressure difference, and the difference in melting points between ordinary NH_3 and 70.6% $N^{15}H_3$, have been measured and the results reported.

Experimental

The ammonia used in this investigation was prepared by the action of a saturated solution of potassium hydroxide on C. P. ammonium chloride. The gas was subjected to preliminary drying by passing it through a vertical glass column containing potassium hydroxide pellets. The ammonia was then condensed over sodium in one of a series of distillation bulbs. About 1 g. of NH_3 was treated in this way. Following each distillation the sample was cooled to the temperature of liquid nitrogen and the apparatus was then evacuated to 10^{-4} mm. or better. The 70.6% $N^{15}H_3$ samples were treated in a similar manner, except that the original samples had to be recrystallized from ethyl alcohol to remove traces of amines which concentrated along with the N^{15} in the chemical separation process. The samples were considered pure when further purification produced no change, within experimental error, in the vapor pressure difference between the two samples.

The apparatus is shown diagrammatically in Fig. 1. It consists of an 8-mm. glass tube C, divided into two com-

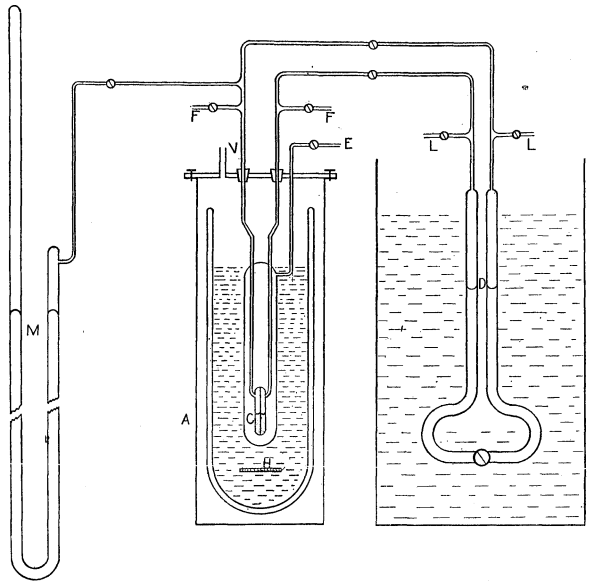

Fig. 1.

partments by a platinum partition, with each compartment partially filled with coiled platinum wire. The platinum partition and the coiled platinum serve to equalize the temperature between the two samples of ammonia whose vapor pressures are to be compared. The sample cells and the lead tubes are enclosed in a glass jacket which can be evacuated at E, and the whole apparatus is immersed in a liquid ammonia cryostat. The temperature of the cryostat is varied by regulating the pressure under which the liquid ammonia boils, with a vacuum pump and pressure regulator at V. A small heater H serves to stir the ammonia bath. The temperature of the cryostat could be controlled to 0.1°. Both the dewar flask and the steel container of the cryostat have windows through which the samples can be observed. However, during measurements the windows and lead tubes are covered with aluminum foil to keep out radiation. The two compartments at C can be connected by lead tubes to the arms of a differential oil (Apiezon) manometer D, thermostated at 27.2°, and one compartment can also be connected to a mercury manometer M. The two samples of ammonia, about half a gram of each, are condensed into the two compartments of C. The cryostat is regulated to the desired temperature and the glass jacket enclosing the two samples is evacuated. The differential manometer is then connected to the two samples and after twenty minutes readings are made with a cathetometer. The absolute vapor pressure of ordinary ammonia is measured on the mercury manometer before and after each reading of the vapor pressure difference on the differential oil manometer. From the absolute vapor pressure of ordinary ammonia the absolute temperature is deduced, using the vapor pressure data of Overstreet and Giauque for liquid ammonia.[4] With the above apparatus the measured vapor pressure difference between two samples of ordinary ammonia was found to be less than ±0.0005 cm. at 239°K. This corresponds to a difference in temperature between the two samples of ±0.00013°.

(4) Roy Overstreet and W. F. Giauque, THIS JOURNAL, **59**, 254 (1937).

The Vapor Pressure Difference.—The vapor pressure data for the liquids can be represented by the equation

$$\log_{10}(P_1/P_2) = (0.9593/T) - 0.003252 \qquad (1)$$

where P_1 is the vapor pressure of ordinary NH_3 (0.38% N^{15}), P_2 that of 70.6% $N^{15}H_3$, and T is the absolute temperature. The assumption is made that the differences in the vapor pressures of the two samples follow an equation of the type

$$\log_{10}(P_1/P_2) = (A/T) + B$$

and equation 1 is obtained by the application of least squares to the data in Table I. The ratio P_1/P_2 is obtained from the difference $(P_1 - P_2)$.

TABLE I

P_1, cm.	Temp., °K.	$P_1 - P_2$, cm. oil	$P_1 - P_2$, cm.	$(P_1 - P_2)$ (calcd.) − $(P_1 - P_2)$ (obsd.)	P_1/P_2, calcd.
5.488	197.7	0.320	0.0202	−0.00002	1.00369
9.060	204.4	.475	.0299	+ .00001	1.00332
12.593	208.8	.583	.0368	+ .00200	1.00310
21.570	217.2	.916	.0578	+ .00020	1.00268
41.030	228.2	1.462	.0922	− .00220	1.00219
41.550	228.4	1.478	.0933	− .00280	1.00218
59.560	234.9	1.797	.1134	+ .00060	1.00192
75.340	239.5	2.095	.1322	− .00170	1.00173

Table I includes the vapor pressure P_1 as determined on the mercury manometer, the temperature corresponding to the pressure P_1, and the vapor pressure difference $(P_1 - P_2)$ in cm. of oil as measured on the differential oil manometer. The table also includes the difference between calculated and observed $(P_1 - P_2)$, and the calculated ratios P_1/P_2.

Although the absolute temperature as deduced from the observed absolute vapor pressure of the ordinary ammonia is given to the nearest 0.1°, the difference in temperature between the two samples, as pointed out above, was probably less than 0.0002° at 239°K. Each arm of the oil manometer was read to the nearest 0.001 cm. with a probable error of ±0.003 cm. The mean difference between calculated and observed values of the vapor pressure difference $(P_1 - P_2)$ is ± 2%.

If the simple assumption is made that the vapor pressure of an isotopic mixture is a linear function of the mole fractions, we get the equation

$$\log_{10}\frac{P_{N^{14}H_3}}{P_{N^{15}H_3}} = \frac{1.3665}{T} - 0.004632 \qquad (2)$$

The Difference in Heats of Vaporization.—If the vapor pressures of each of the samples of am-

monia follow an equation of the form

$$\log_{10} P_n = \frac{\Delta H_n}{2.303RT} + C$$

then

$$\log_{10} P_1/P_2 = (\Delta H_2 - \Delta H_1)/2.303RT + C' \quad (3)$$

The subscripts 1 and 2 refer to ordinary ammonia and 70.6% N^{15} ammonia, respectively. The difference in the heats of vaporization of the two isotopic samples of ammonia can be calculated from the experimental data by comparing equation 3 with equation 1

$$\Delta H_2 - \Delta H_1 = 4.39 \text{ cal.} \quad (4)$$

where ΔH_1 is given in the literature[4] as 5581 ± 9 cal. By simple extrapolation, the heat of vaporization of pure N^{15} ammonia is calculated to be 6.25 cal. higher than the heat of vaporization of N^{14} ammonia.

The normal boiling point difference for the two forms of ammonia can be calculated from equation 1 by successive approximations, when T = 239.720°K., P_2 = 759.99 mm. or the n. b. p. difference. is 0.040°K., giving 0.055° for the pure N^{15} form.

The Difference in Melting Points.—A sample of ordinary ammonia was condensed into one cell of the apparatus and frozen with a liquid nitrogen bath. The jacket around the samples was then evacuated and the liquid nitrogen bath removed. A cooled dewar was placed around the apparatus to prevent the sample from warming up too fast. The vapor pressure of the sample was followed and a time–vapor pressure curve plotted. It was found that the sharp break in this curve, which occurs at the melting point, could be reproduced from experiment to experiment with great accuracy. The same procedure was followed for a sample of 70.6% $N^{15}H_3$; the results obtained are given in Table II.

TABLE II

V. P. at triple point in cm.

Sample 1, Ordinary NH_3 (0.38% N^{15})	Sample 2, 70.6% $N^{15}H_3$
4.560	4.574
4.562	4.572
4.561	4.576
Av. 4.561	4.574

From these data, and from the vapor pressure difference equation, the melting point difference between the two samples can be deduced. With the two samples at the same temperature, the triple point of ordinary ammonia (195.36°K., 4.558 cm.),[3] the vapor pressure of sample 1 will be 0.0173 cm. higher than the vapor pressure of sample 2 (from equation 1). However, from Table II it is seen that sample 2 has a higher vapor pressure at its melting point than sample 1 has at its melting point (0.013 cm.). Therefore sample 2 must melt at a higher temperature than sample 1, and the two effects must be additive. From the relation between temperature and pressure for liquid ammonia given by Overstreet and Giauque,[4] we find that dP/dT equals 0.365 cm./deg. at the triple point of N^{14} ammonia. Thus we calculate the melting point difference between ordinary and 70.6% N^{15} ammonia to be

$$(0.0173 + 0.013)/0.365 = 0.083°\text{K.}$$

If we make the simple assumption that the difference in triple points for isotopic mixtures is proportional to the mole fraction of one constituent, we find that N^{15} ammonia melts at a temperature 0.118° higher than N^{14} ammonia. The experimental error in this result may be as high as 10%.

The author is indebted to Professor H. C. Urey for making this experiment possible and for helpful suggestions.

Summary

The vapor pressure difference between 70.6% $N^{15}H_3$ and ordinary ammonia has been measured for the liquids over a range of temperatures by means of a differential oil manometer. The vapor pressure data for the liquids can be represented by the equation: $\log_{10} (P_1/P_2) = 0.9593/T - 0.00325$, where P_1 is the vapor pressure of ordinary ammonia and P_2 that of the 70.6% material. The vapor pressure of ordinary ammonia is 0.371 and 0.174% higher than the heavy ammonia sample at 195°K. (triple point of ammonia) and 239.68°K. (n. b. p.), respectively. The heavier sample of ammonia has a heat of vaporization 4.39 cal. per mole higher than that of ordinary ammonia. The triple points of the two samples differ by 0.081°, that of the 70.6% material being higher.

The Heat of Dilution of Aqueous Hydrochloric Acid at 25°

BY JULIAN M. STURTEVANT

In connection with some projected calorimetric experiments with amino acids and proteins, it became necessary to have reliable values for the integral heats of dilution of aqueous hydrogen chloride. Since very considerable discrepancies exist between the calorimetric heats available in the literature and those calculated from electromotive force measurements, it seemed advisable to redetermine these quantities.

Experimental Part

The calorimeter used in these measurements will be described elsewhere. Because of the limited size of the dilution cup, three different types of dilution were made:

Type 1. Varying amounts of the stock solution of hydrochloric acid were diluted with water.

Type 2. The stock solution of hydrochloric acid was diluted with less concentrated acid. The heat effect in an experiment of this type is due to diluting the stock solution to the final concentration and concentrating the weaker solution to this concentration.

Type 3. A solution composed of appropriate quantities of stock solution and water was diluted with water.

The hydrochloric acid used was a J. T. Baker analyzed product. The stock solution was analyzed gravimetrically at the start and finish of the measurements, and its concentration is considered to be known within $\pm 0.05\%$. All weighings were corrected for the buoyancy of the air.

The thermometer used to measure the temperature of the oil thermostat was calibrated against a platinum resistance thermometer certified by the Bureau of Standards. The standard cell used in the measurement of electrical energy input into the calorimeter was checked against the laboratory standard set of six calibrated cells. All timing was done with a synchronous clock furnishing audible signals and driven by a precision tuning fork. The over-all sensitivity of the thermometric system was 0.05 joule per mm. on the galvanometer scale.

Experimental Results.—The observed heats of dilution are summarized in Table I. The first and second columns in this table give the initial and final molalities, respectively. In the third column are listed, for dilutions of Type 2, the molalities of the diluting solutions. In the fourth column are the heats of dilution, expressed in international joules per mole of hydrogen chloride. In the case of dilutions of Type 2 these values are calculated according to the formula

$$\Delta H = \frac{\Delta q + a_2 \Delta H_1}{a_1 + a_2} \qquad (1)$$

where Δq is the observed heat absorption in joules, a_1, a_2 are the number of moles of hydrogen chloride in the dilution cup and in the calorimeter before the dilution, and ΔH_1 is the heat of the dilution, per mole of solute, of the stock solution to the molality of the solution originally present in the calorimeter. This latter quantity was obtained by graphical interpolation in the results of the pre-

vious runs, a method of successive approximations being employed if necessary. The heats of dilution have been corrected to 25.00° using the following temperature coefficient which is based on the data of Rossini[1] for the apparent molal heat capacity of the solute

$$d(\Delta H)/dt = 30.1(m_2^{1/2} - m_1^{1/2}) \qquad (2)$$

where m_1, m_2 are the initial and final molalities, respectively. Since the heat capacity used to evaluate the energy change during the dilution was that of the products plus the calorimeter, the observed heat of dilution corresponds to the initial temperature of the experiment. The initial temperatures deviated on the average about ±0.1° from 25°.

It should be noted that according to the work of Gucker and Schminke[2] the factor in equation (2) is about 21. However, the temperature correction amounts to only 0.1 to 0.2%, so that no serious uncertainties are introduced from this source.

Measurements of the heat capacity of the empty calorimeter, and of the calorimeter filled with water, were made. From these additional data the specific heat of the final solution in each run can be calculated. However, no attention was paid to keeping constant the amount of gold foil, vaseline and paraffin used to seal the dilution cup, so that the specific heats are not sufficiently precise to allow the calculation of the apparent molal heat capacities of the solute, since these quantities are very sensitive to errors in the specific heats for dilute solutions. The observed specific heats showed an average deviation of ±0.2% from those calculated from Rossini's values of Φ_C, and a slightly smaller deviation when Gucker and Schminke's values were used.

Treatment of Results.—The heats of dilution of the stock solution to molalities of 0.3 or lower were plotted against the square root of the molality on a large scale, and extrapolated to infinite dilution with the slope required by the limiting law of Debye and Hückel

$$\Phi_H - \Phi_H^0 = 1997\, m^{1/2} \qquad (3)$$

where $\Phi_H - \Phi_H^0$ is the apparent relative molal heat content of the hydrochloric acid. The slope was calculated according to the constants given by Harned and Ehlers.[3] The uncertainty in this extrapolation does not seem to exceed 10 joules per mole. The extrapolated value is the value of the apparent heat content of the stock solution. It is then a simple matter to evaluate this quantity for the solutions obtained by dilution. The values obtained are plotted against the square root of the molality in Fig. 1, the experimental points showing an average deviation from the smooth curve of ±5 joules per mole, corresponding to about ±0.15% of the observed dilution heats. Values read from the smooth curve at round values of $m^{1/2}$ are listed in the second column of Table II. These values are satisfac-

torily represented at concentrations up to $m^{1/2} = 1.2$ by the expression

$$\Phi_H - \Phi_H^0 = \frac{1997m^{1/2}}{1 + 1.123m^{1/2}} + 747m \qquad (4)$$

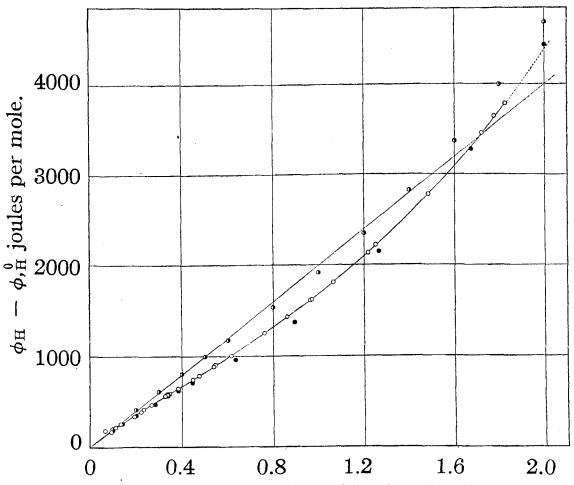

Fig. 1.—Relative apparent molal heat content of hydrochloric acid. The straight line is the Debye–Hückel limiting law. Open circles, this research; half-inked circles, Rossini; inked circles, Harned and Ehlers.

Values of $\bar{L}_2$, the partial relative molal heat content of the solute, were calculated according to the equation

$$\bar{L}_2 = \Phi_H - \Phi_H^0 + {}^1/_2 m^{1/2} \frac{d(\Phi_H - \Phi_H^0)}{dm^{1/2}} \qquad (5)$$

the necessary slopes being read from the large-scale plot of the original heat data. These quantities are listed in the third column of Table II, and are plotted in Fig. 2. An idea of the accuracy of the reading of the slopes is given by the closeness with which the calculated values fall on a smooth curve, the average deviation being of the order of ±5 joules per mole.

The relative partial molal heat content of the solvent is readily calculated from the relation

$$\Phi_H - \Phi_H^0 = \bar{L}_2 + \frac{55.506}{m}\bar{L}_1 \qquad (6)$$

The last column of Table II gives the values obtained in this way.

Estimate of Accuracy.—As mentioned above, all due care has been taken in the calibration of the instruments used in this research. It is therefore considered, since no sources of systematic error are believed to have been overlooked, that a reasonable estimate of the reliability of the results can be based on their internal consistency and the reliability of the extrapolation to infinite dilution.

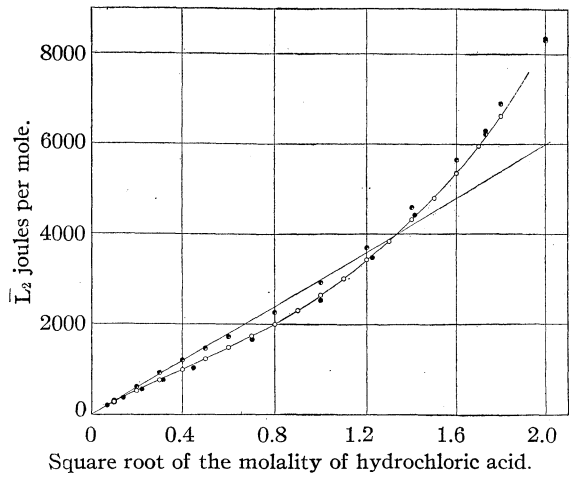

Fig. 2.—Relative partial molal heat content of hydrochloric acid. The straight line is the Debye–Hückel limiting law. Open circles, this research; half-inked circles, Åkerlöf and Teare ($m^{1/2} = 1.732$ and 2.0 only); three-quarters-inked circles, Rossini; full-inked circles, Harned and Ehlers. In the plot, Rossini's points at $m^{1/2} = 0.1$ and 2.0 are obscured by those of Harned and Ehlers.

On this basis it is concluded that the smoothed values of the apparent molal heat content should be reliable to about ±20 joules per mole, with considerably smaller limits of error associated with differences between these quantities. Since the values of the partial molal heat content involve slopes read from a graph, they are subject to somewhat larger uncertainties.

Discussion of Results

Several previous calorimetric determinations of the heat of dilution of aqueous hydrochloric acid have been made at various temperatures. These data have been summarized and calculated to 25° by Rossini,[1] who used the Debye–Hückel theory to extrapolate them to infinite dilution, and tabulated values of the apparent and partial relative molal heat contents at round values of the square root of the molality. The values given by Rossini are plotted in Figs. 1 and 2. Part of the relatively large discrepancy between these values and the ones found in the present research is due to the fact that the older values scatter rather badly below $m^{1/2} = 0.5$, so that the extrapolation to infinite dilution is somewhat arbitrary. Thus, if the values given by Rossini for $\Phi_H - \Phi_H^0$ are brought into coincidence with the present values at $m^{1/2} = 0.5$, the differences between the values thus obtained and the present ones gradually increase to a value of 130 joules per mole at $m^{1/2} =$

1.8, as compared with a difference of 300 joules per mole before making this change.

A small part of the discrepancy is due to the fact that the limiting Debye–Hückel slope used by Rossini is a little larger than the correct one, because of omission of the term involving the change of density with temperature. This fact can account for about 30 joules per mole difference.

One source of systematic error in calorimetric observations on hydrochloric acid might be corrosion of the various metallic parts of the calorimeter. It is believed that errors from this source are eliminated in the present research since the calorimeter is composed of tantalum, platinum–iridium, and pure gold solder, while the dilution cup is closed by pure gold foil. Whether corrosion is a cause of the remaining differences between the older work and the present work cannot, of course, be definitely established. Some of the discrepancy to be accounted for may arise in the fact that most of the older work was done at temperatures other than 25°, so that corrections based on the heat capacities of hydrochloric acid solutions are involved.

Doehlemann and Lange[4] have measured the heat of dilution of hydrochloric acid in concentrations up to 0.09 molal. It seems impossible to reconcile their data below 0.0025 molal with the requirements of the Debye–Hückel theory, since these data lie on a curve which is apparently approaching an infinite slope at infinite dilution. Their data from 0.0025 to 0.02 molal fall on a straight line having the limiting Debye–Hückel slope; the intercept of this line gives values of the relative apparent molal heat content which are 20 to 30 joules per mole above the values found in the present research. Also the present values indicate definite divergence from the limiting slope at concentrations below 0.01 molal, while the values of Doehlemann and Lange follow this slope to 0.02 molal, except at the very lowest concentrations, as mentioned above.

Values of the relative partial molal heat content have been calculated by Harned and Ehlers, and by Åkerlöf and Teare,[5] from their measurements of the temperature coefficient of the electromotive force of the cell

$$H_2/HCl\ (m)/AgCl/Ag$$

Harned and Ehlers measured this cell in the concentration range up to 4 molal, and reported values of $\overline{L}_2$ from infinite dilution up to this concentration. By graphical integration (counting squares, and checking the result with a planimeter) values of the apparent heat content have been calculated from their values of $\overline{L}_2$. These quantities are plotted in Fig. 1, and are seen to agree more closely with the present calorimetric values than do the earlier calorimetric data. This agreement is especially satisfactory when it is considered that an error of 1 microvolt per degree in the temperature coefficient of electromotive force causes an error of about 30 joules per mole in $\overline{L}_2$.

Harned and Ehler's values of $\overline{L}_2$ are compared with the present ones in Fig. 2. They show a maximum deviation, at 3 molal, of about 130 joules per mole, which is within the estimated accuracy of the e. m. f. measurements. It should be noted that the value obtained by Åkerlöf and Teare at this concentration shows a deviation of only about 60 joules per mole. Further comparison with their values is impossible since this is the lowest concentration at which they worked.

Summary

The heat of dilution of aqueous solutions of hydrogen chloride at 25° has been measured up to a concentration of 3.3 molal. From these data have been calculated the apparent and partial relative molal heat content of the solute, and the partial relative molal heat content of the solvent.

The Iodine-Sensitized Decomposition of Methyl Alcohol

BY G. K. ROLLEFSON AND WARREN GARRISON

Some years ago it was found by Bairstow and Hinshelwood[1] that the rates of decomposition of a number of simple organic compounds were greatly increased by the addition of iodine and in some cases the nature of the products was changed. Later, Rollefson and Faull[2] found that under the experimental conditions prevailing in these experiments the concentration of free iodine is extremely low during most of the reaction but returns to its original value as the decomposition of the organic compound approaches completion. They also showed that in mixtures of acetaldehyde or propionaldehyde with iodine the decomposition is the net result of a reaction of the iodine with the aldehyde to give carbon monoxide, hydrogen iodide, and alkyl iodide followed by the reaction of the alkyl iodide with hydrogen iodide to form the corresponding hydrocarbon and iodine. The latter reaction is the rate determining step. In this paper we wish to present a study of the iodine-sensitized decomposition of methyl alcohol which differs from that of the aldehydes in that the products are not the same as are obtained in unsensitized decomposition. In this case also we have found that the action of the iodine can be expressed in terms of ordinary chemical reactions.

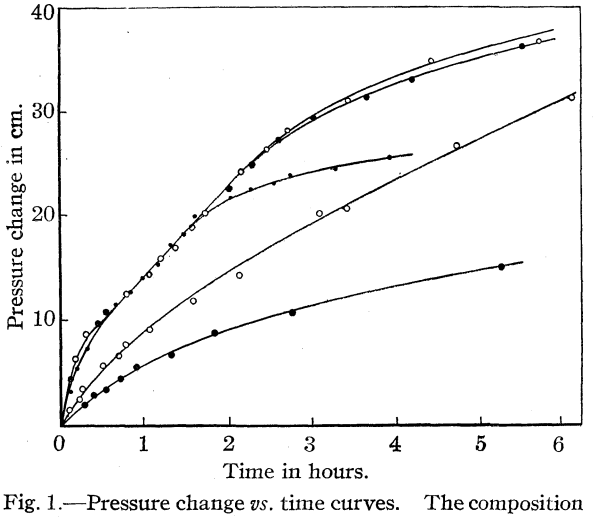

Fig. 1.—Pressure change *vs.* time curves. The composition of the reaction mixtures for the various curves is:

Curve	Iodine added, mole	Alcohol added, mole
1	1.67×10^{-4}	29.4×10^{-4}
2	2.66	29.4
3	4.00	20.0
4	4.00	28.6
5	4.00	30.9

(2) Rollefson and Faull, THIS JOURNAL, **58**, 1755 (1936); **59**, 625 (1937).

In order to obtain the maximum amount of information concerning conditions which affect the rate, it is desirable to have the iodine concentration measurable during the course of the reaction. Preliminary tests showed that at 325° the unsensitized decomposition was negligible and the sensitized reaction proceeded at a convenient rate with appreciable amounts of free iodine present at all times. All of the quantitative measurements were made at this temperature.

The reaction vessel was made of Pyrex, cylindrical in shape, and of approximately 250 cc. capacity. It was connected through a click gage to a mercury manometer and through another tube, which was sealed off during the reaction, to vacuum pumps and a supply of methyl alcohol. The vessel was mounted in an electric furnace which was kept within a degree of the desired temperature by hand regulation. The temperature was measured by a chrome–alumel thermocouple placed in a small glass tube which was sealed into the reaction vessel.

The alcohol was distilled over anhydrous potassium carbonate; the middle fraction with a boiling range of less than one degree was used (boiling range, 64.0–64.6°). The iodine was resublimed Merck reagent.

The procedure followed in filling the reaction vessel was to introduce sufficient alcohol vapor to give the desired pressure at 325°, and seal the reaction vessel off from the vacuum system and alcohol supply. The temperature of the system was raised to 325° and then a bulb containing a weighed quantity of iodine was broken in the vessel. The curves obtained by plotting the pressure against the time were found to be very reproducible and showed no anomalies which might be attributed to slowness of mixing of the iodine and alcohol vapors. A few typical curves are shown in Fig. 1.

It was found that the pressure–time curves were quite reproducible for any given mixture.

Consequently we found it more convenient to carry out most of the determinations of the composition of the reaction products at different degrees of completion of the reaction by heating a mixture of alcohol and iodine vapors for various definite times in sealed bulbs identical in size and shape with the one used in the pressure measurements. When the bulbs had been heated long enough to bring the reaction to the desired degree of completion the bulbs were removed from the furnace and cooled rapidly. Different rates of cooling were tried but were not found to affect the results appreciably. In order to analyze the reaction mixture the tip of the reaction vessel was broken under the surface of a known volume of potassium iodide solution and this solution was used to force the gases into an Orsat gas analyzer. A sample of the iodide solution was titrated for iodine using 0.05 *N* thiosulfate solution. The hydrogen ion concentration was determined by adding excess of potassium iodate to the same sample of the iodide solution and titrating again with the thiosulfate. The gases were analyzed for carbon monoxide, carbon dioxide, hydrogen and methane by conventional methods. Carbon dioxide and hydrogen were found to be negligible. The amounts of carbon monoxide and methane present at various states of the reaction are shown in Table I.

TABLE I

METHANE AND CARBON MONOXIDE PRESENT DURING THE REACTION

CH_3OH added = 25×10^{-4} mole. I_2 added = 3.9×10^{-4} mole.

Hours	Moles $\times 10^4$ CH_4	CO	CH_4/CO
0.75	2.40	3.40	0.71
.75	2.30	3.40	.68

5.5	15.10	7.50	2.01
5.5	15.0	7.50	2.00
9.0	15.8	7.56	2.08
9.0	15.9	7.56	2.10
18.0	16.0	7.60	2.10

The condition of the iodine during that part of a run corresponding to the relatively straight section of the pressure–time curve is shown by the data in Table II.

TABLE II

DISTRIBUTION OF IODINE DURING A REACTION

I_2 added = 1.67×10^{-4} moles. CH_3OH added = 25.0×10^{-4} moles.

Hours reacted	$I_2 \times 10^4$ mole	HI $\times 10^4$ mole	Other iodides $\times 10^4$ mole
1	0.314	0.340	2.38
1.5	.348	.360	2.228
2	.308	.340	2.38
3	.394	.368	2.20

The presence of hydrogen iodide was demonstrated by shaking water and carbon tetrachloride in a bulb filled with the gases to be analyzed. In this way hydrogen iodide and iodine were extracted from the gases. The water and carbon tetrachloride were separated, the water layer extracted again with carbon tetrachloride and then titrated for hydrogen and iodide ions. The iodide was found to be about 1% higher than the hydrogen ion but this slight discrepancy was attributed to incomplete removal of the iodine by the carbon tetrachloride.

The data which have been obtained show that the net over-all reaction may be represented by the equation

$$3CH_3OH = 2CH_4 + CO + 2H_2O \qquad (1)$$

Additional support for this equation is found in that the total pressure change observed in reaction mixtures which were run to completion was two-thirds the original methyl alcohol pressure. However, the variation of the methane–carbon monoxide ratio in the course of the reaction shows that this net reaction must be the resultant of two parallel reactions, one an oxidation of the alcohol to carbon monoxide, the other a reduction to methane. Iodine is the oxidizing agent for the first and hydrogen iodide the reducing agent for the second. The equations representing the changes are

$$CH_3OH + 2I_2 = CO + 4HI \qquad (2)$$

$$CH_3OH + 2HI = CH_4 + I_2 + H_2O \qquad (3)$$

The preponderance of carbon monoxide in the early stages of the reaction is caused by the first of these reactions proceeding faster than the second until the steady state is reached. During the steady state the methane and carbon monoxide are formed in the proportions of two to one as required by the over-all reaction as written above. In the final stages of the reaction when the iodine is regenerated methane is produced thus compensating for the excess carbon monoxide produced in the initial stage. This behavior is apparent from an inspection of the data in Table I.

The formation of methyl iodide in the reaction mixture can be accounted for by

$$CH_3OH + HI = CH_3I + H_2O \qquad (4)$$

which may be one of the steps in the mechanism of (3). The net change in the reaction mixture from the time of mixing is given by a combination of the equations (2), (3), (4). When the reaction is carried to completion the contribution from (4) is zero and the net effect is the combination of (2) and (3) so as to give (1).

No mechanisms which we have devised for the reactions (2) and (3) will account for all the experimental observations. The possibility that methane is formed from methyl iodide and hydrogen iodide was considered. Assuming that the iodine not in the form of hydrogen iodide or free iodine was all methyl iodide, we calculated the rate of formation of methane from Ogg's data. The observed rate during the steady state was 12.6×10^{-7} mole/cc./hr. and the calculated rate was 18.5×10^{-7} mole/cc./hr. The agreement is not sufficiently good to warrant the conclusion that the methane must be formed by this reaction but it seems to be a reasonable possibility at these temperatures. The constancy of the rate of formation of methane during a large percentage of the reaction could be accounted for by this reaction since the concentrations of methyl iodide and hydrogen iodide are constant over the same range.

Summary

The iodine sensitized decomposition of methyl alcohol has been studied at 325°. It has been shown that although the net effect in systems in which the reaction was carried to completion may be represented by the equation $3CH_3OH = 2CH_4 + CO + 2H_2O$ this is the resultant of two other reactions. One of these is the oxidation of the alcohol to carbon monoxide by the iodine, the other the reduction of the alcohol to methane by hydrogen iodide.

The Dilituric (5-Nitrobarbituric) of Some Physiologically Important Bases

BY C. E. REDEMANN AND CARL NIEMANN

The qualitative or quantitative isolation of basic compounds from natural sources is, in general, most satisfactorily accomplished when the base in question can be obtained as the salt of a suitable acid.[1] Of the acidic reagents that have been employed in the past, it is certain that compounds such as picric acid, styphnic acid, picrolonic acid, nitranilic acid[2] and 3-nitrodiketohydrindene[3] have found the greatest application and it is noteworthy that all of these compounds are characterized by the presence of a contiguous nitrophenolic (or enolic) array in an ensemble of atoms capable of forming a resonating system.

We have found that dilituric acid (5-nitrobarbituric acid) surpasses the above nitro-enolic compounds as a reagent for the isolation of many naturally occurring bases and it is the purpose of this communication to call attention to the properties of some of the salts of this acid and their use in isolation problems.

Dilituric acid[4] prepared by the direct nitration of barbituric acid[4b,c,f,h,i] is readily purified. The solubility of the acid, in millimoles per liter of solution at 25°, in methanol is 99; in 95% ethanol, 85; in water, 63; in absolute ethanol, 35; in acetone, 25; in ethyl ether, 0.9; and in benzene, 0.4. Dilituric acid behaves like a strong monobasic acid and from the electrometric titration of a 0.00904 *N* aqueous solution it appears that the acid strength of dilituric acid is intermediate between that of picric acid and hydrochloric acid.[5]

Examination of Table I reveals that dilituric acid is a satisfactory reagent for the separation of potassium from binary mixtures containing so-

[a] In water at 25°.

In Table II we have tabulated the properties of salts formed by the interaction of dilituric acid with seventy-one organic bases. The dilliturates of the primary aliphatic amines are surprisingly insoluble in water at 25° and, within limits, the solubility in water increases with increasing chain length. The transition from a primary amine to a secondary amine diliturate is accompanied by a decrease in solubility; however, the salts of the tertiary amines are much more soluble than those of the corresponding secondary amines. The heterocyclic bases, quinoline, imidazole, and pyridine form sparingly soluble dilliturates but in con-

(6) (a) H. Frediani, Meeting of the American Chemical Society, Boston, September, 1939; (b) O. C. Dermer and V. H. Dermer, THIS JOURNAL, **61**, 3302 (1939).

(7) With the aid of dilituric acid we have been able to establish the presence of magnesium in the crude phospholipids obtained from bovine spinal cord.

trast to morpholine it was found that ethylmorpholine dilituratе was very soluble in water.

The isolation of ethanolamine from the hydrolyzates of phospholipids by the methods hitherto available has been a very laborious task and, still more serious, the methods are not capable of being developed to the point of yielding quantitative data.[8] The observation that ethanolamine dilituratе possesses but limited solubility in water has not only offered a means for the qualitative isolation of this base but in addition has provided a reagent that can be used for the quantitative estimation of ethanolamine and other alkanolamines by the so-called solubility product method of analysis.[1,9] Dilituric acid is also a suitable reagent for the isolation and estimation of glucosamine.

An extensive study of the dilituratеs of the amino acids has been made and in Table II are listed the properties of thirty-four salts. The dilituratеs of the aliphatic monoamino monocarboxylic acids present an interesting situation in that as the length of the side chain increases from zero to three carbon atoms the solubility of the dilituratе increases in a regular manner. Exactly the opposite is observed when one considers the solubility of the amino acids themselves. In addition it was noted that a branching of the side chain resulted in a decrease in the solubility of the dilituratе. Examination of Table II can leave no doubt that there are many amino acid mixtures that can be separated with the aid of dilituric acid. The dilituratеs of the proteinogenic amines are only slightly soluble in water at 25° and it is clear that dilituric acid is a suitable reagent for their isolation.

The fact that dilituric acid is not exceedingly soluble in water at 25° creates a demand for a more soluble form of this reagent. Fortunately the trimethylamine and the ethylmorpholine dilituratеs are very soluble in water and these salts may be used in lieu of the acid.

One of the advantages of isolating bases in the form of their salts is that the base can be easily regenerated. We have found that the regeneration of bases from their dilituratеs can be achieved in the majority of cases by simply replacing the base in question by either ethylenediamine, magnesium or ammonium, as the salts of these three substances are exceedingly insoluble in water. Thus in a typical case, the decomposition of glycine dilituratе with ammonia gave an 89% yield of crystalline glycine.

In conclusion it can be stated that dilituric acid possesses many of the characteristics of the ideal acidic precipitant in that: (a) it is readily available at low cost; (b) in aqueous solution it behaves as a strong monobasic acid thereby diminishing the possibility of forming mixed salts; (c) it is moderately soluble in water and the alcohols; (d) several very soluble salts are known; (e) all of the dilituratеs that were prepared were well-defined crystalline substances thereby facilitating their isolation; (f) the salts were characterized by a wide variation in solubility, thereby permitting fractionation of mixtures; (g) both the acid and the salts possess a high temperature coefficient of solubility which allows ready purification by recrystallization and enhances the possibility of resolving mixtures whose dilituratеs have similar solubilities at any one temperature; and (h) in the majority of cases the base can be obtained easily from the salt by a simple double decomposition.

Experimental

Dilituric Acid (5-Nitrobarbituric Acid).—The acid was prepared according to the directions given in Organic Syntheses.[4h] A solution of 0.2317 g. of thrice recrystallized anhydrous dilituric acid in 150 ml. of water (*p*H 2.03) was titrated electrometrically and examination of the titration curve revealed that the strength of this acid was intermediate between that of picric acid and hydrochloric acid.

Preparation of the Dilituratеs.—A solution of 5 millimoles of dilituric acid and 5 millimoles of the base[10] (2.5 millimoles for a diacidic base) was prepared with the minimum amount of boiling water and allowed to cool to 25°. The salts were recrystallized one or more times before determining their composition and solubility.

Analysis of the Dilituratеs.—Fifteen to twenty mg. samples of the inorganic salts, dried at 80°, were ignited in the presence of sulfuric acid and the average deviation of the percentage metal found from that calculated was ±0.11. In order to obtain satisfactory values for the carbon and hydrogen content of the organic dilituratеs it was necessary to replace the ordinary Pregl copper oxide–lead chromate combustion zone filling[11] by copper oxide and all of the silver plugs, in front of the combustion zone, by 10% platinized asbestos. In addition the sample, (20–30 mg.) dried at 80°, was mixed with powdered cupric

oxide prior to ignition. The average deviation of the percentages found from those calculated was ±0.15; the maximum in any case did not exceed 0.3 except for the following salts: ethylamine, % H, calcd. 4.6, found 4.2; *m*-amylamine, % H, calcd. 6.2, found 5.8; *l*-aspartic acid, % H, calcd. 3.3, found 3.7; *dl*-leucine, % C, calcd. 39.4, found 38.9; guanidine, % H, calcd. 3.5, found 3.1.

Determination of Solubilities.—The saturated solutions were approached from the supersaturated side by placing samples saturated at 40–50° and containing an excess of the solid phase in a thermostat at 25.0 ± 0.5° and allowing forty-eight or more hours, with shaking, for the attainment of equilibrium.[12] 10.00-ml. aliquots were withdrawn, evaporated to dryness at 80° and the residues weighed. The solubilities of the various dilituratates, in water at 25°, are given in Tables I and II and those of dilituric acid, in a number of different solvents at 25°, in the text. The over-all accuracy (*i. e.*, reproducibility) of the solubility data in these tabulations is ±4%.

Recovery of Glycine from its Dilituratate.—To 8.4 g. of glycine dilituratate in 100 ml. of hot water was added 3 ml. of 15 *N* ammonium hydroxide. The solution was cooled to room temperature, the precipitate removed and the filtrate evaporated to 20 ml. Upon adding 100 ml. of ethanol to the concentrate, glycine began to precipitate. After cooling to 5° the pure white product was recovered and dried *in vacuo*. The weight was 2.30 g. or 89% of the theoretical amount.

(12) Preliminary experiments with a monovalent salt, soluble in water at 25° to the extent of 50 millimoles per liter, gave identical results, within the limits of experimental error (±2%), when the saturated solution was approached from both sides.

Summary

A number of salts of dilituric acid (5-nitrobarbituric acid) have been prepared and a study of their properties has shown that dilituric acid is a satisfactory reagent for the isolation and determination of many organic and inorganic bases.

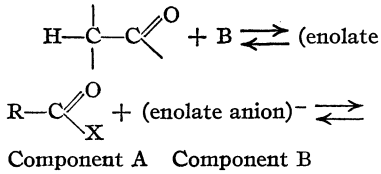
Condensations Brought about by Bases. IX. The Relationship between the Claisen and Perkin Types of Condensations[1,2]

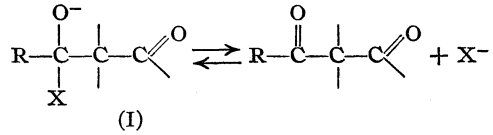
BY CHARLES R. HAUSER AND DAVID S. BRESLOW

The mechanisms for the Claisen[3] (acetoacetic ester) and Perkin[4] types of condensations in the presence of a base B have been represented by the following ionic equations.

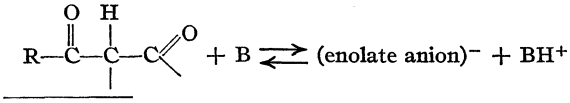
Claisen Type



Component A Component B



(I)



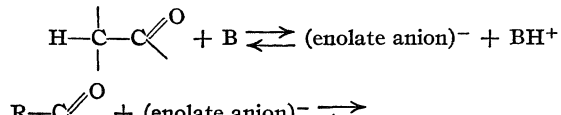
(1) Paper VIII, THIS JOURNAL, **62**, 62 (1940).

(2) This paper was presented before the Division of Organic Chemistry at the Baltimore meeting of the American Chemical Society, April, 1939.

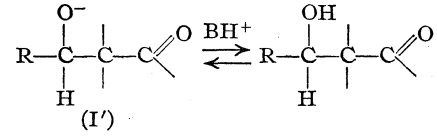
(3) Two types of reaction are known as Claisen condensations, the acetoacetic ester type and the condensation of a ketone with benzaldehyde by means of alkali. In the present paper the Claisen condensation refers only to the acetoacetic ester type. See (a) Hauser and Renfrow, THIS JOURNAL, **59**, 1823 (1937); (b) Hauser, *ibid.*, **60**, 1957 (1938).

(4) See Hauser and Breslow, *ibid.*, **61**, 793 (1939).

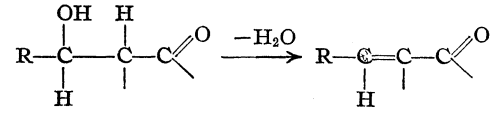
Perkin Type



Component A Component B



(I′)



The purpose of this paper is to compare these two types of condensation and to discuss certain experiments in which it is possible for either or both types to occur.

It is evident from the above equations that in both the Claisen and Perkin reactions component B is the enolate anion of a compound of the type  (ester, anhydride, aldehyde, ketone, etc.). Component A, however, is different in the two condensations. In the Claisen reaction

component A is a compound of the type R—C(=O)—X (ester, anhydride, acid chloride, etc.), where X is an atom or group that is released as an anion during reaction; whereas in the Perkin reaction component A is an aldehyde, which contains the hydrogen atom in place of X.

A further inspection of the above equations shows that the first two steps of the Claisen and Perkin reactions are analogous. In both types of condensation a compound of the type H—C(—)—C(=O)— is converted by a base into its enolate anion (component B) which condenses with the carbonyl group of component A, giving the anions (I) and (I′) with the negative charge on the oxygen atom, but here the analogy ends. The anion (I) formed in the second step of the Claisen reaction releases X as an anion, forming the β-keto compound (which may or may not be converted into its enolate anion), whereas in the Perkin reaction this is not possible, as there is no X present in the aldehyde; instead, the corresponding anion (I′) takes up a proton from the medium to give the "aldol," which may eliminate water to form an unsaturated compound.

Certain experiments in which it is possible for both the Claisen and Perkin types of condensation to occur now will be considered. Whenever the Perkin reaction is carried out using the enolate of an ester or anhydride as component B, the Claisen type of condensation also is possible, since the ester or anhydride may serve as component A for the latter type of condensation. Thus the fact, noted by Perkin,[5] that carbon dioxide and a ketone are formed when an anhydride is heated with its sodium salt, is best explained on the basis that the anhydride undergoes self-condensation (Claisen type) to give an acetoacetic ester type of intermediate; it is well known that acetoacetic acid gives carbon dioxide and acetone on heating. In this Laboratory we have observed that phenylacetic anhydride[6] (in which the hydrogen on the α-carbon is reactive), when heated with sodium acetate, gives dibenzyl ketone. The latter is formed presumably by the decomposition of an acetoacetic ester type of intermediate. Actually, however, when benzaldehyde is present, an ester or anhydride undergoes very little self-condensation (Claisen type) on treatment with a base, the main reaction being the Perkin condensation giving cinnamic acid or one of its derivatives. Thus, for example, benzaldehyde with acetic anhydride and a base (sodium acetate or a tertiary amine) gives mainly cinnamic acid, and with ethyl acetate and a base (sodium ethoxide or sodium triphenylmethyl), mainly ethyl cinnamate.

It is rather striking that while ethyl acetate when treated with sodium triphenylmethyl is converted to acetoacetic ester within a few minutes,[7] a mixture of ethyl acetate and benzaldehyde when treated with this base gives mainly ethyl cinnamate; if the latter reaction is stopped within one minute the intermediate "aldol," ethyl β-phenyl-β-hydroxypropionate, is obtained in fair yield (20%).[4] Thus, although the Claisen type of condensation occurs very rapidly in the presence of the strong base, sodium triphenylmethyl, the Perkin type of reaction occurs even more rapidly. This is what might be expected, however, since the carbonyl group of benzaldehyde is more active than that of the ester[8] (or anhydride); moreover, when equimolar quantities of ethyl acetate, benzaldehyde and sodium triphenylmethyl are used, most of the ester is probably rapidly converted into its enolate, which cannot serve as component A in the condensation.

The reaction in which component B is a compound of the type H—C(R)(R)—C(=O)—, such as ethyl isobutyrate, is of especial interest. Scheibler reported[9] that ethyl isobutyrate condenses with benzaldehyde in the presence of sodium ethoxide to give the "aldol," ethyl β-phenyl-β-hydroxypi-

(5) Perkin, *J. Chem. Soc.*, **49**, 322 (1886).

(6) Actually, in this experiment sodium phenylacetate and acetic anhydride were used, but under the experimental conditions phenylacetic anhydride and sodium acetate were formed by double decomposition. See Breslow and Hauser, THIS JOURNAL, **61**, 786 (1939).

(7) Hudson, Dick and Hauser, *ibid.*, **60**, 1960 (1938).

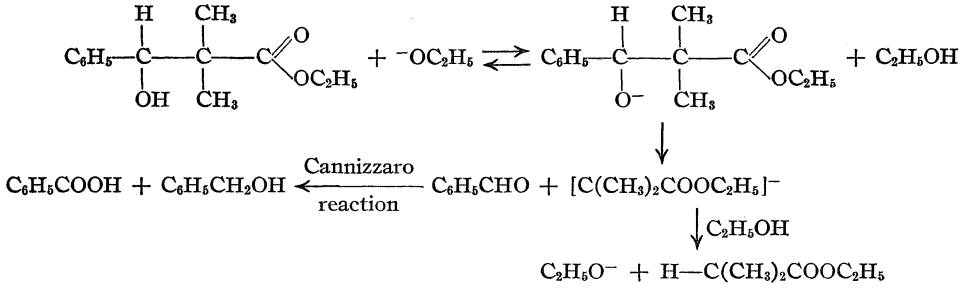
(8) The relative order of activity of the carbonyl group has been indicated by the reaction with the Grignard reagent; the following order is found

$$R-C(=O)-H > R-C(=O)-Cl > R-C(=O)-OC_2H_5$$

(See Gilman, "Organic Chemistry," John Wiley and Sons, Inc., New York, N. Y., 1938, p. 418). This order may be explained on the basis of the tendency for the T effect; the positive charge on the carbon atom that would result from the change C=O is partially neutralized in the last two compounds, thus, R—C(=O)—X: .

(9) Scheibler and Friese, *Ann.*, **445**, 158 (1925).

valate, but Müller, Gawlick and Kreutzmann[10] were unable to confirm this result. In agreement with Müller and co-workers, we have obtained the Cannizzaro reaction products, benzyl alcohol and benzoic acid, when benzaldehyde and ethyl isobutyrate were allowed to stand with sodium ethoxide and we were unable to isolate any of the hydroxy-ester reported by Scheibler. We have shown further that when this ester, ethyl β-phenyl-β-hydroxypivalate, is allowed to stand with sodium ethoxide, it is decomposed practically completely giving benzaldehyde (most of which undergoes the Cannizzaro reaction forming benzoic acid and benzyl alcohol) and ethyl isobutyrate. This reaction may be illustrated by the following ionic equations in which the enolate anion is represented by a non-committal formula.



Müller and co-workers reported that ethyl isobutyrate does not condense with benzaldehyde even in the presence of the stronger base, sodium triphenylmethyl. Recently, however, we have shown[4] that condensation does occur in the presence of this base, and that the "aldol," ethyl β-phenyl-β-hydroxypivalate, can be isolated if the reaction is stopped by acidification within a short time (twenty minutes). We have now shown that this hydroxy ester on standing with sodium triphenylmethyl is partly decomposed, as is illustrated above with the ethoxyl anion from sodium ethoxide, into benzaldehyde (most of which undergoes the irreversible Cannizzaro reaction) and, presumably, the enolate of ethyl isobutyrate. This enolate then condenses with ethyl isobutyrate (formed from some of the enolate and triphenylmethane) to give ethyl isobutyryl-isobutyrate, which seemed to be present in small amounts among the reaction products.

Experimental

Preparation and Purification of Materials.—Benzaldehyde and ethyl isobutyrate were purified as previously described.[4,6]

Ethyl β-phenyl-β-hydroxypivalate was prepared according to the method of Blaise and Herman.[11] The zinc complex was hydrolyzed with cold 20% sulfuric acid until an extraction with dilute sodium carbonate gave no precipitate. The ester was collected at 153–158° at 11 mm. and recrystallized by dissolving it in an equal volume of petroleum ether (30–60°) and chilling the resulting solution for several days; m. p. 38.5–39°.

Sodium ethoxide was prepared from a weighed amount of sodium wire and excess absolute alcohol. The last traces of alcohol were removed by heating the sodium ethoxide for a half-hour at 150° at 20 mm., the flask being flushed out with nitrogen.

Sodium triphenylmethyl was prepared from Eastman Kodak Co. triphenylchloromethane according to the method previously described.[3a]

Attempted Condensation of Benzaldehyde with Ethyl Isobutyrate in the Presence of Sodium Ethoxide.—Sodium ethoxide (prepared from 4.6 g. of sodium) was covered with 100 cc. of dry ether and 17.4 g. (0.15 mole) of ethyl isobutyrate and 15.9 (0.15 mole) of benzaldehyde was added. The mixture was stirred mechanically. Heat was evolved, the ether refluxing, and the mixture turned a dark brown. After standing at room temperature for a week, the mixture was acidified with 30 cc. of glacial acetic acid, extracted with sodium carbonate until alkaline and dried over Drierite. The alkaline solution was acidified and the precipitate that formed recrystallized from hot water; in this way 1.0 g. of benzoic acid, m. p. 120–121°, was obtained. The ether was distilled off from the dried ethereal solution and the deep red residue distilled up to 120° at atmospheric pressure to remove ethyl isobutyrate. The residue was then collected up to 120° at 12 mm. A small residue was left behind, which started decomposing at 120° and gave only a small amount of dark red distillate up to 160°, showing the absence of ethyl phenylhydroxypivalate (b. p. 155–156° at 11 mm.[11]). The fraction boiling up to 120° at 12 mm. presumably consisted mostly of benzyl alcohol. This fraction yielded 7.2 g. of benzyl 3,5-dinitrobenzoate, m. p. 111–112°.[12] This is equivalent to 2.6 g. of benzyl alcohol.

The experiment was also run in the absence of any solvent, the mixture being allowed to stand for twenty-four hours before acidification. Essentially the same results were obtained.

(12) This is the melting point recorded in the literature for this compound. See Shriner and Fuson, "Systematic Identification of Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 1935, p. 87.

Decomposition of Ethyl β-Phenyl-β-hydroxypivalate with Sodium Ethoxide.—Sodium ethoxide (prepared from 2.3 g. of sodium) was covered with 500 cc. of dry ether and 22.2 g. (0.10 mole) of ethyl phenylhydroxypivalate added. The mixture was shaken mechanically for several hours. No heat was evolved but the mixture turned a dark red-brown. It was allowed to stand for sixteen days with occasional shaking. The mixture, which still contained a precipitate, was acidified with 20 cc. of glacial acetic acid in 75 cc. of ether, extracted with dilute sodium carbonate until alkaline and dried over Drierite. The alkaline solution, on acidification and subsequent recrystallization of the precipitate from hot water, yielded 1.1 g. of benzoic acid, m. p. 120–121°.

The ether was distilled off from the dried solution through a long Widmer column and the residue was transferred to a 125 cc. Claisen flask, using as little ether as possible. The ether was carefully distilled off and the residue distilled at atmospheric pressure. The fraction boiling at 105–115° was collected (3.0 g.), most of it coming over at 108–112°. It was identified as ethyl isobutyrate (b. p. 111°) by converting it to isobutyramide, m. p. 127.5–128.5°.[13] The residue from the atmospheric distillation was distilled at 11 mm. The first fraction (5.6 g.) was collected at 75–96°. The second fraction (0.5 g.) boiled at 101–130°, and the third (1.1 g.) at 130–165°. A deep red residue was left weighing 3.0 g.

The first fraction was treated with a saturated solution of sodium bisulfite. No precipitate was formed, showing the absence of any benzaldehyde. The mixture was extracted with ether, the ether evaporated and the residue refluxed with 25 cc. of 25% sodium hydroxide solution for six hours in order to hydrolyze any ethyl benzoate present.[14] The mixture was extracted with ether and the alkaline solution acidified. The precipitate formed was recrystallized from hot water, 0.24 g. of benzoic acid, m. p. 121–122°, being obtained. The ether solution was dried, the ether distilled off and the residue distilled at atmospheric pressure; 3.4 g. boiling at 203–204° was obtained. It was identified as benzyl alcohol by its 3,5-dinitrobenzoate, m. p. 110–111°.

The second fraction (mid-fraction) was discarded. The third fraction, which was an oily solid at room temperature, was water-insoluble. This was presumably recovered ethyl phenylhydroxypivalate, but it would not yield a crystalline solid even after several recrystallizations from 30–60° ligroin. A previous duplicate run yielded no recovered ester.

The yield of ethyl isobutyrate was 3.0 g. (25.9%). The yield of benzaldehyde, based on benzoic acid, benzyl alcohol and the benzoic acid formed by the hydrolysis of the small amount of ethyl benzoate in fraction one, was 4.5 g. (42.5%).

Decomposition of Ethyl β-Phenyl-β-hydroxypivalate with Sodium Triphenylmethyl.—Sodium triphenylmethyl was prepared from 41.8 g. (0.15 mole) of triphenylchloromethane dissolved in a liter of ether and 1000 g. of 1% sodium amalgam. The resulting solution was analyzed according to the method of Hudson, Dick and Hauser.[7] To the solution, containing 0.10 mole of sodium triphenylmethyl, was added an equivalent amount (22.2 g., 0.10 mole) of ethyl phenylhydroxypivalate. No appreciable amount of heat was evolved, but the resulting solution was colored a much lighter red than the original. A copious precipitate formed on standing. After standing sixteen days at room temperature, the mixture was acidified with 20 cc. of glacial acetic acid in 75 cc. of ether, extracted with sodium carbonate until alkaline and dried over Drierite. The carbonate extract on acidification gave a precipitate which, after recrystallization from hot water, yielded 0.14 g. of benzoic acid, m. p. 121–122°.

The dried ethereal solution was distilled from a water-bath through a short Widmer column. After the ether had been removed, the liquid remaining in the flask was heated to 120° at atmospheric pressure, but no distillate was obtained; evidently no appreciable amount of ethyl isobutyrate (b. p. 111°) was present in the reaction mixture. The residue was distilled at 12 mm. collecting everything up to 190°. A large residue remained, consisting at least partly of triphenylmethane. The distillate was then redistilled at 10 mm. Two fractions were collected, the first boiling up to 120° (3.9 g.) and the second at 140–165° (5.4 g.). The second fraction was chilled for several days with 5 cc. of petroleum ether (30–60°), the petroleum ether decanted off and the resulting precipitate dried *in vacuo*. In this manner 4.4 g. of ethyl phenylhydroxypivalate, m. p. 38.5–39.5°, was recovered unchanged.

The first fraction (3.9 g.) boiling up to 120° at 10 mm. consisted of a mixture of benzaldehyde, benzyl alcohol and apparently ethyl isobutyryl-isobutyrate. The benzaldehyde was first removed as the sodium bisulfite addition complex (0.05 g.). The mixture was then heated with alkali in an attempt to hydrolyze the ethyl isobutyryl-isobutyrate, but no di-isopropyl ketone could be isolated; however the alkaline solution on acidification gave a strong odor of isobutyric acid. It should be mentioned that hydrolysis of this β-keto ester usually gives a poor yield of di-isopropyl ketone. The organic liquid left after the attempted hydrolysis consisted mostly of benzyl alcohol, which was identified as the 3,5-dinitrobenzoate, 2.1 g. of the latter being obtained.

Summary

1. The mechanisms for the Claisen and Perkin types of condensation are compared and reactions in which both types of condensation are possible are discussed.

2. It has been shown that in the presence of sodium ethoxide ethyl isobutyrate does not condense with benzaldehyde. The condensation product that would be formed, ethyl β-phenyl-β-hydroxypivalate, is decomposed by sodium ethoxide to give benzaldehyde and ethyl isobutyrate.

3. Although ethyl isobutyrate condenses with benzaldehyde in the presence of sodium triphenyl-

(13) Shriner and Fuson, ref. 12, p. 131.

(14) Claisen reported the presence of methyl benzoate when benzaldehyde was treated with sodium methoxide. See Claisen, *Ber.*, **20**, 646 (1887).

methyl to give ethyl β-phenyl-β-hydroxypivalate, the latter on standing in the presence of this base is again decomposed.

4. The mechanisms of the above decompositions are discussed.

DURHAM, NORTH CAROLINA RECEIVED NOVEMBER 9, 1939

The Constituents of Certain Species of Helenium. III. The Ester Nature of Tenulin

BY E. P. CLARK

A description of tenulin and some of its derivatives was given in the second paper of this series.[1] No attempt was made to interpret the reactions reported, but as work on the material has progressed facts have emerged that warrant comment.

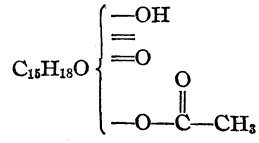
From the data already recorded the following conclusions may be drawn: Tenulin has a double bond, as two atoms of bromine *add* to form a dibromotenulin and hydrogenation with Adams catalyst yields a dihydro compound. Dihydrotenulin, as well as its isomer, dihydroisotenulin, readily forms phenylhydrazones, whereas the unhydrogenated materials do not. It is inferred, therefore, that both tenulin and isotenulin have a carbonyl group, which is sterically hindered by the presence of the double bond. Although tenulin does not give ordinary reactions for hydroxyl groups, the fact that heating it to 300° for a very short time produces an anhydro derivative is a reasonable indication that a sterically hindered hydroxyl group is present.

The work reported at this time shows that tenulin has also another hydroxyl group esterified as an acetate. This information was obtained in experiments having two different lines of approach. First it has been found that alkaline hydrogen peroxide oxidizes both tenulin and isotenulin to a monocarboxylic acid, $C_{15}H_{20}O_7$, which has been named "tenulinic acid." If potassium permanganate is used as the oxidizing agent, another acid, which crystallizes as $C_{17}H_{22}O_8 \cdot {}^1/_2H_2O$, is obtained. The difference between these two acids, aside from the water of crystallization, is C_2H_2O, which should result from the hydrolysis of an acetyl compound. Furthermore, tenulinic acid may be acetylated readily to give a quantitative yield of the second acid, and on hydrolysis it gives back tenulinic acid. The acid obtained by permanganate oxidation of both tenulin and isotenulin is therefore acetyltenulinic acid. The correctness of the formulas of the two acids was checked by the analysis of the acids themselves as well as by the analysis of their methyl esters.

The second approach was to apply hydrolytic reactions to isotenulin. When isotenulin is dissolved in concentrated sulfuric acid and heated for a short time, a substance, $C_{15}H_{20}O_4$, m. p. 255°, is obtained. This has the composition that would result from the hydrolytic loss of an acetyl group from isotenulin. At the same time exactly one mole of acetic acid is formed. The compound $C_{15}H_{20}O_4$, m. p. 255°, is identical with the by-product obtained by the action of 0.1 *N* sodium hydroxide or by prolonged action of 5% sodium carbonate solution on tenulin,[1] and this fact explains its formation as a by-product in the more drastic methods of preparing isotenulin. Further proof that the $C_{15}H_{20}O_4$ compound is deacetylated isotenulin is furnished by its ready reacetylation to isotenulin.

The same hydrolytic action takes place when concentrated sulfuric acid reacts on dihydroisotenulin. The deacetylated product $C_{15}H_{22}O_4$ melts at 203°. Alkali does not have the deep-seated action on dihydroisotenulin that it does on tenulin, and the hydrolysis may be brought about with little loss when aqueous alkali is employed. Both 10 and 50% potassium hydroxide solutions were used, and in each case the desacetyldihydroisotenulin, m. p. 203°, was obtained.

These facts constitute sufficient evidence of the presence of an acetoxy group in tenulin. It thus follows that tenulin may be represented as

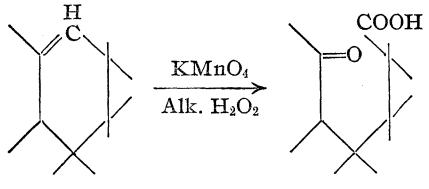


In further consideration of the acetyl group at-

(1) Clark, THIS JOURNAL, 61, 1836 (1939).

tention is directed to the fact that it is more firmly bound than ordinary *o*-acyls. Thus tenulin gave 10.1% acetyl by the standard acetyl method[2] and 12.8% when it was boiled with the alkali reagent for half an hour. The theoretical value is 14.05%. Again the standard procedure for the determination of acetyl in acetyltenulinic acid gave only 3.3% acetyl, and acetyltenulinic acid methyl ester was prepared in good yield by refluxing a solution of the acid in a methanolic hydrochloric acid mixture for one and one-half hours. This phenomenon may be interpreted in several ways, but it seems best to withhold comment until more pertinent facts are accumulated.

Likewise the reaction involving the formation of tenulinic acid is significant aside from the interpretation placed upon it in connection with the ester nature of tenulin. Since neither permanganate nor alkaline hydrogen peroxide attacks desacetyldihyroisotenulin, it is obvious that, in the reaction under consideration, the double bond is involved. The most likely mechanism to account for the addition of three oxygen atoms is the breaking of a double bond in an alicyclic ring to form a ketonic acid. This may be shown schematically as follows



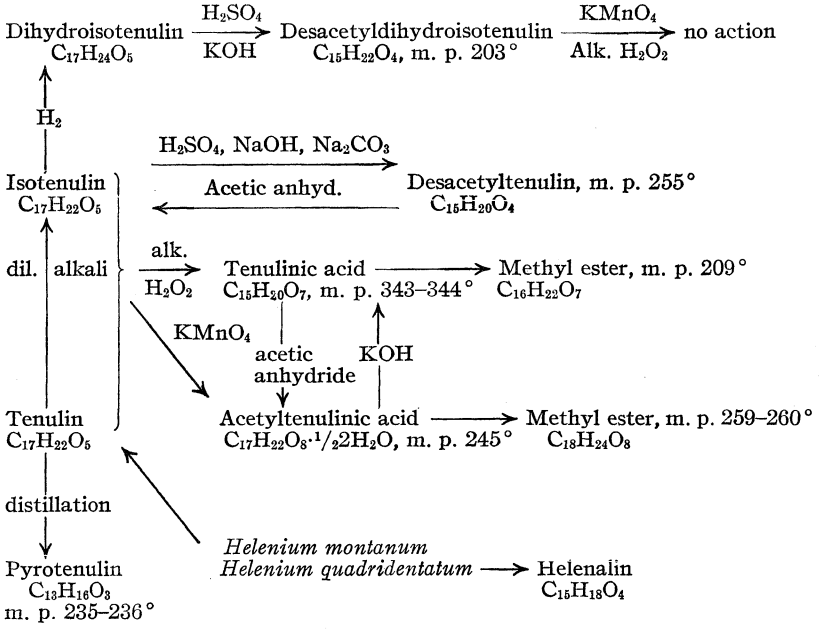
Attempts to prove such a reaction, however, have led to difficulties and further comment is therefore withheld until more information is available.

Another reaction, presented at this time for record only, is that when tenulin is distilled rapidly at atmospheric pressure, it yields a small quantity of a white crystalline compound whose composition is $C_{13}H_{16}O_3$. This has been named "pyrotenulin."

(2) Clark, *Ind. Eng. Chem., Anal. Ed.*, **9**, 539 (1937).

Two hitherto unexamined species of *Helenium*, *H. quadridentatum* and *H. montanum*, also were investigated for bitter and sternutative substances. The procedure followed was the same as that previously used.[1] It was found that *H. quadridentatum* contains helenalin and *H. montanum* yields tenulin.

DIAGRAM SHOWING THE INTERRELATIONS OF PREVIOUSLY UNRECORDED MATERIALS UNDER DISCUSSION



Experimental

Tenulinic Acid.—A solution of 1 g. of tenulin in 10 cc. of acetone, 10 cc. of water, and 8 cc. of 30% hydrogen peroxide was heated to boiling and treated portion-wise with 5 cc. of 10% sodium hydroxide solution. As the reaction and boiling proceeded, 10 cc. of water was added. After all the alkali had been added and the frothing had subsided, the solution was filtered and acidified with sulfuric acid (congo red). Crystallization began at once and yielded 0.57 g. of material which melted at 338–339°. This was recrystallized by acidifying a solution of its sodium salt with sulfuric acid until it had a constant melting point of 343–344°.

The purified product consisted of six-sided rods, many of which were broken into angular fragments. Its refractive indices as determined by the immersion method[3] were η_α, 1.507; η_β, indeterminate; η_γ, 1.595. In parallel polarized light (crossed nicols) the birefringence was extremely strong. Extinction on rods was usually inclined, and the elongation was negative. In convergent polarized light (crossed nicols) no interference figures were observed. The refractive indices were therefore determined by the statistical method. Those rods and fragments showing the maximum double refraction were se-

(3) The optical data recorded in this communication were determined by George L. Keenan, of the Food and Drug Administration of the U. S. Department of Agriculture.

lected for measuring the lowest and the highest indices of refraction.

Anal. Calcd. for $C_{15}H_{20}O_7$: mol. wt., 312.3; C, 57.68; H, 6.46.

Found: mol. wt. (by titration, calcd. to one COOH group), 311; C, 57.65; H, 6.50.

Isotenulin reacted in the same manner as tenulin. The resulting acid was obtained in the same yield as from tenulin, its melting point and composition were identical with those of tenulinic acid, and when the two substances were mixed there was no depression of the melting point.

Anal. C, 57.61; H, 6.63.

Tenulinic Acid Methyl Ester.—This material was made by two procedures. An acetone solution of the acid (0.5 g. in 10 cc.) was treated with an excess of diazomethane. The reaction took place at once, and the resulting solution was evaporated to dryness under reduced pressure. The residue was dissolved in 10 cc. of methanol, and then 30 cc. of water was added. The ester immediately crystallized. It had a m. p. of 208°. Upon recrystallization from methanol–water (1–4), long colorless rods that melted at 209° were obtained.

Anal. Calcd. for $C_{16}H_{22}O_7$: C, 58.88; H, 6.80; OCH_3(1), 9.51. Found: C, 58.94; H, 6.83; OCH_3, 9.55.

The second procedure for preparing the ester consisted in refluxing for one and one-half hours a solution of 0.2 g. of the acid in 5 cc. of methanol and 0.25 cc. of concentrated hydrochloric acid. Upon diluting the reaction mixture with water, long colorless rods were obtained (m. p. 207°). After recrystallization this material did not depress the melting point of the ester made with diazomethane.

Acetylation of Tenulinic Acid.—Tenulinic acid was acetylated by allowing a solution of 0.2 g. of the acid in 2 cc. of pyridine and 1 cc. of acetic anhydride to stand at room temperature overnight. The solution was then diluted with water and acidified with sulfuric acid (congo red). Crystallization began at once, and a quantitative yield of the acetate was obtained. It melted at 243°, and further recrystallizations did not alter the melting point. When mixed with acetyltenulinic acid obtained by permanganate oxidation of tenulin (see below), the melting point was not depressed.

Acetyltenulinic Acid.—A well-stirred solution of 3 g. of tenulin dissolved in 50 cc. of acetone and 25 cc. of water was slowly treated with 330 cc. of 1% aqueous solution of potassium permanganate, and then 3.3 g. of crystalline potassium permanganate was added portionwise. When the reaction was finished, the manganese dioxide was removed by filtration and the filtrate was evaporated, under reduced pressure, to about 60 cc. The concentrate was acidified with sulfuric acid (congo red) and allowed to crystallize. The yield was 1.8 g. of dense colorless crystals, usually joined together in fern-like aggregates. The material melted at 236°. It was recrystallized from its solution in acetone by adding three volumes of water. It then melted at 245°, with the evolution of gas. When it was recrystallized from other liquids its melting point varied from 234 to 245° depending upon the solvent used. Judged from analysis of the various preparations the material was pure, but slight variations in the water of crystallization influenced the melting points. Material crystallized from glacial acetic acid melted at 234–235°. It consisted of sphenoids belonging to the tetragonal system. Many of them broke into irregular fragments. Their refractive indices as determined by the immersion method were as follows: η_ω, 1.544; η_ϵ, 1.552; both ± 0.002. In parallel polarized light (crossed nicols) the fragments invariably extinguished sharply, and birefringence was weak. In convergent polarized light (crossed nicols) no interference figures were observed. The refractive indices, therefore, were determined for two positions of extinction on a number of grains in random orientation. One of the values, η_ω, was the same in all grains, while the other of maximum numerical magnitude was designated as η_ϵ.

Anal. Calcd. for $C_{17}H_{22}O_8 \cdot {}^1/_2H_2O$: mol. wt., 363.4; C, 56.19; H, 6.38; acetyl, 11.84. Found: material recrystallized from acetone–water, m. p. 245°; mol. wt. (by titration, calcd. to one COOH group), 363; C, 56.69; H, 6.66; acetyl (standard procedure), 3.3.

As with tenulin, isotenulin also gave acetyltenulinic acid. The identity of the material thus obtained was established by its melting point, mixed melting point and analysis.

Anal. C, 56.53; H, 6.74.

Hydrolysis of Acetyltenulinic Acid.—A solution of 0.1 g. of acetyltenulinic acid in 5 cc. of 10% sodium hydroxide solution was boiled for fifteen minutes. The reaction mixture was then made acid with sulfuric acid (congo red) and allowed to crystallize. This material, after two recrystallizations, melted with decomposition at 343–344°, and there was no depression of the melting point when it was mixed with an authentic sample of tenulinic acid.

Acetyltenulinic Acid Methyl Ester.—This compound was prepared by the two methods used to obtain tenulinic acid methyl ester except that it was crystallized from acetone by adding three volumes of water. When recrystallized to a constant melting point of 259–260°, preparations obtained in both ways consisted of thick plates and prisms.

Anal. Calcd. for $C_{18}H_{24}O_8$: C, 58.69; H, 6.57; OCH_3, 8.42. Found: C, 58.95; H, 6.58; OCH_3, 8.48.

Desacetylisotenulin.—A solution of 1 g. of isotenulin in 4 cc. of concentrated sulfuric acid was heated for one minute in a water-bath at 90°. Crushed ice and water were then added to dilute the mixture to about 50 cc. In a short time crystallization began, and on completion 0.3 g. of white crystals, m. p. 175–183°, was obtained. This product was recrystallized from *n*-butanol to a constant melting point of 255°. When mixed with the compound melting at 255° previously obtained as a by-product from the preparation of isotenulin, there was no depression of the melting point.

Anal. Calcd. for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63. Found: C, 68.32; H, 7.78.

The acid mother liquors from the above experiment contained a volatile acid, which was recovered by distillation and estimated and identified by the Dyer procedure.[4]

(4) Clark and Hillig, *J. Assoc. Official Agr. Chem.*, **21**, 684 (1938).

The distillation curve for the recovered acid was a straight line with a distillation constant characteristic of acetic acid. The acid was therefore acetic, and the quantity recovered corresponded to one mole of acid from a mole of isotenulin.

Acetylation of Desacetylisotenulin.—A solution of 0.1 g. of the $C_{15}H_{20}O_4$ compound in 1 cc. of pyridine and 0.5 cc. of acetic anhydride was allowed to react overnight. Water was then added, causing the liquid to crystallize. Long colorless rods that melted at 160° were obtained. Recrystallization of these from methanol and water (1–3) raised their melting point to 161°. The product was identified as isotenulin by its melting point, mixed melting point with an authentic sample of isotenulin, and its optical crystallographic properties.

Hydrolysis of Dihydroisotenulin.—Dihydroisotenulin was hydrolyzed with concentrated sulfuric acid by the procedure used with isotenulin. Several days were required for complete crystallization from the reaction mixture. The product was purified by recrystallization from its methanol solution by adding water. It melted at 203°.

Anal. Calcd. for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33. Found: C, 67.88; H, 8.61.

Sodium hydroxide was also used as a hydrolyzing agent. A mixture of 0.5 g. of dihydroisotenulin and 10 cc. of 10% sodium hydroxide was heated and stirred until a homogeneous solution resulted. This was then diluted with water to *ca.* 50 cc. and acidified to congo red with sulfuric acid. Colorless crystals (240 mg.) separated. They melted at 202°, and when they were mixed with the compound obtained above with sulfuric acid there was no depression of the melting point. The acid mother liquors were examined for acetic acid as reported under isotenulin. The results were identical.

Pyrotenulin.—A half gram of purified tenulin was heated until the first violent evolution of gas ceased. The resulting melt was then placed in a strong Bunsen flame and rapidly distilled. The distillate was caught in a thin-walled bulb blown close to the bottom of the test-tube. This was broken, and its contents dissolved in chloroform. The solution was filtered through Norit and diluted with several volumes of methanol. The liquid was distilled until the chloroform was removed, whereupon the methanol concentrate crystallized. The product consisted of colorless hexagonal plates, m. p. 235–236°.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.88; H, 7.32. Found: C, 70.90; H, 7.22.

Summary

Evidence has been presented to show that tenulin contains a double bond, an acetoxyl group, and a hydroxyl and a carbonyl group, both of which are sterically hindered.

A summary of the reactions of tenulin which have been used in this discussion and which have hitherto been unrecorded is shown diagrammatically in a chart.

Two hitherto unexamined species of *Helenium*, *i. e.*, *H. quadridentatum* and *H. montanum*, have been investigated for bitter and sternutative substances. *H. quadridentatum* contains helenalin, while *H. montanum* contains tenulin.

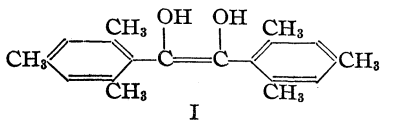
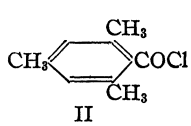
Enediols. III. 1,2-Dimesitylacetylene Glycol

BY REYNOLD C. FUSON, C. H. MCKEEVER[1] AND JOSEPH CORSE

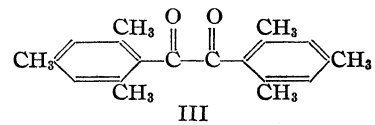
The isolation of a stable enediol, 1,2-dimesitylacetylene glycol (I), was reported recently.[2] The present paper presents the experimental details upon which the earlier communication was based. The enediol was obtained by the action of the binary mixture, Mg + MgI_2,[3] on mesitoyl chloride (II) or mesitil (III). The products from the two sources were identical. Both reverted to the benzil when exposed to the air or other oxidizing agents, and both rearranged to mesitoin (IV) under the influence of hydrochloric acid.



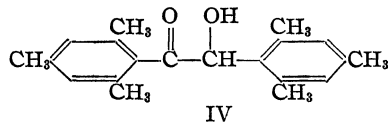
I



II



III



IV

Treatment of this enediol with acetic anhydride gave a diacetate (m. p. 164–165°) accompanied by a very small amount of a second diacetate (m. p. 218°). Mesitil and the acetate of mesitoin were also isolated.

Benzoylation with benzoyl chloride in the presence of pyridine converted the enediol into a dibenzoate melting at 188.5–189.5°.

By hydrogenation of mesitil in methanol,

(1) Röhm and Haas Research Assistant.

(3) Gomberg and Bachmann, *ibid.*, **49**, 236 (1927).

Thompson[4] obtained an enediol which gave a dibenzoate melting at 235°, and concluded that he had a stereoisomer of the enediol of Fuson and Corse. We have shown that the enediol made by Thompson's method yields chiefly the high-melting diacetate when treated with acetic anhydride. However, a small amount of the low-melting diacetate is formed also along with a large amount of the acetate of mesitoin.

In view of this result, the benzoylation was repeated and the mother liquors from the crystallization of the high-melting dibenzoate were examined with great care. A small amount of the low-melting dibenzoate was found. The very remarkable discovery was then made that this dibenzoate was the sole product when the catalytic hydrogenation was carried out in low-boiling petroleum ether instead of methanol. It is, therefore, not entirely clear what relationship obtains between the source of the enediol and its behavior toward acylating agents. However, it can be said that any given sample of enediol, regardless of its history, yields predominantly one form or the other of the expected diester. The second diester if produced at all is always in small amount. This observation supports Thompson's conclusion that the enediol exists in two stereoisomeric forms. However, it implies that the samples which have been described may be mixtures. The alternative is to assume partial isomerization during esterification. This question is being studied.

Experimental

Action of the Binary Mixture on Mesitoyl Chloride.—The binary mixture was prepared according to the directions of Gomberg and Bachmann.[3] To 3 g. of magnesium turnings, 60 cc. of dry ether and 120 cc. of dry benzene was added 15.3 g. of iodine in several small portions. When the reaction mixture had become colorless and cooled to room temperature, the air in the flask was swept out by a stream of dry, oxygen-free nitrogen. A solution of 11 g. of the chloride in 10 cc. of dry ether was then added over a period of fifteen minutes by means of a dropping funnel. Stirring was continued for sixteen to eighteen hours, in a nitrogen atmosphere. At the end of this time the magnesium had nearly disappeared and the solution was dark red.

The reaction mixture was filtered through folded cheesecloth into a separatory funnel containing 8 cc. of acetic acid and 100 cc. of ice water. The ether–benzene layer was separated and washed *rapidly* with water, with 5% sodium thiosulfate solution, again with water, then with 10% potassium bicarbonate solution and finally once more with water. The solution was then dried for a few minutes over calcium chloride, filtered and evaporated to a thin sirup as rapidly as possible with the aid of the water pump. Dilution of the brown sirup with 50 cc. of petroleum ether and cooling, precipitated the enediol as a white crystalline material which was separated and washed with petroleum ether. The yield amounted to 3.1 g. or 35% of the theoretical.

The enediol was unstable in the presence of oxygen, being rapidly autoxidized to the benzil. It was soluble in ether, benzene and alcohol but insoluble in petroleum ether and aqueous alkali. It immediately decolorized solutions of 2,6-dichlorobenzeneoneindophenol; Tollens' reagent and cold cupric acetate solutions were also immediately reduced.

The mother liquors from the enediol yielded 3 g. of mesitil or 34% of the theoretical. A little tarry material also was isolated.

When only 1.5 g. of iodine was used instead of the usual 15.3 g., and the procedure carried out as before, no reaction was apparent; only mesitoic acid was isolated.

In one run out of thirteen mesitoin was isolated (28% yield) instead of the enediol.

Action of the Binary Mixture on Mesitil.—To the binary mixture, made from 1.5 g. of magnesium and 7.6 g. of iodine in 60 cc. of benzene and 30 cc. of ether, was added 4.4 g. of mesitil. Stirring was continued for twenty-four hours, the mixture being kept under a nitrogen atmosphere. When the mesitil was added the solution turned dark red-brown, probably because of the liberation of iodine.[3] After a few hours, a dark red-brown precipitate formed which later disappeared. At the end of the reaction the mixture had the same appearance as that obtained from mesitoyl chloride and the binary mixture; it was decomposed and treated in the same manner as in the preceding experiment. Two and seven-tenths grams of the enediol was obtained, a yield of 60% of the theoretical. In addition, mesitil was recovered.

Hydrogenation of Mesitil.—The enediol also was made by the hydrogenation of mesitil in low-boiling petroleum ether.

One and one-half grams of mesitil was almost completely dissolved in 50 cc. of low-boiling petroleum ether. Approximately 0.02 g. of platinum oxide catalyst was added and the mixture reduced at room temperature under a pressure of one and one-half atmospheres. The enediol precipitated as it was formed and the reduction was complete when the solution became colorless. The reaction mixture was filtered, the enediol dissolved in ether, this solution filtered to remove the catalyst, the ether evaporated to a small volume and the enediol precipitated by addition of low-boiling petroleum ether. The yields varied from 85 to 95% of the theoretical amount.

Ketonization of the Enediol.—A solution of 1.3 g. of the enediol and 6 cc. of methanol which previously had been saturated with dry hydrogen chloride was refluxed for forty-five minutes, allowed to cool and poured into 70 cc. of water. A white crystalline compound separated. It was collected on a filter and recrystallized from 70% aqueous methanol; yield 1.2 g. The compound melted at 130–131°, and a mixed melting point with an authentic sample of mesitoin[5] showed no depression.

(5) Fuson, Emerson and Weinstock, *ibid.*, **61**, 412 (1939).

The Acetate of Mesitoin.—A solution of 1.2 g. of mesitoin in 5 cc. of acetyl chloride was refluxed for two hours. It was poured into water, extracted with ether and the ether extracts were washed with water, 10% potassium bicarbonate and again with water. The ether solution was dried over calcium chloride and after filtration the ether was removed by an air blast. The solid which remained crystallized as long white needles from ether–petroleum ether and melted 106–107°; the yield was 1.2 g.

Anal. Calcd. for $C_{22}H_{26}O_3$: C, 78.07; H, 7.75; acetyl no., 12.7. Found: C, 78.11; H, 7.28; acetyl no., 10.6, 11.5.

Refluxing a solution of 0.085 g. of the acetate in 2.1 cc. of methanol and 0.2 cc. of concentrated hydrochloric acid for two hours gave mesitoin in good yield.

The Diacetates of the Enediol.—A solution of 1 g. of the enediol, prepared by the bimolecular reduction of mesitoyl chloride, and 5 cc. of acetic anhydride was refluxed for three hours and poured into water; the mixture was warmed to decompose the excess acetic anhydride and extracted with ether. The ether extracts were washed twice with a 10% solution of potassium bicarbonate, then with water and dried over calcium chloride; the ether was allowed to evaporate at room temperature. There was obtained a mixture of four compounds, which were separated as follows. The mixture was taken up in methyl alcohol; the very small amount of a diacetate which was insoluble was removed by filtration. After recrystallization from a benzene–low-boiling petroleum ether mixture it melted at 218°. It could be hydrolyzed to mesitil with dilute alcoholic potassium hydroxide.

Anal. Calcd. for $C_{24}H_{38}O_4$: C, 75.76; H, 7.43. Found: C, 75.69; H, 7.48.

When the methyl alcohol solution cooled to room temperature there precipitated a second diacetate, m. p. 156–160°, which after several recrystallizations from methyl alcohol melted at 164–165°.

Anal. Calcd. for $C_{24}H_{28}O_4$: C, 75.76; H, 7.43; acetyl no., 22.6. Found: C, 75.41; H, 7.61; acetyl no., 20.7.

When the methyl alcohol solution was evaporated to dryness, there was obtained the acetate of mesitoin contaminated with a small amount of mesitil. The structure of these compounds was proven by mixed melting point determinations with known samples.

All four compounds were obtained no matter how the enediol had been prepared. The enediol prepared by bimolecular reduction of the acid chloride and the one prepared by reduction of mesitil in low-boiling petroleum ether behaved exactly alike. They gave only a trace of the high-melting diacetate, a 30–40% yield of the diacetate melting at 164–165° and a mixture of mesitil and acetate of mesitoin.

In the case of the enediol prepared by catalytic reduction in methyl alcohol,[4] the amounts of the products were very different; the product consisted of a 20–30% yield of the high-melting diacetate, a trace (and sometimes none) of the diacetate which melted at 164–165° and a good yield of the acetate of mesitoin contaminated with small amounts of mesitil.

If mesitil is reduced in acetic anhydride according to the method of Thompson[4] a 90% yield of the diacetate, m. p. 164–165°, is obtained. This compound was also obtained when mesitil was treated with sodium according to the method of Kohler and Baltzly[6] with subsequent treatment with acetyl chloride rather than benzoyl chloride.

When acetyl chloride was used instead of acetic anhydride, the enediol yielded the acetate of mesitoin in 70–80% yield, together with only small amounts of the diacetates.

The Benzoates of the Enediol.—To 2 cc. of benzoyl chloride and 10 cc. of pyridine was added 0.3 g. of the enediol prepared by the bimolecular reduction of mesitoyl chloride. The mixture was refluxed gently for two hours, poured into water, acidified with dilute hydrochloric acid and extracted with ether. The ether extract was washed thoroughly with a 10% solution of potassium bicarbonate, water, dilute hydrochloric acid and water; it was then dried over calcium chloride and the ether was evaporated. The dibenzoate crystallized from ether–petroleum ether mixture, m. p. 188.5–189.5°. A second dibenzoate could not be found. The enediol prepared by catalytic reduction of mesitil in low-boiling petroleum ether, when treated as above, yielded the same compound, m. p. 188–189°. The enediol prepared from catalytic reduction in *methyl alcohol* yielded a dibenzoate, m. p. 235°.[2] Upon evaporation of the solvent, there was precipitated a second compound which after two recrystallizations from absolute alcohol melted at 188–189°. A mixed melting point determination proved it to be identical with the dibenzoate prepared above.

Summary

1,2-Dimesitylacetylene glycol has been prepared in three different ways. It has been caused to rearrange to the benzoin. The enediol gives two diacetates and two dibenzoates, presumably pairs of *cis-trans* isomers.

Identification of Organic Compounds. III. Chlorosulfonic Acid as a Reagent for the Characterization of Aromatic Ethers[1,2]

BY ERNEST H. HUNTRESS AND FREDERICK H. CARTEN

The use of chlorosulfonic acid as a tool for the characterization of organic compounds whose application to the identification of aryl halides was reported in the first paper[3] of this series has now been extended to thirty-six aromatic ethers. The principle employed is twofold: first, introduction of one sulfonyl chloride group into each aromatic nucleus by direct treatment with chlorosulfonic acid, and, second, conversion of the resultant sulfonyl chlorides into the corresponding sulfonamides. The sulfonyl chlorides were generally obtained in excellent yields and their conversion to sulfonamides was nearly quantitative. The resultant products crystallize well and possess sharp and characteristic melting points. Data expressing the results of this study are given in Table I.

TABLE I

SULFONAMIDES[a] FROM AROMATIC ETHERS

Original compound	Sulfonamide	Yield, %	M. p. obsd. uncor., °C.
A. Substituted benzenesulfonamides			
Anisole	*p*-Methoxy-	53	110–111[b]
Phenetole	*p*-Ethoxy-	78	149–150[c]
n-Propyl phenyl ether	*p*-(*n*-Propoxy)-	68	116–117
n-Butyl phenyl ether	*p*-(*n*-Butoxy)-	35	103–104
o-Tolyl methyl ether	3-Methyl-4-methoxy-	84	137[d,e,f]
m-Tolyl methyl ether	2-Methyl-4-methoxy-	69	129–130[g]
p-Tolyl methyl ether	5-Methyl-2-methoxy-	86	182[h]
o-Tolyl ethyl ether	3-Methyl-4-ethoxy-	71	148–149[i]
m-Tolyl ethyl ether	2-Methyl-4-ethoxy-	61	110–111[b]
p-Tolyl ethyl ether	5-Methyl-2-ethoxy-	77	138–138.5[j,f]
n-Propyl *p*-tolyl ether	2-(*n*-Propoxy)-4-methyl-	54	126–127
n-Butyl *o*-tolyl ether	4-(*n*-Butoxy)-5-methyl-	44	95–96
Catechol dimethyl ether	3,4-Dimethoxy-	89	135–136[k]
Resorcinol dimethyl ether	2,4-Dimethoxy-	53	166–167[l]
Hydroquinone dimethyl ether	2,5-Dimethoxy-	53	148[i,m]
Catechol diethyl ether	3,4-Diethoxy-	81	162–163
Resorcinol diethyl ether	2,4-Diethoxy-	59	184–185

point of 3-chloro-4-ethoxybenzenesulfonamide (m. p. 132–133°) with 5-chloro-2-ethoxybenzenesulfonamide (m. p. 134–134.5°) was depressed to 129–130°. [r] Recorded m. p. 131–132°, Suter, THIS JOURNAL, **53**, 1115 (1931). [s] With these compounds use of the usual quantity (5.0 g.) of chlorosulfonic acid yielded mainly water-soluble products. Upon reduction of the chlorosulfonic acid to two grams, however, the sulfonamides were obtained readily in the indicated yields. [t] A mixed melting point of 4-methoxynaphthalenesulfonamide-1 (m. p. 156–157°) with 7-methoxynaphthalenesulfonamide (m. p. 150–151°) was depressed to 146–147.5°. [u] Recorded m. p. 167°, Witt and Schneider, *Ber.*, **34**, 3182 (1901). [v] Recorded m. p. 155°, Lapworth, *Chem. News*, **71**, 206 (1895). [w] Recorded m. p. 158–160°, ref. *r*.

Experimental

The melting points reported in this paper are uncorrected. They were determined on a standard rod form 360° melting point thermometer in a copper melting point block of the Berl and Kullmann type. Observation of the sample was facilitated by means of a small twenty-five power microscope permanently attached to the apparatus.

The purification of all materials used in this work was the same as stated in our earlier paper. The chlorosulfonylation procedure was identical with Procedure I of the earlier paper. Since with the ethers the intermediate sulfonyl chlorides were sometimes difficult to purify, their chloroform solution (resulting from Procedure I) was treated directly with dry powdered ammonium carbonate (2.0 g.) and the mixture evaporated to dryness. After washing the dry residue with several 10-cc. portions of cold distilled water (to remove ammonium chloride), the crude sulfonamide was recrystallized from dilute alcohol. If desired the sulfonamides may be purified by solution in 6 *N* alkali and reprecipitation with acid (removal of traces of sulfonamides).

The color usually observed during the reaction of chlorosulfonic acid with aromatic ethers varies from pale yellow to brown. In a few cases, however, other colors were noted which appear to have diagnostic value. A red color was observed in three cases, *viz.*, *o*-tolyl methyl ether, *o*-tolyl *n*-butyl ether and trimethylene glycol diphenyl ether. A blue color was observed in one case, *viz.*, *p*-methoxybiphenyl. Shades of green were noted with eight compounds, *viz.*, *o*- and *p*-chloroanisole, *o*- and *p*-chlorophenetole, α- and β-naphthyl methyl ether, and α- and β-naphthyl ethyl ether.

Satisfactory monochlorosulfonylation could not be obtained with six other compounds which were studied, *viz.*, *o*- and *p*-methoxybiphenyl, methyl and ethyl benzyl ether, diphenylene oxide, and 4,4′-dibromodiphenyl ether.

Summary

1. A method for the identification of aromatic ethers by chlorosulfonylation with chlorosulfonic acid has been shown to yield excellent results.

2. Of forty-two aromatic ethers examined, thirty-six yield monosulfonyl chlorides readily converted to characteristic sulfonamides.

3. Eighteen previously unreported sulfonamides prepared in the course of this work have been characterized and structures tentatively assigned.

Some Fluorine and Chlorine Derivatives of Sulfanilamidobenzenesulfonic Acids

BY C. M. SUTER AND ARTHUR W. WESTON[1]

Recently it has been reported that the three isomeric sulfanilamidobenzenesulfonic acids[2] have a marked therapeutic effect against β-hemolytic streptococcus infections in mice, the ortho compound being superior to sulfanilamide. In an extension of the investigation on fluorine derivatives of aromatic medicinals in progress in this Laboratory,[3] several fluorine and chlorine derivatives of sulfanilamidobenzenesulfonic acid have been prepared.

4-Fluoroaniline-2-sulfonic acid was obtained readily by sulfonation of *p*-fluoroacetanilide with 100% sulfuric acid, whereas *p*-fluoroaniline remains unchanged under the same conditions. When 15% oleum was employed as the sulfonating agent the anilide gave the isomeric 3-sulfonic acid. 4-Chloroacetanilide behaved in similar fashion.[4] This convenient method for obtaining the isomeric 4-haloanilinesulfonic acids was developed by Kreis[5] for the case of *p*-bromoacetanilide. Both acids have been obtained[6] by direct sulfonation of *p*-chloroaniline with 15% oleum. The structures of the sulfonic acids were determined by bromination in aqueous solution, sulfonic acid groups ortho to amino groups under-

going replacement with halogen[7] whereas in meta sulfonic acids the sulfo substituent is unaffected.[8]

The sulfonic acids were condensed with *p*-acetaminobenzenesulfonyl chloride in alkaline solution,[2] and the acetyl group removed by alkaline or acid[9] hydrolysis, the latter giving the better results.

The sodium salts of the sulfanilamidobenzenesulfonic acids and also N-sulfanilyl-4-fluoroaniline were tested for their therapeutic action against Streptococcus infections in white mice.[10]

None of the compounds evidenced any therapeutic effect when administered orally in daily doses of 10 mg. per 20 g. mouse for four days, except the N-sulfanilyl-4-fluoroaniline and this was much less effective than sulfanilamide. The sodium sulfonates were further tested against Type I Pneumococcus infections, also in white mice, employing 20 mg. per dose. Doses were administered simultaneously with the inoculation of the organisms, seven hours later and then at 24-hour intervals for a total of six doses in five days.

Here also the results showed an absence of therapeutic effect. Crossley, Northey and Hultquist[2] have shown that the presence of a methyl, ethoxyl or hydroxyl attached to the ring bearing the sulfonic acid group nullifies the therapeutic activity of otherwise active compounds. Fluorine and chlorine are in the same category.

Experimental

Materials.—*p*-Fluoroacetanilide[11] melting[12] at 150–151° and *p*-chloroacetanilide were obtained in 80% yields by acetylation of *p*-fluoroaniline in aqueous solution with acetic anhydride at 50°. The *p*-acetaminobenzenesulfonyl chloride was the crude product obtained in the usual manner.

4-Fluoro- and 4-Chloroaniline-2-sulfonic Acids.—A mixture of 10.7 g. (0.07 mole) of *p*-fluoroacetanilide and 7 g. (0.07 mole) of 100% sulfuric acid was heated until the solid melted and kept at this temperature until acetic acid was no longer evolved. The thick paste was then heated in an oil-bath at 170–180° for two hours, cooled and mixed with water. Recrystallization from hot water (Darco) gave 8.6 g. (64%) of white flaky crystals which decomposed above 310°.

Anal. Calcd. for $C_6H_6O_3NSF$: neut. equiv., 191.1. Found: neut. equiv., 190.8.

4-Chloroaniline-2-sulfonic acid[4,6] was obtained in a 49% yield by a similar procedure as fine white needles which decomposed above 325°.

Anal. Calcd. for $C_6H_6O_3NSCl$: neut. equiv., 207.5. Found: neut. equiv., 206.9, 206.6.

Bromination of 0.5 g. of 4-fluoroaniline-2-sulfonic acid in aqueous solution with excess 5% aqueous bromine gave 0.6 g. of a slightly pink solid which crystallized from dilute acetic acid as white needles melting at 64–65°. A mixture of this with the 2,6-dibromo-4-fluoroaniline obtained from *p*-fluoroaniline, m. p. 63–64°, showed no depression of the melting point.

Anal.[13] (Kjeldahl) Calcd. for $C_6H_4NBr_2F$: N, 5.21. Found: N, 5.09.

Bromination of 4-chloroaniline-2-sulfonic acid similarly gave 2,6-dibromo-4-chloroaniline, m. p. 94.5–95.5°. This melting point is about the average of those given in the literature for this compound.[14]

4-Fluoro- and 4-Chloroaniline-3-sulfonic Acids.—A mixture of 10.7 g. (0.07 mole) of 4-fluoroacetanilide and 65 ml. of 15% oleum was heated to 130° where frothing occurred and the temperature rose to 145°. After fifteen minutes at 140–145° the mixture was allowed to cool, poured on ice and the solid crystallized from hot water using decolorizing carbon. The yield of fine white needles was 8.4 g. (63%). These decomposed above 310°.

Anal. Calcd. for $C_6H_6O_3NSF$: neut. equiv., 191.1. Found: neut. equiv., 190.7.

4-Chloroaniline-3-sulfonic acid was obtained in 30–34% yield. It crystallized in white needles which decomposed above 310°.

Anal. Calcd. for $C_6H_6O_3NSCl$: neut. equiv., 207.5. Found: neut. equiv., 206.6.

Bromination of an aqueous solution containing 0.5 g. of the 4-fluoroaniline-3-sulfonic acid gave no precipitate. Evaporation of the solution to dryness gave a solid which was very soluble in water and alcohol but crystallized from concentrated hydrochloric acid. It was not obtained in a high state of purity. The basic properties of the amine group are here so completely lost that internal salt (dipolar ion) formation does not occur.

Anal. Calcd. for $C_6H_4O_3SNBr_2F$: neut. equiv., 349. Found: neut. equiv., 342.

Bromination of the 4-chloroaniline-3-sulfonic acid likewise gave no precipitate, confirming its structure. The anhydrous bromosulfonic acid was hygroscopic but the nature of the resulting hydrate was not determined. The compound crystallized as fine white needles which decomposed above 310°.

Anal. Calcd. for $C_6H_4O_3NSClBr_2$: neut. equiv., 365.5. Found: neut. equiv., 370, 372.

N-Sulfanilyl-4-fluoroaniline.—To a well-stirred mixture of 8.9 g. (0.08 mole) of *p*-fluoroaniline, 1.6 g. (0.015 mole)

(7) Limpricht, *Ann.*, **181**, 193 (1876); *Ber.*, **9**, 474 (1876).

(8) The two sulfonating agents lead to different products even though acetic acid is lost in both reactions. One explanation for this is that when the theoretical amount of 100% sulfuric acid is employed the first-formed phenylaminosulfonic acid rearranges when heated to 170–180°, while with the excess oleum the phenylaminosulfonic acid is sulfonated by the excess reagent. This is substantiated by the fact that *p*-fluoroaniline sulfate remains unchanged at 170–180° as already mentioned.

(12) All melting points are corrected.

(13) Analysis by Mr. E. Washburn of this Laboratory.

(14) Chattaway and Orton, *J. Chem. Soc.*, **79**, 825 (1901); Zincke, Heuser and Möller, *Ann.*, **333**, 338 (1904); Reed and Orton, *J. Chem. Soc.*, **91**, 1552 (1907); Gilbert, THIS JOURNAL, **48**, 2242 (1926).

of sodium carbonate and 60 ml. of water, was added simultaneously and gradually 18.7 g. (0.08 mole) of *p*-acetaminobenzenesulfonyl chloride and enough 30% sodium hydroxide to maintain a *p*H of about 10. Stirring was continued for thirty minutes after the additions were complete and then 8 g. of solid sodium hydroxide was added and the mixture refluxed for ninety minutes. Exact neutralization gave 10 g. (47%) of the anilide which after crystallization from dilute methanol melted at 163–164°. Considerable unchanged *p*-fluoroaniline was recovered.

Anal. (Kjeldahl) Calcd. for $C_{12}H_{11}O_2SN_2F$: N, 10.53. Found: N, 10.8.

Sulfanilamidofluoro- and -chlorobenzenesulfonic Acids.—*p*-Acetaminobenzenesulfonyl chloride was condensed with the aminosulfonic acids essentially according to the procedure of Crossley, Northey and Hultquist,[2] and the sulfanilamido compounds were isolated as the free acids. The sodium salts of these were very soluble in water. The yields and analyses are summarized in Table I.

TABLE I

Compound, -benzenesulfonic acid	Yield,[a] %	Decompn. temp., °C.	Neutral eq.[b] Calcd.	Found
2-Sulfanilamido-5-fluoro-	14[c]	285	346	343
5-Sulfanilamido-2-fluoro-	42	260	346[d]	345
2-Sulfanilamido-5-chloro-	20[c]	300	380.5[e]	383
5-Sulfanilamido-2-chloro-	57	310	362.5	360

[a] These percentages do not take into account unreacted starting materials which were recovered. [b] The indicator used was methyl red–methylene blue. [c] The low yields were partly due to the low solubilities of the original sodium sulfonates. [d] This compound crystallized as the monohydrate. *Anal.* Calcd. for $C_{12}H_{11}O_5N_2S_2F \cdot H_2O$: neut. equiv., 364. Found: neut. equiv., 361.2. [e] This compound crystallized as the monohydrate. *Anal.* Calcd. for $C_{12}H_{11}O_5N_2S_2Cl \cdot H_2O$: H_2O, 4.72. Found: H_2O, 4.89. The dry material absorbed water rapidly when exposed to the air.

Summary

The isomeric 4-fluoroaniline- and 4-chloroaniline-sulfonic acids have been prepared. The sulfanilamidohalobenzenesulfonic acids prepared from these did not exhibit therapeutic action against Streptococcus and Type I Pneumococcus infections in white mice. N-Sulfanilyl-4-fluoroaniline showed a slight effect against Streptococcus infections.

A Series of 2-Methyl-5-alkyl-4,6-dihydroxypyrimidines

BY LIVINGSTON P. FERRIS II* AND ANTHONY R. RONZIO

E. L. Pinner[1] prepared 2-phenyl-4,6-dihydroxypyrimidine by the condensation of benzamidine with malonic ester. Dox and Yoder[2] continued this investigation obtaining more members of the same series. At this time they pointed out that the condensation using aliphatic amidines had not been tried. Remfry[3] discovered a reaction in which malonamide condensed with substituted malonic esters to give pyrimidines, identical in structure to those which theoretically should form if aliphatic amidines successfully condensed with substituted malonic esters.

We have investigated this reaction using acetamidine and substituted malonic esters in the presence of sodium alcoholate and have found that the expected pyrimidines are formed. The first six members of the series have been prepared for the purpose of a pharmacological study. Absorption spectra data were taken for the first member of the series.

Experimental Part

Acetamidine hydrochloride, one-eighth mole, and either the redistilled malonic ester or the redistilled monoalkyl substituted malonic ester, one-twentieth mole, were added in the order given, to about 150 cc. of absolute alcohol in which had been dissolved 3.3 g. of sodium (slight excess over one-eighth mole). After standing for two to three days, the solution was exactly neutralized with concentrated hydrochloric acid. Enough water to dissolve the precipitated sodium chloride was then added. The un-

[a] First prepared by Remfry, ref. 3.

dissolved pyrimidine was filtered, decolorized in boiling glacial acetic acid, and reprecipitated by the addition of ether. After several reprecipitations in this manner, the pyrimidines left no residue when ignited and, after drying over phosphorus pentoxide *in vacuo* at 100°, gave correct analyses.

The pyrimidines prepared, as well as experimental and analytical data, are shown in Table I.

The pyrimidines are colorless compounds, slightly soluble in water, the solubility decreasing with increase in molecular weight. Definite melting points were not shown by any member of the series but sublimation took place between 260–350°. In a sealed tube they decomposed without melting.

The pyrimidines required a special Dumas method for correct nitrogen analyses.

The absorption spectra curves for 2-methyl-4,6-dihydroxypyrimidine in neutral, acid and basic solution are shown in Fig. 1. The curves show a maxima at about 2600 Å. The absorption spectrum curve for this pyrimidine in neutral solution shows a slight break at 2700 Å.

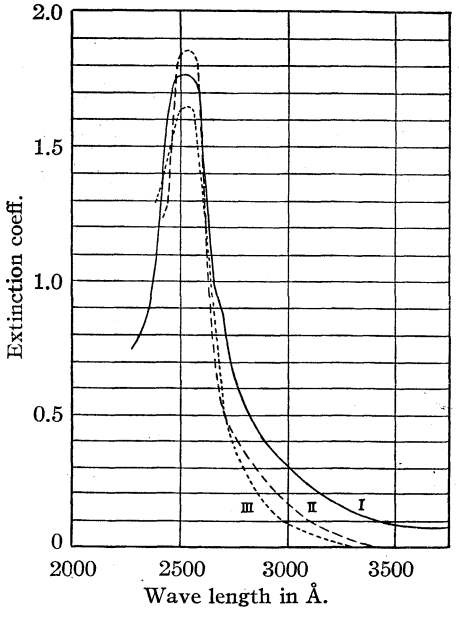

Fig. 1.—2-Methyl-4,6-dihydroxypyrimidine: I, 1.06 mg./50 cc. H_2O; II, 1.01 mg./50 cc. H_2O, 1 cc. concd. HCl; III, 2.06 mg./50 cc. H_2O, 1 cc. 50% KOH. 1-Cm. cell used throughout.

For purposes of comparison the absorption spectrum of 2-phenyl-5-*n*-butyl-4,6-dihydroxypyrimidine in alcoholic solution was taken (Fig. 2). A slight break in the curve at 3350 Å. not reported by Dox and Yoder[2] was observed.

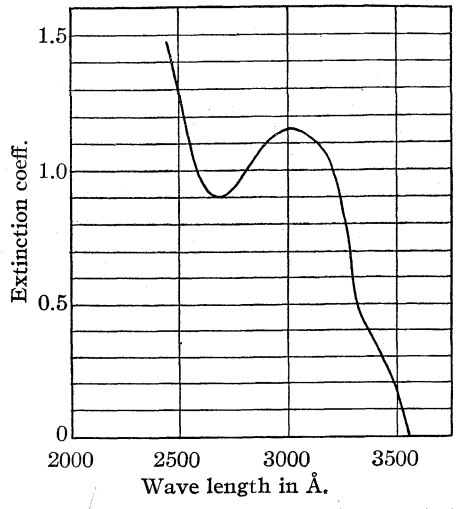

Fig. 2.—2-Phenyl-5-*n*-butyl-4,6-dihydroxypyrimidine: 1.61 mg./50 cc. ethyl alcohol, 1-cm. cell.

These data were obtained using a Hilger E3 spectrograph, Hilger sector photometer and Eastman Panchromatic plates. An under water spark served as light source.

Summary

A series of 2-methyl-5-alkyl-4,6-dihydroxypyrimidines has been prepared.

Absorption spectra curves of 2-methyl-4,6-dihydroxypyrimidine in neutral, acid and basic solution are shown.

The absorption spectrum curve of 2-phenyl-5-*n*-butyl-4,6-dihydroxypyrimidine in neutral solution has been retaken.

Analytical Procedures Employing Karl Fischer Reagent.[1] IV. The Determination of Acid Anhydrides

BY DONALD MILTON SMITH, W. M. D. BRYANT AND J. MITCHELL, JR.

Many of the older methods of determining anhydrides of carboxylic acids do not distinguish sharply between anhydride and free acid. A procedure developed by the senior authors[2] avoids this difficulty by a scheme based on separate titrations with sodium hydroxide and sodium methylate. This method, however, is subject to interference by easily hydrolyzed esters and certain acidic inorganic compounds.

Recent studies of the versatile Karl Fischer reagent have led to the development of new quantitative procedures for hydroxyl[3] and carboxyl[4] compounds, and now a similar method for anhydrides has been completed. This application depends on the hydrolysis of the anhydride in acetic acid solution under the influence of boron trifluoride. Introduction of a known quantity of water, somewhat in excess of stoichiometric requirements, and determination of the residual water by titration with Karl Fischer reagent permit an exact correlation of anhydride content with water removal according to the equation, $RCOOCOR + H_2O = 2RCOOH$.

Unlike the acidimetric procedures free acids do not react and easily hydrolyzed esters remain unchanged due to the relatively low water concentration and the great excess of acid present. Substances interfering with the hydroxyl procedure[3] also affect the new anhydride method.

A group of thirteen anhydrides were analyzed by this method and checked by the sodium hydroxide–sodium methylate procedure.[2] The precision and accuracy are usually within ±0.3%. Experimental results are given in Table I.

Although glutaric anhydride hydrolyzed quantitatively, other anhydrides derived from dibasic acids failed to react completely. Results with maleic, phthalic and succinic anhydrides showed 0, 11 and 91% hydrolysis, respectively.

Changes in catalyst concentration had a marked effect on these anhydrides, as indicated by data given in Table II.

TABLE I

ANALYTICAL DATA FOR ANHYDRIDES

Anhydride		% of theoretical —CO—O—CO— Catalytic hydrolysis	NaOH–NaOCH₃
Acetic	(6)[a]	100.0 ± 0.2	99.9
Propionic	(4)	97.0 ± 0.3	97.2
n-Butyric	(2)	85.5 ± 0.5	85.4
Crotonic	(2)	89.6 ± 0.0	
n-Valeric[b]	(2)	2.0 ± 0.4	1.9
Caproic	(2)	78.6 ± 0.4	78.4
Heptylic	(2)	92.0 ± 0.3	92.1
Glutaric	(2)	95.3 ± 0.3	95.5
Benzoic	(4)	99.0 ± 0.3	99.2
Furoic	(4)	95.1 ± 0.5	94.8

[a] Figures in parentheses indicate number of individual determinations. [b] Old sample, mainly *n*-valeric acid, used to test method in low anhydride range.

TABLE II

HYDROLYSIS OF ANHYDRIDES USING CATALYST SOLUTIONS OF VARIOUS CONCENTRATIONS[a]

Anhydride	% Hydrolysis[b] 100 g.	50 g.	25 g.	15 g.	5 g.	0 g.
Acetic	100.0		98.0			
Caproic	100.0		97.0			
Succinic	91.2	95.4	99.5	93.2	63.9	27.1
Maleic	0.0	1.0	2.3	42.0	36.5	24.5
Glutaric	100.0	100.0	100.0	100.0	93.7	47.6
Phthalic	10.9	13.8	15.5	18.7	16.9	14.0

[a] Catalyst concentration expressed as grams per liter of solution. [b] All results corrected for inert diluents.

From an examination of Table II it is evident that in isolated cases a procedure could be devised for distinguishing between certain anhydrides. For such cases control experiments should be run as a means of fixing the relative error.

Although the anhydrides in dioxane solution react only partially with the carboxyl catalyst,[4] the aliphatic acid anhydrides in methanol solution react quantitatively. The probable reactions

$(RCO)_2O + CH_3OH \longrightarrow RCOOCH_3 + RCOOH$ and
$RCOOH + CH_3OH \longrightarrow RCOOCH_3 + H_2O$

liberate one mole of water per mole of anhydride. Representative results, after correction for free acidity, are given in Table III.

It is interesting to note that maleic and succinic anhydrides react stoichiometrically under these conditions, whereas hydrolysis, as stated

(1) This reagent, discussed in detail in the first paper of the series (Smith, Bryant and Mitchell, THIS JOURNAL, **61**, 2407 (1939)), consists of a solution of iodine, sulfur dioxide and pyridine in methanol. It is specific for water.

(2) Smith and Bryant, *ibid.*, **58**, 2452 (1936).

(3) Bryant, Mitchell and Smith, *ibid.*, **62**, 1 (1940).

(4) Mitchell, Smith and Bryant, *ibid.*, **62**, 4 (1940).

TABLE III

ANALYTICAL DATA FOR ANHYDRIDES

Anhydride	% of Theoretical —CO—O—CO Carboxyl catalyst[4]	NaOH–NaOCH$_3$
Acetic	100.3 ± 0.3	99.9
Propionic	97.1 ± 0.3	97.2
Succinic	94.2 ± 0.4	94.5
Maleic	90.0 ± 0.2	90.0

above, is incomplete. As would be expected, the aromatic anhydrides only partially react.[4]

In the course of the present research several nitrogen bases, including pyridine and tri-*n*-butylamine, were substituted for the acid catalyst solution. It was previously thought that hydrolysis of acid anhydrides in the presence of slightly more than the theoretical quantity of water would be complete where large excesses of these bases are used. However, the anhydrides studied, with one exception, failed to react completely on heating at 100° for periods up to four hours. The exception was acetic anhydride, which hydrolyzed quantitatively in one hour at 60° using pyridine as the base.

Some experiments on the dehydration of glacial acetic acid by means of the anhydride without any catalyst or acid acceptor are of interest. The acid containing about half a per cent. of water was mixed with slightly more than the calculated amount of acetic anhydride required to produce anhydrous acid. The mixture was allowed to stand at room temperature and was analyzed at intervals by the Karl Fischer procedure. The following results were obtained.

Wt. % H_2O	Time, standing at room temperature
0.54	0
.52	4 min.
.47	1.5 hrs.
.36	4.5
.08	21
.015	48

The reaction is slow but proceeds to completion without a catalyst.

Experimental

Compounds Investigated.—With two exceptions all of the anhydrides studied in the present investigation were Eastman Kodak Co. products, and were used without further purification. The *n*-valeric anhydride was an old sample which was used primarily to determine the precision of the method for small quantities of anhydride.

Phthalic anhydride ("Aero" Brand) was obtained from American Cyanamide Corp., and glutaric anhydride was prepared from the acid by the method of Mol.[5] In order to prevent adsorption of water vapor, a simple "dry manipulator" was used to dispense the solid anhydrides.[2]

Analytical Procedure.—Five to 10 ml. of sample is weighed into a 100-ml. g. s. volumetric flask about one-third filled with Merck C. P. glacial acetic acid. The solution is adjusted to volume with more acetic acid, after thermostating at 25 ± 1°. Five ml. (using calibrated pipet) of this solution is transferred to a 250 ml. g. s. volumetric flask and 20 ml. of catalyst solution added.[6] The flask together with a blank containing 5 ml. of acetic acid and 20 ml. of catalyst solution is placed in a water-bath at 60 ± 1°. The stopper is loosened momentarily to allow for expansion of included air, tightened and heated for two hours. After the flasks have been allowed to cool spontaneously to room temperature and 5 ml. of Baker C. P. pyridine is added, the excess water is titrated with Karl Fischer reagent. The total anhydride is measured by the difference between the water added, *i. e.*, the water content of the blank, and the water found by titration after reaction.

Summary

1. A quantitative procedure for the determination of carboxylic acid anhydrides has been described. The method depends on complete hydrolysis of the anhydride in the presence of excess water and subsequent titration of the residual water with Karl Fischer reagent. It is best suited for the determination of acyclic aliphatic anhydrides.

2. Analytical data for ten anhydrides are tabulated.

WILMINGTON, DELAWARE RECEIVED JANUARY 9, 1940

(5) Mol, *Rec. trav. chim.*, **26**, 373 (1907).

(6) The catalyst solution is prepared by dissolving 100 g. of boron trifluoride gas and 4 ml. of water in sufficient Merck C. P. glacial acetic acid to make one liter of solution. Boron trifluoride of suitable quality can be obtained in cylinders from the Ohio Chemical Company, Cleveland, Ohio.

Solubility of Sulfur Dioxide in Water

BY W. L. BEUSCHLEIN AND LOUIS O. SIMENSON

A knowledge of the equilibrium solubilities of sulfur dioxide in water is essential in connection with calculations and research work on absorption. In 1925, Sherwood[1] presented some values calculated from the data of previous workers and in 1928 the "International Critical Tables"[2] published some values. W. Boyd Campbell and O. Maass[3] have determined the solubility of sulfur dioxide in water for the temperature range 25–120° and the concentration range 1.00–7.40%. O. M. Morgan and O. Maass[4] have reported the solubility of sulfur dioxide in water at temperatures between 0 and 25°. This investigation was undertaken to check and extend existing data.

Experimental

The investigation was carried out with the apparatus shown in Fig. 1, consisting of a vertical glass solution tube containing a buoyant stirrer C and a mercury relay G attached to the upper part of the tube. The stirrer contained an iron core B and was activated by means of a solenoid A circumscribing the solution tube, the solenoid being intermittently energized. The whole apparatus was immersed below the oil level E of the temperature controlling bath. The solutions to be run were prepared by passing sulfur dioxide through freshly boiled, distilled water until saturated and then diluting to the desired concentration.

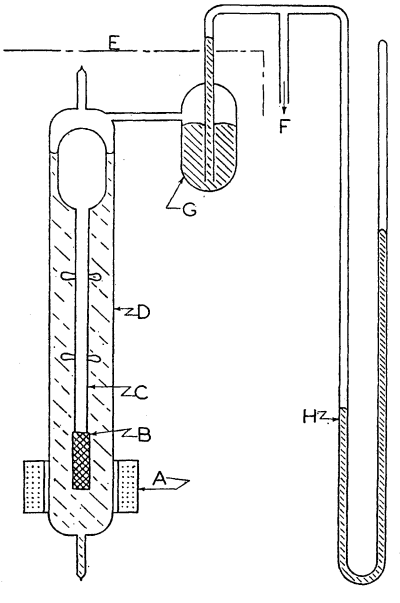

Fig. 1.

The solution was run into the apparatus through the small bottom tube shown in Fig. 1. The inflowing solution was allowed to fill completely all the free space in the solution tube and mercury pressure relay, displacing all the air through the small tube at the top. The end of the upper small tube, previously having been drawn to a hair-like capillary, was sealed with a small flame. The absence of air in the apparatus was indicated by the liquid completely filling the sealed capillary after the latter had cooled. Next, some of the solution was drawn out of the apparatus through the bottom tube by which it entered, great care being taken to maintain equal pressures on each side of the mercury pressure relay. This was done by branching the suction line, running one branch to the external side of the relay and drawing the solution out of the other. Just enough solution was removed to form a vapor space such that the stirrer could function. At this time, a sample of the solution was taken for analysis as to concentration and density. The bottom filling tube was flamed quickly and drawn to a seal at a point where it had previously been drawn to a very fine capillary.

The whole apparatus was then immersed into a thermostated oil-bath maintained to within ±0.2° and held constant for ten minutes before a pressure reading was recorded. The pressures were read to within ±0.5 mm. of mercury on a mercury, sealed in manometer H.

The external pressure on the relay was balanced in such a manner that the mercury head in the relay was constant throughout the whole run. This head, as shown in Fig. 1, was measured with a cathetometer. No particular temperature was selected for a reading, but approximately equal intervals were taken to ensure equilibrium conditions; the temperature of the bath was raised very slowly, one run consuming five hours in going from 20 to 110°.

The pressures were checked by taking measurements as the bath cooled. At the end of the run, a sample of the solution was withdrawn, analyzed and found to check with that at the beginning.

The sulfur dioxide used in this work was "refrigeration dry" and warranted by the manufacturer to be 99.99% pure. No trace of trioxide was found and freshly boiled, distilled water was used in making up the solutions.

The method of analysis consisted of running the sulfur dioxide solution into an excess of iodine with constant agitation and back titrating with sodium thiosulfate.[5] A check was made on the method of pressure measurement by determining the vapor pressure of water. The results

agreed with accepted values[6] within the limits of accuracy of the thermometer and manometer.

Experimental Results

In Table I are given the densities at 23° of the sulfur dioxide solutions used for the vapor pressure determinations. In Table II are given the partial vapor pressure data for the four concentrations, which are expressed as grams of sulfur dioxide in 100 g. of water. The partial vapor pressure of sulfur dioxide above the solution was calculated as the total pressure minus the vapor pressure of pure water at the temperature of the experiment.

(6) "International Critical Tables," Vol. III, McGraw-Hill Book Co., New York, N. Y., p. 212.

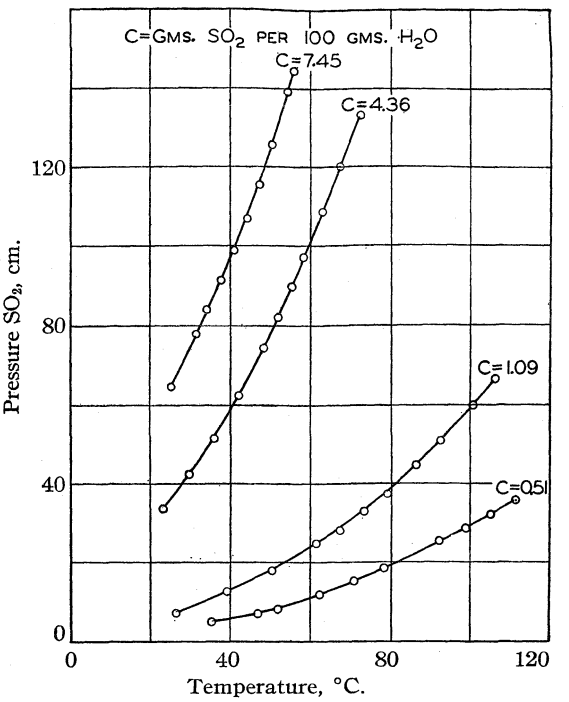

Fig. 2.

In the "International Critical Tables" the partial pressure of the water was calculated using Fulda's values for the ionization constant of sulfurous acid; however, this was neglected in this work because the effect is within the experimental error of the apparatus.

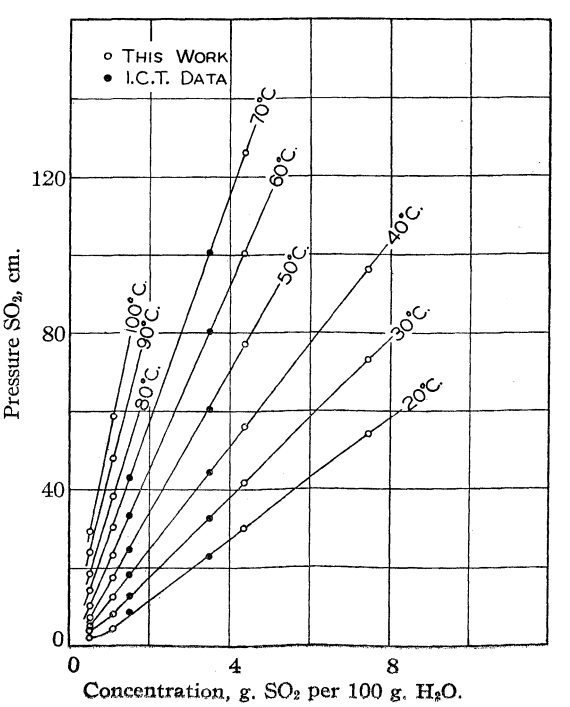

Fig. 3.

The vapor pressure data are shown graphically in Fig. 2 and Fig. 3 shows the isotherms plotted by taking values from Fig. 2. According to the results of Fig. 3, the concentration is a linear function of the sulfur dioxide content except at the lower temperatures of the low concentrations.

Summary

1. Partial vapor pressures for sulfur dioxide in the system sulfur dioxide in water have been determined over the temperature range 20–110° and total pressure range of 10 to 150 cm. of mercury for concentrations of 0.51, 1.09, 4.36 and 7.45 grams of sulfur dioxide in 100 grams of water.

2. These data extend the values of the International Critical Tables and show excellent agreement over the coincident ranges.

The Energy and Entropy of Activation of the Hydrolysis of Ethyl Orthoformate in Deuterium Oxide

BY FRANK BRESCIA* AND VICTOR K. LAMER

Introduction

Current theory of chemical kinetics recognizes the energy of activation and the entropy of activation as the important factors governing the specific rate of a reaction in the presence or absence of a catalyst. LaMer[1] derived the equation

$$k = e^{-\Delta H^*/RT}\, e^{\Delta S_{act}/R}\, Z^\circ \qquad (1)$$

or

$$\log k = -(\Delta H^*/2{\cdot}3RT) + B \qquad (2)$$

where

$$\Delta H^* = RT^2 \frac{\mathrm{d} \ln k}{\mathrm{d}T} \qquad (3)$$

from Tolman's statistical treatment[2] and a collisional mechanism for formation of the intermediate complex. In Eyring's treatment[3]

$$k = \kappa e^{-\Delta H^*/RT}\, e^{\Delta S^*/R}\, RT/Nh \qquad (4)$$

Hence

$$B = \frac{\Delta S^*}{2{\cdot}3R} + \log \kappa \frac{T}{Nh} \qquad (5)$$

Classical theory ascribed the entropy contribution $\Delta S^*/2{\cdot}3R$, to a so-called "steric or probability factor" expressed by P in the equation

$$k = e^{-\Delta H^*/RT}\, PZ^\circ \qquad (6)$$

The symbols have been defined in the literature cited.

Many previous investigators[4] have shown that the deuterium ion is a more effective catalyst than the hydrogen ion in many reactions. A noteworthy exception is the mutarotation of glucose.[5]

This increase in reactivity has been ascribed[6] to an increase in the equilibrium constant for the process Substrate + H^+ = SH^+ on passing from H^+ to D^+. The ratio of the equilibrium constants would be equal to the measured ratio for the specific rates. This is apparent when the theoretical equations for the rate constant are expressed in the form

$$k = \nu K^* \qquad (7)$$

where ν is a frequency term. Several investigators[7] have expressed the view that the increase in the concentration of the deutero complex can be accounted for by the lower zero point energy of the d-complex or, hence, by an observable difference in the activation energies, $\delta\Delta H^*$, of the two systems. ($\delta\Delta H^* = \Delta H^*_H - \Delta H^*_D$.) This is equivalent to the assumption that the ΔH^* factor

is solely responsible for the change in K^* and that the entropy of formation for the two complexes is identical. A test of this hypothesis by Gross, Steiner and Krauss,[8] who investigated the decomposition of diazoacetic ester catalyzed by protons and deutons, shows that the difference in the energies of activation ($\delta\Delta H^*$) is indeed largely responsible for the three-fold increase in the decomposition by deuterium ions. The marked decrease in the rate of reactions involving deuterium in the gas phase may also be explained satisfactorily in many cases on the basis of the lower zero point energy of the deuterium molecule, E_D^0.

However, $\delta E^0 = E_H^0 - E_D^0$, does not account for the reaction rate ratios observed in other gas phase reactions.[9] The resultant $\delta\Delta H^*$ based on δE^0 of the hydrogen and deuterium molecules may be augmented or partially compensated by a δE^0 for the light and heavy complexes or by a difference in the entropy of activation ($\delta\Delta S^* = \Delta S_H^* - \Delta S_D^*$) in forming the two complexes. Similarly, the difference in the ΔH^* factor ($\delta\Delta H^*$) in a liquid phase reaction involving a light and heavy complex may be augmented or compensated by a difference in the ΔS^* factor ($\delta\Delta S^*$).

The hypothesis that the entropy factor may often be of primary importance in determining the rate ratio on passing to D_2O is subjected to test with a study of the rate of hydrolysis of ethyl orthoformate at different temperatures.

Experiment and Calculations.—The rate constants, k, at constant buffer strength, 0.001 M Ac_2O/0.1 M NaAc, measured, in ordinary water and in a deuterium oxide mixture at 14.977 and 35.008°, by the dilatometric method previously used[10] to study the rate at 25°, are converted to specific rate constants by dividing k by the total hydrogen ion concentration. Hydrogen ion concentrations in ordinary water are obtained from the dissociation constants of protoacetic acid[11] at an ionic strength of 0.1; 2.85×10^{-5} at 35° and 2.81×10^{-5} at 15°.

The specific rate constant in the H_2O–D_2O mixture, k_m, is obtained from the concentrations of protons and deuterons calculated from the equations

$$K = \frac{1}{C_{D^+}}\left[\frac{2C_{Ac_2O}}{C_{Ac^-}}(K_H - K_M) + C_{D^+}\right] \quad (8)$$

and

$$K_M = \frac{(C_{H^+} + C_{D^+})C_{Ac^-}}{2C_{Ac_2O}} \quad (9)$$

Equation (8) is derivable from equations 2, 3, 4 of our previous work[10] and equation (9), this paper. $K = K_H/K_D$, where K_H is the dissociation constant of protoacetic acid and K_D is the dissociation constant of the deuteroacetic acid. K_M is the dissociation constant in the mixed waters. K is 3.39 at 15°, 3.26 at 35°; K_M is obtained from the ratios $K_H/K_M = 3.02$ at 15° and $= 2.91$ at 35°.[12]

The specific rate constant in pure deuterium oxide, k_{D^+}, is then obtainable from the equation

$$k = k_{H^+}\,C_{H^+} + k_{D^+}\,C_{D^+} \quad (10)$$

where k_{H^+} is the specific rate constant in ordinary water.

The energy of activation is obtained from equation (3), B from (2), and ΔS^* from (5) assuming, as usual, $\kappa = 1$. All results are summarized in Tables I and II. The value for the energy of activation in ordinary water is in substantial agreement with that of Harned and Samaras.[13]

TABLE I

H_2O	15.7 ± 0.2	16.3	7.83
D_2O	14.3 ± 0.2	15.7	4.90

Discussion

The observed difference in the energy of activation predicts a nine-fold increase in the rate in passing from ordinary water to deuterium oxide, whereas the observed increase is about threefold. The large decrease in ΔH_D^* is partially compensated by a decrease in the ΔS^* on deuterium substitution. Both factors are, therefore, important in explaining the observed increase in the rate of the hydrolysis of ethyl orthoformate in D_2O. The importance of an entropy of activation has already been emphasized for several ionic reactions,[14] and for the base catalyzed[15] decomposi-

tion of nitramide in D_2O. The observed difference for the rate of mutarotation of glucose[16] in H_2O and D_2O is accounted for mainly by the change in the entropy term since $\delta \Delta H^*$ is zero within the experimental error.

Recently, Stern, Johnston and Clark[17] picture two general cases covering the effect of a catalyst on the reactant and the activated complex which may lead to positive or negative catalysis. A decrease in the energy of activation in passing from one solvent to another is taken to indicate that the catalyst has a greater tendency to combine with the activated complex than with the reactant and this effect is partly compensated by a decrease in ΔS^*. This mechanism corresponds to the explanation given previously that the increased rate in passing to D_2O is due to an equilibrium shift favoring the formation of the D-complex.

(16) Hammill and LaMer, *J. Chem. Phys.*, **4**, 395 (1936).
(17) Stern, Johnston and Clark, *J. Chem. Phys.*, **7**, 970 (1939).

Summary

1. The rate of hydrolysis of ethyl orthoformate has been measured at 14.977 and 35.008° in ordinary water and in deuterium water.

2. The observed difference in the energy of activation predicts a nine-fold increase in the rate; experimentally the increase is about threefold. The entropy of activation is, therefore, an important factor in determining the ratio of the two rates.

The Temperature Dependence of the Dissociation Constant of Deuteroacetic Acid

BY FRANK BRESCIA,* VICTOR K. LAMER AND FREDERICK C. NACHOD*

Introduction

Current investigations of the activation energies for reactions involving deuteroacetic acid, for example, the hydrolysis of ethyl orthoformate[1] in ordinary water and deuterium oxide, require data for the dissociation constants of deuteroacetic acid which are comparable in precision with those available for the protoacetic acid. Some preliminary data for the dissociation constant of deuteroacetic acid obtained on severely limited quantities of solvent at 12.5°, 25° and 37.5° using the quinhydrone electrode[2] indicated a possible minimum, while the corresponding and well-established constants for protoacetic acid[3] exhibit a maximum. In general,[4] differences between the properties of the deutero and proto compounds tend to become less important at higher temperatures, since the differences in zero point energies ΔE^0 of the two hydrogens determine the properties as an exponential factor, exp. $[\Delta E^0/RT]$. Also, Rule and LaMer[5] have demonstrated that the temperature coefficient of the electromotive force of the cell $Pt/QQH_2\text{-}QQD$ HCl-DCl $(H_2O\text{-}D_2O)/AgCl\text{-}Ag$ involving the strong acid HCl–DCl is identical in pure H_2O and in pure D_2O. It is questionable, therefore, whether the temperature dependence of the two weak acids should be opposite in sign.

The determination of the dissociation constant of deuteroacetic acid at different temperatures has, therefore, been undertaken, using the conductance method.

Experimental

The equivalent conductances of sodium acetate, sodium chloride, hydrochloric acid and acetic acid solutions have been determined at 14.36, 25, 35 and 44.86°, for a solvent whose deuterium content, $F_D = S_g/0.1079$, where S_g is the difference in specific gravity of the solvent and of ordinary water, was approximately 0.925. A vacuum tube oscillator of the heat frequency type[6] and a Jones bridge[7] were employed. The constants, 0.4481 and 0.7017, of the two conductance cells, designed to be free from the Parker effect, were determined at 25° by the method of Kohlrausch. The temperatures were standardized with a Pt resistance thermometer, B. S. calibration.

The preparation of the salts, acetic anhydride,

constant boiling deuterochloric acid (DCl), purification of the water, and the details of the semi-micro technique have been described.[8]

Calculations.—The maximum equivalent conductances, Λ_0, for the strong electrolytes in H_2O–D_2O were calculated from the measured equivalent conductance, Λ_c, using the equation

$$\left(\frac{\Lambda_c}{\Lambda_0}\right)_{H_2O} = \left(\frac{\Lambda_c}{\Lambda_0}\right)_{D_2O} \qquad (1)$$

derivable from the Onsager equation and shown to be of satisfactory accuracy.[9] The ratios $(\Lambda_c/\Lambda_0)_{H_2O}$ were taken from the "Int. Crit. Tables."[10] The measured Λ_c values and the calculated Λ_0 values are shown for sodium chloride, deuterochloric acid, and sodium acetate in Tables I, II, III, respectively. The Λ_0 values for deuteroacetic acid are given in Table IV. The measured Λ_c values for the deuteroacetic acid and the dissociation constants, K_M, calculated by the equation

$$K_M = \frac{C_i^2}{C - C_i} \qquad (2)$$

are shown in Table V. $C_i = \kappa\,(1000)/\Lambda_0$, κ is the specific conductance of the solution, and C is the stoichiometric concentration of the acid.

(9) LaMer and Chittum, *ibid.*, **58**, 1642 (1936).

(10) "Int. Crit. Tables," Vol. VI, pp. 230–248.

The excellent agreement between the conductance and e. m. f. data at 25° is not obtained at other temperatures. In the preliminary work on acetic acid,[2] the various precautions necessary to establish that the quinhydrone electrode had not deteriorated over the period of time that was required to obtain electrode equilibrium at a second (later) temperature were not realized as fully as in the later work on HCl.[5]

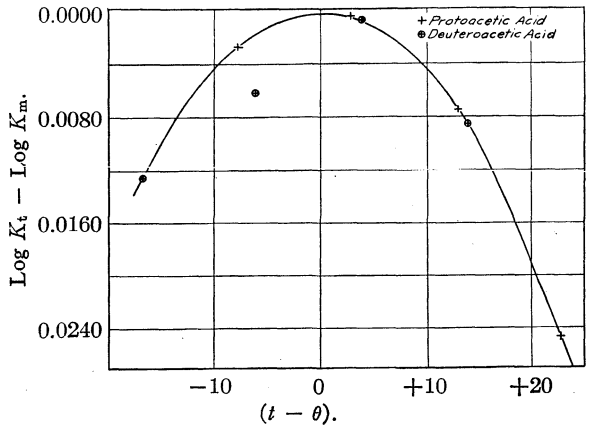

Fig. 1.—Protoacetic acid, +; deuteroacetic acid, ⊕.

K_D was determined by extrapolating the dissociation constant K_M observed in the mixed waters (H_2O–D_2O) to $F_D = 1$ with the equation[11]

$$K_M = K_D\left[1 + 3.76\,\frac{C_{H_2O}}{C_{HDO}}\Big/1 + 3.76\left(\frac{K_D}{K_M}\right)\frac{C_{H_2O}}{C_{HDO}}\right] \quad (3)$$

In equation (3), K_D is the dissociation constant of the deuteroacid; K_H, the dissociation constant of the protoacid. K_H values (converted to the classical dissociation constant) at the different centigrade temperatures t were calculated from the equation.

$$\log K_{H,t} - \log K_{H,m} = -p(t - \theta)^2 \quad (4)$$

$K_{H,m}$ is the maximum value of K_H which occurs at the characteristic temperature θ; p is a constant.

The K_H and K_D values and their ratios are given in Table VI.

(11) Brescia, THIS JOURNAL, 60, 2811 (1938).

Discussion

As was expected, the temperature dependences of K_H and K_D follow the same general type of parabolic curve as shown in Fig. 1. K_D however, passes through the maximum at a higher temperature than K_H. Thus, the characteristic temperature θ is about 22° for protoacetic acid and about 31° for deuteroacetic acid. The ratio of K_H/K_D, Table VI, decreases with increasing temperature so that the two values probably approach each other at higher temperatures.

The data for K_D for the range of temperatures investigated may be represented by

$$\log K_{D,t} + 5.2550 = -4.5 \times 10^{-5}(t - 31.06)^2 \quad (5)$$

with an accuracy of 1%. The corresponding equation for protoacetic acid, over the same temperature range, is

$$\log K_{H,t} + 4.7348 = -4.5 \times 10^{-5}(t - 22.09)^2 \quad (5a)$$

A plot of equations (5) and (5a) is given in Fig. 1 in which it is seen that the resulting curves for each acid are superimposable. This behavior is quite general for weak protoacids,[3] and shows that p is the same for deutero- and protoacetic acids.

The differences of the heats, free energies and entropies of dissociation of the deutero- and protoacetic acids, corresponding to the exchange process

$$HOAc(H_2O) + D^+(D_2O) + OAc^-(D_2O) = DOAc(D_2O) + H^+(H_2O) + OAc^-(H_2O) \quad (6)$$

where the solvent involved[12] is inclosed in parentheses, have been calculated (Table VII). The

TABLE VII

DIFFERENCES OF HEATS, FREE ENERGIES, AND ENTROPIES OF DISSOCIATION, CORRESPONDING TO THE THERMODYNAMIC PROPERTIES OF THE EXCHANGE PROCESS (6)

Subscript D refers to deuteroacetic acid; subscript H to protoacetic acid.

Temp., °C.	$\Delta H_D - \Delta H_H$, cal.	$\Delta F_D - \Delta F_H$, cal.	$\Delta S_D - \Delta S_H$, cal./deg.	K_6
14.36	308.6	697.6	−1.3	0.530
25.00	329.2	717.7	−1.3	.526
35.00	349.2	724.0	−1.3	.513
44.86	368.9	733.6	−1.1	.504

chemical equation (6) is obtained by subtracting equation (6b) from equation (6a)

$$HOAc(H_2O) = H^+(H_2O) + OAc^-(H_2O) \quad (6a)$$
$$DOAc(D_2O) = D^+(D_2O) + OAc^-(D_2O) \quad (6b)$$

The ΔH for deuteroacetic acid decreases more slowly with increasing temperature than the corresponding function for protoacetic acid. Also,

(12) See reference 13 for the importance of including the solvent.

ΔF for the dissociation of DOAc increases more rapidly with the temperature than does ΔF for the dissociation of HOAc. On the other hand, the entropy differences are constant. Thus, the greater increase in K_D with increasing temperature is due to the greater increase in ΔH_D over ΔH_H. Since $\Delta F_D - \Delta F_H$ equals $-\Delta F$ for the exchange process (6), the reverse reaction, as expected, is favored on increasing temperature. The values for K_6, the equilibrium constant for the exchange process (6), calculated from $\Delta F_D - \Delta F_H$, are given in Table VII. Also

$$\left(\frac{\partial \Delta H_D}{\partial T}\right)_p - \left(\frac{\partial \Delta H_H}{\partial T}\right)_p = \Delta C_p$$

for process (6) is sensibly independent of temperature and equal to 2.0 cal. deg.$^{-1}$ mole^{-1}. Noonan and LaMer,[13] who made a careful study of the e. m. f. of the cell without transport

$$\begin{array}{c|c|c|c} D_2 & DCl & D_2O & \\ & & & \text{AgCl-Ag} \\ H_2 & HCl & H_2O & \end{array}$$

over a wide range of deuterium solvents, found that ΔC_p for the process

$$^1/_2H_2 + DCl(D_2O) = {}^1/_2D_2 + HCl(H_2O) \quad (7)$$

is also very small if not zero.

The almost zero value of ΔC_p in these exchange processes results from the fact that ions of the same valence type and almost identical chemical properties are involved in these equilibria. The partial molal heat capacity of an ionic species is determined primarily by its net charge and only secondarily by its internal constitution.[14]

Summary

1. The equivalent conductances of sodium chloride, sodium acetate, hydrochloric acid, and acetic acid have been measured at 14.36, 25, 35 and 44.86° in a solvent whose deuterium fraction is 0.925. From these data, the dissociation constant of deuteroacetic acid at $F_D = 1$ is calculated at corresponding temperatures.

2. The dissociation constant of deuteroacetic acid follows the Harned–Embree equation and passes through a maximum at 31°; protoacetic acid at 22°.

3. The ratio K_H/K_D decreases with increasing temperature.

4. The differences in the heats, free energies and entropies of ionization of the deutero and proto acids have been calculated. ΔC_p for the exchange process $HOAc(H_2O) + D^+(D_2O) + OAc^-(D_2O) = DOAc(D_2O) + H^+(H_2O) + OAc^-(H_2O)$ is sensibly zero; ΔS is sensibly constant and equal to -1.3 cal. deg.$^{-1}$ mole^{-1}.

Electrostatic Effects on Ionization Constants

BY VICTOR K. LAMER AND FRANK BRESCIA*

In a recent paper, E. C. Baughan[1] derived on the basis of theoretical suggestions of Gurney,[2] the equation

$$\Delta H_T = \Delta H_x + c\, 1/D_T \left[1 + T\frac{\partial \ln D}{\partial T}\right]_T \quad (1)$$

for the heat of ionization ΔH_T of a weak acid of the electric charge type $HA + H_2O \rightleftarrows H_3O^+ + A^-$, as a function of the temperature T, on the assumption that the electrical work involved in creating the electric field is adequately expressed by the well known formula of Born

$$c = \frac{\epsilon^2}{2}\left(\frac{1}{r_+} + \frac{1}{r_-}\right)$$

where ϵ is the elementary electric charge, r_+ and r_- are the radii of the cation and anion, and D is the dielectric constant of the solvent.

ΔH_x may be regarded either as the heat of ionization in a medium of infinite dielectric constant where no electrical work would be involved, or as the heat effect if there were no separation of electric charges in the dissociation process.

Since ΔH is zero at the characteristic temperature for which the dissociation constant is a maximum, equation (1) may also be expressed as

$$\Delta H_T = c\left[1/D_T\left(1 + T\frac{\partial \ln D}{\partial T}\right) - 1/D_\Theta\left(1 + \Theta\frac{\partial \ln \Theta}{\partial T}\right)\right] \quad (1a)$$

* Instructor, Chemistry Department, The College of the City of New York.

(1) E. C. Baughan, *J. Chem. Phys.*, **7**, 951 (1939).

(2) Gurney, *ibid.*, **6**, 499 (1938).

Hence, ΔH_T is determined solely by the parameters Θ and r.

We have recently completed a series of accurate determinations of the dissociation constants of deuteroacetic acid by the conductance method,[3] which with the data of Harned and co-workers on protoacetic acid should serve as a particularly good test of these equations.

The dielectric behavior of both ordinary water and deuterium oxide has been carefully investigated by Wyman and his collaborators,[4] and is expressible in the form

$$D = ae^{-bT} \qquad (2)$$

When the experimental values of ΔH_T for a given acid are plotted against $X = \frac{1}{D_T}\left(1 + T\frac{\partial \ln D}{\partial T}\right)$ equation (1) requires a linear relationship. The mean radius r, defined by $\frac{2}{r} = \left(\frac{1}{r_+} + \frac{1}{r_-}\right)$, is calculable from the slope and ΔH_x from the intercept at $X = 0$. Both should be constants independent of temperature if equation (1) is valid. Baughan showed that equation (1) held for the best available data on weak acids in H_2O.

In Fig. 1 we plot our data for DOAc and for comparison the corresponding data for HOAc recalculated from Harned and Embree's equation and Wyman's dielectric data.

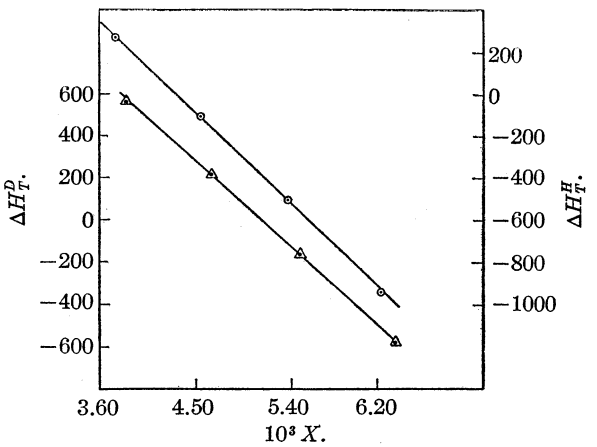

Fig. 1.—$X = \frac{1}{D_T}\left(1 + T\frac{\partial \ln D}{\partial T}\right)$: ⊙, HOAc; ▲, DOAc.

The values of the parameter c for the two acids have been obtained by simultaneous solution for two temperatures using the data[3,4] given in Table I and the equation:

$$\Delta H_T^D - \Delta H_T^H = c^D\left[1/D_\Theta^D\left(1 + T\frac{\partial \ln D^D}{\partial T}\right) - 1/D_\Theta^D\left(1 + \Theta^D\frac{\partial \ln D^D}{\partial T}\right)\right] + c^H\left[1/D_\Theta^H\left(1 + \Theta^H\frac{\partial \ln D^H}{\partial T}\right) - 1/D_T^H\left(1 + T\frac{\partial \ln D^H}{\partial T}\right)\right] \qquad (3)$$

The superscripts H and D refer to HOAc and DOAc, respectively.

TABLE I

t°C.	$\Delta H^D - \Delta H^H$	
14.36	308.6	$\log D^H = 1.9446 - 0.00198\,t$
25.00	329.1	$\log D^D = 1.9433 - 0.00199\,t$
35.00	348.9	$\Theta^H = 22.09$°C.
44.86	368.9	$\Theta^D = 31.06$°C.

TABLE II

Temperature, °C.	$c^H \times 10^{-5}$	$c^D \times 10^{-5}$
14.36–25.00	4.725	4.410
25.00–35.00	4.709	4.412
35.00–44.86	4.708	4.408
	Av. $c^H = 4.714 \times 10^5$	$c^D = 4.410 \times 10^5$
	a. d. = 0.15%	a. d. = 0.02%

The values of c (cal. mole^{-1}) are constant. Setting $\epsilon = 4.796 \times 10^{-10}$ e. s. u. and $N = 6.03 \times 10^{23}$ yields for the harmonic mean radius:

r^H (for protoacetic acid) = 0.704 Å.
r^D (for deuteroacetic acid) = 0.753 Å.

Using these values of r, we find as shown in Tables III and IV that $\Delta H_x^D = 2260$ cal. and $\Delta H_x^H = 2030$ cal. The difference, 230 cal., should be independent of electrostatic effects and hence should arise from the differences in fundamental vibration frequencies of the molecules involved in the dissociation process.

TABLE III

DEUTEROACETIC ACID

t,°C.	ΔH_x^D (calcd.)	ΔH^D (exptl.)	ΔH^D (calcd.)
14.36	226×10^1	570.9	569
25.00	227	222.6	210
35.00	226	−154.7	−158
44.86	223	−577.4	−547

TABLE IV

PROTOACETIC ACID

t,°C.	ΔH_x^H (calcd.)	ΔH^H (exptl.)	ΔH^H (calcd.)
14.36	203×10^1	262.3	265
25.00	204	−106.5	−114
35.00	203	−503.6	−502
44.86	200	−946.3	−912

Since r^H and r^D, D_T^H and D_T^D, and $\partial \ln D^H/\partial T$ and $\partial \ln D^D/\partial T$ are practically identical, equation (3) can be reduced to

$$\Delta H_T^D - \Delta H_T^H = c\left[1/D_{\Theta^H}\left(1 + \Theta^H\frac{\partial \ln D}{\partial T}\right) - 1/D_{\Theta^D}\left(1 + \Theta^D\frac{\partial \ln D}{\partial T}\right)\right] \qquad (4$$

According to this equation, the difference between the heats of ionization of the proto and deutero forms of an acid should be independent of temperature and, practically speaking, a function only of their respective characteristic temperatures, Θ. This requires that

$$\left(\frac{\partial \Delta H^D}{\partial T}\right)_p - \left(\frac{\partial \Delta H^H}{\partial T}\right)_p = \Delta C_p$$

should equal zero for the corresponding exchange reaction

$$\mathrm{HOAc} + \mathrm{D^+(D_2O)} + \mathrm{OAc^-(D_2O)} = \mathrm{DOAc(D_2O)} + \mathrm{H^+(H_2O)} + \mathrm{OAc^-(H_2O)} \quad (5)$$

Experimentally, ΔC_p for the exchange process where HOAc is acetic acid[3] is 2 cal. mole^{-1} deg.$^{-1}$; ΔC_p for the corresponding benzoic acid exchange process[5] is about 9.5 cal. mole^{-1} deg.$^{-1}$; but is exactly zero for the HCl–DCl exchange.[6] Presumably these very small ΔC_p values may be attributed to the small differences in the radii of $H^+(H_2O)$ and $D^+(D_2O)$, and of the anions in the respective waters, as well as in the dielectric properties of the two waters.

The validity of equation (1) is evidence that log K can be adequately expressed as

$$\frac{-\Delta F^\circ}{2.3RT} = \log K = A - B/T - \frac{C}{D}\frac{1}{T} \quad (6)$$

where A, $B = \Delta H_x/_{2.3R}$, and $C = c$ (eq. 1)$/2.3R$ are constants for each acid in a given solvent.

As a means of testing whether or not log K is a function of D and of T only, it may prove helpful to introduce a procedure which recently has found application in the analogous problem of interpreting the energies and entropies of activation in the kinetics of ionic reactions.[7]

The procedure consists in determining the temperature coefficients not only in media of constant composition but also in media of constant dielectric constant (isodielectric temperature coefficient). Thus the customary coefficient is composed of an isodielectric coefficient and a correction term involving $\partial D/\partial T$.

$$\left(\frac{\mathrm{d}\log K}{\mathrm{d}(1/T)}\right)_{\text{comp.}} = \left(\frac{\partial \log K}{\partial(1/T)}\right)_D + \left(\frac{\partial \log K}{\partial D}\right)_T \left(\frac{\partial D}{\partial T}\right)_{\text{comp.}} \left(\frac{\partial T}{\partial 1/T}\right) \quad (7)$$

where each term may be identified as

$$\left(\frac{-\Delta H}{2.3R}\right)_{\text{comp.}} = \left(\frac{-\Delta H}{2.3R}\right)_D - \frac{C}{D}\left[\frac{T}{D}\frac{\partial D}{\partial T}\right] \quad (8)$$

$$= -\left(B + \frac{C}{D}\right) - \frac{C}{D}\left[\frac{T}{D}\frac{\partial D}{\partial T}\right]$$

$$= -B - \frac{C}{D}\left[1 + \frac{T}{D}\frac{\partial D}{\partial T}\right] \quad (9)$$

Similarly for the entropy of dissociation in the standard state

$$\left(\frac{\Delta S^0}{2.3R}\right)_{\text{comp.}} = \left(\frac{\mathrm{d}(T\log K)}{\mathrm{d}T}\right)_{\text{comp.}} = A + \frac{C}{D}\left[\frac{T}{D}\frac{\partial D}{\partial T}\right] \quad (10)$$

From (9), which is identical with equation (1), it is evident that the slope of log K *vs.* $1/T$ should reduce to $-(B + C/D)$ in isodielectric solvents where $\partial D/\partial T = 0$. Similarly from equation (10), $\Delta S^0/2.3R$, obtained by plotting T log K against T, reduces to A for isodielectric solvents. $2.3RA$ is the increase in entropy in the standard state for the dissociation process corrected for all electrostatic contributions.

It is evident, therefore, that by determining isodielectric temperature coefficients by adjusting the composition of the medium to maintain D constant, one should determine directly the thermodynamic quantities for the process freed from electrostatic contributions; in other words, for a dissociation process which does not involve electrostatic work dependent upon the dielectric constant of the medium surrounding the molecules involved.

The neutral molecule quantities can of course be calculated from the temperature coefficient at constant composition by introducing the correction factors in $\partial D/\partial T$. This is the essence of equations (1) and (9), and their merit resides in the fact that the medium is not changed in composition with changing temperature.

Agreement between such calculated values of $(\partial \ln K/\partial(1/T))_D$ and those determined directly in isodielectric media will only be obtained if it is legitimate to express log K as function of D and T only (equation 6) and if r remains independent of temperature and of solvent. That $(\partial r/\partial T)$ is negligible now appears to be generally accepted. That r is indeed an adjustable parameter which takes into account undetermined specific solvent effects and only approximates the physical meaning ascribed to it is becoming more generally recognized.

The evidence[7] which is accumulating upon the kinetics of the bromoacetate–thiosulfate replacement and the ammonium cyanate → urea reactions demonstrate that when the isodielectric char-

(5) Rule and LaMer, THIS JOURNAL, **60**, 1974 (1938).

(6) Noonan and LaMer, *J. Phys. Chem.*, **43**, 247 (1939).

(7) LaMer, *J. Franklin Inst.*, **225**, 709 (1938); Amis and LaMer, THIS JOURNAL, **61**, 905 (1939); Svirbely and Warner, *ibid.*, **57**, 1883 (1935); Svirbely and collaborators, *ibid.*, **60**, 330, 1613 (1938); **61**, 3534, 3538 (1939).

acter of the medium is maintained by the addition of methanol and ethanol, the kinetic analog of A in equation (10) remains remarkably constant. On the other hand, when isopropanol, diethylene glycol, and particularly dioxane, are employed to produce media of very low dielectric constant, exact constancy of A is not obtained. This is to be expected since the addition of dioxane produces a greater change in specific solvent properties than does the addition of an alcohol most closely resembling water.

Differentiating equation (9) and evaluating coefficients from equation (2) yields

$$\Delta C_p = -b^2Tc/D \qquad (11)$$

The value of ΔC_p calculated for protoacetic acid (r = 0.70 Å.) is −39.9, whereas the experimental value is −41.3 cal. deg.$^{-1}$ mole^{-1}.

Treating in the same manner the empirical Harned–Embree[8] equation

$$\log K_T = \log K_M - p(T - \Theta)^2 \qquad (12)$$

$$[\Delta C_p/2.3R]_{T=\Theta} = -6pT^2 + 4pT\Theta = -2p\Theta^2 \qquad (13)$$

Equating (11) and (13)

$$p = \frac{\epsilon^2}{(2.3R)rD^3}\left(\frac{\partial D}{\partial T}\right)^2\frac{1}{2\Theta} \qquad (14)$$

Equation (14) can be shown to be correct by introducing numerical values for $T = \Theta$ and recovering the experimental value of $p \cong 4.5 \times 10^{-5}$.

Since D does not vary much for the values of $T = \Theta$ encountered for this group of acids and r proves to be almost a constant we have an explanation of why equation (12) represents the facts so well with an almost universal value of p.[8]

(8) Harned and Embree, THIS JOURNAL, **56**, 1050 (1934); Walde, *J. Phys. Chem.*, **39**, 478 (1935).

Summary and Conclusions

1. The equation

$$\Delta H_T = \Delta H_x + c\,1/D_T\left[1 + T\frac{\partial \ln D}{\partial T}\right]$$

represents with high precision ΔH, the heat of dissociation of deuteroacetic acid as a function of temperature, when ΔH_x = 2260, and c = 4.410 × 10^{+5}. The values for protoacetic acid are 2030 cal. and 4.714 × 10^{+5}, corresponding to (Born) r values of 0.75 and 0.70 Å., respectively.

2. ΔC_p for an acid–base exchange reaction involving deuterium and hydrogen in D_2O and in H_2O is practically zero since the radii of the ions and the dielectric properties of the two media are practically identical.

3. The difference in the heats of ionization of deutero and proto acids appears to be a function only of the characteristic temperature Θ at which the maximum value of the dissociation constants occurs.

4. The desirability of determining the temperature coefficients of dissociation constants of acids, not only in solvents of constant composition but also in solvents of constant dielectric constant, is pointed out.

5. The empirical constant $p \cong 4.5 \times 10^{-5}$ in the Harned–Embree equation is shown on theoretical grounds to be equal to

$$p = \frac{\epsilon^2}{(2.3R)rD^3}\cdot\left(\frac{\partial D}{\partial T}\right)^2\cdot\frac{1}{2\Theta}$$

Thermodynamics of Concentrated Aqueous Solutions of Sodium Hydroxide[1,2]

BY GÖSTA ÅKERLÖF AND GERSON KEGELES

Introduction

The thermodynamic properties of strong electrolytes in highly concentrated solutions over a large temperature range may conceivably be obtained by a number of different methods. In most cases, however, the methods applicable narrow down to a single one, the determination of the vapor pressure of the solution. The alkali hydroxides and hydrochloric acid belong to the few electrolytes forming exceptions to this general rule since it would appear to be possible to study their solutions using an electromotive force method. The properties of hydrochloric acid already have been studied for a considerable temperature range by Åkerlöf and Teare,[3] who used solutions up to 16 molal. Solutions of the alkali hydroxides have been the subject of a series of studies by Harned

(2) The tables of this paper are published with the financial assistance of the authors and of Yale University.

(3) Åkerlöf and Teare, THIS JOURNAL, **59**, 1855 (1937).

and co-workers,[4] but the upper limit of the concentration range covered was only 4 molal. Since there is no particular reason to suspect that either the flowing amalgam or hydrogen electrodes employed would fail at still higher concentrations it was considered worth while to attempt to extend these measurements in the case of solutions of sodium hydroxide to cover as large a concentration range as possible. As a result we have succeeded in getting accurate measurements for the concentration range 0.1–17 molal over the temperature range 0 to 70°.

Experimental Procedure.—In older set-ups for measurements of cells with flowing amalgam electrodes as a general rule so-called "droppers" were used. During the introduction of this dropper in the cell it was unavoidable to expose the surface of the solutions at least momentarily to the air. Since the initial speed with which oxygen is absorbed by an air-free solution is very high and the flowing amalgam would tend to give a rapid mixing of the surface layers of the solutions with the underlying ones, the observed electromotive force would tend to vary slightly erratically on account of the high sensitivity of the amalgam electrodes toward oxygen. Furthermore, in the case of measurements extending over a larger temperature range elaborate precautions are necessary to keep droppers at the correct temperature. Some of our electromotive force measurements showed a temperature coefficient of over one millivolt per degree, which sufficiently illustrates the necessity of precise temperature control of the amalgam.

Another possible source of error in older amalgam cell measurements should also be pointed out. For every new measurement it was as a rule also necessary or customary to make up a new reference solution. A small error in the absolute concentration of this solution would apparently be less serious than individual fluctuations of the same magnitude for the different solutions employed as reference, since what is measured is a ratio of activities. In our case we made up about 60 liters of the reference solution, stored it in a closed stainless steel tank and piped it directly from the tank into the cell, thus avoiding any possibility of variations in its concentration.

A diagrammatical sketch of the apparatus is shown in Fig. 1. The thermostat was mounted inside an angle iron frame which on top carried the tank for the reference solution and a two-liter flask for the amalgam. Under the thermostat the frame carried a shelf for receivers of used amalgam and solutions, which were blown out as needed with compressed air. Each half of the cell was provided with an individual receiver in order to eliminate any possibility of internal electrical leakage during the measurements. To prevent freezing of the stopcocks by the hydroxide solutions when unused for some time a number of them were provided with plugs of stainless steel, bored obliquely. All tubing used was made of Pyrex glass, but

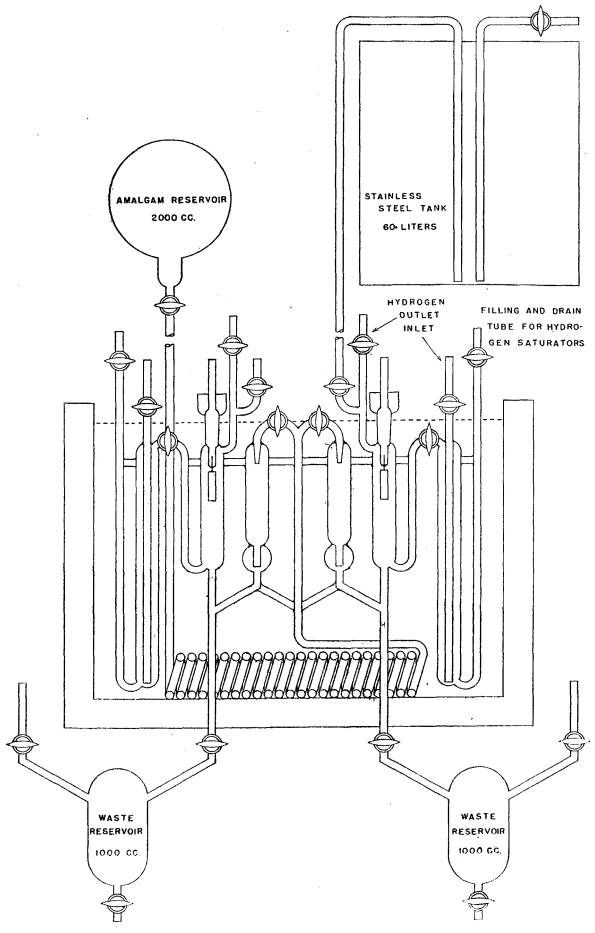

Fig. 1.—Diagrammatical sketch of apparatus used.

all parts of the cell had been left filled with concentrated sodium hydroxide solution for over a month and then carefully washed out with boiling hot solution and pure water before any of the final measurements were made. Errors due to subsequently dissolved silica should be negligible as already clearly shown by us in a previous paper.[5]

In setting up the cells all the usual precautions with regard to testing for leaks and pinholes were carefully observed and repeated several times during the course of the measurements due to the constant danger of cracks that might have developed, since it was impossible to relieve the cells entirely from small mechanical stresses. The design adopted proved, however, to be sufficiently strong and no cracks were found at any time. Due to the precautions taken and the absence of electrical leaks it was also found possible to extend our measurements up to 70°. A few measurements at 80° were, however, fairly erratic and the data for 70° have probably somewhat larger errors than those for lower temperatures.

The amalgam flowed from the reservoir through a heavy capillary down to the bottom of the thermostat, where it entered a long glass spiral to acquire the correct temperature. The exit tube from the glass spiral carried the amalgam upward and led it through two all-glass stopcocks

into the two halves of the cell. The entrance tubes had a bore of about 0.5 mm. and their tips were properly drawn out and adjusted before the tubes were sealed in. The hydrogen electrodes were made as usual of platinum foil covered with platinum black deposited from a strongly acidified solution of platinum chloride using a current of about 0.5 ampere for two minutes.

As already mentioned the reference solution was stored in a stainless steel tank. The tank was first, after proper cleaning, filled with distilled water and then a steady stream of oxygen-free hydrogen was bubbled through the water continuously over a period of about one week. With the gas still streaming, the calculated amount of the standard concentrated sodium hydroxide solution, prepared as previously described,[5] was added so as to give a 0.1 molal solution. Since the tank could not be moved the hydrogen bubbling was continued for four to five days after the hydroxide had been added to ensure uniform concentration of the solution throughout the tank. The reference solution was afterward always kept under a small excess gas pressure to prevent any possibility of air contamination. At various times during the course of the measurements, samples were taken and analyzed gravimetrically by neutralizing with hydrochloric acid and weighing the residue after light ignition. The different analyses all agreed to about one part in 5000 and gave as a general average 0.10166 as the molality of the reference solution. The hydroxide solution to be measured was prepared by diluting in a nitrogen atmosphere the standard concentrated solution, which was available in sufficient quantity (18 liters) to last for all our measurements without change. The diluting apparatus was the same as the one previously employed by Åkerlöf and Teare for the study of the thermodynamics of hydrochloric acid. The finished solutions were analyzed in triplicate in the same manner as already indicated for the analysis of the reference solution.

The electromotive force of the cells was measured with a Leeds and Northrup type K potentiometer. The working standard cells were thermostated and at frequent intervals checked against the laboratory primary standard set certified by the Bureau of Standards and permanently kept immersed in oil at 30.00°. The temperature of the cell thermostat was controlled by a mercury thermoregulator having a sensitivity of about 0.02°. The solid stem thermometer employed had previously been calibrated against a Bureau of Standards certified platinum resistance thermometer using a Mueller resistance bridge.

The cells were filled with the reference and the measuring solutions after they had been cleaned with hot hydroxide solution, thoroughly rinsed with warm distilled water and finally dried while evacuated. In all cases the cells were allowed to come to equilibrium over a period of at least twelve to fourteen hours. At increasingly higher concentrations of the measuring solution it was found, however, that longer and longer time was needed for the hydrogen electrodes to come to equilibrium. Above 14–15 molal extremely rigid exclusion of air contamination shortened the time needed to attain equilibrium and get reproducible results very appreciably but for solutions with a hydroxide concentration above 18 molal even after over a week's time definite end-points could not be obtained although the solutions had been swept and saturated with hydrogen for several hours before they were introduced into the highly evacuated cells.

Preliminary Treatment of the Experimental Results.—Since it would have been very difficult and time consuming to adjust the thermoregulator for each new measurement to an exact temperature, the electromotive force values observed were first corrected linearly to round temperatures. The corrections needed were always very small and seldom exceeded 0.1 millivolt. Next in order to be considered are corrections due to changes in atmospheric pressure and the vapor pressure of the solutions. The cell measured has the following composition

$$\mathrm{Pt,H_2/NaOH}\ (m_1)/\mathrm{Na_xHg/NaOH}\ (m_2)/\mathrm{H_2,Pt}$$

where m_1 and m_2 represent the concentrations of the sodium hydroxide. The electromotive force E of the cell is given by the equation

$$E = \frac{RT}{F} \ln \frac{a_{\mathrm{NaOH}(m_1)} a_{\mathrm{H_2O}(m_2)} a_{\mathrm{H_2}(m_1)}^{\frac{1}{2}}}{a_{\mathrm{NaOH}(m_2)} a_{\mathrm{H_2O}(m_1)} a_{\mathrm{H_2}(m_2)}^{\frac{1}{2}}} \qquad (1a)$$

where a denotes the thermodynamic activity of the species indicated. R, T and F have their usual significance. Differentiating with respect to pressure we obtain

$$\frac{\partial E}{\partial P} = \frac{1}{F}\left[(\bar{v}_{2(m_1)} - \bar{v}_{2(m_2)}) - (\bar{v}_{1(m_1)} - \bar{v}_{1(m_2)})\right] + \frac{1}{2F}\left[(v_{\mathrm{H_2}(m_1)} - v_{\mathrm{H_2}(m_2)})\right] \qquad (2a)$$

where $\bar{v}_1$ and $\bar{v}_2$ represent the partial molal volumes of solvent and hydroxide, respectively. Since $v_{\mathrm{H_2}} = RT/p_{\mathrm{H_2}}$ and $p_{\mathrm{H_2}} = P - p$, where P is the atmospheric and p the vapor pressure of the solution, equation (2a) takes the form

$$\frac{\partial E}{\partial P} = \frac{1}{F}\left[(\bar{v}_{2(m_1)} - \bar{v}_{2(m_2)}) - (\bar{v}_{1(m_1)} - \bar{v}_{1(m_2)})\right] + \frac{RT}{2F}\left[\frac{1}{P - p_{(m_1)}} - \frac{1}{P - p_{(m_2)}}\right] \qquad (2b)$$

Neglecting compressibilities and integrating between P and $P + \Delta P$, the atmospheric pressure correction would thus be given by the equation

$$\Delta E_p = \frac{1}{F}\left[(\bar{v}_{2(m_1)} - \bar{v}_{2(m_2)}) - (\bar{v}_{1(m_1)} - \bar{v}_{1(m_2)})\right]\Delta P + \frac{RT}{2F} \ln \frac{(P - p_{(m_1)} + \Delta P)(P - p_{(m_2)})}{(P - p_{(m_2)} + \Delta P)(P - p_{(m_1)})} \qquad (2c)$$

Using the values for $\bar{v}_1$ and $\bar{v}_2$ calculated from the density measurements of Åkerlöf and Kegeles,[5] it has been found that equation (2c) gives values for ΔE_p which even for unusually large variations of the atmospheric pressure are negligible. For a pressure change of 10 millimeters the order of magnitude of the first term is 10^{-7} and of the second 10^{-5} volt.

As already indicated the next correction to be considered is due to the vapor pressure of the solutions. To evaluate this correction we may write equation (2a) in the form

$$dE = \frac{1}{F}\left[(\bar{v}_{2(m_1)} - \bar{v}_{1(m_1)} + {}^1/_2 v_{H_2(m_1)})\, dP_{(m_1)} - (\bar{v}_{2(m_2)} - \bar{v}_{1(m_2)} + {}^1/_2 v_{H_2(m_2)})\, dP_{(m_2)}\right] \quad (2a')$$

Neglecting the partial molal volume terms which in the worst case amount to 10^{-6} volt and using the ideal gas law for v_{H_2}, we may correct the electromotive forces measured to 760 mm. partial hydrogen pressure in each half cell by adding the following correction term

$$\Delta E_p = \frac{RT}{2F}\left[\int_{P=p}^{760+p_{(m_1)}} \frac{dP}{P - p_{(m_1)}} - \int_{P=p}^{760+p_{(m_2)}} \frac{dP}{P - p_{(m_2)}}\right] = \frac{RT}{2F} \ln \frac{P - p_{(m_2)}}{P - p_{(m_1)}} \approx \frac{RT}{2F} \ln \frac{760 - p_{(m_2)}}{760 - p_{(m_1)}} \quad (3)$$

To compute the value of this correction the measurements given in the literature[6] for the vapor pressure of sodium hydroxide solutions were plotted logarithmically and interpolated with respect to both temperature and concentration. Table I gives a summary of the values for log p thus obtained. As will be shown in the following, the data in Table I agree on the whole surprisingly well with the values calculated from our electromotive force measurements. The vapor pressure of the reference solution was computed using Raoult's law assuming that sodium hydroxide in 0.1 molal solution has an activity coefficient of 0.77 at all temperatures. The value of ΔE_p increases with temperature and concentration and reaches 4.0 millivolts at 70° and 17 molal. Table II gives a summary of the observed electromotive forces as corrected according to equation (3) and least squared at each concentration with respect to temperature using a second order equation.

The Calculation of the Water Transfer Potential.—Using mean ion activities for the electrolyte the expression for the observed electromotive force corrected to 760 mm. partial hydrogen pressure in each half cell takes according to equation (1a) the form

$$E = \frac{2RT}{F} \ln \frac{a_{NaOH(m_1)}^{\frac{1}{2}} a_{H_2O(m_2)}^{\frac{1}{2}}}{a_{NaOH(m_2)}^{\frac{1}{2}} a_{H_2O(m_1)}^{\frac{1}{2}}} \quad (1b)$$

The activity of the solvent is related to the activity of the solute according to the Gibbs–Duhem equation

$$d \ln a_{NaOH} = -55.507/m \; d \ln a_{H_2O} \quad (4)$$

Differentiating (1b) at constant temperature and pressure regarding m_1 as a variable while keeping m_2 constant as reference concentration and introducing equation (4), gives

$$dE = -\frac{RT}{F}(55.507/m + 1)\, d \ln a_{H_2O} \quad (5)$$

Rearrangement and integration of equation (5) from $m = m_2$ to $m = m_1$ results then in the following expression for the water transfer potential E_{H_2O}

$$E_{H_2O} = -\frac{RT}{F} \ln \frac{a_{H_2O(m_1)}}{a_{H_2O(m_2)}} = \int_{m_2}^{m_1} \frac{m}{55.507 + m}\left(\frac{dE}{dm}\right) dm \quad (6a)$$

To obtain the coefficients dE/dm needed for the application of equation (6a), the data of Table II were plotted and least squared at each temperature with respect to m. It was found necessary, due to the shape of the E *vs.* m curves, to separate the least squaring into two ranges, one from 0.1 to 4 and the other from 4 to 17 molal. In the lower range it was found that E was adequately expressed by the formula

$$E = a \log m/0.10166 + b(m - 0.10166) + c(m - 0.10166)^2 \quad (6b)$$

where 0.10166 is the reference concentration. In the upper range E was computed from a somewhat simpler equation

$$E = A + Bm + Cm^2 \quad (6c)$$

TABLE II

The constants obtained for equations (6b) and (6c) were then least squared as a function of temperature. Introduction of (6b) and (6c) into (6a) and integration leads to the following expressions:

A. For the lower concentration range 0.1 to 4 molal

$$E_{H_2O} = [a - 2.303 \cdot 55.507b - 4.605 \cdot 55.507(55.507 + 0.10166)c] \log \frac{55.507 + m}{55.507 + 0.10166} + [b - 2(0.10166 +$$

$$2\cdot55.507)c](m - 0.10166) - c[(55.507 + m)^2 - (55.507 + 0.10166)^2] \quad (6d)$$

B. For the upper concentration range 4 to 17 molal

$$E_{H_2O} = 2.303\cdot55.507(-B + 2\cdot55.507C)\log\frac{55.507 + m}{55.507 + 0.10166} + (B - 4\cdot55.507C)(m - 0.10166) + C[(55.507 + m)^2 - (55.507 + 0.10166)^2] \quad (6e)$$

From equations (6d) and (6e) values of E_{H_2O} were calculated at the concentrations and temperatures given in Table II. These values were then cross-plotted with an accuracy of 0.01 millivolt. A summary of the interpolated values appears in Table III. Still better values could be obtained by a second approximation using smoothed values for the activity coefficient of the solute and the activity of the solvent. However, the experimental accuracy does not justify such a refinement. Subtraction of the data in Table III from the corresponding ones in Table II gives the sodium hydroxide transfer potential

$$E_{NaOH} = \frac{2RT}{F}\ln\frac{a_m}{a_{ref.}} = \frac{2RT}{F}\ln\frac{\gamma_m m}{\gamma_{ref.} m_{ref.}} \quad (7)$$

where γ represents the mean ion activity coefficient of sodium hydroxide.

Equations for the Activity Coefficient of Sodium Hydroxide.—The formal equation employed for this purpose was identical with the one used by Åkerlöf and Teare for hydrochloric acid solutions

$$\log\gamma = -\frac{u\sqrt{m}}{1 + \sqrt{2m}} + Bm + Cm^2 + Dm^3 + Em^4 \quad (8)$$

where u is the universal constant of the limiting law, B, C, D and E are empirical constants. In the case of the acid these constants were found to vary linearly with the temperature. In the case of sodium hydroxide, however, the data indicated a more complicated behavior. Therefore the observed values for $\log \gamma_m/\gamma_{ref.}$ in the concentration range 0.1 to 12.2 molal were least squared according to the equation

$$y = \log\frac{\gamma_m}{\gamma_{ref.}} + u\alpha = B(m - 0.10166) + C(m^2 - 0.10166^2) + D(m^3 - 0.10166^3) + E(m^4 - 0.10166^4) \quad (9a)$$

where α is given by the formula

$$\alpha = \frac{\sqrt{m}}{1 + \sqrt{2m}} - \frac{\sqrt{0.10166}}{1 + \sqrt{2\cdot0.10166}}$$

We thus obtain for the normal equations the expressions

$$\Sigma y(m - 0.10166) = B\Sigma(m - 0.10166)^2 + C\Sigma(m - 0.10166)(m^2 - 0.10166^2) + D\Sigma(m - 0.10166)(m^3 - 0.10166^3) + E\Sigma(m - 0.10166)(m^4 - 0.10166^4) \quad (9b)$$

..... (9c)

..... (9d)

$$\Sigma y(m^4 - 0.10166^4) = B\Sigma(m^4 - 0.10166^4)(m - 0.10166) + C\Sigma(m^4 - 0.10166^4)(m^2 - 0.10166^2) + D\Sigma(m^4 - 0.10166^4)(m^3 - 0.10166^3) + E\Sigma(m^4 - 0.10166^4)^2 \quad (9e)$$

The values for B, C, D and E calculated using equations (9b, c, d and e) were found to give curves very nearly having the form of symmetrical parabolas when plotted against the temperature. These constants were accordingly least squared assuming a second order equation in the following manner. The least squared values of B which were computed first were re-introduced in the normal equations and a new set of C values was obtained. The least squared new values for C changed the D values again a little and after they also had been treated the final values of E were calculated and least squared. A summary of the

TABLE IV

CONSTANTS USED FOR THE CALCULATION OF THE ACTIVITY COEFFICIENT OF THE SOLUTE IN AQUEOUS SOLUTIONS OF SODIUM HYDROXIDE

Part I. Constants for the concentration range 0 to 12 molal

$B = 0.006519 + 0.0015995\,t - 0.000018327\,t^2$

$C = 0.013713 - 0.00050071\,t + 0.0000056385\,t^2$

$D = 0.0005994 + 0.000050215\,t - 0.00000064754\,t^2$

$E = 0.00000596 - 0.0000018056\,t + 0.000000024073\,t^2$

Values of constants B, C, D and E at 10° intervals

Temp.	B	C	D	E
0°	0.006519	0.013713	−0.0005994	0.00000596
10	.021681	.009270	− .0001620	− .00000969
20	.031178	.005954	.0001459	− .00002052
30	.038010	.003767	.0003243	− .00002654
40	.041176	.002707	.0003731	− .00002774
50	.040676	.002773	.0002925	− .00002414
60	.036512	.003969	.0000824	− .00001572
70	.028682	.006292	− .0002573	− .00000247

Part II. Constants for the concentration range above 12 molal

$a = -0.32747 + 0.0030936\,t - 0.000032946\,t^2$

$b = 0.09880 - 0.000586\,t$

$c = -0.000002139 - 0.0000003927\,t + 0.000000005268\,t^2$

Values of constants a, b, c and u at 10° intervals

Temp.	a	b	c	u
0°	−0.32747	0.09880	−0.00000214	0.487
10	.29982	.09294	.00000554	.494
20	.27878	.08708	.00000789	.502
30	.26431	.08122	.00000918	.511
40	.25644	.07536	.00000942	.522
50	.25516	.06950	.00000861	.534
60	.26046	.06364	.00000674	.549
70	.27236	.05778	.00000382	.565

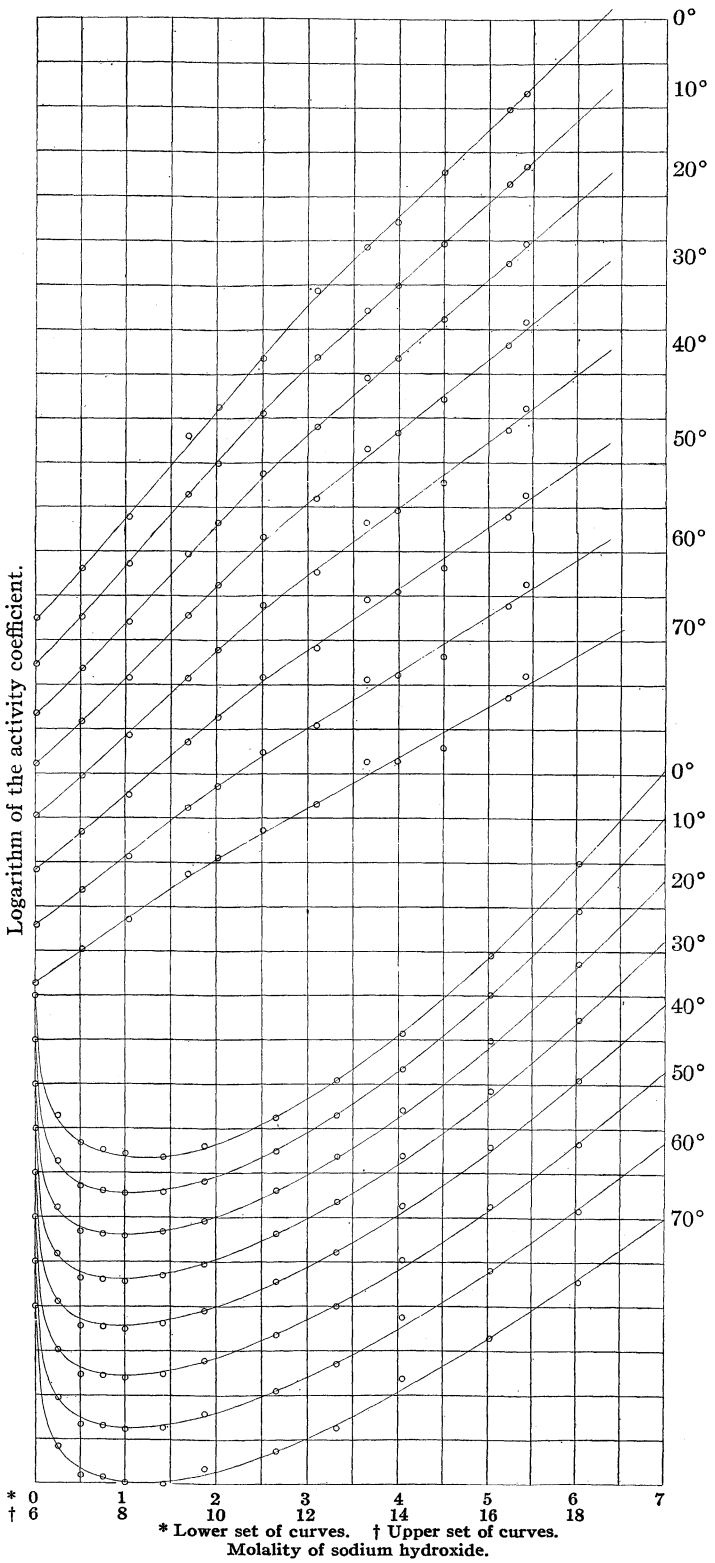

Fig. 2.—Isotherms for the logarithm of the activity coefficient of sodium hydroxide. The curves for the concentration range 6 to 17 molal are plotted on half the scale of those for the range 0 to 7 molal. Ordinates are shifted successively to avoid interference of the different curves.

constants obtained is given in Part I of Table IV. It is interesting to note that while the temperature variation of all the constants is given by parabolas, the corresponding values for B and C give when plotted against each other a practically straight line.

Equations for the activity coefficient of sodium hydroxide at concentrations above 12 molal were obtained by least squaring the observed values according to second order equations. Part II of Table IV summarizes the result. The purpose of dividing up our data in two groups, one for solutions with concentrations lower and the other one higher than 12 molal, was that this possibly would give us an indication whether the curves for the activity coefficient show a break at the concentrations where the corresponding curves for the apparent partial molal volume of the hydroxide appear to have one. As shown graphically in Fig. 2 the observed values for log γ do not have sufficient accuracy to give any definite indication of the presence of similar breaks. Due to thermodynamical reasons we know that breaks, if present, must be very faint and require an unusually high degree of accuracy in the experimental data for their detection.

Using the constants given in Table IV the value of the logarithm of the activity coefficient of sodium hydroxide has been calculated at a series of round concentrations. Table V contains the computed values. They agree quite well with those of Harned at 25° but differ particularly at higher concentrations appreciably from those of Harned and Hecker. On the other hand, our observed and calculated values agree very closely at concentrations up to 10 molal with an average difference of less than 0.2 millivolt in the corresponding electromotive force values.

Activity and Vapor Pressure of the Solvent.—The activity of the solvent may be computed most simply from the values of E_{H_2O} given in Table III but more accurate values for the concentration range 0.1 to 12 molal are ob-

16	1.2528	1.1858	1.1125	1.0329	.9469	.8546	.7560	.6511
17	1.3515	1.2786	1.1993	1.1138	1.0220	.9238	.8195	.7088

tained by using the equation

$$\log a_1 = -\frac{2m}{2.303\cdot 55.51} + \frac{u}{55.51\sqrt{2}}\left[(1+\sqrt{2m}) - 2\ln(1+\sqrt{2m}) - \frac{1}{1+\sqrt{2m}}\right] - \frac{2}{55.51}(Bm^2/2 + 2Cm^3/3 + 3Dm^4/4 + 4Em^5/5) \quad (10)$$

At concentrations above 12 molal $\log a_1$ may be obtained in the following manner

$$\log a_1 = -\frac{2m}{2.303\cdot 55.51} - \frac{2}{55.51}\int_0^m m\,\mathrm{d}\log\gamma \quad (11)$$

Above 12 molal the value of $\log\gamma$ is given by a second order equation, which when introduced in (11) results in the expression

$$\log a_{1(m>12)} = \log a_{12} - \frac{2(m-12)}{2.303\cdot 55.51} - \frac{2}{55.51}\int_{12}^m m(b+2cm)\mathrm{d}m \quad (12)$$

where b and c are empirical constants given in Part II of Table IV. The last term of equation (12) when integrated gives the formula

$$-\frac{2}{55.51}\int_{12}^m m(b+2cm)\,\mathrm{d}m = -\frac{(m^2-144)b}{55.51} - \frac{4(m^3-1728)c}{3\cdot 55.51}$$

The vapor pressure of the solutions may finally be calculated from the simple relation

$$\log p_{m_1} = \log a_1 p_0$$

where p_0 is the vapor pressure of the pure solvent.

The result of the calculation of solvent activity and vapor pressure is summarized in Tables VI and VII. A comparison between the data in Tables I and VII shows the good agreement obtained between experimentally observed values and those computed from our electromotive force measurements. However, even though this is the case, the accuracy of the vapor pressure data is far too low to allow their use for the reverse procedure, the calculation of the thermodynamic properties of the solute. In Fig. 3 the variation of $\log a_1$ with the hydroxide concentration is shown graphically. The different isotherms are quite similar to the corresponding ones for hydrochloric acid but their curvature and dispersion is considerably larger. The direct measurements of Shibata and Murata[6a] of $\log a_1$ give values which agree very closely with ours at 20 and 30° over the entire concentration range.

Relative Partial Molal Free Energy of Solute and Solvent.—These quantities which we will need for the calculation of the entropy changes may be computed from the equations

$$\bar{F}_2 - \bar{F}_2^\circ = 2RT\,2.303\log\gamma m \quad (13)$$

$$\bar{F}_1 - \bar{F}_1^\circ = RT\,2.303\log a_1 \quad (14)$$

The calculated values are collected in Tables VIII and IX.

(6a) Shibata and Murata, *J. Chem. Soc. Japan*, **52**, 393 (1931).

Relative Partial Molal Heat Content of Solute and Solvent.—The former quantity is given in the case of sodium hydroxide concentrations below 12 molal by the formula

$$\bar{L}_2 = -6.9078RT\frac{u\sqrt{m}}{1+\sqrt{2m}}(1-\beta T) - 4.6052RT^2\left[m\frac{dB}{dT} + m^2\frac{dC}{dT} + m^3\frac{dD}{dT} + m^4\frac{dE}{dT}\right] \quad (15)$$

where β is the constant of Åkerlöf[7] for expressing the change of the dielectric constant of the solvent with temperature. For concentrations above 12

(7) Åkerlöf, THIS JOURNAL, 54, 4125 (1932).

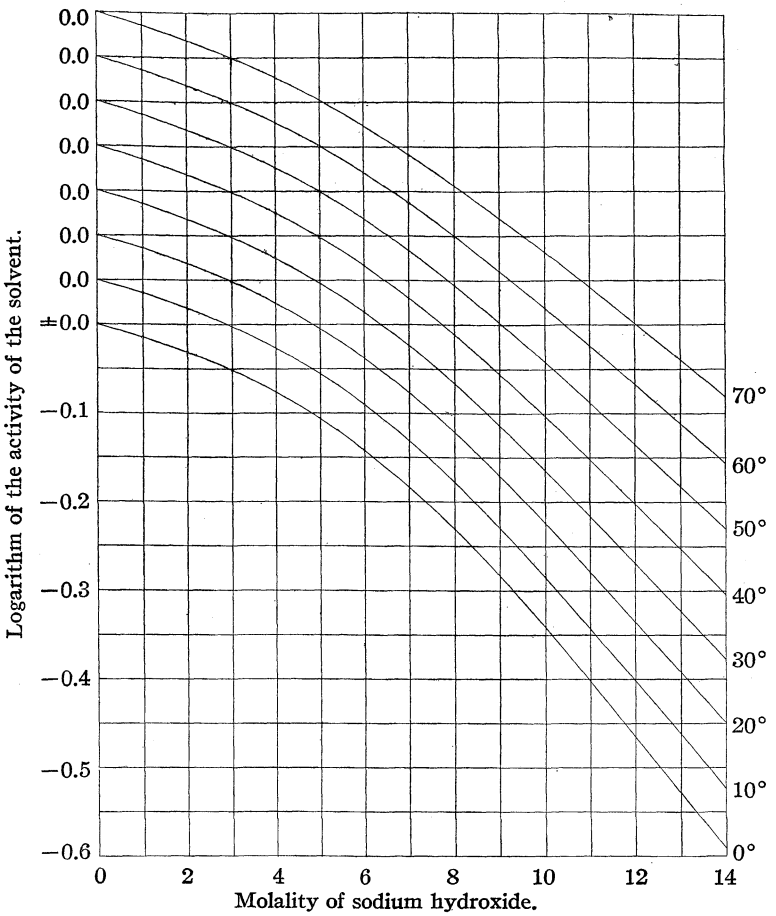

Fig. 3.—Isotherms for the logarithm of the activity of the solvent in aqueous solutions of sodium hydroxide. Ordinates are shifted successively for the different curves.

molal the following equation should be used

$$\bar{L}_2 = -2RT^2\, 2.303\ \mathrm{d}\log\gamma/\mathrm{d}T = -4.6052RT^2[\mathrm{d}a/\mathrm{d}t - m\,\mathrm{d}b/\mathrm{d}t - m^2\,\mathrm{d}c/\mathrm{d}t] \quad (16)$$

where a, b and c are the empirical constants given in Table IV for the equation

$$\log\gamma = a + bm + cm^2$$

The heat content of the solvent in solutions belonging to the lower concentration range may be computed from the formula

$$\bar{L}_1 = \frac{6.9078RTu(1-\beta T)}{2\cdot 55.51\cdot\sqrt{2}}\left[(1+\sqrt{2m}) - 4.6052\log(1+\sqrt{2m}) - \frac{1}{1+\sqrt{2m}}\right] + \frac{4.6052RT^2}{55.51}\left[\frac{m^2}{2}\frac{\mathrm{d}B}{\mathrm{d}T} + \frac{2m^3}{3}\frac{\mathrm{d}C}{\mathrm{d}T} + \frac{3m^4}{4}\frac{\mathrm{d}D}{\mathrm{d}T} + \frac{4m^5}{5}\frac{\mathrm{d}E}{\mathrm{d}T}\right] \quad (17)$$

where the constant β has the same meaning as in equation (15). For the higher concentration range we obtain the expression

$$\bar{L}_{1(m>12)} = -2.303RT^2\ \mathrm{d}\log a_1/\mathrm{d}T = \bar{L}_{1(12)} + \frac{2.303RT^2}{55.51}[(m^2-144)\mathrm{d}b/\mathrm{d}t + 4/3(m^3-1728)\mathrm{d}c/\mathrm{d}t] \quad (18)$$

Tables X and XI contain a summary of the values computed for $\bar{L}_1$ and $\bar{L}_2$. The values of the latter quantity calculated by Harned and Hecker from their data agree in dilute solutions quite well with ours but separate appreciably at higher concentrations. A graphical representation of our results is shown in Figs. 4 and 5. The former figure illustrates in particular the large deviations of the heat content of the hydroxide from the limiting law already in fairly dilute solutions.

Relative Partial Molal Entropy of Solute and Solvent.—As $F = H - TS$ the relative partial molal entropies may most simply be calculated from the free energies and heat contents

$$-(\bar{S}_2 - \bar{S}_2^\circ) = [(\bar{F}_2 - \bar{F}_2^\circ) - (\bar{H}_2 - \bar{H}_2^\circ)]/T \text{ and} \quad (19)$$

$$-(\bar{S}_1 - \bar{S}_1^\circ) = [(\bar{F}_1 - \bar{F}_1^\circ) - (\bar{H}_1 - \bar{H}_1^\circ)]/T \quad (20)$$

The results of the calculations appear in Tables XII and XIII. A graphical representation is given in Figs. 6 and 7. The curves for the solute show an increasingly sharper minimum and large changes of form with increasing temperature. As a comparison the corresponding entropy curves for hydrochloric acid are all practically symmetrical parabolas.

Relative Partial Molal Heat Capacity of the Solute.—According to definition $\bar{c}_{p_2} - \bar{c}_{p_2}^\circ = d\bar{L}_2/dT$ and we thus obtain for the lower concentration range the following expression for the calculation of the heat capacity of the solute

$$\bar{c}_{p_2} - \bar{c}_{p_2}^\circ = 3.4539R(1 - 2\beta T + 3\beta^2T^2)\frac{u\sqrt{m}}{1+\sqrt{2m}} - 9.2104RT\left[m\frac{dB}{dT} + m^2\frac{dC}{dT} + m^3\frac{dD}{dT} + m^4\frac{dE}{dT}\right] -$$

$$4.6052RT^2\left[m\frac{d^2B}{dT^2} + m^2\frac{d^2C}{dT^2} + m^3\frac{d^2D}{dT^2} + m^4\frac{d^2E}{dT^2}\right] \quad (21)$$

For the upper concentration range differentiation of equation (16) would give the desired quantity, but the accuracy of the measurements is too low to warrant a second differentiation. The values calculated from equation (21) are presented in Table XIV. In the first part of Table XV our values at 25° are compared with values obtained

from direct calorimetric measurements made by Rossini[8] and by Gucker and Schminke[9] through 2 molal solutions. The agreement is remarkably good, our values above 0.6 molal all falling between the two sets of calorimetric data. The values calculated by Harned and Hecker are also in good agreement with ours. A graphical representation of the changes of the heat capacity of the hydroxide is given in Fig. 8. All the curves show a maximum around 3, a minimum around 6, and a second maximum near 12 molal seems to be indicated. In contrast the corresponding curves for hydrochloric acid are practically straight lines.

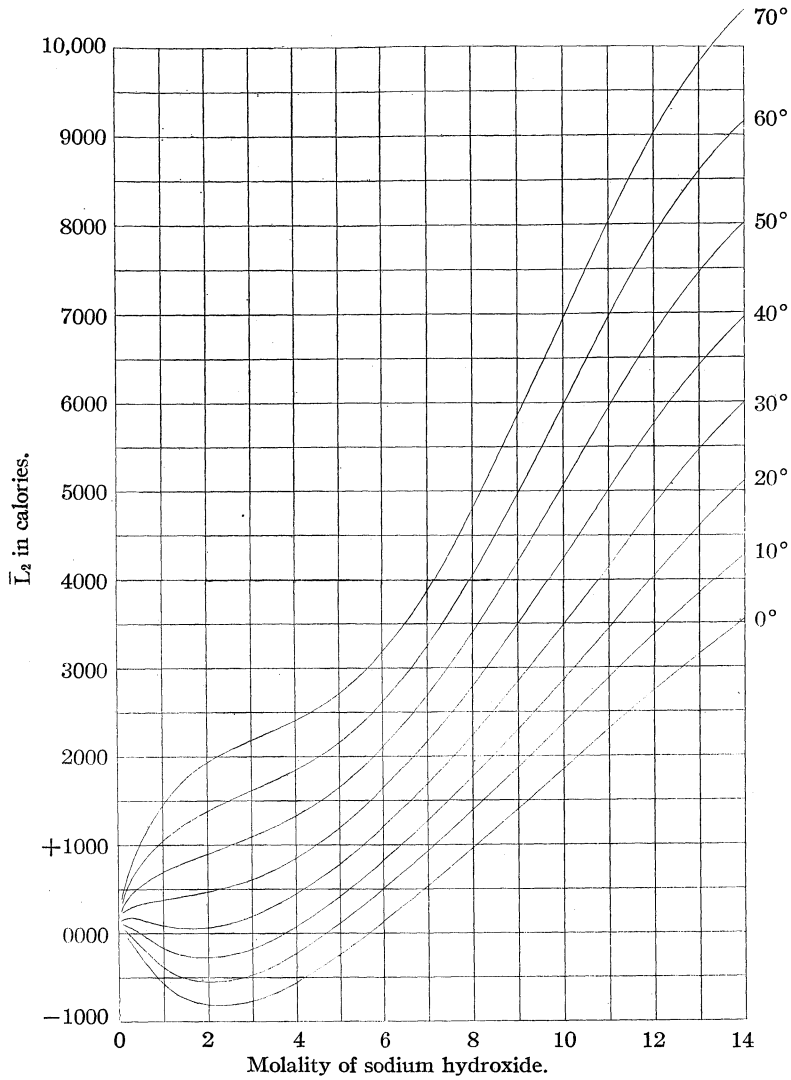

Fig. 4.—Isotherms for the relative partial molal heat content of the solute in aqueous solutions of sodium hydroxide.

Relative Partial Molal Heat Capacity of the Solvent.—For the lower concentration range differentiation of equation (17) gives directly

$$\bar{c}_{p_1} - \bar{c}_{p_1}^{\circ} = \frac{3.4539Ru}{2\cdot 55.51\sqrt{2}}(1 - 2\beta T + 3\beta^2T^2)\left[1 + \sqrt{2m} - 4.6052 \log (1 + \sqrt{2m}) - \frac{1}{1 + \sqrt{2m}}\right] + \frac{9.2104RT}{55.51}\left[\frac{m^2}{2}\frac{dB}{dT} + \frac{2m^3}{3}\frac{dC}{dT} + \frac{3m^4}{4}\frac{dD}{dT} + \frac{4m^5}{5}\frac{dE}{dT}\right] + \frac{4.6052RT^2}{55.51}\left[\frac{m^2}{2}\frac{d^2B}{dT^2} + \frac{2m^3}{3}\frac{d^2C}{dT^2} + \frac{3m^4}{4}\frac{d^2D}{dT^2} + \frac{4m^5}{5}\frac{d^2E}{dT^2}\right] \quad (22)$$

As in the case of the solute, values of the heat capacity of the solvent above 12 molal have not been calculated, although rough values could be obtained by differentiation of equation (18). Table XVI contains a summary of the values calculated from equation (22). In the second part of Table XV is again made a direct comparison with the result of the calorimetric measurements of Rossini and of Gucker and Schminke. As in the case of the solute the absolute agreement is quite good and only in one case, near the upper limit of the extrapolation function used by these authors, is the discrepancy between their values and ours greater than 0.1 calorie. Figure 9 gives a graphical representation of the changes of the heat capacity of the solvent. The curves have a very uniform appearance over the entire temperature range employed, but they are complicated in form. As a comparison the corresponding curves for hydrochloric acid solutions are practically

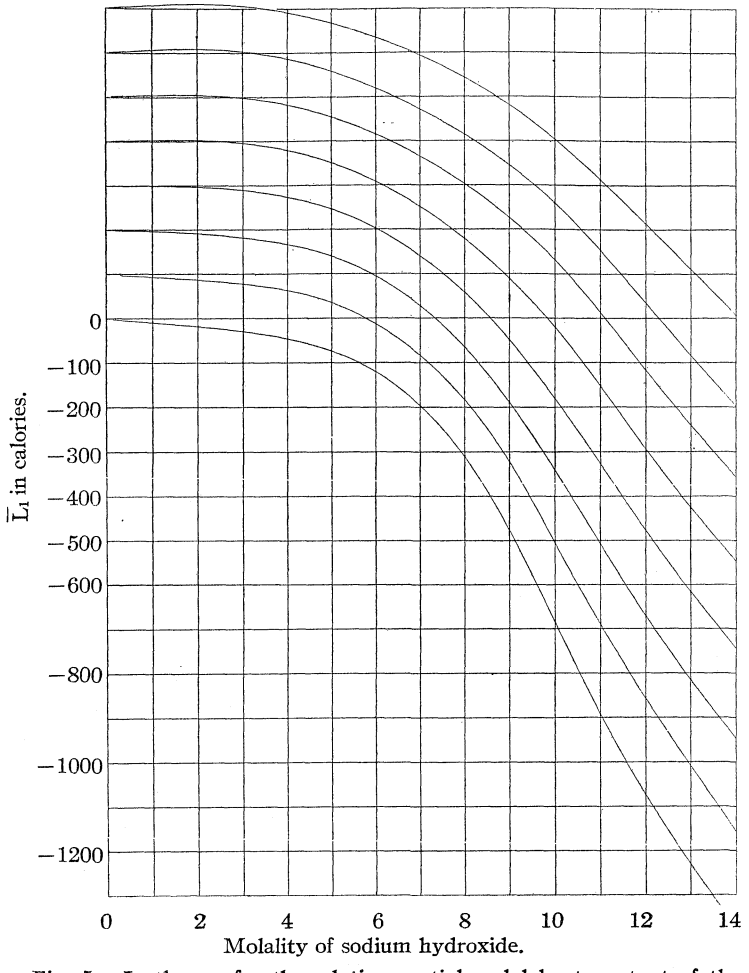

Fig. 5.—Isotherms for the relative partial molal heat content of the solvent in aqueous solutions of sodium hydroxide. Ordinates are shifted successively for the different curves.

linear when plotted against the square of the molality.

The Total Heat Capacity and the Specific Heat of the Solution.—These quantities are obtained from the relations: $C_p = 55.51\bar{c}_{p_1} + m\bar{c}_{p_2}$ per $1000 + Mm$ grams of solution and $s = C_p/(1000 + Mm)$ per gram of solution (M molecular weight of sodium hydroxide) respectively, in cases where it is possible to obtain values of $\bar{c}^\circ_{p_1}$ and $\bar{c}^\circ_{p_2}$. For sodium hydroxide solutions values of the latter quantity are given by Rossini at 18 and 21.5° and by Gucker and Schminke at 25°. Rossini also gives as a mean value for $d\bar{c}^\circ_{p_2}/dT = {}^2/_7$ cal. per degree. Using the value −26.6 of Gucker and Schminke, whose data are in better agreement with ours than those of Rossini, and the latter's value for $d\bar{c}^\circ_{p_2}/dT$ we get at 20° $\bar{c}^\circ_{p_2} = -28.0$ calories. This value combined with the values of $\bar{c}^\circ_{p_2} - \bar{c}^\circ_{p_2}$ in Table XIV for 20° would give values for $\bar{c}_{p_2}$ up to 12 molal.

The value of $\bar{c}^\circ_{p_1}$ is obtained by multiplying the specific heat of water by its molecular weight. The value used for the specific heat is 0.9988 cal. per degree, giving $\bar{c}^\circ_{p_1} = 18.014$. This value combined with the data in Table XVI for $\bar{c}^\circ_{p_1} - \bar{c}^\circ_{p_1}$ at 20° would give values for $\bar{c}_{p_1}$ up to 12 molal. With both $\bar{c}^\circ_{p_2}$ and $\bar{c}^\circ_{p_1}$ known, the total heat capacity and specific heat of the solutions may be calculated using the relations given above. A summary of the results is shown in Table XVII. An error analysis based on the data in Table XV indicates that the specific heats should have an accuracy of one unit in the third decimal place up to concentrations well above 2 molal. At higher concentrations the errors would be increasingly larger as found by a comparison with the calorimetric data of Bartetti and McCabe.[9a]

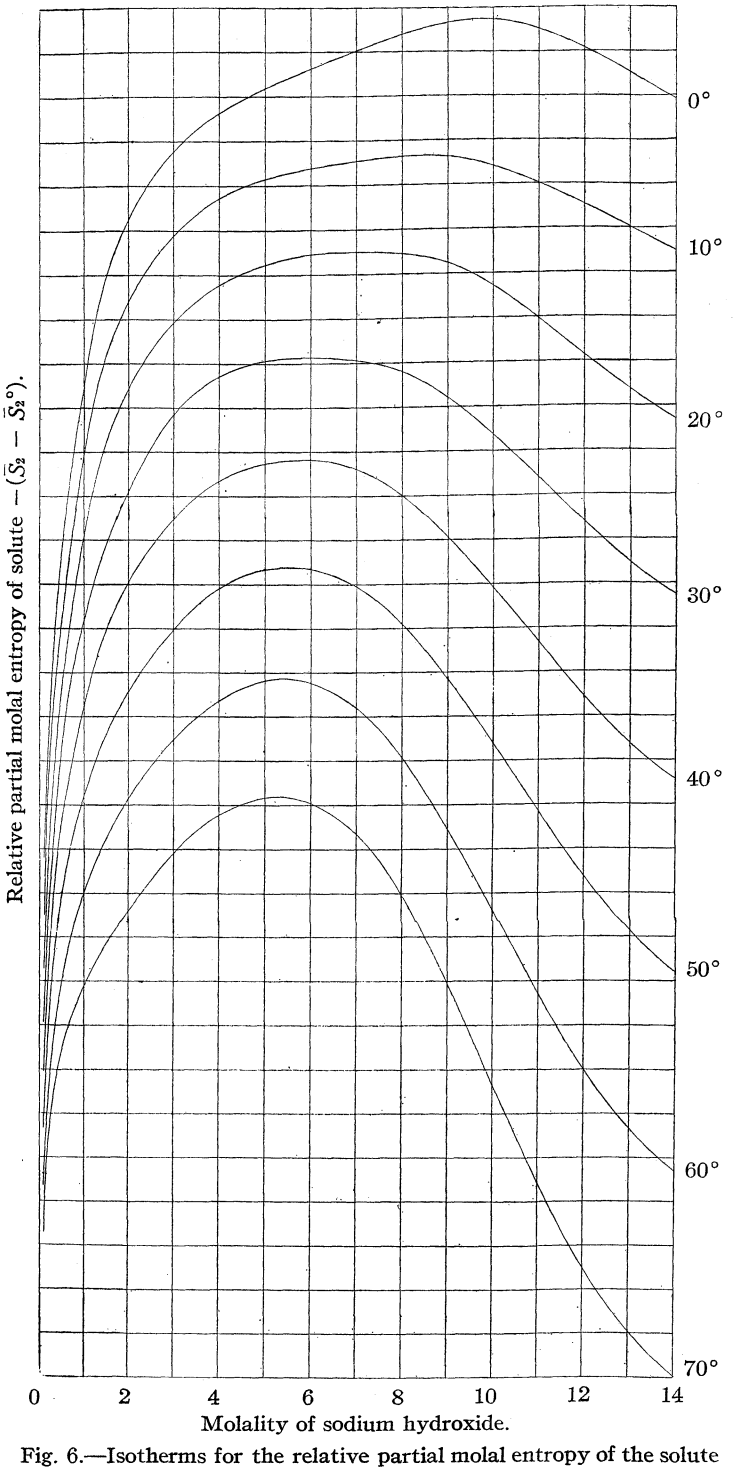

Fig. 6.—Isotherms for the relative partial molal entropy of the solute in aqueous solutions of sodium hydroxide. Ordinates are shifted successively for the different curves.

The Total Relative Heat Content of the Solutions.—This quantity which is equal to the heat evolved upon dilution to zero concentration is defined by the relation: $L_{(m)} = 55.51\ \bar{L}_1 + m\bar{L}_2$ per $1000 + Mm$ grams of solution. The molal value L/m, usually called the integral heat of dilution, also has considerable interest. Values

(9a) Bartetti and McCabe, *Ind. Eng. Chem.*, **28**, 375 (1936).

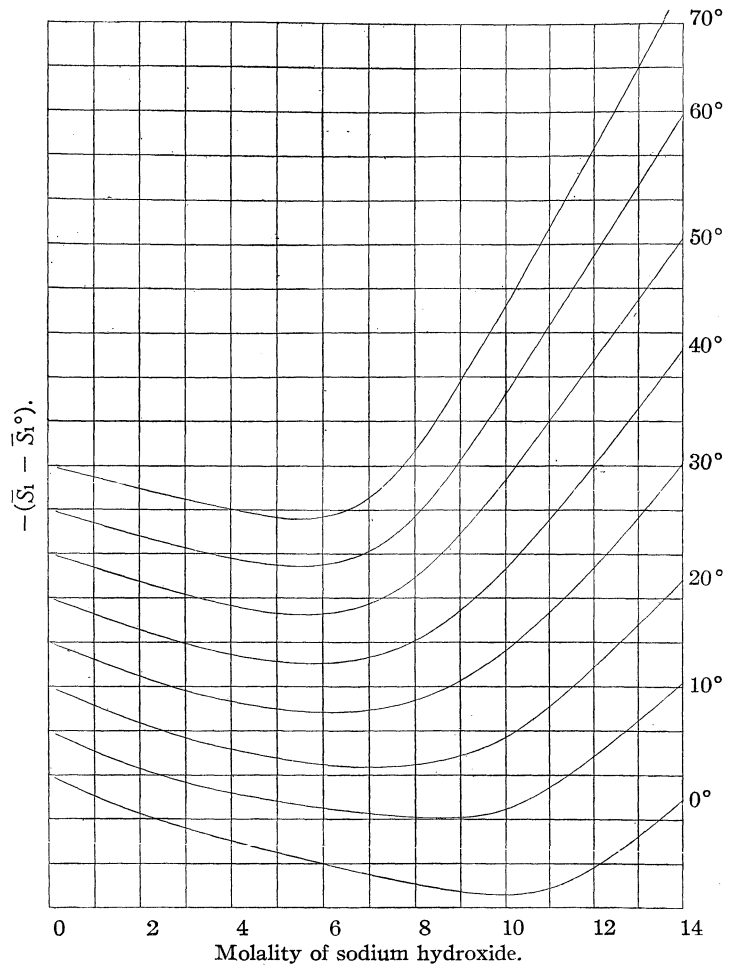

Fig. 7.—Isotherms for the relative partial molal entropy of the solvent in aqueous solutions of sodium hydroxide. Ordinates are shifted successively for the different curves.

of L and L/m are simply obtained by the use of the data in Tables X and XI for $\bar{L}_2$ and $\bar{L}_1$, respectively. Those calculated for 20° are collected in Table XVIII. They are needed for the computation of the following quantity which has a practical value.

TABLE XVII

TOTAL HEAT CAPACITY AND SPECIFIC HEAT OF AQUEOUS SOLUTIONS OF SODIUM HYDROXIDE AT 20°

m	C_p	s
0.1	997.58	0.9936
.2	995.75	.9878
.4	992.67	.9770
.6	990.37	.9672
.8	988.48	.9578
1.0	987.3	.9493
1.5	985.9	.9300
2.0	984.9	.9119
3.0	982.0	.8767

The Heat of Dilution between Two Finite Concentrations.—If n moles of water are used to dilute a solution of mass M and molality m to a molality m'

$$m' = \frac{55.51 \cdot M \cdot m}{55.51M + (1000 + 40m)n} \quad (23)$$

the isothermal heat absorbed by the system is given by the equation

$$\Delta H = \frac{M}{1000 + 40m}[L_{(m')} - L_{(m)}] + \frac{Mnm\bar{L}_{2(m')}}{55.51M + (1000 + 40m)n} + n\bar{L}_{1(m')} \quad (24)$$

The use of equation (24) permits the calculation of the heat of dilution of sodium hydroxide solutions at any temperature in the range 0 to 70° for any arbitrary amount of solution between any two molalities from 0.1 to 17 molal. Values of $\Delta H/m$ calculated from (24) agree remarkably well with the data of Richards and co-workers and Fricke.[9b]

The Differential Heat of Vaporization.—This quantity ΔH_v is defined as the amount of heat necessary to vaporize one mole of the solvent at constant temperature and pressure from a sufficiently large body of the solution so that no concentration change takes place. To calculate this quantity we will make use of the relationship

$$\bar{L}_1 = -RT^2\partial \ln p_1/\partial T + RT^2\partial \ln p_1°/\partial T \quad (25)$$

The second term of equation (25) is recognized immediately as the approximate Clausius–Clapey-

ron expression for the heat of vaporization $\Delta H_v°$ of one mole of the pure solvent. By rigorous thermodynamic methods the first term is found to represent the analogous quantity for solvent in the solution, provided no concentration change takes place during the loss of one mole of solvent. This quantity is therefore the differential heat of vaporization as defined above.

Using the measurements of $\Delta H_v°$ for water by Keyes, Smith and Gerry[10] after conversion from cc. atm./g. to cal./mole and the values of $\bar{L}_1$ in Table XI, the values calculated for ΔH_v have been collected in Table XIX. These data are limiting values for the next quantity to be considered.

The Integral Heat of Vaporization.—This quantity is defined as the amount of heat necessary to vaporize one mole of solvent from a given finite amount of solution, the accompanying concentration change being determined by the original concentration and mass of the solution. If one mole of water is vaporized from a sodium hydroxide solution of original mass M and molality m, the isothermal heat absorbed by the system is thus given by the integral heat of vaporization

$$Q = \Delta H_v° + \frac{M}{1000 + 40m}[L_{(m')} - L_{(m)}] - \frac{MmL_{2(m')}}{55.51M - 1000 - 40m} - \bar{L}_{1(m')} \quad (26)$$

where the resulting concentration m' should be computed from the following formula, analogous to equation (23)

$$m' = \frac{55.51Mm}{55.51M - 1000 - 40m}$$

For the vaporization of n moles of water from the same solution a similar equation is obtained

$$Q' = n\Delta H_v^{\circ} + \frac{M}{1000 + 40m}[L_{(m')} - L_{(m)}] - \frac{Mnm\bar{L}_{2(m')}}{55.51M - (1000 + 40m)n} - n\bar{L}_{1(m')} \quad (27)$$

$$\text{where } m' = \frac{55.51Mm}{55.51M - (1000 + 40m)n}$$

By use of the data in Tables X and XI and the values of ΔH_v° in Table XIX, equation (27) allows the calculation of the heat absorbed when an arbitrary amount of solvent is vaporized from a sodium hydroxide solution in the temperature range 0 to 70° at any concentrations between 0.1 to 17 molal. From Table XIX, $\Delta H_v^{\circ} = 1070.5$ cal., while ΔH_v for a ten molal solution is 1436.9 cal. This is to be compared with 1501.6 cal., the integral heat in going from 10 to 11 molal, computed from equation (26) with $M = 277.45$ g.

Pressure Variations of the Thermodynamic Properties of Solute and Solvent.—The rate of change of the chemical potentials of solute and solvent with pressure is given by the expressions

$$\left[\frac{\partial(\bar{F}_2 - \bar{F}_2^{\circ})}{\partial P}\right]_T = 2RT\left[\frac{\partial \ln \gamma}{\partial P}\right]_T = \bar{v}_2 - \bar{v}_2^{\circ} \quad (28)$$

$$\left[\frac{\partial(\bar{F}_1 - \bar{F}_1^{\circ})}{\partial P}\right]_T = RT\left[\frac{\partial \ln a_1}{\partial P}\right]_T = \bar{v}_1 - \bar{v}_1^{\circ} \quad (29)$$

The measurements of Smith and Keyes[11] show that the specific volume of pure liquid water changes by only 1 part in 1000 for a pressure change from 1 to 25 atmospheres. Since there is no reason to expect the compressibility of aqueous solutions to be much different from that of pure water, we may assume that in the pressure range mentioned the values of the partial molal volumes in equations (28) and (29) are constant within the experimental errors. This would give the following simple integrated equations

$$\log \gamma_P = \log \gamma + \frac{\bar{v}_2 - \bar{v}_2^{\circ}}{2 \cdot 2.303RT}(P - 1) \quad (30)$$

$$\log a_{1P} = \log a_1 + \frac{\bar{v}_1 - \bar{v}_1^{\circ}}{2.303RT}(P - 1) \quad (31)$$

where the pressure P is measured in atmospheres. The data for $\bar{v}_1$ and $\bar{v}_2$ needed for calculations using equations (30) and (31) are given in our previous study of the density of solutions of sodium hydroxide, which covers the temperature range 0 to 70° up to 27 molal.

Using the same fundamental thermodynamic relationships with $\log \gamma_P$ and $\log a_{1P}$ as those employed with $\log \gamma$ and $\log a_1$ in relation to other properties treated above, it is possible to calculate the values of the latter at higher pressures. It should be noted that in general the pressure correction term is so small that even if it has a large percentage error, this will not contribute any appreciable error to the final quantity obtained. Hence it would probably be quite feasible to apply equations (30) and (31) and all equations derived from them up to pressures of 100 atmospheres without introducing any serious errors. To obtain the derived equations it is necessary to know the temperature dependence of $\bar{v}_2$ and $\bar{v}_1$.

(11) Smith and Keyes, *Proc. Am. Acad. Arts Sci.*, **69** 285 (1934).

This may be calculated from the known variation of k with temperature according to the expressions

$$\bar{v}_2 - \bar{v}_2^\circ = k_1\sqrt{m} \quad \text{and} \quad \bar{v}_1 - \bar{v}_1^\circ = -\frac{18.016}{2000}k_1 m^{3/2}$$

where the concentration ranges from $m = 0$ to the density "break." The explicit temperature dependence of k_1 is obtained from third order equations given in our density paper.

The Chemical Significance of the Data.—Ions composed of single atoms like those of the alkali halides may probably without any large errors be considered to be non-deformable. The activity coefficients of strong electrolytes dissociating into ions of this type seem to follow with surprising accuracy, as has been tested for a large number of cases, the approximate rule of Åkerlöf and Thomas[12]

$$\log \gamma_1/\gamma_2 = km \qquad (32)$$

where the indices designate two electrolytes of the same valence type. The value of k is practically independent of the concentration except in very dilute solutions. The hydroxyl ion of the alkali hydroxides is composed of two atoms and should, in contrast to the behavior of single atom ions, be polarizable since it is unsymmetrical with respect to the electrical field of its associated positive ions. At infinite dilution the electrical strain and distortion must be at its minimum. With increasing concentration of the hydroxide the electrical distortion or induced polarization may be assumed as a first approximation to grow proportionally but the size of the effect would be unknown as there is no method available for the calculation of the "normal" thermodynamic properties of the alkali hydroxides. However, a saturation effect also should be present since the force needed to change the dimensions of an already stressed structure by a given amount would tend to increase with the hydroxide concentration or expressed in other words, the polarization per mole decreases with increasing concentration.

The presence of polarization of the hydroxyl ion is indicated already by the reversal of the behavior of the alkali hydroxides when compared to that of the corresponding alkali halides as previously pointed out by Harned and Åkerlöf.[13] A further support should according to the above be obtained by applying the rule of Åkerlöf and Thomas, which would indicate the presence of a saturation effect. The result is shown graphically in Fig. 10 where the value of k in equation (32) is plotted against the concentration. The data of Åkerlof and Teare for the activity coefficient of hydrochloric acid were used for the calculations since they were the only ones available in the literature covering the temperature and concentration ranges needed.

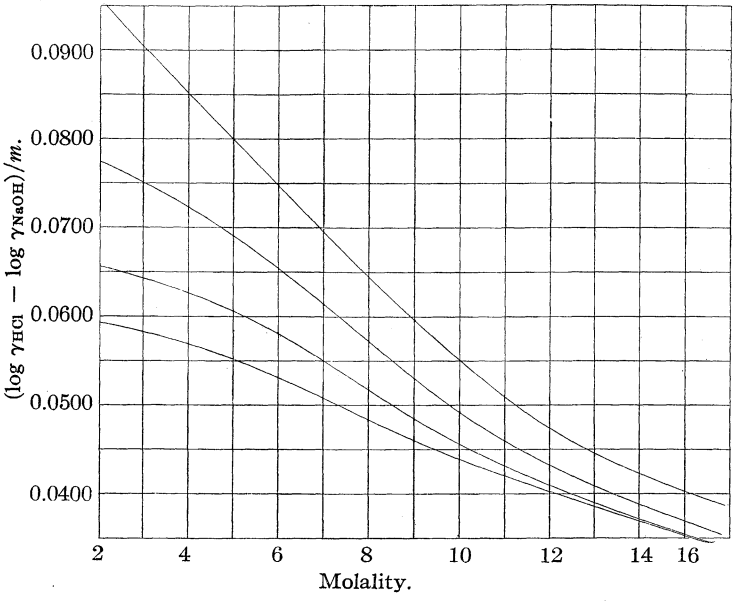

Fig. 10.—Isotherms at 0 (top curve), 20, 40 and 60° of the value for $(\log \gamma_{HCl} - \log \gamma_{NaOH})/m$.

The curves in Fig. 10 illustrate clearly the expected behavior of sodium hydroxide. Instead of a series of practically horizontal straight lines, they show a rapidly decreasing value of k with increasing concentration. The tendency of the curves to converge at higher concentrations and temperatures had also to be expected since when the ions of the hydroxide are brought closer and closer to each other the hydroxyl ion approaches its maximum polarization and the influence of the nature of the surrounding medium must decrease.

Summary

The electromotive force of the cell: $Pt,H_2/NaOH\ (m_1)/Na_xHg/NaOH\ (m_2)/H_2,Pt$ has been measured at a large number of hydroxide concentrations from 0.1 to 17 molal over the tempera-

(12) Åkerlöf and Thomas, THIS JOURNAL, 56, 593 (1934); Åkerlöf, *J. Phys. Chem.*, 41 1053 (1937).

(13) Harned and Åkerlöf, *Physik. Z.*, 27, 411 (1926).

ture range 0 to 70° using a considerably improved experimental procedure. The water transfer potential of the cell was calculated by a direct method eliminating tedious successive approximations.

The activity coefficient of the hydroxide for the concentration range 0.1 to 12 molal was found to be expressed adequately by the equation

$$\log \gamma = -\frac{u\sqrt{m}}{1+\sqrt{2m}} + Bm + Cm^2 + Dm^3 + Em^4$$

where u is the universal constant of the limiting law, m the molality of the hydroxide, B, C, D and E empirical constants varying according to second order equations with the temperature.

At higher concentrations a second order equation was used for the calculation of log γ. The curves for log γ do not within the experimental accuracy show any breaks at higher concentrations like those of the apparent partial molal volumes.

Using the formulas for log γ equations have been given for the calculation of the activity and vapor pressure of the solvent, the relative partial molal free energy, heat content, entropy, and heat capacity of both solute and solvent. Other properties that have been discussed are the total heat capacity, specific heat and relative heat content of the solutions, the heat of dilution between two finite concentrations, differential and integral heats of vaporization of the solvent and finally the effect of pressure upon the thermodynamic properties of sodium hydroxide. The computed values of most of the properties treated are given in a series of tables.

The Fluorination of Thionyl Chloride[1]

BY HAROLD SIMMONS BOOTH AND FRANCIS CARL MERICOLA

In 1896, M. Meslans[2] found that when thionyl chloride was treated with certain metallic fluorides such as zinc fluoride, a gaseous product, thionyl fluoride was formed. He reported this gas as being colorless and boiling in the neighborhood of −30° and added that the gas attacked the respiratory organs vigorously. Later Moissan and Lebeau[3] prepared this gas using free fluorine and also arsenic trifluoride as the fluorinating agents.

In 1905, Ruff and Thiel[4] prepared thionyl fluoride by heating N_4S_4 and hydrogen fluoride in the presence of water and cupric oxide in a sealed glass tube for two hours at 100°.

Since none of the previous investigators found any intermediate fluorination products, it seemed advisable to study the fluorination of thionyl chloride by means of antimony fluoride in the presence of a catalyst. This reaction has been successfully applied to the stepwise fluorination of various non-polar halides in this Laboratory.[5,6]

Experimental

The generator was similar to that described by Booth and Bozarth.[6] The sublimed antimony trifluoride was slowly fed into the refluxing reaction mixture of 80% thionyl chloride and 20% antimony pentachloride (maintained at 50°, and at 200 mm. pressure) at such a rate that the automatic bleed-off valve would be continually in the open position but such that it would not allow the pressure to rise more than a few millimeters above this point. In this way as soon as any thionyl chlorofluoride was formed it was immediately removed from the reaction zone, thus ensuring the maximum yield. Reaction took place immediately.

The distillation analysis revealed the product to consist of 50% thionyl fluoride, 20% thionyl chlorofluoride, 5% sulfur dioxide and about 25% unreacted thionyl chloride. The yields were dependent upon the conditions of the reaction. Higher temperatures and pressures increased the percentage of thionyl fluoride and thus decreased the yield of the chlorofluoride. If the pressure were kept too low, thionyl chloride would distil out of the reaction zone.

The design and operation of the purification system was as already described[7] save that a glass spiral replaced the copper spiral in the fractionating column since copper was attacked. After the first rough separation two distillations in the column were sufficient to obtain pure gases for the determination of properties.

Analysis.—The samples were taken in small bulbs as liquids and absorbed in aqueous sodium hydroxide as usual.[8] Chlorine was determined gravimetrically as silver

chloride and sulfur as barium sulfate. In the latter case the solution was kept strongly acidic to avoid coprecipitation of barium fluoride. The oxygen was established indirectly by titration of the solution, alkaline with sodium bicarbonate, with excess iodine and back titration of the excess with sodium thiosulfate. The presence of fluorine was established qualitatively.

[a] Samples A and B were from different distillations. [b] The calculated values were determined by use of the equations.

Physical Properties.—The liquid density was determined by means of a special pycnometer.[9] Freezing points, vapor pressures and gas densities were measured according to the standard practice in this Laboratory.[7] With thionyl chloride supercooling of from 10 to 15° occurred, but with thionyl fluoride none was observed. In the case of thionyl chlorofluoride much difficulty was encountered in measuring the freezing point. Upon cooling, the liquefied gas slowly solidified to a viscous transparent glassy solid which upon further cooling crystallized spontaneously with such force that on several occasions it burst the melting point tube. To obviate this difficulty the gas was first crystallized in the melting point tube and then allowed to melt slowly by placing a dewar flask, with a little liquid nitrogen in the bottom, around the jacketed melting point tube and the *melting point* of the thionyl chlorofluoride was obtained in this way.

Critical Constants.—The critical constants of thionyl chloride and thionyl chlorofluoride were not determined due to the fact that mercury reacts with both these compounds. The critical and vapor pressure data of thionyl fluoride at high pressures were obtained. The measurements were made in the apparatus and as described by Booth and Swinehart.[10]

TABLE III

Chemical Properties.—Thionyl fluoride in the absence of moisture was found to be the most stable of the three compounds studied. It was found to be so stable that it would not decompose at red heat in an iron retort although in glass it reacted with the silica forming sulfur dioxide and silicon tetrafluoride. Water reacts with thionyl fluoride giving hydrogen fluoride and sulfur dioxide. It is very inert toward such elements as iron, nickel, copper, mercury, silicon, manganese, boron, magnesium, aluminum, zinc, etc., even at temperatures up to 125°.

An attempt to chlorinate thionyl fluoride by passing chlorine and thionyl fluoride over activated charcoal gave negative results, whereas this chlorination runs smoothly in the case of sulfur dioxide and chlorine, giving sulfuryl chloride.[11]

In contrast to thionyl fluoride, thionyl chloride is quite reactive with metals. Its reactions may be represented by the equations[12]

$$3M + 4SOCl_2 \longrightarrow 3MCl_2 + 2SO_2 + S_2Cl_2$$
$$3M + 2SOCl_2 \longrightarrow 2MCl_2 + MS + SO_2$$

With zinc, cadmium, magnesium, lead, chromium and nickel, no reaction was observed up to 200°.

In the case of metal sulfides, the reaction may be represented by

$$MS + SOCl_2 \longrightarrow MCl_2 + SO_2 + S_2Cl_2$$

These reactions were corroborated in this Laboratory.

Thionyl chlorofluoride reacts with very few metals at temperatures up to 150°. Tests with such metals and metalloids as boron, magnesium, silver, aluminum, silicon, zinc, phosphorus, manganese, arsenic and antimony were negative.

(11) "Inorganic Syntheses," Vol. I, McGraw-Hill Book Co., Inc., New York, N. Y., p. 114.

(12) H. B. North, THIS JOURNAL, **32**, 184 (1910); H. B. North and C. B. Conover, *ibid.*, **37**, 2486 (1915); H. B. North and A. M. Hageman, *ibid.*, **34**, 890 (1912).

With copper and mercury, reaction took place readily at room temperature. With iron reaction took place at about 70°. The products of the reaction were identified as SOF_2, SO_2, MS and MCl_2. In all cases some thionyl chloride was also found. This would indicate that a decomposition probably first occurs and that the speed of this reaction is greater than that of the reaction of the metals with thionyl chloride.

$$2SOClF + (Hg) \longrightarrow SOCl_2 + SOF_2 \text{ (fast)}$$
$$2SOCl_2 + 3Hg \longrightarrow 2HgCl_2 + HgS + SO_2 \text{ (slow)}$$

This is borne out by the fact that thionyl chlorofluoride on standing for some months in the gaseous state at room temperature decomposed to a considerable extent to $SOCl_2$ and SOF_2. In general, thionyl chlorofluoride behaves chemically like thionyl chloride.

An attempt to remove the chlorine by reaction with sodium amalgam in order to produce a condensation product of the formula $(SOF)_2$ was not successful. Instead, the reaction was one of oxidation–reduction. Reactions with Grignard reagents were analogous to those of thionyl chloride. No attempt was made to isolate the reaction products. When pure, all three substances are colorless in all states. They hydrolyze in moist air or water very readily.

Summary

The fluorination of thionyl chloride using antimony fluoride and antimony pentachloride, yields two gaseous products, thionyl fluoride, first described by Meslans, and a new compound, thionyl chlorofluoride. Physical and chemical properties of these two gases have been determined. The freezing point of thionyl chloride has also been redetermined.

The Effect of Phosphate Buffers on the Electrical Mobility of Hemoglobin

BY M. H. GORIN, H. A. ABRAMSON AND L. S. MOYER

This communication deals with part of the data in a recent article by Davis and Cohn[1] entitled, "The Influence of *p*H and Ionic Strength on Electrophoretic Mobility." It is clear that the influence of ionic strength on the electric mobility of proteins at a given *p*H must embody two important effects: (1) the direct effect of the ions on the charge of the particle, (2) the effect of the ionic atmosphere on the electric mobility of a molecule of given charge. It has been shown[2,3,4,5] previously that the second effect, the effect of the ion atmosphere on the motion of the particle, could be accounted for in certain simple systems by some form of the Debye equation

$$u = u_0/(1 + \kappa r) \qquad (1)$$

(where u is the electric mobility, u_0 the value of the mobility at infinite dilution, κ the well-known function of ionic strength) when suitable corrections for shifts in the isoelectric point due to specific ion effects (of the first type) were considered. Davis and Cohn[1] have stated that their data are not satisfied by equation (1). In doing so they reject the methods previously employed by us[2-5] as applied to their data. It will be shown in this communication that the methods previously employed by us are applicable to the more complicated systems studied by Davis and Cohn.

The method employed by Davis and Cohn[1] to apply equation (1), as far as we can judge from their paper, implies that at a given value of the *p*H the net charge of the protein molecule is the same for all ionic strengths. This obviously is impossible, for an inspection of their data discloses very large shifts in the isoelectric point. Since the net charge is zero only at the isoelectric point, the complete family of curves indicates protein molecules having net charges of zero and finite values at any given *p*H in the range investigated.

To use our previous approach[2,3,4,5] it is necessary to make some assumption regarding the change in net charge with ionic strength. For uni-univalent electrolytes it is generally agreed that the influence of ionic strength on the shape of the net charge–*p*H curve is not very great.[6] Indeed, the change in shape may be neglected for small shifts in ionic strength. To obtain a reference point where the net charge is zero at all ionic strengths, we have previously shifted all curves to the same isoelectric point, keeping the curves parallel along the mobility axis. That these assumptions also may apply to systems containing phosphate buffers is demonstrated by treatment of the data of Davis and Cohn which follows.

Without any assumptions, except those inherent in the theory itself, we may apply the Debye theory by multiplying all the mobilities by the expression $(2 + \kappa r)$, to calculate the value of the mobility at zero ionic strength for a molecule of the same net charge. The empirical function $(2 + \kappa r)$ is used here because it gives essentially the same results ($\mu = 0.02$ to 0.15) as the theoretical functions derived by Gorin,[5] in which the asymmetry of the protein and the finite size of the other ions in the solution are considered.[5,7] The value of $r = 27$ Å. was employed.

In Fig. 1 the data of Davis and Cohn[1] on the effect of phosphate buffers on the electric mobility of hemoglobin are plotted as smooth curves. The dashed lines passing through the same isoelectric points are corresponding values of the mobility multiplied by $(2 + \kappa r)$. It may be observed that all of the dashed curves are closely parallel to one another, any deviation being at the limit of experimental error. This is made more evident by an inspection of Fig. 2, in which all of the data have been plotted by shifting the parallel curves to the same isoelectric point. It therefore appears that the assumptions we have heretofore employed for proteins in solutions of uni-univalent electrolytes, contrary to the view of Davis and Cohn,[1] may be applied to their data in the case

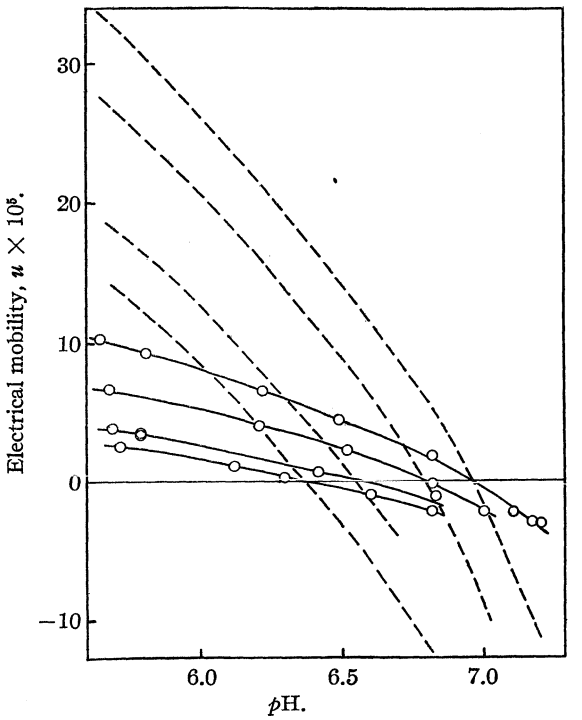

Fig. 1.—The data of Davis and Cohn at ionic strengths 0.02, 0.05, 0.10, 0.15, respectively, from top to bottom, are represented by the solid curves. The dashed lines represent their data multiplied by the function (κr + 2).

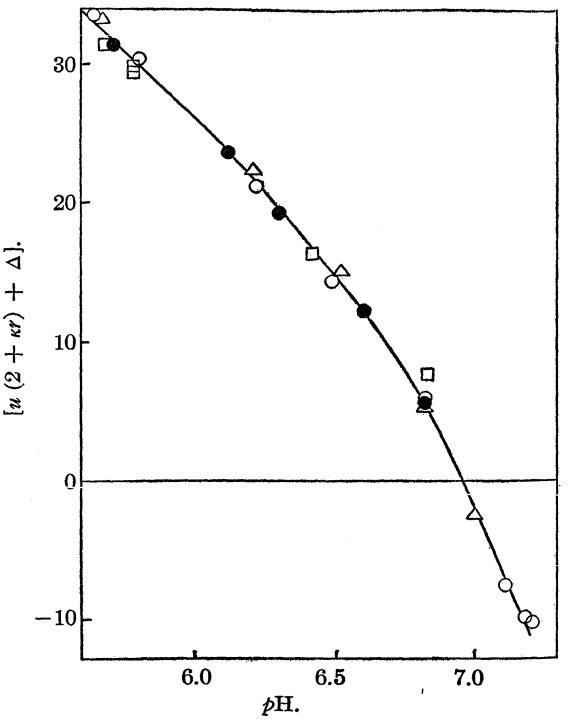

Fig. 2.—The recalculated data of Davis and Cohn have been brought to the same isoelectric point (that for ionic strength 0.02). The following symbols ○, △, □, ●, are for the data at ionic strengths 0.02, 0.05, 0.10 and 0.15, respectively. The values of △ are 0, 6.4, 13.0, 17.7, respectively.

under discussion. If the incomplete function, $(1 + \kappa r)$, is employed the agreement is not quite as good. This confirms similar observations made for proteins in simpler buffer solutions.[2,3,4,5]

In conclusion, with a view to avoiding confusion, it should be pointed out that the equation finally adopted by Davis and Cohn[1] (employing shifts in the isoelectric point)

$$u = u_0 - \beta\sqrt{\mu}/(1 + \sqrt{\mu}r/3) \qquad (2)$$

was in reality used as an empirical form of the equation[8]

$$u = u_0/(1 + \kappa r) \qquad (1)$$

(8) Compare D. A. MacInnes, "The Principles of Electrochemistry," Reinhold Publishing Corp., New York, 1939, page 325, with Abramson,[2] p. 104.

Summary

Variations of the ionic strength of a buffer at constant *p*H can affect the electric mobility of a protein in two ways: (1) a change in ion atmosphere will occur, (2) a change in the charge of the protein might occur due to specific interaction with the ions of the buffer. It is shown that when both effects are taken into consideration in a way that has previously been applied to proteins in buffer systems containing only uni-univalent ions the recent data of Davis and Cohn on the electric mobility of hemoglobin in phosphate buffers are reasonably explained.

Sterols. XCI. Oxidation of the Diacetate of Cholestanediol-3,6

BY RUSSELL E. MARKER, JOHN KRUEGER, JOHN R. ADAMS, JR., AND ELDON M. JONES

Windaus and Hossfeld[1] were unable to obtain *allo*-hyodesoxycholic acid by oxidation of the diacetate of cholestanediol-3,6. The oxidative opening of ring A occurred before the side chain was attacked and the product obtained was a lactone carboxylic acid. Recently we reported[2] the preparation of cholestanediol-3,6 of m. p. 190° which was epimeric with the cholestanediol-3,6 of m. p. 216° reported by Windaus.[3]

We have investigated the oxidation of the diacetate of cholestanediol (m. p. of the diol, 190°) and have obtained both *allo*-hyodesoxycholic acid and 6-hydroxyisoandrosterone from the reaction. *allo*-Hyodesoxycholic acid prepared in this way was characterized by direct comparison with a sample of *allo*-hyodesoxycholic acid and its methyl ester prepared from hyodesoxycholic acid by the method of Windaus.[4]

We have also degraded *allo*-hyodesoxycholic acid to *nor-allo*-hyodesoxycholic acid. *bis-nor-allo*-Hyodesoxycholic acid was prepared from *bis-nor*-hyodesoxycholic acid by the method of Windaus.[4]

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part

Reduction of 6-Hydroxycholestanone.—6-Hydroxycholestanone (2.2 g.) in 125 cc. of 95% ethanol and 0.2 g. of Adams catalyst was shaken under 3 atmospheres of hydrogen for two hours. The catalyst was filtered off and the filtrate was concentrated by evaporation. The cholestanediol-3,6 which separated on cooling was recrystallized from ethanol. The substance melted at 191° and showed no depression in melting point when mixed with cholestanediol-3,6[2] prepared by reduction of 6-ketocholestanol; yield 2 g.

Oxidation of the Diacetate of Cholestanediol-3,6.—The cholestanediol used was prepared by reduction of 6-ketocholestanol in acetic acid rather than in ethanol as previously reported.[2] The diacetyl derivative (200 g.) was mixed with 8 liters of acetic acid and was heated to 90° on a steam-bath. The solution was stirred mechanically and 440 g. of chromic anhydride in 250 cc. of water and 1300 cc. of acetic acid was added dropwise during five hours. The reaction mixture was heated four hours longer. After cooling, excess chromic anhydride was destroyed by cautious addition of 200 cc. of ethanol. The reaction mixture was evaporated *in vacuo* to 25% of its volume. Water and ether were added and the layers separated. The ethereal layer water washed with and was then extracted with 10% sodium hydroxide. The insoluble sodium salt was filtered off and saponified. The free acid was crystallized by extraction from a Soxhlet thimble with boiling ethyl acetate. The *allo*-hyodesoxycholic acid so obtained melted at 280° and gave no depression upon mixing with *allo*-hyodesoxycholic acid prepared from hyodesoxycholic acid.

Anal. Calcd. for $C_{24}H_{40}O_4$: C, 73.4; H, 10.3. Found: C, 73.4; H, 10.2.

The methyl ester prepared with diazomethane melted at 179°. The mixed melting point with the methyl ester of *allo*-hyodesoxycholic acid (m. p. 181°) prepared from hyodesoxycholic acid was 180°.

Anal. Calcd. for $C_{25}H_{42}O_4$: C, 73.8; H, 10.4 Found: C, 73.7; H, 10.3.

The ethereal solution from which *allo*-hyodesoxycholic acid had been extracted was washed with water, and then evaporated. The oily residue was dissolved in 500 cc. of ethanol, chilled in ice, and the crystalline unchanged diacetate of cholestanediol was filtered off. The filtrate was evaporated to dryness *in vacuo* and was then steam distilled to remove volatile ketones. The oily suspension was extracted with ether and the ethereal layer was evaporated to dryness. The residue was dissolved in 600 cc. of ethanol, and to this solution was added 15 g. of semicarbazide hydrochloride and 18 g. of sodium acetate. The mixture was refluxed two hours on a steam-bath, then the alcohol was evaporated to half its volume. Addition of 1500 cc. of ether caused a precipitate of sodium chloride which was dissolved in water. The ether layer was washed repeatedly with water in order to remove alcohol. The semicarbazone of the diacetate of 6-hydroxyisoandrosterone was precipitated from the ether layer with pentane. After one recrystallization from methanol–ether–pentane and two recrystallizations from methanol it was obtained as small white needles melting at 222°; yield 3.1 g.

Anal. Calcd. for $C_{24}H_{37}O_5N_3$: C, 64.4; H, 8.3. Found: C, 64.4; H, 8.3.

One gram of this semicarbazone in 50 cc. of ethanol was refluxed one-half hour with 5 cc. of sulfuric acid in 10 cc. of water. The mixture was poured into water and was extracted with ether. The ether was evaporated and the residue was refluxed one hour with 30 cc. of 2% methanolic potassium hydroxide. The solution was poured into water and was extracted with ether. The ether layer was washed well with water and then pentane was added to precipitate the diol. 6-Hydroxyisoandrosterone, crystallized from methanol–ether–pentane, melted at 205°.

Anal. Calcd. for $C_{19}H_{30}O_3$: C, 74.4; H, 9.9. Found: C, 74.4; H, 9.9.

(4) Windaus, *Ann.*, **447**, 233 (1926).

nor-allo-**Hyodesoxycholic Acid.**—Fifty grams of *allo*-hyodesoxycholic acid was refluxed for two hours with 1 l. of 1% methanolic hydrogen chloride. The solution was concentrated by evaporation *in vacuo*. On cooling, the methyl ester which crystallized out was filtered, dried and dissolved in hot toluene. The toluene solution was added to 16 moles of ethereal phenylmagnesium bromide. The suspension was refluxed for two hours, then the ether was distilled off and was replaced with dry toluene. The mixture was heated overnight on a steam-bath. The carbinol was isolated, acetylated and dehydrated in the usual way. The ethylenic compound so obtained was oxidized with chromic oxide and *nor-allo*-hyodesoxycholic acid was thus obtained.[2] The acid, recrystallized from methanol melted at 225°.

Anal. Calcd. for $C_{23}H_{38}O_4$: C, 73.0; H, 10.1. Found: C, 73.2; H, 10.1.

3,6-Diketo-*bis-nor*-cholanic Acid.—Fifteen grams of *bis-nor*-hyodesoxycholic acid[2] dissolved in 300 cc. of acetic acid was treated at 12–15° during fifteen minutes with 15 g. of chromic oxide dissolved in 15 cc. of water and 35 cc. of acetic acid. The mixture was stirred a further ten minutes and then was diluted with water. The suspension was extracted with ether and the ethereal layer after washing with water was evaporated to dryness. The residue was crystallized from ether–pentane. 3,6-Diketo-*bis-nor*-cholanic acid melted at 185°; yield 12 g.

Anal. Calcd. for $C_{22}H_{32}O_4$: C, 73.3; H, 8.9. Found: C, 72.7; H, 8.9.

The methyl ester of 3,6-diketo-*bis-nor*-cholanic acid was prepared with ethereal diazomethane. It melted at 170° after crystallization from ether–pentane. The mixed melting point with the acid (m. p. 185°) was 160°.

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.7; H, 9.1. Found: C, 73.9; H, 8.9.

3,6-Diketo-*bis-nor-allo*-cholanic Acid.—The diketo acid of m. p. 185° prepared above was refluxed for forty-five minutes with 150 cc. of acetic acid containing 1.5 cc. of C. P. hydrochloric acid. The mixture was concentrated to incipient crystallization by evaporation *in vacuo*. Ether was added and the gray precipitate was filtered off. The acid crystallized from ethanol as leaflets of m. p. 244°.

Anal. Calcd. for $C_{22}H_{32}O_4$: C, 73.3; H, 8.9. Found: C, 73.0; H, 8.9.

The methyl ester prepared with ethereal diazomethane after recrystallization from ether–pentane melted at 211°. The mixed melting point with acid of m. p. 244° was 200°.

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.7; H, 9.1. Found: C, 73.8; H, 9.3.

bis-nor-allo-**Hyodesoxycholic Acid.**—Five and one-half grams of 3,6-diketo-*bis-nor-allo*-cholanic acid in 100 cc. of acetic acid was shaken with Adams catalyst under 3 atm. of hydrogen for three hours. The catalyst was filtered off and the filtrate was concentrated by evaporation *in vacuo*. The acid crystallized from methanol as white needles, of m. p. 259°; yield 5 g.

Anal. Calcd. for $C_{22}H_{36}O_4$: C, 72.5; H, 10.0. Found: C, 72.1; H, 9.9.

The methyl ester was prepared with ethereal diazomethane. It crystallized from ether–pentane as white leaflets of m. p. 233°. The mixed melting point with acid of m. p. 256° was 233°.

Anal. Calcd. for $C_{23}H_{38}O_4$: C, 72.9; H, 10.1. Found: C, 73.0; H, 10.1.

Diacetate of *bis-nor-allo*-hyodesoxycholic Acid.—One-half a gram of *bis-nor-allo*-hyodesoxycholic acid was refluxed for ten minutes with 20 cc. of acetic anhydride. The solvent was evaporated *in vacuo* and the residue was dissolved in methyl alcohol. The crystals obtained melted at 115°.

Anal. Calcd. for $C_{26}H_{40}O_6 \cdot 0.5CH_3OH$: C, 68.5; H, 9.1. Found: C, 68.2; H, 9.0.

The methyl ester was prepared with ethereal diazomethane. The substance crystallized by rubbing with pentane melted at 135°. The mixed melting point with acid (m. p. 115°) was 111°.

Anal. Calcd. for $C_{27}H_{42}O_6$: C, 70.1; H, 9.2. Found: C, 70.1; H, 9.0.

Summary

allo-Hyodesoxycholic acid and 6-hydroxyisoandrosterone have been prepared by oxidation of the diacetate of cholestanediol-3,6. The preparation of *nor-allo*-hyodesoxycholic acid and of *bis-nor-allo*-hyodesoxycholic acid has been described.

Sterols. XCII. The Preparation of Neotigogenin from Sarsasapogenin

BY RUSSELL E. MARKER AND EWALD ROHRMANN

The fact that tigogenin,[1,2,3] chlorogenin,[4] gitogenin[3,5] and digitogenin[3,5] show no noticeable tendency to react with boiling aqueous ethanolic hydrochloric acid indicates that the side chains of these sapogenins differ in configuration from that of sarsasapogenin which by similar treatment is isomerized to isosarsasapogenin[6] (smilagenin[7]).

We have now obtained substantiating evidence which conclusively shows that tigogenin differs from sarsasapogenin not only in its configuration at C-5 but also in the configuration of the side chain. Sarsasapogenone upon bromination with two moles of bromine yields dibromosarsasapogenone, a substance which has a bromine in the C-4 position as well as one in the side chain.[8] Dibromosarsasapogenone upon treatment with boiling pyridine yields bromo-$\Delta^{4,5}$-dehydro-sarsasapogenone. Reduction of this product with sodium and ethanol and separation of the isomers with digitonin yields a digitonin precipitable product, m. p. 198–200°, which is different from tigogenin and sarsasapogenin but which appears to be identical with neotigogenin, a substance recently obtained by Goodson and Noller[1] from the sapogenins of *Chlorogalum pomeridianum*. Inasmuch as tigogenin, chlorogenin and diosgenin[9] have been converted to the same desoxy compound it follows that these substances all have the same side chain configuration.

These results definitely indicate that the side chain of neotigogenin is of the "sarsasapogenin configuration." It seems most probable that the side chain of tigogenin, chlorogenin and diosgenin is of the "isosarsasapogenin configuration," although it is evident that final proof of this supposition is dependent upon the conversion of isosarsasapogenin to tigogenin. The stability of gitogenin and digitogenin to aqueous ethanolic hydrochloric acid suggests that these substances likewise have the isosarsasapogenin side chain configuration.

Experimental Part

Treatment of Dibromosarsasapogenone with Pyridine.—A solution of 5 g. of dibromosarsasapogenone[8] in 50 cc. of dry pyridine was refluxed for eight hours. Some crystalline material had separated at the end of this time. This was filtered, washed with water and dried to give small white crystals, m. p. 235° dec. The product is probably a pyridinium salt.

Anal. Calcd. for $C_{32}H_{45}O_3NBr_2$: C, 59.0; H, 7.0. Found: C, 58.6; H, 7.3.

The filtrate from the above was diluted with aqueous sulfuric acid and the precipitated solid taken up in ether, treated with Norite and crystallized from acetone to give small compact white crystals, m. p. 185–188° dec. This is bromo-$\Delta^{4,5}$-dehydrosarsasapogenone, yield 2.2 g.

Anal. Calcd. for $C_{27}H_{39}O_3Br$: C, 66.0; H, 8.0. Found: C, 66.2; H, 8.1.

Reduction of Bromo-$\Delta^{4,5}$-dehydrosarsasapogenone with Sodium and Ethanol.—To a boiling solution of 2 g. of bromo-$\Delta^{4,5}$-dehydrosarsasapogenone in 400 cc. of absolute ethanol was added 17 g. of sodium over a period of one hour. Water was added and the precipitated solid taken up in ether, washed well with water and the ether evaporated. A precipitate formed when a solution of the residual sirup was treated with digitonin in 80% ethanol. The insoluble digitonide was decomposed with pyridine in the usual manner. The product was dissolved in methanol and treated with norite. It crystallized from methanol as small white crystals, m. p. 198–200°; yield, 600 mg. A mixture with tigogenin, m. p. 204–206°, melted at 179–192° and a mixture with a sarsasapogenin, m. p. 199–201°, melted at 160–170°. It gave no depression with a sample of neotigogenin, m. p. 199–201°, isolated from *Chlorogalum pomeridianum*.

Anal. Calcd. for $C_{27}H_{44}O_3$: C, 77.8; H, 10.6. Found: C, 77.7; H, 10.6.

With boiling acetic anhydride the product gave an acetate which crystallized from methanol as white plates, m. p. 173–175°. This gave no depression with a sample of neotigogenin acetate, m. p. 173–175°.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 75.9; H, 10.0.

Neotigogenone.—When oxidized with chromic anhydride at room temperature in acetic acid solution for thirty minutes, the neotigogenin yielded a product which crystallized from acetone as white plates, m. p. 207–210°. A mixture with tigogenone, m. p. 202–205°, melted at 198–204°. The mixture with neotigogenone, m. p. 208–211°, melted at 207–210°.

Anal. Calcd. for $C_{27}H_{42}O_3$: C, 78.2; H, 10.2. Found: C, 78.5; H, 10.2.

Summary

The preparation of $\Delta^{4,5}$-bromosarsasapogenone is described.

$\Delta^{4,5}$-Bromosarsasapogenone upon reduction with sodium and ethanol yields neotigogenin, indicating that tigogenin, chlorogenin and diosgenin differ from sarsasapogenin in the side chain configurations.

STATE COLLEGE, PENNA. RECEIVED JANUARY 10, 1940

Sterols. XCIII. *epi*-Pseudosarsasapogenin, Pseudosarsasapogenone and Pseudochlorogenin

BY RUSSELL E. MARKER, EWALD ROHRMANN AND ELDON M. JONES

In continuation of our study of the pseudosapogenins[1,2,3,4] we have extended the acetic anhydride isomerization to *epi*-sarsasapogenin, sarsasapogenone, isosarsasapogenin and chlorogenin. All of these substances are thus isomerized to give pseudo compounds.

As in the case with pseudosarsasapogenin[3] both *epi*-pseudosarsasapogenin and pseudochlorogenin take up a mole of hydrogen in the presence of Adams catalyst to yield dihydropseudosapogenins. Dihydropseudochlorogenin forms a triacetate and *epi*-dihydropseudosarsasapogenin a di-*p*-nitrobenzoate. Pseudosarsasapogenone forms a monosemicarbazone.

As would be expected from the previous results with pseudosarsasapogenin[1,2,3] both *epi*-pseudosarsasapogenin and pseudosarsasapogenone yield $\Delta^{16,17}$-pregnenedione-3,20 on mild oxidation with chromic anhydride.

From the suggested structures of sarsasapogenin[5] and isosarsasapogenin[5] one might expect these substances to yield the same pseudo compound, which was found to be the case. It is a significant fact that dihydrosarsasapogenin[5] was unaffected by treatment with acetic anhydride.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part[6]

Reduction of Sarsasapogenone with Sodium and Ethanol.—To a boiling solution of 6 g. of sarsasapogenone in 800 cc. of absolute ethanol was added 25 g. of sodium over a period of two hours. Water was added and the precipitated solid taken up in ether, washed with water and crystallized from acetone as white needles, m. p. 205–207°, yield 5.1 g. This gave no depression with a sample of *epi*-sarsasapogenin, m. p. 205–207°.

With hot acetic anhydride the product gave an **acetate** which crystallized from acetone as white plates, m. p. 191–193°.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 75.8; H, 10.0.

***epi*-Pseudosarsasapogenin.**—A mixture of 2 g. of *epi*-sarsasapogenin acetate and 20 cc. of acetic anhydride was heated at 200° for ten hours in a sealed tube. The acetic anhydride was evaporated *in vacuo* and the residue hydrolyzed with hot ethanolic potassium hydroxide. The neutral fraction was crystallized from acetone as white needles, m. p. 211–213°. This gave a large depression with both *epi*-sarsasapogenin, m. p. 205–207°, and sarsasapogenin, m. p. 199–201°.

Anal. Calcd. for $C_{27}H_{44}O_3$: C, 77.8; H, 10.6. Found: C, 77.6; H, 10.6.

***epi*-Dihydropseudosarsasapogenin.**—A mixture of 1.5 g. of *epi*-pseudosarsasapogenin, 1 g. of Adams catalyst and 150 cc. of acetic acid was shaken with hydrogen at 3 atm. pressure at room temperature for seventeen hours. After removal of the catalyst, concentration *in vacuo* gave a residue which was saponified for five minutes with ethanolic potassium hydroxide. The product was crystallized from acetone to give white needles, m. p. 135–137°.

Anal. Calcd. for $C_{27}H_{46}O_3$: C, 77.4; H, 11.1. Found: C, 77.3; H, 11.0.

With *p*-nitrobenzoyl chloride in pyridine at 60° the product gave a **di-*p*-nitrobenzoate** which crystallized from acetone as white needles, m. p. 207–209°.

Anal. Calcd. for $C_{41}H_{52}O_9N_2$: C, 68.7; H, 7.3. Found: C, 68.6; H, 7.3.

$\Delta^{16,17}$-Pregnenedione-3,20 from *epi*-Pseudosarsasapogenin.—To a solution of 100 mg. of *epi*-pseudosarsasapogenin in 10 cc. of acetic acid was added a solution of 300 mg. of chromic anhydride in 8 cc. of 80% acetic acid. After standing at room temperature for one hour, water was added and the precipitate taken up in ether and washed free from acids with a solution of sodium hydroxide. The neutral fraction crystallized from acetone as white

plates, m. p. 199–201°. This gave no depression with a sample of $\Delta^{16,17}$-pregnenedione-3,20, m. p. 200–202°.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6. Found: C, 79.9; H, 9.5.

Pseudosarsasapogenone.—A mixture of 4 g. of sarsasapogenone and 30 cc. of acetic anhydride was heated in a sealed tube at 200° for ten hours. The product was worked up as described for *epi*-pseudosarsasapogenin. The neutral fraction after treatment with Norite in methanol was crystallized from aqueous acetone to give white needles, m. p. 165–166°.

Anal. Calcd. for $C_{27}H_{42}O_3$: C, 78.2; H, 10.2. Found: C, 78.2; H, 10.3.

With semicarbazide acetate under the usual conditions the product gave a **semicarbazone** which was crystallized from aqueous ethanol, m. p. 215–216°, dec.

Anal. Calcd. for $C_{28}H_{45}O_3N_3$: C, 71.3; H, 9.6. Found: C, 71.1; H, 9.5.

$\Delta^{16,17}$-Pregnenedione-3,20 from Pseudosarsasapogenone.—To a solution of 1.5 g. of pseudosarsasapogenin in 50 cc. of acetic acid was added a solution of 1.5 g. of chromic anhydride in 25 cc. of 80% acetic acid. After standing at room temperature for ninety minutes water was added and the precipitated solids taken up in ether and freed from acids with 5% sodium hydroxide. The neutral fraction was crystallized from acetone to give white plates, m. p. 199–201°. This gave no depression with a sample of $\Delta^{16,17}$-pregnenedione-3,20, m. p. 200–202°.

Reaction of Isosarsasapogenin with Acetic Anhydride.—A mixture of 3.3 g. of isosarsasapogenin acetate, m. p. 149–151°, and 25 cc. of acetic anhydride was heated at 195° for nine hours and worked up as described in previous reactions. The neutral fraction was crystallized from acetone to give 1.7 g. of fine white needles, m. p. 169–172°. This gave no depression with a sample of pseudosarsasapogenin.

Dihydrosarsasapogenin when treated with acetic anhydride as in previous experiments was recovered unchanged.

Pseudochlorogenin.—A mixture of 2.5 g. of chlorogenin and 30 cc. of acetic anhydride was heated at 200° for ten hours. The acetic anhydride was evaporated *in vacuo* and the non-crystalline residue hydrolyzed with hot ethanolic potassium hydroxide. Small crystals which separated from the saponification mixture were collected and washed well with ethanol. The product was recrystallized from methanol in a Soxhlet extractor to give a product of m. p. 268–270°, yield 1.4 g. This gave a depression of 30° with a sample of chlorogenin, m. p. 265–268°. The substance is very sparingly soluble in nearly all solvents.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 74.9; H, 10.2. Found: C, 74.5; H, 10.2.

Dihydropseudochlorogenin.—A mixture of 1 g. of pseudochlorogenin, 300 cc. of absolute ethanol, 50 cc. of acetic acid and 800 mg. of Adams catalyst was shaken at 3 atm. pressure of hydrogen at room temperature for twenty hours. Crystalline material had separated at the end of this time. This was dissolved by the addition of 75 cc. of hot acetic acid and the catalyst filtered. The filtrate was evaporated to a volume of 125 cc., diluted with water and the precipitated solid taken up in chloroform and crystallized from methanol as fine white needles, m. p. 269–272°. This gave a 20° depression with the starting material. It also gave a large depression with chlorogenin.

Anal. Calcd. for $C_{27}H_{46}O_4$: C, 74.6; H, 10.7. Found: C, 74.8; H, 10.7.

With boiling acetic anhydride this yielded a **triacetate** which crystallized from aqueous acetone as fine white needles, m. p. 149–152°, and gave a 20° depression with a sample of chlorogenin diacetate, m. p. 149–151°.

Anal. Calcd. for $C_{33}H_{52}O_7$: C, 70.7; H, 9.35. Found: C, 70.3; H, 9.2.

Summary

epi-Pseudosarsasapogenin and pseudosarsasapogenone have been prepared. Oxidation of these products with chromic anhydride yields $\Delta^{16,17}$-pregenedione-3,20.

Isosarsasapogenin reacts with acetic anhydride to give pseudosarsasapogenin.

Pseudochlorogenin has been prepared.

Sterols. XCIV. Persulfate Oxidation of *allo*-Pregnane Derivatives

BY RUSSELL E. MARKER, EWALD ROHRMANN, EUGENE L. WITTLE, HARRY M. CROOKS, JR., AND ELDON M. JONES

Although potassium persulfate has been used rather extensively to oxidize ketones of the terpene group[1,2,3] it has not been used to any appreciable extent in the oxidation of sterol ketones. In this Laboratory it was recently used in the oxidation of sarsasapogenin to pregnanetriol-3,16,20.[4]

The fact that persulfate oxidations bring about a cleavage of a carbon–carbon linkage adjacent to a carbonyl group suggested its possible use in the oxidation of C-20 keto *allo*-pregnane compounds to androstane derivatives. The oxidation of *allo*-preganone-20 with potassium persulfate yielded a neutral carbinol mixture which we were unable to separate. The acidic fraction from this oxidation gave an acid of the composition $C_{20}H_{32}O_2$, m. p. 228–230°. This formed a methyl ester, m. p. 141–143°. This acid is undoubtedly *etio-allo*-cholanic acid which was prepared by Tschesche.[5] His acid melted at 228–230° and the methyl ester at 140–142°.

The oxidation of *allo*-pregnanol-3(β)-one-20 yielded an acidic fraction which consisted of 3(β)-hydroxy-*etio-allo*-cholanic acid.[6,7] The neutral fraction which appeared to be a mixture was oxidized with chromic anhydride to yield androstanedione.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part[8]

Treatment of *allo*-Pregnanone-20 with Persulfuric Acid.—A mixture of 5 g. of *allo*-pregnanone-20, 500 cc. of 90% acetic acid, 5 cc. of concentrated sulfuric acid and 25 g. of potassium persulfate was refluxed for four hours, cooled, diluted with water and extracted with ether. The acids were removed from the ether by washing with water and sodium carbonate solution. The ether was evaporated and the residue was hydrolyzed with boiling ethanolic potassium hydroxide. Water was added and the neutral product extracted with ether. The carbinols were separated from the neutral fraction by means of their half-succinates. This apparently gave a mixture of epimeric carbinols which melted over a range of 110–142°, and could not be separated.

Anal. Calcd. for $C_{19}H_{32}O$: C, 82.8; H, 11.7. Found: C, 82.6; H, 11.5.

The water layer from the alkaline hydrolysis above was acidified and the precipitated acids taken up with ether. The solvent was removed and the product was recrystallized from ethyl acetate to give white crystals, m. p. 228–230°. This product is *etio-allo*-cholanic acid.

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.9; H, 10.6. Found: C, 78.5; H, 10.6.

Upon treatment with diazomethane the acid gave a **methyl ester** which crystallized from dilute acetone as white crystals, m. p. 141–143°.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 79.2; H, 10.6.

Treatment of *allo*-Pregnanol-3(β)-one-20 with Persulfuric Acid.—A mixture of 2.3 g. of *allo*-pregnanol-3(β)-one-20 acetate, 250 cc. of 90% acetic acid, 2.5 cc. of concentrated sulfuric acid and 10 g. of potassium persulfate was refluxed for four hours. The products were separated and hydrolyzed as in the preceding experiment. The neutral fraction was freed from some unchanged ketones by means of Girard's reagent in ethanol. The non-ketonic fraction upon crystallization from dilute methanol and dilute acetone gave crystalline material melting at 170–185°, which apparently consisted of a mixture of epimeric carbinols. The solvent was removed and the total product was dissolved in 25 cc. of acetic acid and 1 g. of chromic anhydride in 5 cc. of 80% acetic acid added. After standing one hour at 25° water was added and the precipitated solid extracted with ether and the acids removed by washing with water and sodium carbonate solution. The residue remaining after evaporation of the ether was crystallized from ether–pentane and from dilute acetone to give a product m. p. 128–130°. This gave no depression in melting point when mixed with androstanedione, m. p. 130°.

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.1; H, 9.8. Found: C, 78.9; H, 9.8.

The water layer from the above alkaline hydrolysis was acidified and the precipitated acids taken up with ether. After removal of the ether, the residue was crystallized from dilute methanol to give a product, m. p. 249–252°. It gave no depression in melting point when mixed with an authentic sample of 3(β)-hydroxy-*etio-allo*-cholanic acid, m. p. 250–252°.[7]

Anal. Calcd. for $C_{20}H_{32}O_3$: C, 74.9; H, 10.1. Found: C, 74.8; H, 10.1.

Osage Orange Pigments. III. Fractionation and Oxidation

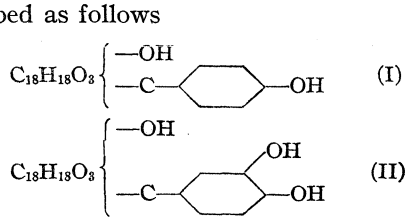
BY M. L. WOLFROM AND A. S. GREGORY

In continuation of our studies[1] on the pigments of the fruit of the osage orange tree (*Maclura pomifera* Raf.) we have made a rather exhaustive fractionation of the naturally occurring mixture of the two pigments, the results of which indicate that the two are probably present in about equal amounts.

The melting point–composition diagram obtained from mixtures of the two pure substances is shown in Fig. 1. The melting point behavior obtained on mixing the pure compounds is probably slightly different from the behavior of mixtures of equal composition which have been formed by co-crystallization.

The trimethyl ether of pomiferin has been reported previously.[1b] We have now obtained the corresponding dimethyl ether of osajin. When the former is subjected to oxidation, in acetone solution, with alkaline hydrogen peroxide, veratric (3,4-dimethoxybenzoic) acid is produced. Under the same conditions, osajin dimethyl ether yields anisic (*p*-methoxybenzoic) acid. These two acids were identified by analysis, by preparation of the anilide and amide of each, and by comparison with authentic specimens in all cases. The two acids have practically identical melting points. This is also true for their amides and anilides. Mixed melting points, however, give definite depressions.

The formulas of osajin (I) and pomiferin (II), both of which are methoxyl-free, may now be developed as follows



Further work on the structure of these two substances is in progress in this Laboratory.

(1) (a) E. D. Walter, M. L. Wolfrom and W. W. Hess, THIS JOURNAL, **60**, 574 (1938); (b) M. L. Wolfrom, F. L. Benton, A. S. Gregory, W. W. Hess, J. E. Mahan and P. W. Morgan, *ibid.*, **61**, 2832 (1939).

Experimental

Fractionation.—The whole fruit of the osage orange tree (*Maclura pomifera* Raf.) was cut, dried and crushed to a coarse meal. The meal (1500 g.) was extracted successively with petroleum ether and ether. From the latter extract was obtained a yellow solid; yield 47.8 g., m. p. 180–182°. This material was recrystallized from ten parts of hot xylene, the crop being removed by filtration when the temperature of the solution had reached approximately 40°. On repeated recrystallization in this manner pure pomiferin was obtained; yield 10.0 g., m. p. 200.5°. The combined mother liquors were concentrated to give a product melting at 173–175° and after repeated recrystallization from 95% ethanol pure osajin was obtained; yield 5.6 g., m. p. 189°. By employing a method of crystallizing the xylene mother liquor material from 95% alcohol, and then the alcohol mother liquor material from xylene again, and continuing this cycle, a total of 14.1 g. of high purity osajin and 15.8 g. of high purity pomiferin was obtained.

Although not all the material was accounted for, the above results would seem to indicate that the two substances are present in the crude extract in very nearly equal amounts. The total yield of crude extract in this lot of material was not as high as in the crops of previous seasons. The melting point–composition diagram obtained from mixtures of the two pure substances is shown in Fig. 1. The melting point behavior obtained on mixing the two pure substances is probably slightly different from the behavior of mixtures of equal composition which have been formed by co-crystallization.

Osajin Dimethyl Ether.—To a boiling solution of osajin (2 g., m. p. 189°) in acetone (130 cc.) were added under reflux the following portions of reagents over a period of forty minutes: 24 cc. of dimethyl sulfate, 14 cc. of 50% aqueous potassium hydroxide, then six alternate portions of 6 cc. each of dimethyl sulfate and 8 cc. each of 50% aqueous potassium hydroxide. The refluxing was continued for two hours longer and then the reaction mixture was poured on 1.5 l. of crushed ice and allowed to stand until the ice had melted before filtration of the precipitated solid; yield 2.16 g., m. p. 109°. Pure material was obtained on several recrystallizations from ethanol (95%); m. p. 118.5° unchanged on recrystallization from methanol, propanol-1 and benzene–petroleum ether. The substance crystallized in long, colorless needles and gave a negative ferric chloride–alcohol phenol test.

Anal. Calcd. for $C_{25}H_{22}O_3(OCH_3)_2$: C, 74.98; H, 6.53; OCH_3, 14.35. Found: C, 74.91; H, 6.53; OCH_3, 14.3.

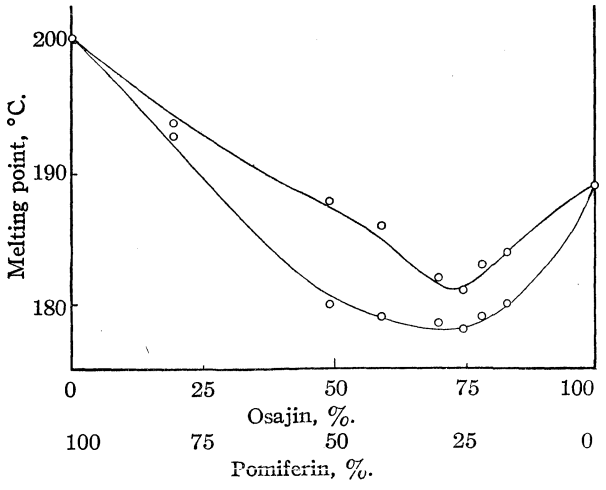


Fig. 1.—Melting point–composition diagram for mixtures of osajin and pomiferin. Lower curve represents beginning of melting and upper curve represents complete fusion.

Isolation of Anisic Acid from the Oxidation of Osajin Dimethyl Ether with Alkaline Peroxide.—Osajin dimethyl ether (1.7 g., m. p. 118°) dissolved in acetone (150 cc.) was treated under mechanical stirring with 1.5 cc. of 50% aqueous potassium hydroxide, followed by the dropwise addition of 20 cc. of 30% aqueous hydrogen peroxide. The oxidation was continued for forty-eight hours at room temperature, whereupon the solution tested only faintly oxidizing to potassium iodide paper. Saturated aqueous sodium bisulfite solution (5 cc.) was added slowly with cooling and the mixture then was neutral to potassium iodide paper and basic to litmus. The acetone was removed under reduced pressure, 50 cc. of 1% hydrochloric acid added and the solution extracted with ether. The concentrated ethereal extract (75 cc.) was extracted with several portions of 5% ammonium carbonate solution. This carbonate solution was concentrated to 50 cc., some tarry material removed by filtration, and the white precipitate that formed on acidification with hydrochloric acid was recrystallized from hot water; yield 0.10 g., m. p. 178°. After two further recrystallizations from water (decolorizing charcoal) the product appeared as fine white needles melting at 180°, which formed an anilide of melting point 167–168° and an amide of melting point 163–164°. Authentic specimens of anisic acid (m. p. 180°), anisic acid anilide (m. p. 167–168°) and anisic acid amide (m. p. 163–164°) were prepared and showed no depression in melting point with the corresponding products obtained from the oxidation.

Anal. Calcd. for $C_8H_8O_3$ (anisic acid): OCH_3, 20.4; neutral equivalent, 152. Found: OCH_3, 21.0; neutral equivalent, 157. Calcd. for $C_8H_9O_2N$ (anisic acid amide): OCH_3, 20.5. Found: OCH_3, 20.3.

Isolation of Veratric Acid from the Oxidation of Pomiferin Trimethyl Ether with Alkaline Peroxide.—In the description of the synthesis of pomiferin trimethyl ether[1b] previously described from this Laboratory, the addition of 14 cc. of 50% aqueous potassium hydroxide should follow the addition of the first amount of dimethyl sulfate. Pomiferin trimethyl ether (1.7 g.) was oxidized with alkaline peroxide exactly as described for osajin dimethyl ether. On the addition of the alkali and hydrogen peroxide a turbidity appeared which cleared slowly on continued stirring. The acid fraction of the oxidation mixture was isolated as described for the osajin dimethyl ether and yielded a crystalline product; yield 0.24 g., m. p. 173–175°. Pure material was obtained on several recrystallizations from hot water (decolorizing charcoal); m. p. 179.5°. The substance was identified as veratric acid by preparation of its anilide (m. p. 166.5–167°) and amide (m. p. 164°). The substance and its two derivatives showed no depression in melting point on admixture with authentic specimens of veratric acid, veratric acid anilide and veratric acid amide. Mixed melting points of (1) veratric acid (179.5°) with anisic acid (180°), (2) veratric anilide (166.5°) with anisic anilide (167–168°) and (3) veratric amide (164°) with anisic amide (163–164°) were, respectively: (1) 146–162°, (2) 138–142° and (3) 132–140°. The isolated substance also showed the sublimation characteristic of veratric acid.

Anal. Calcd. for $C_9H_{10}O_4$ (veratric acid): OCH_3, 34.1; neutral equivalent, 182. Found: OCH_3, 33.5; neutral equivalent, 182.

We are indebted to Mr. John Walker (W. P. A. Project 18062) for assistance rendered in the analytical determinations and to Mr. Joseph Tracht (N. Y. A. Project O. S. U. 181) for assistance in preparing the plant material.

Summary

1. It is shown that the two pigments of the fruit of the osage orange (*Maclura pomifera* Raf.) are present in approximately equal amounts.

2. Osajin dimethyl ether has been prepared.

3. Anisic (*p*-methoxybenzoic) acid has been obtained from the oxidation of osajin dimethyl ether with alkaline hydrogen peroxide.

4. Veratric (3,4-dimethoxybenzoic) acid has been obtained from the oxidation of pomiferin trimethyl ether with alkaline hydrogen peroxide.

Addition of Oxy Compounds to Acetylenic Alcohols[1]

BY J. F. FRONING AND G. F. HENNION

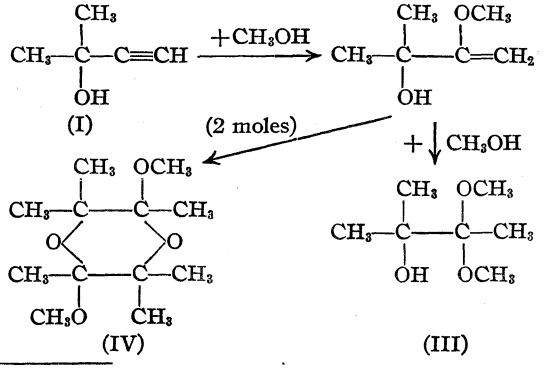
Introduction

Numerous examples of catalytic addition reactions of alcohols and carboxylic acids to acetylenic hydrocarbons have been reported from this Laboratory.[2] It was thought of interest to continue these investigations, particularly with acetylenes containing a reactive group in addition to the triple bond. The products found by the reaction of dimethylethynylcarbinol (I) and of the corresponding glycol, 2,5-dimethyl-3-hexyne-2,5-diol (II) with methanol and with acetic acid have now been investigated.

(I) and (II) were selected because they can be obtained readily by the reaction of acetone with sodium acetylide in liquid ammonia.[3,4] The carbinol (I) was obtained in yields up to 88%. High yields are favored by conducting the reaction at about −50° in the presence of excess acetylene. The glycol (II) was obtained as a by-product of the synthesis, in yields from 0–45%, depending on conditions. When excess acetylene is avoided in the reaction and the product aged for several days before hydrolysis, the yield of carbinol (I) is decreased and the yield of glycol (II) markedly increased.

As anticipated, certain anomalies in the behavior of these compounds toward methanol and acetic acid were noted.

In the presence of small amounts of mercuric oxide and boron trifluoride, methanol reacted smoothly with dimethylethynylcarbinol (I) to form principally 3,3-dimethoxy-2-methyl-2-butanol (III). A small amount of 2,5-dimethoxy-2,3,3,5,6,6-hexamethyl-1,4-dioxane (IV) was obtained as a by-product. The reactions are indicated by the equations just given.



When heated with dilute acid both (III) and (IV) hydrolyze to 2-hydroxy-2-methyl-3-butanone, $(CH_3)_2C(OH)COCH_3$ (V), previously reported[5] by direct hydration of the carbinol (I). When boiled with methanol containing a trace of acid (IV) reacts to form (III).

The reaction of the carbinol (I) with glacial acetic acid is particularly unique; the hydroxyl group is acetylated and the triple bond hydrated.

$$(CH_3)_2C(OH)-C\equiv CH + CH_3COOH \xrightarrow[BF_3]{Hg^{++}} (CH_3)_2C(OCOCH_3)-COCH_3$$

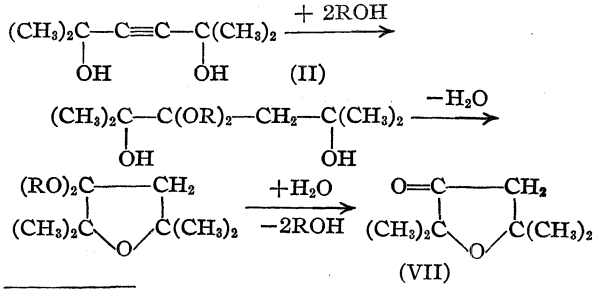
(VI)

The mechanism for this reaction is a matter of speculation. The product is identical with that obtained by Scheibler and Fischer[5] who acetylated the hydroxy ketone (V) with acetic anhydride.

$$(CH_3)_2C(OH)-COCH_3 \xrightarrow{(CH_3CO)_2O} (CH_3)_2C(OCOCH_3)-COCH_3$$

(V) (VI)

When either methanol or acetic acid reacted with the glycol (II) the triple bond was hydrated and the compound cyclized to form 2,2,5,5-tetramethyltetrahydro-3-furanone (VII). It is necessary for the triple bond to be saturated, at least partially, before cyclization can occur. The following mechanism is offered based on this fact (R is CH_3- or CH_3CO-).



(1) Paper XXXVII on the chemistry of substituted acetylenes and their derivatives; previous paper, THIS JOURNAL, **62**, 449 (1940).

(2) Hennion, Nieuwland, *et al.*, *ibid.*, **56**, 1130, 1384, 1802 (1934); **57**, 2006 (1935); **58**, 80 (1936).

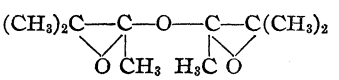
(3) Kreimeier, U. S. Patent 2,106,180 (1938).

(4) Campbell, Campbell and Eby, THIS JOURNAL, **60**, 2882 (1938).

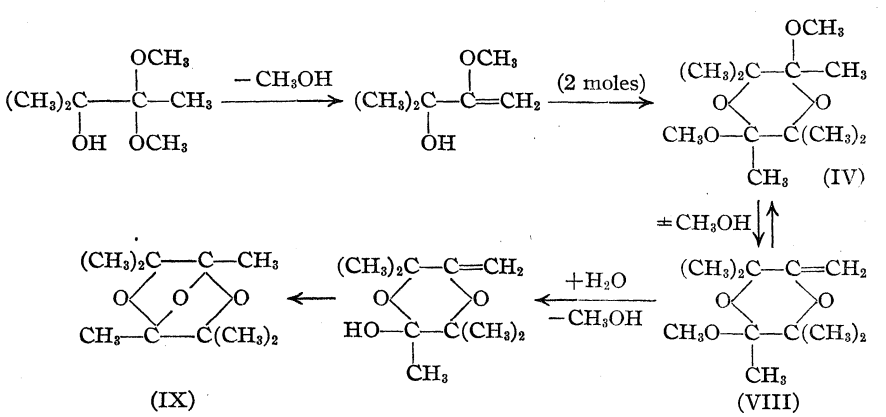
(5) Scheibler and Fischer, *Ber.*, **55**, 2903 (1922).

The product (VII) has been prepared previously[6] from the glycol (II) by heating with water in the presence of mercuric sulfate.

Since ketals are known to desaturate to vinyl ethers when heated with toluenesulfonic acid,[7] this reaction was applied to 3,3-dimethoxy-2-methyl-2-butanol (III). Methanol was eliminated upon heating with acid but the residue boiled over a wide temperature range. Two products were isolated, however, and their structures determined. The first of these was found to have the molecular formula $C_{10}H_{18}O_3$ as the structure 1,3,3,4,6,6-hexamethyl-2,5,7-trioxabicyclo[2-2-1]heptane (IX). This same compound was obtained by Scheibler and Fischer[5] upon treatment of the ketone (V) with phosphorus pentoxide. However, these investigators erroneously ascribed to this compound the structure



Distinction between these formulas was made by parachor measurement. Also the compound is unaffected by prolonged boiling with methanol containing toluenesulfonic acid, a fact which argues against the ethylene oxide structure. The second desaturation product was found to have a dioxane structure (VIII). These compounds are related in the following equations.



In the conversion of (VIII) to (IX) water is required. Presumably this is supplied by dehydration of (III) as a secondary reaction. In the presence of acid (VIII) adds methanol to its methylene group and reverts to (IV). When heated with a trace of acid (IV) loses methanol and yields (VIII) and (IX). These transformations confirm the mechanism cited above.

Experimental

Preparation of Dimethylethynylcarbinol (I).—Using the procedure[8] previously described, 7.35 moles of sodium acetylide was prepared as a solution in 3–4 liters of liquid ammonia. This was cooled to $-50 \pm 5°$ by immersion of the flask in a carbice bath. Acetylene was passed in for ten minutes. Acetone (465 g., 8 moles) was then added during a period of thirty minutes. Meanwhile the admission of acetylene was continued. The ammonia was then allowed to evaporate (usually overnight), 1 liter of ether added, followed by sufficient iced 35% sulfuric acid to dissolve the solid. The water layer was separated and extracted with ether. The extract was combined with the original ether layer, the whole dried over anhydrous potassium carbonate and fractionally distilled. Fractions boiling between 60 and 102° were redried and redistilled. The yield of dimethylethynylcarbinol, b. p. 102–104°, was 545 g. (88%). Constants for a pure specimen were b. p. 103.8° at 757 mm.; $n^{20}D$ 1.4211; d^{20} 0.8623.

Preparation of 2,5-Dimethyl-3-hexyne-2,5-diol (II).—The above procedure was followed except that the reaction product was aged for one week after evaporation of the ammonia. The residue after distillation of the dimethylethynylcarbinol was crystallized several times from carbon tetrachloride. Yields varied, usually between 20 and 45%. Large white needles were obtained, m. p. 95°. The compound may be prepared in better yields by heating the sodium salt of the carbinol (I) for several hours in an atmosphere of ammonia.[9]

Preparation of 3,3-Dimethoxy-2-methyl-2-butanol (III).—The catalyst was prepared by heating together 4–5 g. of red mercuric oxide, 5 ml. of ether–boron fluoride, 5 ml. of methanol and 1–3 g. of trichloroacetic acid in a 2-liter 3-necked flask. The flask was provided with a reflux condenser, mechanical stirrer and dropping funnel. Reagent grade methanol (100 g.) was poured over the catalyst, the stirrer started, and 300 g. (3.13 moles) of dimethylethynylcarbinol in 300 g. of methanol added dropwise. The temperature was held at 45–55° by occasional cooling. After three hours the mixture was cooled to room temperature and 10 g. of powdered anhydrous potassium carbonate added with vigorous stirring. The sludge was allowed to settle overnight, the supernatant liquid decanted, excess methanol distilled and the residue fractionated at 50 mm. The yield was 371 g. (80%); colorless liquid, b. p. 81° at 50 mm.; $n^{20}D$ 1.4248; d^{20} 0.974; *MR* (calcd.), 39.34; *MR* (obsd.), 38.9.

wt., 148.13. Found: C, 57.15; H, 10.89; mol. wt., cryoscopic in benzene,[10] 149.

Hydrolysis with dilute sulfuric acid gave 2-hydroxy-2-methyl-3-butanone (V); b. p. 139° at 750 mm., 65° at 50 mm.; $n^{20}D$ 1.4150; d^{20} 0.950; *MR* (calcd.), 26.83; *MR* (obsd.), 27.35.

Anal. Calcd. for $C_5H_{10}O_2$: C, 59.41; H, 9.78. Found: C, 58.82; H, 9.80.

Isolation of 2,5-Dimethoxy-2,3,3,5,6,6-hexamethyl-1,4-dioxane (IV).—A solid residue, partially organic, remained after the distillation of (III) described above. The solid was extracted with ether to yield an organic solid which was crystallized from methanol. The yield was 16 g. (4.4%), white rhombic crystals, m. p. 107°.

Anal. Calcd. for $C_{12}H_{24}O_4$: C, 62.02; H, 10.43; CH_3O, 26.72; mol. wt., 232.2. Found: C, 62.40; H, 10.50; CH_3O, 25.1; mol. wt., 235.

Preparation of 2-Acetoxy-2-methyl-3-butanone (VI).—Dimethylethynylcarbinol (126 g., 1.5 moles) was treated with glacial acetic acid (180 g., 3 moles) in the presence of mercuric oxide and boron fluoride as described above for the reaction with methanol. After completion of the reaction the product was neutralized with sodium carbonate solution and extracted with ether. The ether layer was dried over calcium chloride, the ether removed by distillation, and the residue fractionated *in vacuo*. There was obtained 105.5 g. (49% yield) of product, a colorless liquid with amyl acetate like odor: b. p. 93° at 50 mm.; $n^{20}D$ 1.4180; d^{20} 1.008; *MR* (calcd.), 36.2; *MR* (obsd.), 36.0.

Anal. Calcd. for $C_7H_{12}O_3$: C, 58.29; H, 8.39; mol. wt., 144.1. Found: C, 58.00; H, 8.65; mol. wt., 145.

This compound was prepared also according to the procedure of Scheibler and Fischer.[5] The yield was 69%.

Preparations of 2,2,5,5-Tetramethyltetrahydro-3-furanone (VII).—The glycol (II) (100 g., 0.7 mole) reacted with methanol (100 ml., 2.5 moles) with the catalyst and under the conditions described above. There was obtained 77 g. (77% yield) of product, a colorless, stable liquid of camphoraceous odor: b. p. 71° at 50 mm.; $n^{20}D$ 1.4197; d^{20} 0.9255; *MR* (calcd.), 38.60; *MR* (obsd.), 38.8; mol. wt. (calcd.), 142; mol. wt. (found), 143.

The melting point of the semicarbazone was 190°, in agreement with the value of Dupont.[6]

Similarly (II) with acetic acid gave (VII) in 78% yield.

(10) All molecular weights reported in this paper were determined in the same manner.

Thermal Desaturation of 3,3-Dimethoxy-2-methyl-2-butanol (III).—The ketal (351.5 g., 2.38 moles) was placed in a 1-liter round-bottomed flask, 0.1 g. of *p*-toluenesulfonic acid added, and the flask attached to a 1 × 30 cm. indented column with variable take-off. Distillation was begun by heating the flask in an oil-bath. Heating for eight hours at 150–180° gave 110 g. of distillate boiling at 64°. The residue was neutralized by shaking with powdered anhydrous potassium carbonate. Subsequent distillation gave several fractions: A, 115 g., b. p. 123–165° at 750 mm.; B, 67 g., b. p. 78–82° at 50 mm.; C, 5.5 g., b. p. 82–110° at 50 mm.; D, 33 g., b. p. 110–112° at 50 mm.; E, 10 g., residue.

Fraction A proved to be an intractable mixture which continued to boil over a wide temperature range, even after numerous distillations. However, redistillation with toluenesulfonic acid gave further quantities of methanol and fractions B and D.

Fraction B distilled at 165° at 750 mm. and at 81–82° at 50 mm.; $n^{20}D$ 1.4199; d^{20} 0.972. The compound is assigned the bicyclic structure (IX) based on analysis and parachor.[11]

Anal. Calcd. for $C_{10}H_{18}O_3$: C, 64.47; H, 9.68; mol. wt., 186.14; *MR*, 48.91; [P], 424.2. Found: C, 64.50; H, 9.75; mol. wt., 186; *MR*, 48.4; [P], 420.35. The parachor calculated for the structure of Scheibler and Fischer[5] is 449.2.

Fraction D redistilled at 110–112° at 50 mm.; $n^{20}D$ 1.4533; d^{20} 0.979. The compound is given structure (VIII) based on its reactions and the following.

Anal. Calcd. for $C_{11}H_{20}O_3$: C, 65.95; H, 10.08; CH_3O, 15.50; mol. wt., 200.16; *MR*, 55.26. Found: C, 65.85; H, 10.34; CH_3O, 14.67; mol. wt., 199.5; *MR*, 54.75.

Summary

The reactions of methanol and acetic acid with dimethylethynylcarbinol and 2,5-dimethyl-3-hexyne-2,5-diol are described. These reactions are more complex than the corresponding ones with acetylenic hydrocarbons.

NOTRE DAME, INDIANA RECEIVED JANUARY 8, 1940

(11) Ray, *J. Indian Chem. Soc.*, **12**, 764–767 (1935), gives the parachor constant for a bridged six-membered ring which was used. Other values are those of Sugden.

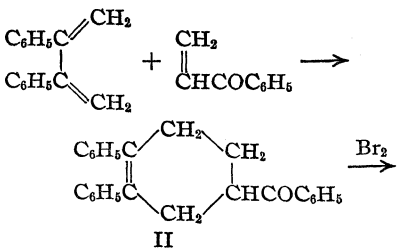
Addition Reactions of Vinyl Phenyl Ketone. VI. The Diene Synthesis

BY C. F. H. ALLEN, A. C. BELL, ALAN BELL AND JAMES VAN ALLAN

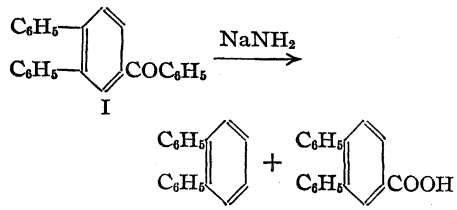
In a paper describing the reactions used in determining the structure of a dimeric diphenylcyclopentadienone,[1] one of the intermediate degradation products was the previously unknown 3,4-diphenylbenzophenone I, which was degraded stepwise to *o*-diphenylbenzene. This series of reactions demonstrated the presence of a benzene ring and two phenyl groups in the *ortho* position, but did not locate the benzoyl group. The original purpose of this work was to synthesize 3,4-diphenylbenzophenone by an unambiguous method, and show its identity with the ketone secured as mentioned. Not only has this been successfully accomplished, but its 6-carboxylic acid XXIV also has been synthetically prepared, proving conclusively the place of attachment of the indene ring in the bimolecular product. In addition, other products resulting from the use of vinyl phenyl ketone in the diene synthesis are described.

Vinyl phenyl ketone adds readily to many substances containing a conjugated system of double bonds, and, in general, the addition products have the expected properties. The reaction is most useful with unsaturated ketones; it is less satisfactory with hydrocarbons, and fails with furans.

2,3-Diphenylbutadiene-1,3[2] added vinyl phenyl ketone on long refluxing in xylene solution. The tetrahydroketone II was dehydrogenated by bromine to 3,4-diphenylbenzophenone I. As prepared in this way the latter proved to be identical with a specimen secured from the original degradation[1]; further, each gave the same oxime and 2,4-dinitrophenylhydrazone. In all instances, mixed melting points were not depressed. Finally, the ketone was cleaved by a sodium amide fusion to yield *o*-diphenylbenzene and 3,4-diphenylbenzoic acid.



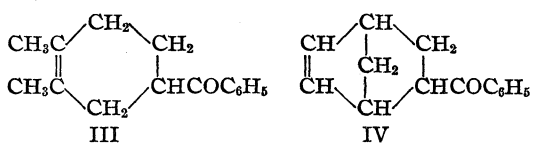
II



I

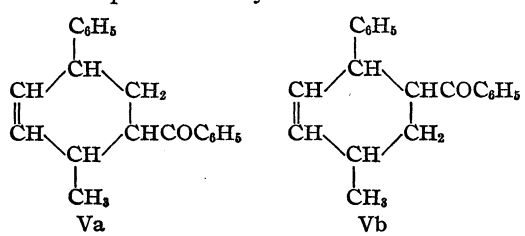
1,4-Diphenylbutadiene did not add vinyl phenyl ketone nearly as readily as the 2,3-isomer, and a crystalline addition product was not obtained. On treatment of the sirupy mixture with sulfur, 2,5-diphenylbenzophenone resulted. This was cleaved with sodium amide to terphenyl, thus showing that a six-membered ring had been formed in the addition.

The addition product from 2,3-dimethylbutadiene resembled the one from 2,3-diphenylbutadiene, except that it formed a dibromide instead of being dehydrogenated by bromine. The dimethyl tetrahydroketone III was dehydrogenated by sulfur to the known 3,4-dimethylbenzophenone.



III IV

Cyclopentadiene gave a homogeneous liquid that undoubtedly is represented by the structure IV. 1-Phenyl-4-methylbutadiene-1,3 gave a solid addition product that readily added bromine. The mode of addition was not determined; the tetrahydrobenzophenone may be either Va or Vb.



Va Vb

The liquid product from isoprene decomposed on distillation, but a ketonic derivative having the correct analysis was prepared from one fraction. Phellandrene gave a hopeless mixture, while with cyclohexadiene no product was obtained except β-ethoxypropiophenone, $C_2H_5OCH_2CH_2COC_6H_5$, VI, when alcohol was used as a solvent.

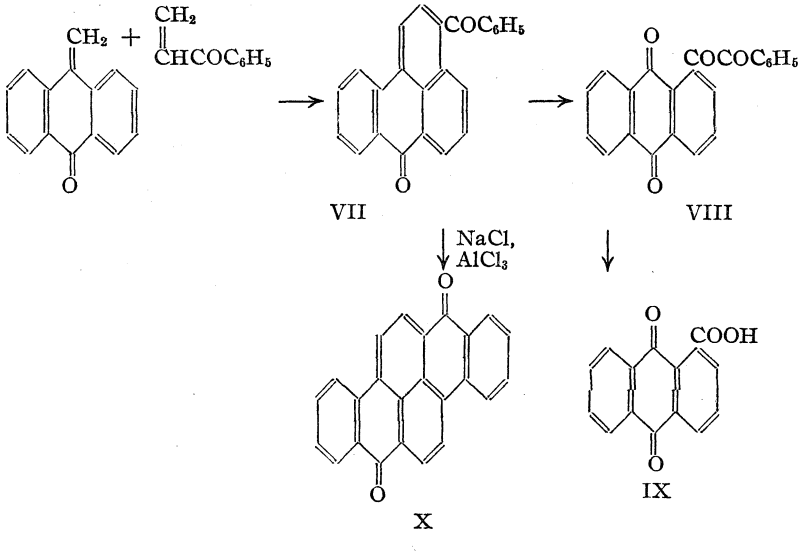
The use of methyleneanthrone furnished Bz-1-benzoylbenzanthrone VII directly. Although the product was identical with a specimen prepared as described in the patent literature,[3] its structure was independently shown by oxidation with chromic acid to α-benzoylformylanthraquinone VIII, which was then cleaved by sodium peroxide to anthraquinone-α-carboxylic acid IX.

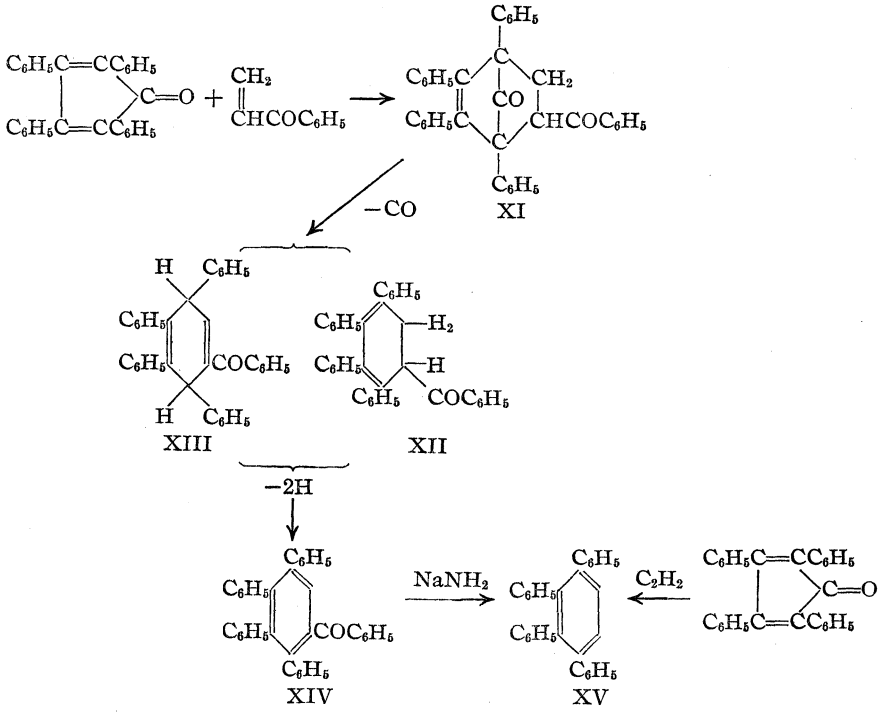


The formation of the benzanthrone VII shows that the direction of addition is that indicated by the formulas to the extent of at least 85%.

The Bz-1-benzoylbenzanthrone VII was also dehydrogenated in a sodium–aluminum chloride melt to 4,5,9,10-dibenzpyrene-3,8-quinone X identical in all respects with a specimen secured by the patent directions.[4]

Vinyl phenyl ketone added very easily to highly arylated cyclopentadienones; the primary addition products containing the carbonyl bridge could usually be isolated as would be expected.[1,5] Thus, tetraphenylcyclopentadienone gave the substance represented by formula XI. On moderate heating the bridge was lost as carbon monoxide, and two isomeric dihydrobenzophenones were formed. These may be geometrical isomers or some of the numerous possible forms differing only in the location of the double bonds, XII, XIII. When the addition reaction was carried out in a high-boiling solvent, these products resulted directly, the lower-melting form being the main product. The latter was also secured by heating the higher-melting modification at elevated temperatures for a short time.

Both the tetraphenyldihydrobenzophenones were easily dehydrogenated to yield tetraphenylbenzophenone XIV, and the latter was cleaved by sodium amide with the consequent formation of the known 1,2,3,4-tetraphenylbenzene XV.[6]



(3) German Patent 420,412; *Frdl.*, **15**, 736 (1928).

(4) German Patent 412,053; *Frdl.*, **15**, 731 (1928). In the patent the color with concd. sulfuric acid is said to be a blue-violet. A specimen of the quinone prepared exactly by the patent directions, as well as the one obtained in this work, gave a red-violet color with concd. sulfuric acid.

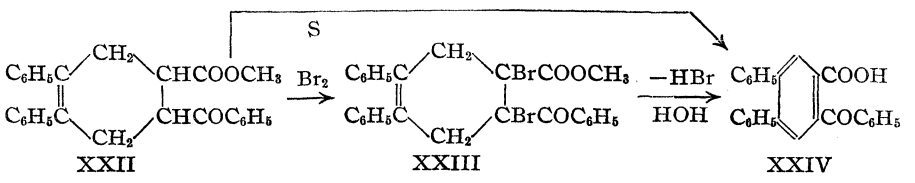
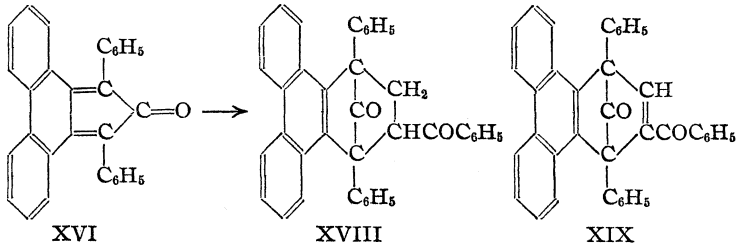
(6) Dilthey, U. S. Patent 2,097,854; *C. A.*, **32**, 367 (1938).

This sequence of reactions clearly demonstrates the presence of a benzene ring in the addition product.

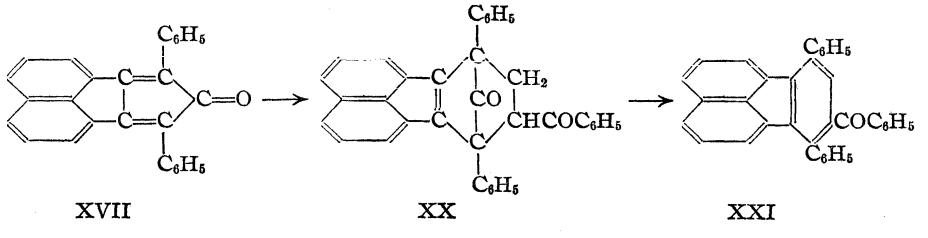


XXII XXIII XXIV

The cyclic ketones XVI and XVII also were used; the former gave an addition product XVIII only, but with the latter the tendency to lose the bridge and yield the aromatic form XXI was so great that the addition product XX was obtained analytically pure only with difficulty. When β-dimethylaminopropiophenone was substituted for β-chloropropiophenone, dimethylamine was eliminated; the resulting compound appeared to be the dihydro bridged ketone XIX or a reduction product.



XVI XVIII XIX

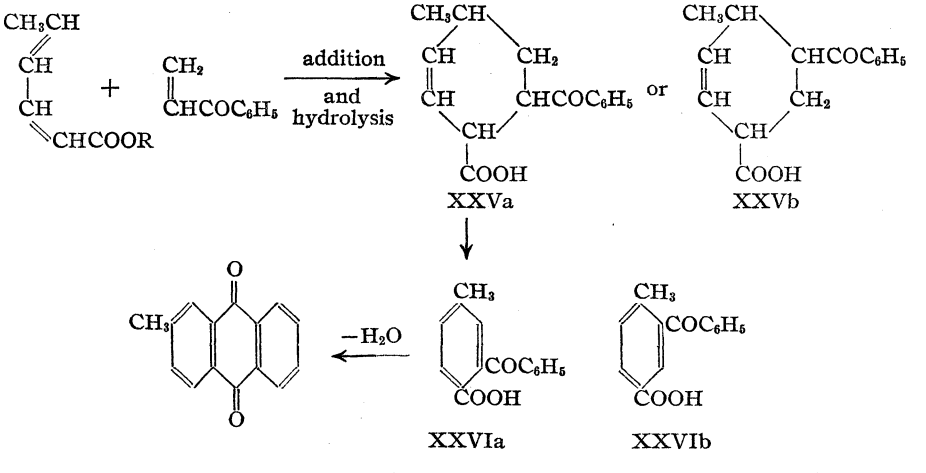


XVII XX XXI

Methyl β-benzoylacrylate and 2,3-diphenylbutadiene easily formed an addition product XXII. This did not decolorize bromine in a cold chloroform solution, but when the solution was heated, the halogen was completely used, hydrogen bromide was evolved, and a crystalline product resulted. Analysis showed the presence of two atoms of bromine. While the substance may be a dibromide, formed by addition of a molecule of bromine, it seems more probable that it is a substitution product XXIII, because (1) tetrahydrodiphenylbenzophenone II is dehydrogenated by bromine with no evidence of formation of a dibromide, and (2) this substance loses hydrogen bromide on heating, to give an oil that with alcoholic potash yields 6-carboxy-3,4-diphenylbenzophenone.

The ester XXII did not give a tractable product on sulfur dehydrogenation, but on treatment of the melt with alcoholic potash, followed by acidification, the aromatic acid XXIV precipitated. This was identical with the specimen secured previously.[1]

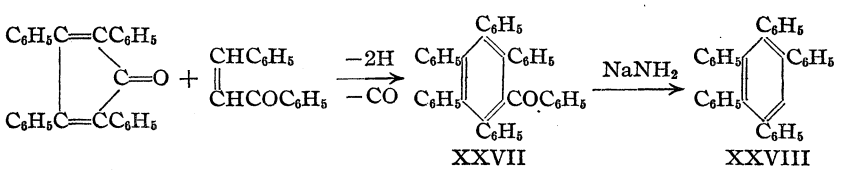
Vinyl phenyl ketone added readily to ethyl sorbate. Since there is a possibility of the formation of eight isomers, no attempt was made to separate the oily ester, but a part was hydrolyzed directly to the solid acids. Addition could have taken place so as to form either XXVa or XXVb. In order to distinguish, the remainder of the ester was dehydrogenated and hydrolyzed to the aromatic keto acids XXVIa or XXVIb, thus reducing the number of isomers to two. Treatment of these by concd. sulfuric acid would be expected to dehydrate XXVIa to β-methylanthraquinone but would have no effect on XXVIb. When this was done,



XXVa XXVb XXVIa XXVIb

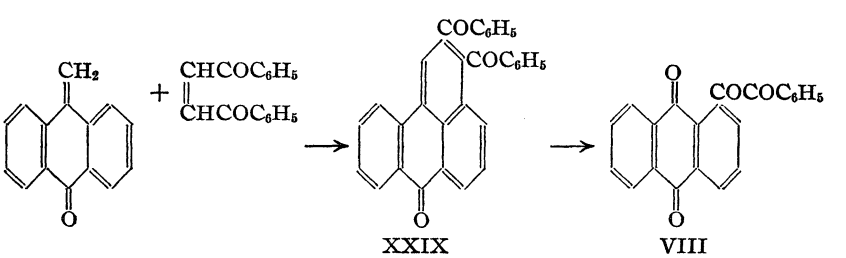
β-methylanthraquinone only was obtained, there being no acidic fraction recovered. Hence, the keto acid must have been almost exclusively XXVIa; the addition product acid must have been XXVa, and addition must have taken place nearly quantitatively in the direction indicated. No attempt was made to secure all the possible stereoisomeric forms of XXVa.

In an earlier paper[7] it was noted that the substituted vinyl phenyl ketone, benzalacetophenone, failed to react with tetraphenylcyclopentadienone. In the meantime, by operating in boiling trichlorobenzene, it has been found possible to force the addition, but the bridge and two hydrogen atoms are lost, so that the product is the aromatic pentaphenylbenzophenone XXVII. The latter was cleaved by the use of sodium amide, to give the known pentaphenylbenzene XXVIII.



XXVII XXVIII

trans-Dibenzoylethylene has been added to methyleneanthrone; the product is Bz-1-Bz-2-dibenzoylbenzanthrone XXIX. Its structure is evident from the production of α-benzoylformylanthraquinone VIII upon oxidation with chromium trioxide.



XXIX VIII

Furan, sylvan, and 2,5-dimethylfuran did not add to the pure ketone. In alcohol, β-ethoxypropiophenone VI was obtained.

Experimental

A. Reactions with Dienes. (a) 2,3-Diphenylbutadiene-1,3; 3,4-Diphenyltetrahydrobenzophenone.—The addition reactions were carried on in the same general manner as has been described in the earlier papers in this series, the main feature being the use of vinyl phenyl ketone in solution, as obtained from the interaction of potassium acetate and β-chloropropiophenone. This enables one to avoid the losses involved in its isolation. It also has been found that the β-dialkylaminoacetophenone hydrochloride can be substituted for the β-chloroketone, though the yields are not as good.[8]

A mixture of 11 g. of the hydrocarbon, 9.2 g. of β-chloropropiophenone, 5.4 g. of sodium acetate, and 75 cc. of xylene was refluxed for sixty hours and the solvent removed *in vacuo*. Most of the residual sirup dissolved in hot methanol, from which 8.5 g. of the ketone separated in fine prisms on cooling; recrystallization from ligroin (90–120°) gave a white product, m. p. 83°.

Anal. Calcd. for $C_{25}H_{22}O$: C, 88.8; H, 6.6. Found: C, 89.1; H, 6.6.

The 2,4-dinitrophenylhydrazone was obtained in the usual manner; it crystallized in orange rods from methanol–dioxane, m. p. 203°.

Anal. Calcd. for $C_{31}H_{26}O_4N_4$: N, 10.8. Found: N, 10.5.

For dehydrogenation 8 g. of bromine in 20 cc. of chloroform was added slowly to 7.8 g. of the addition product in 15 cc. of the same solvent; large amounts of hydrogen bromide were evolved. The sirup left on evaporation of the solvent solidified when treated with methanol; the yield of white solid was 7.5 g. (97%). On recrystallization from ethanol it separated in white prisms, m. p. 133°. A mixed melting point with a sample of the ketone[1] resulting from the degradation was not depressed. The oxime and 2,4-dinitrophenylhydrazone were prepared, compared, and found to be identical. The second derivative is new; it was secured by the usual procedure. It separated from dioxane–methanol in microscopic orange prisms, m. p. 248°.

Anal. Calcd. for $C_{31}H_{22}O_4N_4$: N, 10.9. Found: N, 10.6.

Sodium Amide Fusion.[9]—A mixture of 4 g. of 3,4-diphenylbenzophenone, 10 cc. of cymene, and 0.7 g. of powdered sodium amide was refluxed for six hours. The cooled solution was extracted with water and the alkaline layer separated. The cymene was then removed and the residue distilled with steam; 1.9 g. (70%) of *o*-diphenylbenzene was secured (mixed melting point not depressed). Acidification of the alkaline solution gave 0.2 g. (7%) of 3,4-diphenylbenzoic acid.[2]

(b) 1,4-Diphenylbutadiene; 2,5-Diphenylbenzophenone.—Exactly as described under the 2,3-isomer, a mixture of the same quantities of the components was refluxed for forty-eight hours and the solvent removed under reduced pressure. Upon extraction of the residue with methanol, 3.5 g. of diene remained undissolved. The methanol

(7) Allen and Sheps, *Can. J. Research*, **11**, 173 (1934).

(8) Mannich and Fourneau, *Ber.*, **71**, 2090 (1938).

(9) Haller and Bauer, *Ann. phys. chim.*, [8] **16**, 145 (1909); Lucas, *ibid.*, **17**, 127 (1909).

in the extract was replaced by chloroform and treated with bromine in the usual manner; 8 g. of a halogen-containing solid was obtained. This melted at 215° and analyzed for a dibromide of diphenylbutadiene. This and the unreacted hydrocarbon accounted for 70% of the diene, thus indicating not over 30% of addition.

In a later run, the methanol-soluble fraction was distilled *in vacuo*, and a sirupy distillate, b. p. 250–255° at 4–5 mm., secured; the analysis was about 1% low. It was not further purified, but at once dehydrogenated by heating 2.5 g. with 0.5 g. of sulfur at 200° for two hours; the residue was extracted with hot alcohol, from which 1.3 g. of the ketone separated. 2,5-Diphenylbenzophenone crystallizes in rods, m. p. 130°.

Anal. Calcd. for $C_{25}H_{18}O$: C, 89.8; H, 5.4. Found: C, 89.6; H, 5.4.

Sodium Amide Fusion.—In a similar manner, 0.20 g. of 2,5-diphenylbenzophenone gave 0.11 g. (80%) of *p*-diphenylbenzene; the melting point and mixed melting point with an authentic specimen were 211–212°.

(c) **2,3-Dimethylbutadiene; 3,4-Dimethyltetrahydrobenzophenone III.**—After refluxing a mixture of 8.4 g. of β-chloropropiophenone, 8 g. of potassium acetate and 30 cc. of 2,3-dimethylbutadiene for twenty-four hours, adding ether and filtering the inorganic salts, fractionation *in vacuo* gave the addition product, b. p. 184–188° at 12 mm. On redistillation it boiled from 163–165° at 6 mm.; the yield was 4 g.

Anal. Calcd. for $C_{15}H_{18}O$: C, 84.1; H, 8.4. Found: C, 84.1; H, 8.5.

The 2,4-dinitrophenylhydrazone, secured by the usual procedure, separated from methanol in orange-yellow leaflets, m. p. 152°.

Anal. Calcd. for $C_{21}H_{22}O_4N_4$: N, 14.2. Found: N, 14.1.

On treatment of the addition product with bromine there was no apparent action in the cold; on warming, hydrogen bromide was given off. The only substance isolated was a dibromide; this crystallized from ethanol in long white needles, m. p. 132°.

Anal. Calcd. for $C_{15}H_{18}OBr_2$: C, 48.1; H, 4.8; Br, 42.8. Found: C, 47.7; H, 4.8; Br, 42.8.

Dehydrogenation to the known 3,4-dimethylbenzophenone[10] was readily accomplished by heating 2.1 g. of the substance III with 0.8 g. of sulfur in a metal bath at 190–230°. When gas evolution had become negligible, the cooled melt was extracted with ethanol; 1 g. of ketone was obtained. The melting point (45°) was not depressed on admixture with a specimen secured by Elbs' method.

The 2,4-dinitrophenylhydrazone of this ketone was secured by the usual procedure. It separated from chloroform–methanol in microscopic prisms, m. p. 252°.

Anal. Calcd. for $C_{21}H_{18}O_4N_4$: N, 14.4. Found: N, 13.9.

(d) **Benzoylmethylphenylcyclohexene Va or Vb.**—A mixture of 7.2 g. of 1-phenyl-4-methylbutadiene-1,3,[11] 9.5 g. of β-chloropropiophenone, 6.3 g. of potassium acetate and 20 cc. of trichlorobenzene was refluxed for eight hours and distilled *in vacuo*. The portion of b. p. 150–167° at 1 mm. on redistillation boiled at 157–159° at 1 mm. On standing it crystallized, 5 g. of pure ketone being obtained; this separated from methanol in prisms, m. p. 61°.

Anal. Calcd. for $C_{20}H_{20}O$: C, 87.0; H, 7.1. Found: C, 86.4, 86.4; H, 7.3, 7.2.

The dibromide was obtained readily by treatment with bromine in chloroform, although there was some evolution of hydrogen bromide. It crystallized from methanol in plates or prisms, m. p. 125°.

Anal. Calcd. for $C_{20}H_{20}OBr_2$: Br, 36.7. Found: Br, 36.3.

(e) **1-Benzoyl-1,2,3,6-tetrahydro-3,6-methanobenzene IV.**—A mixture of 13 g. of cyclopentadiene, 25 g. of β-chloropropiophenone, 23 g. of potassium acetate and 50 cc. of toluene was heated in a sealed bottle at 95–100° for thirty hours. Inorganic salts were filtered after adding ether to facilitate manipulation and the solution fractionated *in vacuo*. The portion, b. p. 122–124° at 3 mm., was collected in a yield of 16 g.; $n^{26}D$ 1.5648.

Anal. Calcd. for $C_{14}H_{14}O$: C, 84.7; H, 7.1. Found: C, 84.3; H, 7.1.

The semicarbazone, obtained in the usual manner, separated from alcohol in shiny prisms, m. p. 178–180°.

Anal. Calcd. for $C_{15}H_{17}ON_3$: N, 16.4. Found: N, 16.1.

The addition product decolorizes permanganate and bromine in chloroform instantly.

(f) **Miscellaneous.**—A mixture of 10 g. of isoprene, 16.8 g. of β-chloropropiophenone, 15 g. of potassium acetate, and 15 cc. of toluene was heated in a steam-bath in a pressure bottle for twenty-four hours. After removal of the inorganic salt by precipitation with ether, the liquid was distilled *in vacuo*. The fraction, b. p. 120–122° at 2 mm., gave a 2,4-dinitrophenylhydrazone, m. p. 137°.

Anal. Calcd. for $C_{20}H_{20}O_4N_4$: N, 14.7. Found: N, 14.5.

From commercial phellandrene and the alcoholic solution of vinyl phenyl ketone an oil, b. p. 183–185° at 2 mm., was obtained in a 37% yield. It decolorized bromine instantly, with evolution of hydrogen bromide. The 2,4-dinitrophenylhydrazone was an oil, and a semicarbazone was not secured. The analysis was not satisfactory.

Anal. Calcd. for $C_{19}H_{24}O$: C, 85.1; H, 8.9. Found: C, 84.1; H, 8.6.

β-Ethoxypropiophenone VI was obtained when cyclohexadiene and an alcoholic solution of the unsaturated ketone were allowed to react (described under furan).

B. Reactions with Ketones. (a) **Bz-1-Benzoylbenzanthrone VII.**—A mixture of 5.2 g. of methyleneanthrone,[12] 6 g. of β-chloropropiophenone, 6 g. of potassium acetate, and 35 cc. of nitrobenzene was stirred and refluxed for two and a half hours at 180–190°; it became very dark and set to a mass of crystals on cooling. The solid was filtered after triturating with 125 cc. of methanol, washing with the same solvent until bright yellow, and then with water to remove soluble salts. It dissolved readily in hot acetic acid or chloroform. The analytical

(10) Elbs, *J. prakt. Chem.*, **33**, 180 (1886); **35**, 467 (1887).

(11) Klages, *Ber.*, **40**, 1769 (1907).

(12) Barnett and Matthews, *Ber.*, **59**, 767 (1926).

sample was recrystallized from chloroform–methanol, from which it separated in brownish-yellow needles, m. p. 192°. The yield was 6.5 g., 84%.

Anal. Calcd. for $C_{24}H_{14}O_2$: C, 86.2; H, 4.2. Found: C, 86.0; H, 4.2.

It was also synthesized from Bz-1-carboxybenzanthrone,[3] the requisite acid being secured through the diazo reaction from Bz-1-aminobenzanthrone, and also by the interaction of methyleneanthrone and β-chloropropionic acid.[13]

A mixture of 2 g. of the Bz-1-acid, 4 g. of phosphorus pentachloride, and 20 cc. of benzene was warmed on the steam-bath as long as hydrogen chloride was evolved, then cooled, and, after addition of 4 g. of anhydrous aluminum chloride, warmed for an hour at 70°. It was then poured upon ice, the benzene steam-distilled, and the residue boiled with hydrochloric acid, filtered, and washed. On recrystallization from 4 cc. of nitrobenzene, the Bz-1-benzoylbenzanthrone separated in brownish-yellow needles, m. p. 190–192°. A mixed melting point with the substance secured by the first procedure was 191–192°.

Oxidation by Chromium Trioxide.—To a solution of 1.9 g. of the ketone in 20 cc. of acetic acid, 5 g. of chromic acid in 36 cc. of 50% acetic acid was added slowly, the mixture was refluxed for five minutes, cooled, and 50 cc. of water added to precipitate the diketone VIII. The crystals so obtained were bright yellow, but the surface rapidly became greenish-colored, until after several recrystallizations from chloroform–methanol, from which it separated in rods, m. p. 174°.

Anal. Calcd. for $C_{22}H_{12}O_4$: C, 77.6; H, 3.6. Found: C, 77.6; H, 3.5.

This diketone gave a brown color with concd. sulfuric acid and a clear blue vat with alkaline hydrosulfite.

Cleavage.—To a suspension of 1.5 g. of the diketone in 30 cc. of cold water, 4 g. of sodium peroxide was added; after five hours' standing, the mixture was warmed to 70° and the unreacted solid filtered. Acidification of the filtrate precipitated anthraquinone-α-carboxylic acid. For identification this was converted into the methyl ester through the silver salt; a mixed melting point with an authentic sample was not depressed.

4,5,9,10-Dibenzpyrene-3,8-quinone X.—The sodium–aluminum chloride from 20 g. of anhydrous aluminum chloride and 4 g. of salt was mixed with 2 g. of Bz-1-benzoylbenzanthrone and the temperature raised to 180–200°, where it was held for eight hours. The melt was decomposed by iced hydrochloric acid and the dye filtered. It was then converted to a red vat by alkaline hydrosulfite, the solution was filtered and aerated. The orange-yellow dye was collected on a filter. After recrystallization from nitrobenzene it formed rods that melted at 385–388°. A mixed melting point with an authentic sample[4] (m. p. 386–388°) was 384–386°. Both samples gave the same red-violet color with concd. sulfuric acid.

(b) Tetraphenylbenzophenone and Related Compounds. (1) 3,4,5,6-Tetraphenyl-7-keto-1-benzoyl-1,2,3,-6-tetrahydro-3,6-methanobenzene XI.—A mixture of 134 g. of tetraphenylcyclopentadienone, 230 g. of β-chloropropiophenone, 200 g. of potassium acetate, and 520 cc. of toluene was refluxed for three hours, or until the red color had disappeared. After cooling, the pulverized solid was filtered, digested with warm (50°) water for one hour, filtered, and washed first with water and then with 400 cc. of acetone. Final purification was accomplished by recrystallization from toluene or mixtures of chloroform–methanol and ethyl acetate–methanol. The addition product XI forms prisms which melt at 210° to a red liquid with gas evolution. The yield was practically quantitative.

Anal. Calcd. for $C_{38}H_{28}O_2$: C, 88.4; H, 5.4. Found: C, 88.5; H, 5.4.

This addition product is insoluble in the alcohols and ether, slightly soluble in carbon tetrachloride, but dissolves easily in hot chloroform, ethyl acetate, benzene, toluene, and acetic acid. It was recovered unchanged after boiling with permanganate in acetone, glacial acetic acid, and selenium dioxide or hydrogen peroxide. Bromine in chloroform, and chromic acid in acetic acid slowly attacked it, but gave ill-defined products from which no individual substance could be isolated.

The addition product also resulted, less conveniently, when a benzene solution of vinyl phenyl ketone and tetraphenylcyclopentadienone was refluxed for two hours, or when the components were heated in the absence of a solvent at 130°. It was also obtained when one replaced the β-chloropropiophenone by an equivalent amount of β-dimethylaminopropiophenone hydrochloride; after twenty-four hours the yield was but 25%.

(2) Dihydro-3,4,5,6-tetraphenylbenzophenones XII or XIII.—The dihydroketone was easily secured by pyrolysis of the addition product or by carrying out the addition reactions in boiling trichlorobenzene or nitrobenzene, substituting β-dimethylaminopropiophenone for β-chloropropiophenone.

(i) Pyrolysis: High-Melting Form.—Ten grams of the addition product was heated for ten minutes in a metal bath at 215°; it formed a reddish liquid which evolved carbon monoxide; a few oily drops collected in the upper part of the flask, and the pungent odor of vinyl methyl ketone was evident. The cooled melt was taken up in chloroform and diluted with methanol. The dihydroketone crystallizes in pale yellow rods, m. p. 177°. It is sparingly soluble in the alcohols, acetone, and ether, but dissolves easily in ethyl acetate, chloroform, carbon tetrachloride, acetic acid, and benzene.

Anal. Calcd. for $C_{37}H_{28}O$: C, 91.0; H, 5.7. Found: C, 90.8; H, 5.7.

(ii) Low-Melting Form.—A mixture of 7.6 g. of tetraphenylcyclopentadienone, 6 g. of β-dimethylaminopropiophenone hydrochloride (or an equivalent amount of β-chloropropiophenone), 6 g. of potassium acetate, and 35 cc. of trichlorobenzene was heated at 180–190° for three hours with stirring; dimethylamine was evolved and the mixture became colorless after two hours. The potassium salts were precipitated by the addition of 50 cc. of methanol, and, after filtering, the solvent was removed *in vacuo*. The hard residue was taken up in chloroform and recrystallized in the usual manner. It forms pale yellow very fine rods, m. p. 158–159°.

Anal. Calcd. for $C_{37}H_{28}O$: C, 91.0; H, 5.7. Found: C, 91.2, 91.2; H, 5.5, 5.6.

(13) German Patent 597,325; *Frdl.*, **21**, 1121 (1936).

When nitrobenzene was substituted for trichlorobenzene, the high-melting isomer was isolated; the reaction product was rather sticky and not easy to manipulate.

The high-melting isomer (1 g., m. p. 177°) was heated at 250–270° for fifteen minutes, cooled, taken up in chloroform, and methanol added to incipient crystallization. After filtration, the solid melted at 156–158°; when it was mixed with the analytical sample, the melting point was 157–158°.

Mixtures of the low and high-melting forms may soften as low as 138°, but usually do not form a clear liquid until about 173°. They are often obtained in the pyrolysis of large quantities of the addition product.

(3) 2,3,4,5-Tetraphenylbenzophenone XIV.—This ketone was obtained from both forms of the dihydro compound by the dehydrogenating action of bromine, permanganate, and sulfur. The yields were good by all procedures. In each instance the melting points of the products were the same, and there was no depression on admixture.

(i) **Action of Bromine.**—To a solution of 1.0 g. of the dihydroketone in 8 cc. of chloroform was added 0.4 g. of bromine in 2 cc. of the same solvent. Hydrogen bromide was evolved; after three minutes on the steam-bath, methanol was added to incipient crystallization. After standing several hours, 0.8 g. of the aromatic ketone had separated. It forms long rods, m. p. 190°. The solubilities are the same as those of the dihydro compound.

Anal. Calcd. for $C_{37}H_{26}O$: C, 91.1; H, 5.4. Found: C, 91.3; H, 5.4.

(ii) **Action of Permanganate.**—A solution of 2 g. of the dihydroketone in 30 cc. of acetone was warmed, and potassium permanganate in acetone added as long as it was decolorized. The oxides of manganese were filtered and the solvent evaporated; the residue was crystallized from chloroform–methanol; 1.3 g. of product was secured.

(iii) **Sulfur Fusion.**—A mixture of 2 g. of the dihydroketone and 0.4 g. of sulfur was heated in a metal bath at 240–250° for fifteen to twenty minutes, when the evolution of gas became negligible. The cooled melt was dissolved, filtered, and recrystallized; the yield was 1 g.

(4) 1,2,3,4-Tetraphenylbenzene, XV.—One gram each of the tetraphenylbenzophenone and pulverized sodium amide in 50 cc. of *p*-cymene was refluxed for eight hours. The cooled mixture was washed with water, and the hydrocarbon slowly crystallized in a yield of 50%. Recrystallization from acetic acid gave a product, m. p. 193°. The melting point was not depressed on admixture with a specimen secured by Dilthey's procedure.[6]

(c) **Polynuclear Series.**—A mixture of 2 g. of the green unsaturated ketone XVII, 2.5 g. of β-chloropropiophenone, 2 g. of potassium acetate, and 25 cc. of toluene was heated until the green color disappeared (two hours), cooled, the inorganic salts filtered, and the solution concentrated to about 15 cc. Methanol was added to precipitate the yellow reaction product, which was recrystallized from chloroform–methanol. The addition product XX separated in prisms, m. p. 189–190°.

Anal. Calcd. for $C_{36}H_{24}O_2$: C, 88.5; H, 4.9. Found: C, 88.1, 88.3; H, 5.1, 5.1.

It dissolved readily in hot acetic acid but the melting point of the crystalline product was lowered; subsequent purification from chloroform–methanol gave a yellow substance, m. p. 194–195°, with analytical figures approaching the bridgeless formula XXI.

Anal. Calcd. for $C_{35}H_{24}O$: C, 91.3; H, 5.2. Found: C, 90.2, 90.5; H, 5.1, 5.2.

In a similar manner from β-chloropropiophenone and 3.8 g. of diphenylenediphenylcyclopentadienone XVI there was obtained an addition product XVIII, which separated from chloroform–methanol in white needles, m. p. 273°. Above the melting point it dissociated appreciably into its components.

Anal. Calcd. for $C_{38}H_{26}O_2$: C, 88.7; H, 5.4. Found: C, 88.4; H, 5.1.

When β-dimethylaminovinyl phenyl ketone was substituted for the β-chloropropiophenone, the resulting substance appeared to be the dihydro-bridged ketone XIX or its reduction product; the latter, however, is not identical with XVIII, nor are the two interconvertible. This reaction is being studied further. The ketone XIX separated from chloroform in very fine white needles, m. p. 312–315°.

Anal. Calcd. for $C_{38}H_{24}O_2$: C, 89.1; H, 4.7; for $C_{38}H_{26}O_2$: C, 88.7; H, 5.4. Found: C, 88.8; H, 5.3.

C. Miscellaneous. (a) Methyl Benzoylacrylate; Methyl 2-Benzoyl-4,5-diphenyltetrahydrobenzoate XXII.—A solution of 0.6 g. of 2,3-diphenylbutadiene and 0.6 g. of methyl β-benzoylacrylate was heated for fifteen hours at 165°. The cooled residue was taken up in boiling methanol and treated with Norite; on cooling, the addition product separated in fine white prisms. The yield was 0.6 g., 52% of the theoretical amount. It could also be secured in a yield of 20% by refluxing a xylene solution of the components for sixty hours. The analytical sample was recrystallized from methanol; m. p. 147°.

Anal. Calcd. for $C_{27}H_{24}O_3$: C, 81.8; H, 6.1. Found: C, 82.0; H, 6.0.

The addition product did not react appreciably with bromine in a cold chloroform solution, but, on warming, hydrogen bromide was evolved in considerable amount. On evaporation of the solvent, followed by crystallization from methanol, a substance containing two bromine atoms was secured. It separates in rods, m. p. 183°, with decomposition.

Anal. Calcd. for $C_{27}H_{22}O_3Br_2$: C, 58.5; H, 4.0; Br, 28.9. Found: C, 58.7; H, 4.0; Br, 28.6.

Dehydrogenation was accomplished by heating 0.8 g. of the ester and 0.2 g. of sulfur for several hours at 230°. The untractable melt was warmed with alcoholic potash, evaporated to dryness and extracted with water. Acidification of the filtered solution precipitated the 6-carboxy-3,4-diphenylbenzophenone XXIV, which was recrystallized from dilute methanol. The melting point was 240–241° and was not depressed when mixed with a specimen of the original ketoacid.[1]

(b) From a mixture of 16.8 g. of β-chloropropiophenone, 12.8 g. of ethyl sorbate, 9.8 g. of potassium acetate and 50 cc. of xylene, refluxed eighteen hours and treated in the usual manner, was obtained 13.4 g. of the addition

product (mixed esters), m. p. 165–170° at 3 mm. It was hydrolyzed by refluxing with 3 g. of potassium hydroxide in 50 cc. of ethanol for two and a half hours; the solution was then poured into water, filtered and the oily acid that separated on acidification allowed to crystallize slowly from methanol. In this way, 8 g. of mixed stereoisomers XXVa, m. p. 128–133°, was secured on recrystallization from ethanol; one form was easily isolated in a yield of 75%; it separates in tiny rods, m. p. 162–163°.

Anal. Calcd. for $C_{15}H_{16}O_3$: C, 73.8; H, 6.6. Found: C, 73.7; H, 6.5.

The crude ester (5.2 g.) was also dehydrogenated by heating with 0.7 g. of sulfur at 200–240° for ten minutes; the cooled melt was extracted with alcohol, and the filtered solution refluxed for two hours after the addition of 1.4 g. of potassium hydroxide. After dilution it was treated with Norite, filtered, and acidified, the oily acid being dehydrated directly, as follows: a mixture of 1 g. of this and 4.6 cc. of 20% fuming sulfuric acid was warmed on the steam-bath for two hours, and, after cooling, poured into water. The precipitate was insoluble in sodium hydroxide. After two crystallizations from alcohol it melted at 166° and did not depress the melting point of an authentic sample of β-methylanthraquinone.

(c) **2,3,4,5,6-Pentaphenylbenzophenone XXII.**—A mixture of 9.5 g. of tetraphenylcyclopentadienone, 6 g. of benzalacetophenone, and 30 cc. of trichlorobenzene was refluxed for twenty-four hours (210–213°); the red color gradually diminished but never entirely disappeared. On cooling, the product separated; it was filtered and recrystallized from chloroform–methanol. The melting point and mixed melting point with an authentic sample[7] were 338° (341° cor.). The ketone sublimes in long needles.

Anal. Calcd. for $C_{43}H_{30}O$: C, 91.8; H, 5.4. Found: C, 91.8; H, 5.5.

Pentaphenylbenzene XXIII.—The sodium amide cleavage was carried out as described under the tetraphenyl homolog, using 5 g. of ketone and 8 g. of amide; the yield of hydrocarbon was 1.8 g., m. p. 245–246°. A mixed melting point with a specimen secured by Dilthey's procedure[6] was not depressed.

(d) **Bz-1-Bz-2-Dibenzoylbenzanthrone, XXIX.**—This ketone appears to exist in polymorphic forms, one, melting at 208°, being formed when the components are refluxed in trichlorobenzene, and the other, m. p. 286°, when nitrobenzene is used as a solvent. Both forms separate from solutions as yellow rods, give the same scarlet color in concd. sulfuric acid, and show comparable solubilities in the same solvents, but the lower-melting form is changed into the higher by sulfuric acid.

A mixture of 2 g. of methyleneanthrone, 3 g. of *trans*-dibenzoylethylene, and 10 cc. of trichlorobenzene was refluxed for five hours, cooled, and 15 cc. of methanol added with stirring; the reddish crystals that separated were filtered and washed. This product was a mixture of uncertain composition that required repeated recrystallization before a substance having a constant melting point was obtained. The red color only slowly disappeared, although bromine removed it at once without greatly improving the melting point. The most suitable solvent was chloroform–methanol. When nitrobenzene was used, the high-melting form separated at once. Both forms are insoluble in the alcohols and ether, but dissolve readily in hot chloroform, acetic acid, and dioxane.

Anal. Calcd. for $C_{31}H_{18}O_3$: C, 84.9; H, 4.1. Found: (208°) C, 85.3; H, 4.0; (286°) C, 85.2; H, 4.1.

Oxidation.—A mixture of 2.5 g. of the ketone, 5 g. of chromium trioxide, and 86 cc. of acetic acid was refluxed for ten minutes, cooled, and diluted with 300 cc. of water. After two hours the precipitate was filtered and washed. The solid was extracted with dilute sodium carbonate solution, filtered, and acidified, the benzoic acid being extracted with ether and identified in the usual manner. The solid, insoluble in sodium carbonate, was crystallized from methanol and found to be identical with the α-benzoylformylanthraquinone VIII secured in another way as described above. The dibenzoylbenzanthrone XXIX was unaffected by melting with sodium–aluminum chloride at 170°.

(e) **Mixtures of vinyl phenyl ketone with furan, sylvan, and 2,5-dimethylfuran** did not react when allowed to stand at room temperature. When an alcoholic solution, prepared by the usual treatment of β-chloropropiophenone with potassium acetate, was heated with furan in a sealed tube, β-ethoxypropiophenone VI resulted. The latter was isolated, the 2,4-dinitrophenylhydrazone prepared, and both analyzed. The derivative separates from alcohol in orange prisms, m. p. 158°.

Anal. Calcd. for $C_{11}H_{14}O_2$ (VI): C, 74.2; H, 7.9; for the derivative, $C_{17}H_{18}O_5N_4$: N, 15.6. Found: (VI) C, 74.3; H, 7.8; (2,4-dinitrophenylhydrazone): N, 15.5.

(f) **Isolation of Vinyl Phenyl Ketone.**—In all the papers in this series, an alcoholic solution of β-chloropropiophenone containing an equivalent of potassium acetate has been used just as though it were vinyl phenyl ketone. That it actually does contain the unsaturated ketone, and is not β-acetoxypropiophenone, was shown by isolation of the free ketone. It was only necessary to extract the solution with chloroform (ether was avoided, as traces of peroxide caused polymerization to a tough, horn-like mass), wash out alcohol with water, and distil *in vacuo*. The yield of pale yellow oil was 71–78%, the lower quantity being obtained when 100 g. of chloroketone was employed; there was more loss by polymerization during the time of heating.

The distilled ketone keeps fairly well for several days at a low temperature (−9°), but at room temperature soon becomes solid. The effect of *p*-benzylaminophenol, hydroquinone, phenyl-β-naphthylamine, and copper acetate as stabilizers was examined; the last two were useless, but the others seemed to decrease the rate of polymerization. A specimen containing hydroquinone became quite viscous in six weeks but was not further changed after five years. This specimen was a dimeric form.

Calcd. Mol. wt., $(132)_x$. Found, in benzene: mol. wt., 257, 266, 259, whence $x = 2$.

The formation of the unsaturated ketone by the action of potassium acetate on β-chloropropiophenone would not of necessity be anticipated, for sodium cyanide gives β-cyanopropiophenone.[14]

(14) Allen and Young, *J. Org. Chem.*, **2**, 231 (1937).

Summary

1. Vinyl phenyl ketone adds readily to many substances containing a conjugated system of double bonds.

2. Addition products were obtained from this unsaturated ketone and 2,3- and 1,4-diphenylbutadienes, 1-phenyl-4-methylbutadiene, 2,3-dimethylbutadiene, cyclopentadiene, tetraphenylcyclopentadienone, and ethyl sorbate.

3. Secondary reaction products resulted from vinyl phenyl ketone and methyleneanthrone, *trans*-dibenzoylethylene and methyleneanthrone, and from benzalacetophenone and tetraphenylcyclopentadienone.

4. Methyl β-benzoylacrylate and 2,3-diphenylbutadiene also gave an addition product.

5. 3,4-Diphenylbenzophenone and its 6-carboxylic acid were synthesized and shown to be identical with specimens previously secured by degradation of a polynuclear indene derivative.

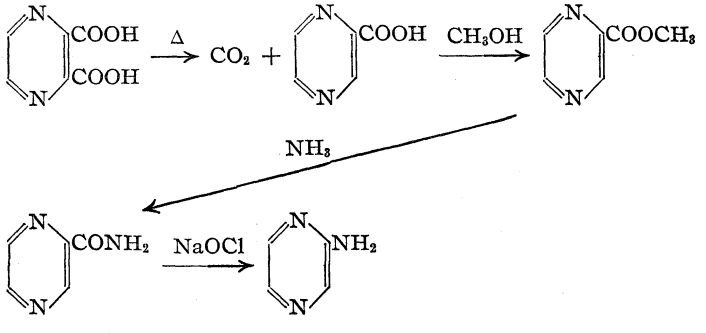
Syntheses in the Pyrazine Series. II. Preparation and Properties of Aminopyrazine

BY STANLEY A. HALL AND PAUL E. SPOERRI

Certain derivatives of diaminopyridine such as pyridium,[1] and its modifications,[2] exhibit valuable bacteriostatic properties.[3] However, little is known about the corresponding amino pyrazines.

Gabriel and Sonn[4] obtained aminopyrazine from pyrazine-2,3-dicarboxylic acid. However, their product was impure; m. p. 110–117°. Moreover, their synthesis is complicated by side reactions.

We have synthesized aminopyrazine by a modification of the method of Gabriel and Sonn



The Hofmann degradation of pyrazine-carboxylamide has not been described in the literature. An interesting intermediate compound was isolated which immediately decomposed with much effervescence in dilute acid (mineral or acetic) to give the desired aminopyrazine. This intermediate compound was identified as sodium pyrazine-carbamate.

(2) Bowie, *Brit. Med. J.*, **II**, 283–284 (1938).
(3) Ostromislensky, THIS JOURNAL, **56**, 1713–1714 (1934).
(4) Gabriel and Sonn, *Ber.*, **40**, 4851–4860 (1907).

Although Mohr,[5] in his study of the mechanism of the Hofmann reaction, isolated barium phenylcarbamate, this is the first time, as far as can be ascertained, that the Hofmann degradation of an amide has proceeded only to the stage of a stable sodium carbamate which must then be decomposed by acidification in order to obtain the amine. This adds confirmation to Mohr's theory of the mechanism of the Hofmann reaction and it also shows up the characteristic stabilizing effect of the pyrazine ring upon certain functional groups.

Aminopyrazine was obtained in pure white crystalline form, m. p. 117–118°. It is very soluble in water, giving a solution neutral to litmus. Aminopyrazine gives only a very faint isonitrile test, which differs from the observations of Gabriel and Sonn who reported a distinct isonitrile test.

Both aminopyrazine and acetaminopyrazine sublime without decomposition.

Experimental

Pyrazine-carboxylic Acid.—33.9 g. of pyrazine-2,3-dicarboxylic acid (m. p. 190°) was heated rapidly to 210° in a vacuum sublimation chamber. At 3 to 4 mm., simultaneous decarboxylation and sublimation took place. After resubliming *in vacuo* the product was recrystallized from hot water.

Fine white needles of pyrazine-carboxylic acid were obtained: m. p. 225° (decompn.); m. p. 225° (decompn.), Gabriel and Sonn; m. p. 229° (decompn.), Stoehr; yield 17.5 g. or 70.0%.

(5) Mohr, *J. prakt. Chem.*, (2) **73**, 117–191, 229 (1906).

Methyl Pyrazine-carboxylate.—10.5 g. of oven-dried pyrazine-carboxylic acid in 105 g. of absolute methyl alcohol saturated with dry hydrogen chloride was distilled at reduced pressure to remove excess hydrogen chloride. The residue was neutralized with saturated sodium carbonate solution and extracted with ethyl acetate. After evaporation of the ethyl acetate the solid reddish-yellow residue was sublimed at 4 mm. in an oil-bath at 100°. The pure white crystals melted at 59° unchanged after several recrystallizations from ether and other solvents (m. p. 62°; British Patent 451,304); yield 8.4 g. or 72%.

Pyrazine-carboxylamide.—8.4 g. of methylpyrazine-carboxylate in 8.4 g. of warm methyl alcohol was added to a saturated absolute methyl alcohol (17 g., 0°) solution of ammonia. The white crystals were filtered off the next day, washed with methanol, ether and dried: m. p. 189° (lit. m. p. 188°; British Patent 451,304); yield 6.9 g. or 92%.

Aminopyrazine.—After dissolving 4.2 g. of chlorine in 13.8 g. of sodium hydroxide and 150 g. of ice and water, 6.9 g. of finely powdered pyrazine-carboxylamide was added. The solution was warmed, with stirring for one hour.

The next day, the needle-like crystals were filtered off and dried; 3.5 g. of the product dissolved in water gave an alkaline solution which evolved carbon dioxide on acidification. The ethyl acetate extract of the neutralized solution was evaporated, leaving a solid yellowish residue which sublimed completely at 3 mm.; temp. of oil-bath 100°; yield, 1.5 g. of pure aminopyrazine.

The original filtrate was acidified and an alcoholic picric acid solution added. The picrate obtained and washed with alcohol, ether and dried had no definite m. p. but decomposed at 214 to 250°. The suspension of the picrate in cooled ether was saturated with hydrogen chloride. The hydrochloride filtered off and washed with ether was neutralized with saturated sodium carbonate solution and extracted with ethyl acetate. The residue remaining after the evaporation of the ethyl acetate was sublimed at 3 mm.; temp. of oil-bath 100°; yield of aminopyrazine, 0.9 g.; combined yields of aminopyrazine 2.9 g. or 55%: m. p. 117–118° (lit. m. p. 110–117°, Gabriel and Sonn).

Anal. Calculated for $C_4H_5N_3$: C, 50.5; H, 5.30; N, 44.2. Found: C, 50.4, 50.3; H, 5.16, 5.16; N, 44.1, 43.9.

Acetaminopyrazine.—M. p. 133°.

Anal. Calculated for $C_6H_7H_3O$: C, 52.54; H, 5.11; N, 30.66. Found: C, 52.50, 52.73; H, 6.25, 6.15; N, 28.99.

Intermediate Product in the Hofmann Reaction.—The properties of the needle-like crystals obtained were found to be as follows: no definite m. p.; began to turn brown at 257°; black at 275°; very soluble in water to give an alkaline solution; insoluble in organic solvents including absolute alcohol; contains sodium; halogen test negative; effervesces (CO_2 evolved) in dilute acid (mineral or acetic) to form aminopyrazine. The intermediate compound evidently is sodium pyrazine carbamate. *Anal.* Calculated for $C_5H_4N_3O_2Na$: N, 26.1; Na, 14.3. Found: N, 25.9; Na, 14.4.

Summary

1. The Hofmann degradation on pyrazine carboxylamide gave a 55% yield of aminopyrazine, m. p. 117–118°.

2. From the Hofmann reaction an intermediate compound was isolated and identified as sodium pyrazine-carbamate, which on acidification gave aminopyrazine and carbon dioxide.

The Conversion of Arylbismuth Halides to Triarylbismuth Compounds

BY HENRY GILMAN AND H. L. YABLUNKY

We have observed that one of the intermediate types formed in the recently described synthesis of triarylbismuth compounds by the diazonium reaction[1] is R_2BiX. This suggested an examination of procedures for the conversion of such compounds to the R_3Bi compounds. The best reagent, we now find, for this purpose is hydrazine hydrate. This reagent was first used to convert 2-furylmercuric chloride and phenylmercuric chloride to 2,2′-difurylmercury and diphenylmercury, respectively[2]; and it was shown subsequently that hydrazine is a reagent of choice for converting RHgX to R_2Hg compounds.[3]

If the equilibrium

$$3R_2BiX \rightleftharpoons 2R_3Bi + BiX_3$$

is valid, then one of the functions of the hydrazine may be to reduce the bismuth halide. The procedure was next extended successfully to the conversion of phenylbismuth dibromide to triphenylbismuth, and to the conversion of R_3BiX_2 compounds to the corresponding triarylbismuth compounds. Attention might be directed to two

(1) Gilman and Svigoon, THIS JOURNAL, **61**, 3586 (1939).

(2) Gilman and Wright, *ibid.*, **55**, 3302 (1933).

(3) Gilman and Barnett, *Rec. trav. chim.*, **55**, 563 (1936).

interesting cases of the conversion of triarylbismuth dihalides to the triarylbismuths. First, the very stable triphenylbismuth difluoride is converted rapidly and practically quantitatively to triphenylbismuth. Challenger and co-workers[4] have shown that triphenylbismuth difluoride is the most stable of a series of compounds like $(C_6H_5)_3BiX_2$ where X is halogen or a pseudo-halogen. Second, the almost quantitative yield of diphenyl-α-naphthylbismuth from diphenyl-α-naphthylbismuth dichloride is additional evidence[4a] for the stability of this unsymmetrical organobismuth compound.

The smooth and rapid reactions leading to excellent yields of R_3Bi compounds, suggest that the procedure might also be applicable to variously substituted organobismuth halides, as well as to analogous arsenicals and antimonials. By analogy with the related reaction with mercurials[3] it is altogether probable that reducing agents related to hydrazine also may be used effectively.

Other reagents have been used for the conversion of organobismuth halides to R_3Bi compounds: hydrogen sulfide,[5] ammonium sulfide,[6] moist silver oxide,[7a,b] alcoholic ammonia,[8] sodium hydrosulfite, formaldehyde, sodium and alcohol, and dimethyl sulfate and alkali.[9] Of these, the most successful one was sodium hydrosulfite which gave about 80% yields of triphenylbismuth and tri-*p*-tolylbismuth from the corresponding R_3BiCl_2 compounds. Unfortunately, secondary reactions took place with nitro-nuclear types.

Experimental Part

Two typical experimental procedures follow.

Conversion of Diphenylbismuth Chloride to Triphenylbismuth.—To a solution of 2.0 g. (0.04 mole) of hydrazine hydrate in 60 cc. of absolute alcohol contained in a 200-cc. three-necked flask equipped with mechanical stirring, was added 4.0 g. (0.01 mole) of diphenylbismuth chloride. Reaction occurred immediately. Stirring at room temperature was continued for an hour, after which the reaction mixture was heated to boiling and filtered. The insoluble material was once again extracted with hot alcohol. The alcoholic filtrate was then poured into 400 cc. of water and the precipitated triphenylbismuth extracted with ether. The ether extracts were dried over anhydrous sodium sulfate, and the ether distilled. The yield of triphenylbismuth was 2.75 g. (93.5%), m. p. 75–76°; mixed m. p. with an authentic sample, 75–76°.

Conversion of Triphenylbismuth Dichloride to Triphenylbismuth.—To a stirred suspension of 2.56 g. (0.005 mole) of triphenylbismuth dichloride in 60 cc. of 95% ethanol was added 2.0 g. of hydrazine hydrate. Reaction occurred immediately and the solution became yellow in color. After about a half-minute, the solution was decolorized and the triphenylbismuth precipitated out of solution. Stirring was continued for an hour, after which the mixture was poured into 300 cc. of water. The aqueous suspension was extracted with ether, the ether layer separated and dried, and the ether distilled. The yield was 2.1 g. (95.4%), m. p. 75–76°; mixed m. p. with triphenylbismuth, 75–76°.

The results are summarized in Table I. The method of mixed melting points was used to complete identity of each of the products.

TABLE I

CONVERSION OF $RBiX_2$, R_2BiX, AND R_3BiX_2 COMPOUNDS TO R_3Bi

Organobismuth halide	Product	Yield, %
$(C_6H_5)_2BiCl$	$(C_6H_5)_3Bi$	93.5
$C_6H_5BiBr_2$[a]	$(C_6H_5)_3Bi$	81.5
$(o\text{-}CH_3C_6H_4)_3BiCl_2$	$(o\text{-}CH_3C_6H_4)_3Bi$	99.0
$(o\text{-}CH_3C_6H_4)_3BiBr_2$	$(o\text{-}CH_3C_6H_4)_3Bi$	100
$(C_6H_5)_3BiCl_2$	$(C_6H_5)_3Bi$	95.4
$(C_6H_5)_3BiBr_2$	$(C_6H_5)_3Bi$	100
$(p\text{-}CH_3C_6H_4)_3BiCl_2$	$(p\text{-}CH_3C_6H_4)_3Bi$	100
$(p\text{-}ClC_6H_4)_3BiCl_2$[b]	$(p\text{-}ClC_6H_4)_3Bi$	78.0
$(C_6H_5)_3BiF_2$	$(C_6H_5)_3Bi$	97.8
$(C_6H_5)_2(C_{10}H_7(\alpha))BiCl_2$	$(C_6H_5)_2(C_{10}H_7(\alpha))Bi$	96.2

[a] In this experiment, dry ether was used as a solvent. [b] This was the only reaction where decomposition was apparent. The reaction mixture was red in color, and the red tint persisted in the final product.

Summary

Hydrazine effects a smooth and rapid conversion of arylbismuth halides of the general types $RBiX_2$, R_2BiX and R_3BiX_2 to R_3Bi compounds in excellent yields.

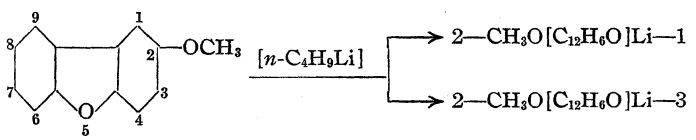
Dibenzofuran. XVIII. Isomeric Metalation Products of Some Phenols and their Methyl Ethers[1]

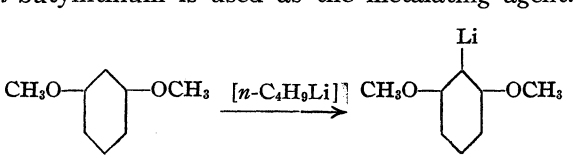
BY HENRY GILMAN, H. B. WILLIS, T. H. COOK, F. J. WEBB AND R. N. MEALS

Metalation in an ortho position is a general reaction not only of ethers but also of the corresponding phenols.[2] However, where isomeric metalation products are possible, the phenols of dibenzofuran appear to form a lesser number of isomers than do the corresponding methyl ethers. For example, metalation of 2-methoxydibenzofuran[3] takes place in the 1- and the 3-positions, whereas metalation of 2-hydroxydibenzofuran apparently involves the 1-position exclusively, for

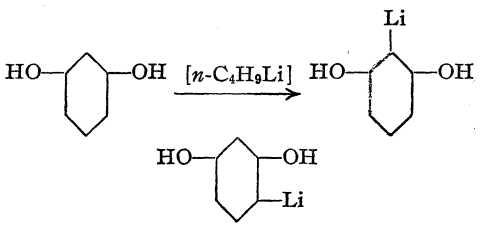


the only acid isolated subsequent to carbonation is 2 - hydroxy - 1 - dibenzofurancarboxylic acid. Similarly, metalation of 4-methoxydibenzofuran, followed by carbonation, gives both 4-methoxy-6-dibenzofurancarboxylic acid and 4-methoxy-3-dibenzofurancarboxylic acid; and metalation of 4-hydroxydibenzofuran gives, subsequent to carbonation, only 4-hydroxy-6-dibenzofurancarboxylic acid.

This more highly selective metalation of phenols is of particular interest in problems of orientation concerned with the dibenzofuran nucleus. However, because metalations of phenols and their ethers are of increasing diagnostic significance in establishing structures of compounds having nuclei other than dibenzofuran, it seemed of interest to examine some simple benzene types. Metalation of resorcinol dimethyl ether by phenyllithium gives 2,6-dimethoxyphenyllithium.[4] We have found that the same product is formed when *n*-butyllithium is used as the metalating agent.



However, metalation of resorcinol by *n*-butyllithium gives the two isomers: 2,6-dihydroxyphenyllithium and 2,4-dihydroxyphenyllithium.[5]



Accordingly there is a complete reversal here, the phenol giving more isomers than the ether. Inasmuch as the ratio of isomers that may result from particular phenols and their ethers might vary markedly, it becomes necessary to establish in each case the structure of the metalation product and not to carry over analogies from phenols to ethers or from ethers to phenols.

Carbonation of Organolithium Compounds.—In the first experiments[4] on the carbonation of 2,6-dimethoxyphenyllithium gaseous carbon dioxide was used, and there was obtained a 14% yield of 2,6-dimethoxybenzoic acid, accompanied by a 25% yield of 2,2′,6,6′-tetramethoxybenzophenone. However, we used solid carbon dioxide which gave a 55% yield of the acid and only traces of the ketone. Gaseous carbon dioxide also can be used under special conditions[6] to give improved yields of carboxylic acids from organolithium compounds, but solid carbon dioxide is more convenient, more rapid and more effective.[6]

Structure Determinations.—For convenience, the products of metalation were carbonated. The resulting acids obtained from resorcinol and its dimethyl ether were compared with previously described compounds. The structures of the dibenzofuran compounds were established by the following sequence of reactions.

The halogen–metal interconversion indicated by the transformation of [A] to [B] was reported

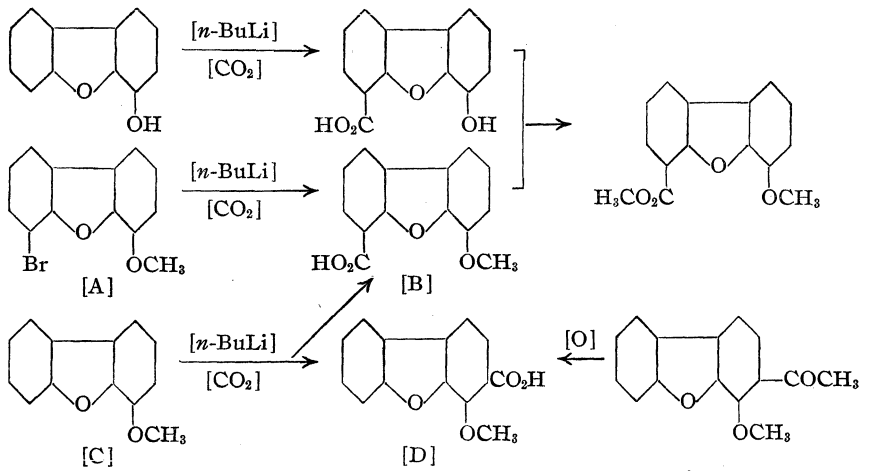
(5) Actually, of course, the active hydrogens of the phenolic groups react first, and the true products are the —OLi salts of the organolithium compounds.

(6) Gilman and Van Ess, THIS JOURNAL, **55**, 1258 (1933).



recently[7a] starting with authentic 4-methoxy-6-bromodibenzofuran [A]. Such halogen–metal interconversions appear to be not only general, but also reliable when an equivalent or more of *n*-butyllithium is used.[7b] Additional supporting evidence for the formation of [B] and [D] from [C] is to be had in the preparation of 4-methoxy-6-hydroxydibenzofuran and 4-methoxy-3-hydroxydibenzofuran by oxidation of the metalation products of 4-methoxydibenzofuran.[7c]

Correlation with Bromination.—It is interesting to note that bromination of 2-hydroxydibenzofuran and of 2-methoxydibenzofuran parallels metalation of these compounds: 2-hydroxydibenzofuran yields 1-bromo-2-hydroxydibenzofuran, whereas 2-methoxydibenzofuran yields the isomeric 1- and 3-bromo-2-methoxydibenzofurans.[7d]

Experimental Part

Metalation of 2-Hydroxydibenzofuran.—A solution of approximately 0.034 mole of *n*-butyllithium in 75 cc. of ether was added slowly with constant stirring to 3.1 g. (0.0168 mole) of 2-hydroxydibenzofuran dissolved in 75 cc. of benzene. The reaction mixture was stirred and heated for four hours and then carbonated by pouring it upon crushed solid carbon dioxide. Following carbonation, the solvent was removed by distillation and the residue was extracted with hot, dilute alkali; then carbon dioxide was passed into the alkaline solution to precipitate the phenol. The bicarbonate solution was extracted three times with 100-cc. portions of ether to remove last traces of the phenol. The acid was precipitated by the addition of hydrochloric acid. The yield of 2-hydroxy-1-dibenzofurancarboxylic acid was 0.830 g. (21.5%); m. p. 209–214° (dec.).

Three-tenths gram of the acid was methylated with alkali and dimethyl sulfate, followed by treatment with diazomethane, to yield the known methyl 2-methoxy-1-dibenzofurancarboxylate, which melted at 98–99° after crystallization from methyl alcohol. A mixed m. p. with an authentic specimen[7d] showed no depression.

Metalation of 4-Hydroxydibenzofuran.—A solution of 0.031 mole of *n*-butyllithium in 35 cc. of ether was added slowly to a solution of 1.84 g. (0.01 mole) of 4-hydroxydibenzofuran dissolved in 35 cc. of dry benzene. During the addition there was a vigorous evolution of gas and a heavy white precipitate formed. The resulting mixture was refluxed with stirring for four hours, after which it was carbonated by pouring it upon crushed solid carbon dioxide. The carbonation mixture was extracted with dilute sodium hydroxide and then carbon dioxide was bubbled through the alkaline solution to precipitate the unchanged phenol, of which 1.22 g. (65%) was recovered. The bicarbonate solution after filtration was acidified to yield a precipitate which was recrystallized from a benzene–acetone solution (4:1). The resulting crystals of 4-hydroxy-6-dibenzofurancarboxylic acid (0.1 g. or 4.4% yield) melted at 251–253° (dec.).

Forty milligrams of the hydroxy acid was treated with diazomethane and the resulting product was recrystallized from alcohol to yield a compound melting at 122.5–124°. This same methyl 4-methoxy-6-dibenzofurancarboxylate (mixed m. p.) was prepared from authentic 6-bromo-4-methoxydibenzofuran by halogen–metal interconversion, followed by methylation.[7a]

Metalation of 4-Methoxydibenzofuran.—A solution of 0.06 mole of *n*-butyllithium in 40 cc. of ether was added to a solution of 10 g. (0.05 mole) of 4-methoxydibenzofuran dissolved in 40 cc. of dry ether and the resulting mixture was refluxed with stirring for four hours, after which it was carbonated in the usual manner. The ether was removed by distillation and the solid residue was extracted with hot dilute sodium hydroxide. Acidification of the hot alkaline solution yielded 3 g. of crude acidic product.

This crude product was dissolved in hot 10% potassium hydroxide solution, filtered, and cooled. The white silky needles were filtered off and the filtrate was acidified with dilute hydrochloric acid. The precipitate was recrystallized several times from glacial acetic acid to yield 0.65 g. (5.3%) of 4-methoxy-3-dibenzofurancarboxylic acid melting at 182–183°. The same 4-methoxy-3-dibenzofurancarboxylic acid (mixed m. p.) was prepared by permanganate oxidation of authentic 3-acetyl-4-methoxydibenzofuran.

Anal. Calcd. for $C_{14}H_{10}O_4$: neut. equiv., 242. Found: neut. equiv., 238, 240.

The white needles obtained from the alkaline solution were dissolved in hot water and the acid was precipitated by addition of hydrochloric acid. Recrystallization from

(7) (a) Gilman, Swislowsky and Brown, THIS JOURNAL, **62**, 348 (1940); (b) Gilman, Langham and Willis, *ibid.*, **62**, 346 (1940); (c) Gilman, Cheney and Willis, *ibid.*, **61**, 951 (1939); (d) Gilman and Van Ess, *ibid.*, **61**, 1365 (1939).

glacial acetic acid gave 1.12 g. or a 9.2% yield of 4-methoxy-6-dibenzofurancarboxylic acid melting at 240–242°.

Anal. Calcd. for $C_{14}H_{10}O_4$: neut. equiv., 242. Found: neut. equiv., 237.

The methyl 4-methoxy-6-dibenzofurancarboxylate prepared by means of diazomethane from the methoxy acid melting at 240–242° was proved identical with both the methoxy ester of the single acid obtained from metalation of 4-hydroxydibenzofuran and an authentic sample of methyl 4-methoxy-6-dibenzofurancarboxylate.

Anal. Calcd. for $C_{15}H_{12}O_4$: methoxyl, 24.20. Found: methoxyl, 24.25.

Metalation of Resorcinol.—To an ice-cold solution of approximately 0.3 mole *n*-butyllithium in 400 cc. of ether was added dropwise with stirring 11.0 g. (0.1 mole) of resorcinol in 75 cc. of ether. Gas was evolved but no precipitate formed during the ensuing twenty-one hour period of refluxing. Carbonation, in the usual manner, was followed by acidification with iced dilute hydrochloric acid and extraction with ether. The crude acid obtained from the ether layer[8] was recrystallized from water to give 3.3 g., m. p. 145–147°, and 0.8 g., m. p. 192–195°. An additional 0.7 g., m. p. 150°, was obtained from the filtrate; combined yield, 31.1%.

The 3.3-g. portion, melting at 150–152° after recrystallization from water, was treated with dimethyl sulfate and sodium hydroxide to form 2,6-dimethoxybenzoic acid,[9] m. p. 183–184°, identified by a mixed melting point determination with a reference sample.

The 0.8-g. portion, m. p. 206–207° after recrystallization from water, was converted with diazomethane to methyl 2-hydroxy-4-methoxybenzoate[10] melting at 49° alone or mixed with an authentic specimen. Hydrolysis of the ester with alcoholic potassium hydroxide gave 2-hydroxy-4-methoxybenzoic acid, m. p. 153–154°. The mixed melting point with a known sample showed no depression.

The third portion was not identified but was probably a mixture of the two acids contaminated with resorcinol.

Metalation of Resorcinol Dimethyl Ether.—A mixture of 0.1 mole of resorcinol dimethyl ether and 0.1 mole of *n*-butyllithium in ether was refluxed for twenty hours. Carbonation, by pouring the mixture jet-wise upon solid carbon dioxide, gave 10 g. (55% yield) of 2,6-dimethoxybenzoic acid melting at 186°. The methyl 2,6-dimethoxybenzoate, prepared by refluxing the silver salt of the dimethoxy acid with methyl iodide, melted at 87°.[9]

A small quantity (0.043 g.) of 2,2′,6,6′-tetramethoxybenzophenone,[4] melting at 204°, was also isolated.

Summary

Metalation by *n*-butyllithium of 2-methoxydibenzofuran gives 2-methoxy-1-dibenzofuryllithium and 2-methoxy-3-dibenzofuryllithium; and metalation of 4-methoxydibenzofuran gives 4-methoxy-6-dibenzofuryllithium and 4-methoxy-3-dibenzofuryllithium. However, metalation of the corresponding phenols gives but one product in each case: 2-hydroxydibenzofuran yielding 2-hydroxy-1-dibenzofuryllithium (as a lithium salt of the phenol); and 4-hydroxydibenzofuran yielding 4-hydroxy-6-dibenzofuryllithium.

In contrast, metalation of resorcinol dimethyl ether gives apparently but one product (2,6-dimethoxyphenyllithium), whereas resorcinol gives the two isomers, 2,6-dihydroxyphenyllithium and 2,4-dihydroxyphenyllithium.

AMES, IOWA RECEIVED JANUARY 15, 1940

Tenth Report of the Committee on Atomic Weights of the International Union of Chemistry

BY G. P. BAXTER (*Chairman*), M. GUICHARD, O. HÖNIGSCHMID AND R. WHYTLAW-GRAY

The following report of the Committee covers the twelve-month period September 30, 1938 to September 30, 1939.[1] Three changes in the table of atomic weights have been adopted:

Hydrogen, from 1.0081 to 1.0080, iron, from 55.84 to 55.85, lutecium, from 175.0 to 174.99.

Hydrogen.—Several investigations of the H^1/H^2 ratio in certain natural waters during the last four years have given values higher than that used in computing the atomic weight of hydrogen for the Table, 5000 (see Eighth Report of this Committee).

	6880

Since with $H^1 = 1.00785$ (chemical scale) and even with $H^1/H^2 = 6000$ the atomic weight of

(1) Authors of papers bearing on the subject are requested to send copies to each of the four members of the Committee at the earliest possible moment: Prof. G. P. Baxter, Coolidge Laboratory, Harvard University, Cambridge, Mass., U. S. A.; Prof. M. Guichard, Faculté des Sciences, Sorbonne, Paris, France; Prof. O. Hönigschmid, Sofienstrasse 9/2, Munich, Germany; Prof. R. Whytlaw-Gray, University of Leeds, Leeds, England.

hydrogen in natural waters becomes 1.0080 this value is adopted for the Table, although the nature of the hydrogen in any compound is bound to be subject to a slight uncertainty.

Chlorine.—Hönigschmid and Hirschbold-Wittner[2] have determined the atomic weight of chlorine in hydrogen chloride samples subjected to isotopic separation by the thermal diffusion method by Clausius and Dickel. Weighed amounts of silver were precipitated with excess acid and the silver chloride was collected and weighed. Vacuum weights are given.

Ag, g.	AgCl, g.	AgCl:Ag	At. wt., Cl
	Heavy fractions		
0.59164	0.78666	1.32963	35.560
.48005	.64450	1.34257	36.956
	Light fractions		
.73019	.96925	1.32739	35.310
.61237	.81188	1.32580	35.147
.58001	.76830	1.32463	35.021
.57969	.76765	1.32428	34.979

If the isotopic weights of the two chief isotopes of chlorine are 36.968 and 34.971 on the chemical scale the separation seems to have been nearly complete.

Iron.—Hönigschmid and Liang[3] have compared ferrous bromide with silver and silver bromide. A solution of Mohr's salt was freed from heavy metals with hydrogen sulfide. After oxidation ferric hydroxide was three times precipitated from acid solution, and the third precipitate was dissolved in sulfuric acid and electrolytically reduced to ferrous sulfate which was recovered by crystallization. Electrolytic precipitation of metallic iron from ammonium oxalate solution followed, and the metallic deposit was dissolved in nitric acid. Carbon was removed by filtration and the ferric nitrate solution evaporated to crystallization. Thermal decomposition to oxide and reduction in hydrogen yielded Sample I. Spectroscopic examination by Gerlach revealed no impurities. The remainder of the ferric nitrate was twice more recrystallized from nitric acid and converted to metal (Sample II).

Synthesis of the bromide was effected by heating the pure metal in a current of dry nitrogen and bromine. The sublimed product was resublimed in pure nitrogen and fused in nitrogen in a quartz weighing tube which could be bottled in dry air. After being weighed the salt was dissolved in very dilute sulfuric acid. The solution was clear and free from ferric salt. After careful oxidation with slightly less than the theoretical quantity of bichromate the solution was compared with silver in the conventional way with the help of a nephelometer. In many of the experiments the silver bromide was collected and weighed. Vacuum weights are given.

The average of all the experiments, 55.850, is slightly higher than that found by analysis of ferrous bromide by Baxter, Thorvaldson and Cobb,[4] 55.838, presumably because the material employed by the latter contained traces of carbon, silica and possibly ferric salt. By reduction of ferric oxide Baxter and Hoover[5] found 55.847, while Hönigschmid, Birckenbach and Zeiss[6] by analysis of ferric chloride obtained the value 55.853.

Recent determinations of abundance ratios with the mass spectrograph, when converted to the chemical scale with the packing fraction -7×10^{-4} (Dempster, *Phys. Rev.*, **53**, 869

(1938)), and the conversion factor 1.000275 give the following values.

	Isotope 54	56	57	58	Mean mass number	At. wt.
de Gier and Zeeman[a]	6.5	90.2	2.8	0.5	55.908	55.853
Nier[b]	6.04	91.57	2.11	0.28	55.906	55.851

[a] *Proc. Roy. Soc. Amsterdam*, **38**, 959 (1935). [b] *Phys. Rev.*, **55**, 1143 (1939).

In view of the evidence the value 55.85 for iron seems more probable than the older one 55.84, and has been adopted for the Table, although the value 55.847 obtained by the most direct method, the reduction of the oxide, might well be looked upon as a maximum owing to the possibility of incomplete reduction.

Molybdenum.—Mattauch and Lichtblau[7] have redetermined the relative abundances of the molybdenum isotopes. In the following table their percentages are compared with those found earlier by Aston. The atomic weight is calculated with the packing fraction -6.0×10^{-4} (Dempster) and the conversion factor 1.000275.

	92	94	95	96	97
Aston	14.2	10.0	15.5	17.8	9.6
Mattauch and Lichtblau	15.5	8.7	16.3	16.8	8.7

	98	100	Mean mass number	At. wt. Mo
Aston	23.0	9.8	95.94[a]	95.86
Mattauch and Lichtblau	25.4	8.6	95.98	95.90

[a] Incorrectly calculated by Aston to be 96.03, *Proc. Roy. Soc.* (London), **A130**, 309 (1931).

Both these values are considerably lower than that obtained by Hönigschmid and Wittner by analysis of molybdenum pentachloride, 95.949, which was adopted for the Table two years ago. (See Eighth Report of this Committee.)

Europium.—Lichtblau[8] has determined the abundance ratio of the europium isotopes, Eu^{151}/Eu^{153}, to be 0.963 ± 0.012. With the packing fraction -2×10^{-4} (Dempster) and the conversion factor 1.000275 the atomic weight of europium is 151.95 ± 0.01. This value for europium agrees far better with that recently found by Baxter and Tuemmler by analysis of europous chloride, 151.96, than with Kapfenberger's recent value, 151.90 (see Ninth Report of this Committee).

Lutecium.—Hönigschmid and Wittner[9] have published details of their analyses of lutecium trichloride, already reported[10]; (see Eighth Report of this Committee). The starting material had been purified by von Welsbach and was identical with that used by him in his determination of the atomic weight. From examination of the X-ray spectrum Noddack estimates a content of 1.18% of ytterbium but no more than 0.04% of any other rare earth. Purification consisted in double precipitation of the hydroxide with solution in hydrochloric acid, double precipitation of the oxalate with subsequent ignition in each case, and double crystallization of the chloride from concentrated hydrochloric acid. The chloride was dehydrated in a stream of dry hydrogen chloride at gradually increasing temperatures finally at 450° and after being weighed was compared with silver in the conventional way. The silver chloride was determined in some cases. Vacuum weights are given.

The authors prefer the result of the former method of analysis, 174.966. Corrected for the ytterbium content this becomes 174.986.

Mattauch and Lichtblau,[11] with the mass spectrograph, find a new isotope of lutecium of mass number 176, to the extent of 2.52%. With the packing fraction $+1 \times 10^{-4}$ (Dempster) and the conversion factor 1.000275 the atomic weight of lutecium is 174.994, in close agreement with that found by Hönigschmid and Wittner.

The value 174.99 is adopted for the Table in place of the older value 175.0 which depends on von Welsbach's analysis of the sulfate.

Lead.—Nier[12] has determined the abundance ratios of the lead isotopes in twenty-one speci-

mens of radiogenic lead, and has computed the atomic weights of these specimens using the packing fraction $+1.55 \times 10^{-4}$ and the conversion factor 1.000275. While in most cases the agreement between the atomic weights found in this way and those which had been determined chemically is fair, in some cases considerable discrepancies appear. If Dempster's packing fraction for lead, $+2.3 \times 10^{-4}$, is used the agreement is far less satisfactory. The latter is also true for the results obtained by Nier with common lead (see Ninth Report of this Committee).

NOTES

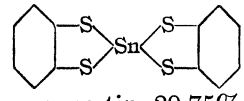
A Tin Derivative of Dithiocatechol

By Harold P. Brown and James A. Austin

In the preparation of dithiocatechol from *o*-benzenedisulfonyl chloride by reduction with tin and hydrochloric acid, Guha and Chackladar[1] obtained a red solid, which they supposed to be the lactone of benzene-1-thiol-2-sulfonic acid. Hurtley and Smiles[2] prepared dithiocatechol from the *o*-benzenedisulfonyl chloride by reduction with zinc dust and acid in the presence of alcohol and avoided the formation of the red solid. Repetition of the procedures described by both of these groups of workers verified the results which they had obtained. However, we cannot agree with the supposition of Guha and Chackladar with regard to the structure of the red solid which they obtained, but have found that it is a tin mercaptide.

The mercaptide can be obtained from the reaction of stannic chloride with dithiocatechol. Also, the same product is obtained when stannous chloride solutions in contact with air react with dithiocatechol. The completeness of the reaction suggests the possible application of dithiocatechol to qualitative and perhaps quantitative determination of tin and certain other elements. Among the other metallic ions which have been found to react with the dithiocatechol are antimony, zinc, ferric ion, lead and thallium. The analytical possibilities of the reagent are being investigated.

When *o*-benzenedisulfonyl chloride is added gradually to a boiling mixture of tin and excess concentrated hydrochloric acid, a red solid soon appears. If the reaction mixture be distilled during the process of reduction, the formation of this red solid is minimized and oily droplets of dithiocatechol distil from the reaction mixture. However, sufficient tin chloride often carries over with the distillate to cause the formation of red solid particles. The use of a large excess of concentrated hydrochloric acid in the reducing media promotes the decomposition of the red solid. Redistillation of distillate containing the red solid from concentrated hydrochloric acid yields pure dithiocatechol. The red mercaptide is insoluble in dilute mineral acid but soluble in alkali. When placed in concentrated hydrochloric acid, the color of the compound disappears and dithiocatechol separates. Addition of water or of alkali to the acid restores the color and precipitates the tin mercaptide. The solubility of the compound in alkali is similar to the solubility of stannic sulfide in alkali. The compound gradually darkens but does not melt below 250°. No traces of divalent tin could be detected in the compound. When stannous chloride reacts with dithiocatechol a yellow solid forms which may be a stannous mercaptide, but this is completely converted to the red stannic mercaptide by contact with air. A sample of the red complex obtained by the reduction of *o*-benzenedisulfonyl chloride with tin in concentrated hydrochloric acid was purified by dissolving in 4 *N* sodium hydroxide, filtering, reprecipitating with hydrochloric acid and drying at 110°. Analysis was accomplished by means of sodium peroxide fusion in a Parr bomb, the tin being precipitated from the alkali fusion mixture as stannic acid by means of nitric acid. The sulfur was precipitated from the filtrate as barium sulfate after elimination of the nitric acid. Analysis showed 29.44% tin and 31.88% sulfur. These values are in accord with the proposed structure



for which the calculated values are tin, 29.75% and sulfur, 32.14%.

Auto-Metalation with *m*-Tolylsodium

By Henry Gilman and H. A. Pacevitz

After carbonation of a reaction mixture of di-*p*-tolylmercury, sodium and benzene which had been allowed to stand for one month, Bachmann and Clarke[1] isolated benzoic acid (34%), *p*-toluic acid (30%) and phenylacetic acid (0.36%). The formation of phenylacetic acid establishes the migration of sodium from *p*-tolylsodium to benzyl-

(1) Bachmann and Clarke, This Journal, **49**, 2096 (1927); see also, Ziegler, *Angew. Chem.*, **49**, 455 (1936).

sodium, and is an interesting variation of the lateral metalation of toluene by ethylsodium which was first examined by Schorigin.[2]

Incidental to studies on interconversions by organometallic compounds, we have investigated procedures for the preparation of organoalkali compounds, particularly the benzylmetallic types.[3] One of the more interesting results is the conversion of *m*-tolylsodium to benzylsodium. *m*-Chlorotoluene and sodium in petroleum ether first give *m*-tolylsodium, as evidenced by the formation of *m*-toluic acid (free of phenylacetic acid) on carbonation. On refluxing the mixture, the *m*-tolylsodium is converted to benzylsodium. In the Bachmann–Clarke[1] migration with *p*-tolylsodium one may be dealing with an allylic rearrangement of the kind frequently observed with a variety of organometallic compounds. However, with *m*-tolylsodium it is difficult to account for the migration on the basis of an allylic rearrangement. Although mechanisms have not been proposed for the migrations cited, it is probable that the meta and para transformations proceed by different routes, if the relative rates of migration are criteria.

Experimental

A mixture of 12.7 g. (0.1 mole) of *m*-chlorotoluene, 5.7 g. (0.25 g. atom) of sodium sand and 100 cc. of petroleum ether (b. p., 85–100°) was heated to reflux temperature and then promptly cooled to room temperature. The reaction then proceeded spontaneously, and the temperature was kept between 35–40°. After two hours, the reaction mixture was black, and the evolution of heat ceased. Carbonation of an aliquot of the mixture by solid carbon dioxide yielded *m*-toluic acid as the only acid.[4] The remaining mixture was refluxed for six hours and then carbonated by pouring upon crushed solid carbon dioxide. From the resulting acids there was isolated a 5.3% yield of phenylacetic acid (mixed m. p.), but no *m*-toluic acid or phenylmalonic acid. A small quantity of clear, oily acidic material has not yet been identified.

With a twenty-hour period of refluxing, the yield of phenylacetic acid was 4.7%. However, with only a one-hour period of refluxing the yield of phenylacetic acid was 8.3%. It should be stated that carbonation after heating a mixture of *p*-chlorotoluene, sodium and petroleum ether yielded 65% of phenylacetic acid.[3]

(3) A detailed report on these studies by the authors together with Dr. Ogden Baine will be published shortly. An account of the reactions and their mechanisms was presented at the Eighth National Organic Symposium, St. Louis, Dec. 30, 1939.

(4) In a separate experiment where carbonation of the entire mixture was effected at this point, the yield of *m*-toluic acid was 84%.

Preparation of Borneol Glucuronide

BY HARVEY K. MURER AND LATHAN A. CRANDALL, JR.

We have had good success in the isolation of the zinc salt of borneol glucuronide by the method of Quick[1] and Pryde and Williams[2] from the urine of dogs fed borneol provided care is taken in the proper adjustment of acidity previous to the lead clarification of the urine.

In their preparation of the free glucuronide the zinc salt was dissolved in hot 3.4 *N* sulfuric acid, filtered and allowed to crystallize from the hot solution. The glucuronide was filtered off and washed with ice water and recrystallized from hot water for further purification. It is difficult to filter and wash this product in water, and several recrystallizations are necessary to obtain a pure product with subsequent loss in yield. Also uronic acids are destroyed by hot acid of this strength and some hydrolysis of the glucuronide takes place, giving rise to the difficulty of removing borneol from the product.

To avoid these difficulties the removal of the zinc was first attempted with hydrogen sulfide. The zinc salt was suspended in acetone. A slow but fairly good removal of zinc was accomplished but the product retained a strong odor of sulfide after several purifications from acetone.

The above use of acetone led to a simple method which has given good results in the preparation of large quantities of borneol glucuronide of good purity.

Two hundred grams of dry zinc borneol glucuronide is added with stirring to 800 ml. of warm acetone containing 14.7 ml. of concentrated sulfuric acid. The zinc sulfate and any unreacted zinc salt are easily centrifuged down and the clear acetone solution decanted. The centrifuge flasks and precipitate are washed once with 50 to 100 ml. of warm acetone, centrifuged and the clear solution added to the original. Fifty ml. of water is added to the acetone solution to allow for crystallization of the hydrate and to keep traces of zinc sulfate in solution. Crystals of fine needles will set the solution almost solid at room temperature. The product is filtered with suction, washed with cold acetone, and vacuum dried at 40°. The filtrate is easily concentrated and again cooled for crystallization without further addition of water, filtered and washed as before. A still

further small amount of pure product may be obtained by a third crystallization of the filtrate. Unreacted zinc salt and remaining glucuronide in the washings may be recovered by dissolving the sludge in hot acidified water, adding an excess of zinc acetate and recovering the insoluble salt by filtration.

Attempts to find some more suitable method for the hydrolysis of borneol glucuronide than the acid hydrolysis suggested by Quick for the preparation of glucuronic acid have not been successful. B-Emulsin will hydrolyze considerable quantities of glucuronide; however, the reaction rate is slow, the equilibrium poor for preparation purposes, and the high acidity produced by the free glucuronic acid destroys emulsin, necessitating continued addition of the enzyme. This last step therefore is the limiting one in the preparation of glucuronic acid by Quick's method.

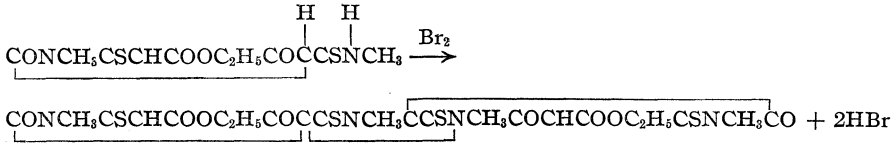
The Action of Methyl Isothiocyanate on Ethyl Acetonedicarboxylate

BY DAVID E. WORRALL

The highly substituted derivatives of piperidine obtained ultimately by the action of aryl isothiocyanates on the sodium enolate of ethyl acetonedicarboxylate undergo further cyclization, in the presence of bromine, into piperidyl benzothiazoles.[1] An examination of similar reactions with an alkyl isothiocyanate has shown that a piperidine is formed which also loses a molecule of hydrogen. Thiazole formation is impossible, therefore the assumption has been made that a spiro piperazine is obtained as the result of a bimolecular condensation.



(1) Worrall, THIS JOURNAL, **61**, 2967 (1939).

Abenius[2] found that a reaction of this type occurs with the bromoacetyl derivative of aniline.

Experimental

1 - Methyl - 2,4 - dioxo - 5 - carbethoxy - 6 - sulfopiperidine-3-thioformomethylamide.—Using the customary technique, 0.1 g. mole of the ester was changed into the disodium derivative and mixed with two equivalents of methyl isothiocyanate. The mixture, after the spontaneous reaction subsided, was heated for an hour and decomposed in the usual manner. The pasty product was extracted with cold alcohol and the residue crystallized from alcohol. Bright yellow platelets resulted, m. p. 98°, yield 4–5 g.

Anal. Calcd. for $C_{11}H_{14}N_2O_4S_2$: C, 43.7; H, 4.6. Found: C, 43.6; H, 4.5.

The substance, soluble in sodium carbonate solution is reprecipitated unchanged by a strong acid. Hot acid changes it into an intractable tar, while boiling with alcoholic potash produces methylamine, hydrogen sulfide and other decomposition products. The original material contained an insoluble portion (0.3 g.) that separated from a large volume of alcohol in slender pale yellow needles, m. p. 235–236°. An analysis indicated the formula $C_{18}H_{14}N_4O_5S_4$, but it was not identified.

1 - Methyl - 2,4 - dioxo - 5 - carbethoxy - 6 - sulfomethoxypiperidine-3-thioformomethylamide.—The product, obtained by heating 1 g. of the amide with methyl iodide–ethyl alcohol mixture for thirty minutes, separated on cooling as slender colorless needles, m. p. 110°.

Anal. Calcd. for $C_{12}H_{16}N_2O_4S_2$: C, 45.6; H, 5.1. Found: C, 45.3; H, 5.0.

Di - spiro - 3,3' - di - (1 - methyl - 2,4 - dioxo - 5 - carbethoxy - 6 - sulfopiperidine) - 3'',3''' - (1,4 - dimethyl - 2,5-disulfopiperazine).—Bromination of 1 g. of the amide in glacial acetic acid formed a precipitate that, after heating on a water-bath for a short time, was crystallized from alcohol. Cream colored needles separated, m. p. 180°.

Anal. Calcd. for $C_{11}H_{12}N_2O_4S_2$: C, 44.0; H, 4.0. Found: C, 43.6; H, 3.9.

It is dissolved by cold concd. sulfuric acid, forms a gelatinous substance with hot alcoholic potash (probably the corresponding carboxy derivative) and is only slightly attacked by long heating with concd. hydrochloric acid.

COMMUNICATIONS TO THE EDITOR

THE GELATION OF MAGNESIUM SILICATE SUSPENSIONS BY CARBON DIOXIDE AND OTHER AGENTS

Sir:

Several months ago, in the course of some experiments with precipitated and washed silicates of magnesium, we observed that the passage of carbon dioxide through fluid suspensions of these silicates in water soon caused the suspensions to "set up" or gel. The resulting gels were found to be thixotropic,[1] that is, capable of an isothermal, reversible sol-gel transformation, being liquefied on shaking and setting spontaneously.[2]

Thus, within one and one-half minutes following the treatment of 10 cc. of an 8.1% suspension of MgO, $1.6SiO_2$ (*p*H 9.3) with a rapid stream of carbon dioxide for one-half minute, the originally fluid suspension had "set up," so that the test-tube (16 by 150 mm.) containing it could be inverted without flow taking place. Vigorous shaking of the solidified material (*p*H 7.2) produced liquefaction; upon standing undisturbed, spontaneous reversion to the gel state occurred in less than a minute. The process could be repeated indefinitely.

Similar observations were made with suspensions of MgO, $1.1SiO_2$ (6.1%) and MgO, $3.6SiO_2$ (8.4%).

The magnesium silicates were prepared by slowly adding water solutions of various silicates of sodium to water solutions of magnesium sulfate,[3] with vigorous stirring. The resulting precipitates were collected and washed in a filter press,[4] and portions of the wet products[5] were ground with water for a few minutes in a mortar to yield the rather coarse suspensions which, after vigorous shaking, were employed in the above experiments.

More recently, we found that hydrochloric acid, sulfuric acid, or acetic acid, in small amounts, could be substituted for carbon dioxide in the above experiments, to give similar results. Thus, following the addition of 0.1 cc. of *N* hydrochloric acid (0.0004 mole) to 10 cc. of an 8.1% suspension of MgO, $1.6SiO_2$ (0.006 mole; *p*H 9.3), contained in a 16 by 150-mm. test-tube, gelation occurred in about half a minute. The setting time of the thixotropic product (*p*H 7.7) was less than fifteen seconds. Further work along these lines is in progress.

Aside from its scientific interest, the present phenomenon may find some application in the arts.[6]

REDUCTION OVER A RANEY CATALYST OF THE ESTERS OF α-AMINO ACIDS TO CORRESPONDING ALKAMINES

Sir:

P. L. de Benneville and Ralph Connor report [THIS JOURNAL, **62**, 283 (1940)] on the reduction of an ester to an alcoholic group by the aid of a nickel catalyst. This is regarded by the authors as the first instance of such a reaction.

We wish to report that within the last two years we have carried out the reduction over nickel catalyst (Raney) of the esters of α-aminoacids to the corresponding alkamines. The reaction was successfully carried out on the esters of leucine ethyl ester, of aminophenylacetic acid ethyl ester and of phenylalanine ethyl ester. In the case of the ester of *l*-leucine and of *levo*-phenylaminoacetic ethyl ester, the alkamines were obtained in active form. Depending on conditions of the reaction, it was possible to obtain from the ester of phenylaminoacetic acid either 2-phenyl-2-aminoethanol, or 2-cyclohexyl-2-aminoethanol. Under still other conditions it was possible to obtain from the esters corresponding secondary amines. Also, condensation to piperazine takes place over nickel (Raney) catalyst. The primary and the secondary amino groups may remain unsubstituted or alkylated, depending upon conditions of the reaction.

In the present note we report the analytical data of the alkamines only. The smallest yield of the active leucinol is 40% of the theoretical and the smallest yield of the phenylaminoethanol is 60%. The yields undoubtedly could be improved on working with larger quantities.

NEW BOOKS

Ausführliches Lehrbuch der organischen Chemie. (Comprehensive Textbook of Organic Chemistry.) Vol. II. By WILH. SCHLENK. Verlag von Franz Deuticke, Helferstorferstrasse 4, Wien I, Germany, 1939. xvii + 896 pp. 11 figs. 17.5 × 26 cm. Price, RM. 30; bound, RM. 33. (Vol. I, now RM. 30; bound, RM. 33.)

This second volume of a contemplated three, the last of which according to the author will appear soon, covers the chemistry of the carbocyclic aromatic compounds. The first volume, published in 1932, was devoted to aliphatic chemistry and the third presumably will describe the heterocyclic compounds.

This publication when complete will be the most extensive modern textbook in organic chemistry available in any language. About 1600 pages have been consigned to aliphatic and aromatic chemistry. Since this work approaches more closely than any other the "Lehrbuch der organischen Chemie" by V. Meyer and P. Jacobson, a comparison is pertinent. Both works are presented in essentially the same style. Meyer and Jacobson, however, include a multitude of original references and devote much space to a description of the physical and chemical properties not only of the basic compounds but of their more important derivatives. Schlenk omits these and consequently is able to include in considerably less space the same amount of textual material. This publication, thus, becomes more literally a textbook from which a reader may acquire many of the important facts about any class of organic compounds, organic theories or mechanisms of reaction. It is not intended as a reference work for the investigator. In view of the ever-broadening scope of organic chemistry, Schlenk's plan appears to the reviewer to be the more feasible since the research man must of necessity search the original literature; such a text as this will supply him with general information about any class of compounds with which he happens to be less familiar.

Each class of aromatic compounds is systematically discussed. The theoretical considerations are correlated with the description of those substances which have been studied most in developing a theory or mechanism. Thus, the theories on the orientation of substituents introduced into the benzene nucleus are given in the chapter on benzene and its simple derivatives; the Fries rearrangement under the discussion of phenol esters and ethers; restricted rotation under biphenyls and the use of oxidation–reduction potentials under quinones, etc. The theoretical discussions are concise and give the reader sufficient information to understand the subjects.

These three volumes should serve admirably as an advanced text of organic chemistry for the student who is beyond the first year of study in this subject as well as for the research man who always requires general reading

in fields outside of his specialty if he is to retain his breadth of knowledge in organic chemistry. They should be a valuable addition to chemical libraries especially to those which are limited in scope. Beyond a text like this, the organic chemist must use monographs, advanced books on special topics or the original literature.

The material presented is entirely up-to-date. The book is well printed, readable and contains a minimum of typographical errors. It can be recommended highly to the organic chemist.

ROGER ADAMS

A Text-Book of Quantitative Inorganic Analysis. Theory and Practice. By ARTHUR I. VOGEL, D. Sc. (Lond.), D.I.C., F.I.C. Head of Chemistry Department, Woolwich Polytechnic: Lately Beit Scientific Research Fellow of the Imperial College. Longmans, Green and Company, 114 Fifth Avenue, New York, N. Y., 1939. 856 pp. Illustrated. 14.5 × 22.5 cm. Price, $5.00.

The author states, in his preface, that this book is designed as a text of quantitative inorganic analysis, theory and practice, to meet the needs of University and College students preparing for the various higher examinations in British universities and colleges.

Besides an appendix of data, the book consists of six chapters, on the theory of quantitative analysis, on experimental technique, and on volumetric, gravimetric, colorimetric and gas analysis. The chapter on theory appears to be adequately presented, the material including topics which are similarly treated in other modern texts on the subject. Emphasis is naturally on solutions. Chapter 2 on technique, has to do with apparatus, reagents and operations. The four chapters on analytical methods are unusually complete for a book of this type and really give it the character of a reference book. For instance, there are four methods given in detail for determining fluorides, and ten for antimony, to mention merely two cases taken at random. One more chapter, on quantitative calculations, particularly in volumetric analysis, would save much repetition in discussing volumetric methods.

References to the literature are not frequent and when given are by author and year without the journal reference, which is inconvenient for the reader. The very full cross-references in the book are to chapter, section and paragraph, with no page number given, which is so inconvenient as to be irritating. This system is an old one, but fortunately most writers have discarded it. There is the same tendency in this book as in many others to consider that the one consideration in analysis is accuracy and that time is not a factor. For instance, in igniting a precipitate with its filter paper, the student is told (p. 272) that it usually takes about twenty minutes to char the paper, and from thirty to sixty minutes to complete an ignition. Again in determining a sulfate as barium sulfate in a Gooch crucible, the student is told (p. 482) to ignite the precipitate for periods of fifteen minutes until constant weight is obtained. These, however, are all minor points. Taken as a whole, the author has produced a very good book indeed, and it will be useful both to beginners as well as to others who use it as a work of reference.

H. W. FOOTE

Physikalische Methoden der analytischen Chemie. Dritter Teil. (Physical Methods of Analytical Chemistry, Vol. III.) Edited by W. BÖTTGER. Akademische Verlagsgesellschaft m. b. H., Leipzig, Germany, 1939. xx + 836 pp. 42 figs. Price, RM. 63; bound, RM. 65.

In this third instalment of Volume III, Professor Böttger, the Editor, has brought the presentation of the whole subject up to date; first, by supplementary chapters covering the fields already discussed in Volumes I and II of this handbook which appeared in 1932 to 1936 and, second, by the addition of further chapters devoted to new physical methods of analysis which have arisen or have become important in the interim.

To the first group belong the chapters on Spectroscopic Analysis, Chemical Analysis by Means of X-Rays, Conductometric Titration, Applied Conductivity, Polarographic Analysis and Potentiometric Analysis. To the second group belong the chapters on chromatographic analysis, as applied both to organic and inorganic chemistry, the rapid analysis of inorganic compounds, particularly metals, by vaporization, analysis by means of Raman spectra and photometric methods of analysis.

The supplementary chapter on Polarographic Analysis consists of a complete bibliography of the new publications in this field between 1936 and 1938. The other supplementary chapters present unified and up-to-date discussions of their particular fields. The chapter on Potentiometric Analysis (282 pages) by Professor Böttger is especially thorough, illuminating and complete.

The chapters on the newer fields are, of course, particularly interesting. The striking results obtained by chromatographic analysis, the simple and rapid separation of metals from complicated alloys and minerals by evaporation, and the rapidity with which Raman rays have been utilized for analytical purposes are certainly impressive and inspiring.

The book will not only interest chemists in general but it will be very useful to those specializing in the fields which it discusses.

ARTHUR B. LAMB

Kurzes Lehrbuch der physikalischen Chemie. (Brief Textbook of Physical Chemistry.) By Prof. Dr. KARL JELLINEK, Emeritus Professor at the Technical Institute of Danzig. Heft 2 (Volume 2). N. V. Uitgevers-Maatschappij AE. E. Kluwer, Deventer, Holland, 1939. xii + 292 pp. 149 figs. 29 tables. 16 × 25 cm. Price, 7.50 Dutch fl.

Part 1 of Professor Karl Jellinek's 4-part brief, elementary textbook of physical chemistry already has been reviewed (THIS JOURNAL, **61**, 1298 (1939)). The present paper-bound section is Part 2 of the text; Parts 3 and 4 are promised for publication soon.

The same fine tone of clear explanation which characterized Part 1 is maintained here; and again the author presents a very extensive and helpful set of problems which are worked out in the body of the text as a part of the exposition. The subject matter is broken down in the different chapters and classified in a highly sub-divided, and quite logical, outline. An idea of the broader groupings of the discussion may be obtained from the following list:

Electrochemistry—A. General properties of solutions of electrolytes; B. Phenomena connected with reversible electrode potentials; C. Chemical equilibria in electrolytes; D. Chemical equilibria in fused salts; Phase Rule—A. Systems containing a single substance; B. Binary systems; Colloid Chemistry—A. Uncharged boundary surfaces; B. Electrically charged surfaces; C. Systems of abnormally large surface area; D. Formation of new phases; Chemical Kinetics—A. Homogeneous systems; B. Heterogeneous systems; C. Irreversible electrode potentials, and electrode reactions.

EDWARD MACK, JR.

A Textbook of Inorganic Chemistry for Colleges. Second edition. By JAMES F. NORRIS, Professor of Organic Chemistry, and RALPH C. YOUNG, Assistant Professor of Chemistry, Massachusetts Institute of Technology. McGraw-Hill Book Company, Inc., 330 West 42nd Street, New York, N. Y., 1938. x + 803 pp. 33 figs. 14.5 × 21 cm. Price, $3.75.

Inorganic Chemistry by Norris and Young is a well written and, for undergraduate work, a fundamental and comprehensive treatise of the subject. The tabulation of properties of the elements and compounds at the beginning of each chapter is a distinct improvement, in that it saves space and gives at a glance the information desired. The book, to my mind, is somewhat lacking in drawings and illustrations of commercial processes, which, I think, tends to increase interest.

J. P. SIMMONS

Physiological Chemistry. A Text-Book for Students. By ALBERT P. MATHEWS, Ph.D., Andrew Carnegie Professor of Biochemistry, The University of Cincinnati. Sixth edition. The Williams and Wilkins Co., Mount Royal and Guilford Avenues, Baltimore, Maryland, 1939. xvi + 1488 pp. 113 figs. 16 × 23.5 cm. Price, $8.00.

The sixth edition of Mathews' text-book has been extensively revised and enlarged. The section on practical methods has been omitted; there has been a rearrangement of some of the chapters, and the book has been set in a clearer type. The new typography accounts for an increase in number of pages of approximately 18% over the fifth edition of 1930. A rough calculation suggests that about 350 pages of new text have been added exclusive of the apparent increase due to the resetting.

The book is intended for the use of medical students and of graduate students and, as in earlier editions, the emphasis is placed on the functions of the organs of the animal body. These functions are discussed so far as possible in terms of chemical reaction. The fundamental chemistry of the carbohydrates, lipides, and proteins is described in the first eleven chapters (450 pages), the remaining two-thirds of the book being devoted to the consideration of the body as a mechanism. Blood is dealt with in seven chapters (177 pages), foods and digestion in four (218 pages), and metabolism in three (106 pages). In addition there are chapters on animal heat, brain and nerve tissue, muscle, connective and supporting tissues, skin, endocrine glands, excretions and vitamins.

The material in general is presented from a broad philosophical point of view; there is not too much insistence on details and the relationship of the separate functions to the whole organism is constantly kept before the reader. Nevertheless it is unfortunate that so much discussion from earlier editions, even from the first edition of 1915, has been retained unchanged. Statements that were at one time entirely proper are apt to lead to confusion in the mind of the student when they are placed in juxtaposition to more recently acquired knowledge, and phraseology that would indicate that many of these earlier conclusions have now only an historical significance is usually omitted. The teacher is faced with the task of pointing out to students what is authoritative and new and what has today been superseded.

The chapter on proteins (Chapter X, pp. 294–364) may be used to illustrate the worst features of this book. As a presentation of the present position of our knowledge of the proteins, this chapter is entirely inadequate. The section on nucleic acid and nucleoproteins, which formed a part of the chapter on proteins in earlier editions, now appears, with minor additions, as Chapter VI. Most of what remains in Chapter X has been transferred unchanged from the fourth edition of 1925, and much of this material was written for the first edition of 1915. A comparison page by page with the fourth edition shows that only about 8 pages of new material have been included. The advances in protein chemistry of the last 14 years are thus presumably dealt with in these 8 pages. Study of the text shows, however, that many of the additions consist merely of a sentence added to an older paragraph.

In the discussion of the molecular weight of proteins, Hüfner and Gansser's pioneering osmotic pressure studies of 1907 are fully described but no mention is made of Sörensen's and of Adair's demonstrations of the fundamental errors in this early work although these contributions appeared upward of 20 years ago. The work of Svedberg's laboratory which has appeared since 1926 is dismissed with four lines of text in which the ultracentrifuge is referred to as a super-centrifuge, and the page and a half of new text on molecular weights contains statements some of which contradict those made on preceding pages. No mention is made of modern diffusion methods nor of recent stoichiometric accomplishments and a student might well be left in a state of considerable misapprehension of what is now known of the molecular weights of proteins.

The list of "kinds of amino acids found in proteins" (pp. 310–312), newly prepared for the sixth edition, contains 31 entries. The inclusion in such a list of γ-hydroxy-α-aminobutyric acid (in canavalline), of citrulline, canavanine, prolysine and still more of the betaine ergothioneine is open to grave question. Some of these substances do in fact occur in plant tissues and one has been found in blood. They are related to the protein amino acids in a most interesting way and doubtless have metabolic significance which should be pointed out; but they have not yet been "found in proteins."

The best features of the book may be illustrated by the chapter on vitamins (Chapter XXXIV, pp. 1347–1428).

This has been entirely rewritten for the new edition and contains only about 4 pages of text from the fifth edition. It is complete, authoritative, and for the most part thoroughly accurate. One might question the failure to mention the share that Osborne and Mendel had in the discovery of vitamin A in 1914, particularly when a diagram from their paper is introduced to illustrate statements made about the work of McCollum and Davis that appeared only a few weeks earlier. But this is a minor omission. The chapter as a whole gives the present status of our knowledge of the vitamins clearly and succinctly.

Other chapters occupy an intermediate position. Some, like that on endocrine glands (Chapter XXIX, pp. 1055–1141), have been very extensively revised and enlarged; others, like that on animal heat (Chapter XII, pp. 462, 502), merely contain a few pages of additional material. On the whole, however, it may be said that the task of bringing this edition up to date has been taken seriously and has been performed with a considerable degree of success.

The bibliographies attached to each chapter are well-chosen but are in urgent need of revision. It is a serious defect that no consistent style of abbreviation of journal names is employed in spite of the inclusion of a list of abbreviations on p. xv; for example, seven different ways of expressing the name of THIS JOURNAL were noted. Furthermore, there is no consistency in the order in which volume number, page, and date are presented nor in the typographical style in which the references are classified. Several ambiguous references were found. This is not a good example to students who may one day be faced with the problem of preparing a bibliography in a style acceptable to the editor of a journal.

Mathews' text has long been held in high esteem by teachers and investigators alike as a source of stimulating ideas. It must, however, be read with careful discrimination since speculation on the meaning of various relationships is so frequently introduced. The distinguished author expressed the hope in the first edition that the book would raise more questions than it answered; there seems little doubt that this is still true of the latest edition.

Measurement of the Heat Capacity of a Small Volume of Liquid by the Piezo-thermometric Method.[1] I. Apparatus for Measuring $(\partial T/\partial P)_S$ and Results for Benzene and Toluene

BY JOHN S. BURLEW[2]

The Piezo-thermometric Method

Precise measurements of the heat capacity of pure organic liquids at frequent intervals over a wide range of temperature are of prime importance in the formulation and testing of a comprehensive theory of the liquid state. In order that compounds difficult and expensive to prepare may be highly purified before use in such an investigation, small samples are desirable. Adiabatic calorimetry, which heretofore has been the most precise method of measuring the heat capacity of liquids, requires a fairly large sample, especially if the heating interval is small, which it should be if the results are to be of any value whatever. The method described in the present series of papers was developed for the purpose of measuring precisely and conveniently the heat capacity of only 5 ml. of a liquid over a wide range of temperature using a cooling interval of 0.4°.

This method involves two independent sets of measurements for the evaluation of the two differential coefficients in equation (1)[3] at the same

$$c_p = T\frac{(\partial V/\partial T)_P}{(\partial T/\partial P)_S} \qquad (1)$$

absolute temperature T. For convenience in reference, I call it "the piezo-thermometric method" because the two principal measurements in the determination of the adiabatic temperature–pressure coefficient $(\partial T/\partial P)_S$ are those of pressure and temperature. Although this quantity is a derivative, it must be measured as the quotient of a finite change of temperature by a finite change of pressure. The coefficient of thermal expansion $(\partial V/\partial T)_P$ is obtained by differentiation of an empirical equation used to express measured values of the specific volume of the liquid as a function of temperature.

Joule[4] had used equation (1) as the basis of an experimental verification of the second law of thermodynamics. Although several later experimenters measured $(\partial T/\partial P)_S$ of various substances at relatively high pressures, only in recent years has it been measured in order to determine c_p of a liquid. Dixon and Rodebush[5] measured

(1) The application of this method to a small volume of liquid was described first in a dissertation accepted by The Johns Hopkins University in partial fulfillment of the requirements for the degree of Doctor of Philosophy, June, 1934. The next year the apparatus was rebuilt at Yale University, and certain refinements were made in it. The apparatus and technique as herein described are those that were used at Yale University. They were described before the Division of Physical and Inorganic Chemistry at the New York Meeting of the American Chemical Society, April 26, 1935.

(2) Sterling Fellow in Chemistry, Yale University, 1934–1936; present address: Geophysical Laboratory, Washington, D. C.

(3) The units in equation (1) are: c_p (the heat capacity) in decijoules per degree per gram, $(\partial V/\partial T)_P$ in cubic centimeters per degree per gram, and $(\partial T/\partial P)_S$ in degrees per bar. For the derivation of this equation from the first and second laws of thermodynamics, see G. N. Lewis and M. Randall, "Thermodynamics," McGraw-Hill Book Co., Inc., New York, 1923, eq. 25, p. 137.

(5) A. L. Dixon and W. H. Rodebush, THIS JOURNAL, **49**, 1162 (1927).

$(\partial T/\partial P)_S$ of molten sodium, potassium, and lead; and Richards and Wallace[6] measured $(\partial T/\partial P)_S$ of five organic liquids. Then they computed c_p, using values of $(\partial V/\partial T)_P$ taken from the literature. In neither case was an effort made to use small samples.

An apparatus for the measurement of $(\partial T/\partial P)_S$ of 5 ml. of a liquid is described in the present paper; and a new type of weight dilatometer for the measurement of $(\partial V/\partial T)_P$ of this same quantity of liquid is described in the one[7] that follows. The values of the heat capacity resulting from a combination of the data obtained with these two pieces of apparatus in the case of benzene and of toluene are given in a third paper.[8]

Apparatus

Pressure System.—The manner of controlling and measuring the pressure is illustrated in Fig. 1. Compressed nitrogen was stored at convenient working pressures in a gas bottle (volume, 400 ml.), to which was connected a pressure distributor supported by cross-bars 7 cm. above the surface of the oil in a thermostat. The bomb (Fig. 2) that contained the piezo-thermometric cell was suspended in the thermostat by a short pipe by means of which it was connected to the under side of the pressure distributor. The release of pressure was very quick because the bore of this pipe was 6 mm. and the holes in the hollow-stem release valve were 3 mm. in diameter. A handle on the release valve enabled it to be opened by a single rapid motion of the operator's hand.

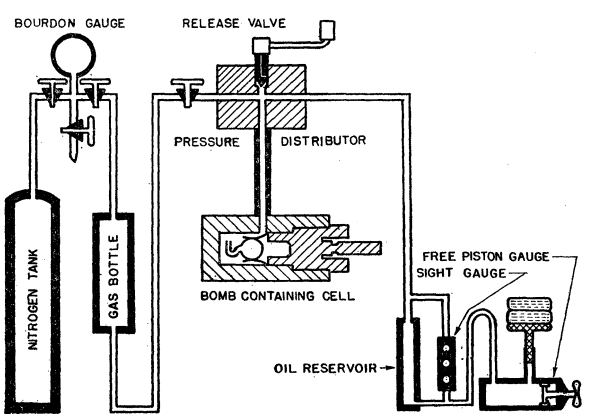

Fig. 1.—Pressure system of the piezo-thermometric apparatus (schematic).

A fourth connection from the pressure distributor led to a free piston gage[9] through an oil reservoir (volume, 50 ml.) and a U-trap. These accessories were needed in order to prevent nitrogen from blowing past the shallow layer of oil[10] in the cylinder of the gage. The level of oil in the reservoir could be adjusted by means of a screw, and the slight hydrostatic pressure from it could be measured to ±1 millibar by means of a sight gage.

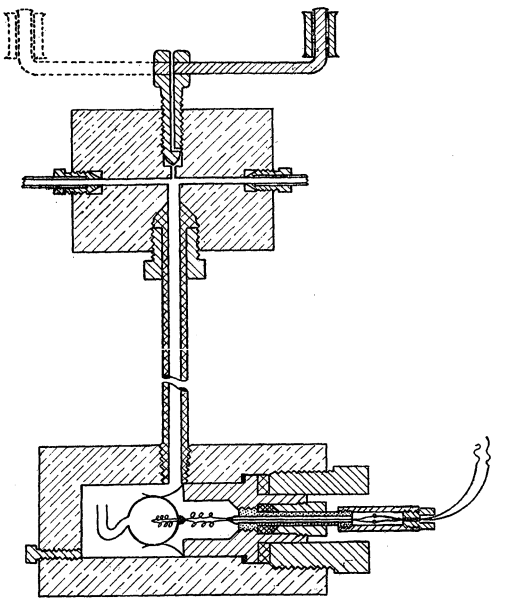

Fig. 2.—Piezo-thermometric cell in bomb attached to pressure distributor (scale, 1/4).

The nominal multiplier ratio of the free piston gage was 16:1. A measurement of the piston diameter with a micrometer agreed with this value within the manufacturer's tolerance limits of ±0.1%. The corresponding gage constant for local gravity in New Haven (980.28 cm./sec.²) was 2.431 bars per kilogram, and its probable error was assumed to be ±0.05%, half the tolerance limits. When the temperature of the gage changed 4.5°, the gage constant changed 0.01%. For the few measurements during which the temperature of the gage differed this much from ordinary room temperature (21°), a correction was applied to the observed pressure.

The masses of the weights were determined in terms of a 100-g. weight that had been calibrated at the Bureau of Standards. As a result of the calibration the mass of each weight was known with a maximum uncertainty of ±0.001%. The height at which the weights were rotated was kept the same in all experiments.

Thermostat.—The fluctuations of the temperature of the 65-liter oil-bath in which the piezo-thermometric bomb was immersed had to be less than ±0.005° in order not to interfere with the measurement of $(\partial T/\partial P)_S$. This degree of regulation was obtained by means of an intermittent bare nichrome heater that was controlled by a thermoregulator made of a long glass tube wound in a helix around a central U-tube and filled with xylene and mercury. Sticking in the capillary was prevented by having the electrical contact with the mercury made at a

point of tangency[11] of a bent piece of No. 32 nichrome wire.

A heater wrapped on the bomb pipe just above the surface of the oil was used to block off heat leak. Without the heater the leak was so great that at 80° the bomb could remain indefinitely at a temperature 1° lower than that of the thermostat.

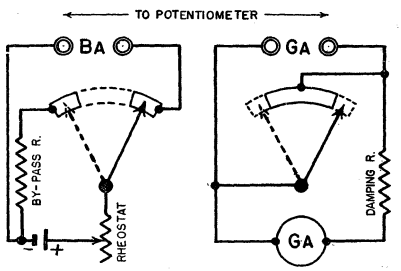

Fig. 3.—Short-circuiting switch for the thermel-galvanometer circuit. (The two contacts rotated simultaneously on a common shaft.)

The temperature of the thermostat up to 80° was measured with a mercury-in-glass thermometer graduated on the stem in 1/10° in accordance with the specifications of the Bureau of Standards. It was calibrated against a platinum resistance thermometer[12] used in conjunction with a Mueller resistance bridge[12] at 5° intervals in the oil thermostat under exactly the same conditions as later prevailed during use. In order to avoid large stem corrections, temperatures from 80 to 110° were measured with another platinum resistance thermometer. The resistance thermometers were calibrated at the ice and steam points. It is believed that the temperature observations had a probable error of ±0.02° up to 50°; ±0.03° from 50 to 80°; and ±0.02° from 80 to 110°.

Potentiometric System.—The potentiometer, a "thermo-free" instrument built to order by the Leeds and Northrup Company, had a range of 550 microvolts in steps of 5 microvolts. The circuit was similar to that in the lower decades of the White potentiometer made by the same company. The battery current was balanced against a self-contained standard cell by means of an auxiliary pointer galvanometer, the sensitivity of which was great enough to permit adjustment to ±0.03%, as determined by a test. The maker's calibration showed that the resistances had been adjusted to their nominal values with an uncertainty of less than 0.1%.

The galvanometer, a Leeds and Northrup narrow-coil, type HS instrument with a period of 6.1 sec., was packed in cotton wool in a wooden box and was mounted 3.15 meters from a ground-glass scale. It was used critically damped, and the working sensitivity then was 16 mm. per microvolt.

The potentiometer was housed in a dry air thermostat at 25°. A wooden cover protected the switches on top of the potentiometer from drafts. The storage battery was kept in a wooden enclosure. The electrical system was separated from its surroundings by a double equipotential shield.[13] The steel pressure bomb was made part of the outer grounded shield. Even in damp weather the parasitic electromotive force did not exceed 0.1 microvolt, and it showed no sudden changes.

A duplex short-circuiting switch (Fig. 3) obviated opening or closing the galvanometer circuit during the course of a measurement. The switch was constructed from two small radio rheostats by mounting them on a common shaft and replacing their resistance windings with copper contacts.

Piezo-thermometric Cell.—The piezo-thermometric cell shown inside the cylindrical steel pressure bomb in Fig. 2 consisted of a soft-glass sphere 20 mm. in outside diameter with a gooseneck opening. It was held in place by a set of phosphor-bronze fingers shaped like a glassblower's flask-holder that were screwed to the recessed face of a cylindrical steel holder. This holder was sealed into the bomb by means of a threaded plug and a lead gasket.

The soldered junction of a copper–constantan thermocouple was at the center of the glass sphere and the wires[14] leading from it were fused through the rear wall. In order to get them out of the pressure bomb, they were fused into the end of a soft-glass capillary tube that previously had been cemented into a steel sheath with glycerol–litharge cement.[15] This sheath was sealed into an axial hole in the cylindrical steel cell holder by means of a packing of asbestos, shredded lead, and graphite.

When the cell was first constructed, the free ends of the thermocouple wires coming out of the open end of the glass capillary tube were drawn through a U-shaped copper conduit that was screwed on the end of the steel sheath. The wires were soldered to copper wires, and these junctions were enclosed in a glass tube that was cemented into the end of the copper conduit, thus forming a closed U-shaped thermocouple.

Before this thermocouple was calibrated it was pressure-seasoned by placing the cell in the bomb under a pressure of 50 bars for twenty hours at a temperature of 70°. Then the cell was subjected to twenty sudden applications and instantaneous releases of pressure of about 50 bars each.

The thermocouple was calibrated in a duplex thermostat by a direct differential method[16] in terms of a copper–constantan reference thermel, the calibration of which is described elsewhere.[16a] After calibration, the thermocouple wires were cut off just beyond where they emerged from the glass capillary tube, and new junctions to copper wires were made[17] and imbedded in paraffin in a thin-walled

(12) Made by the Leeds and Northrup Company.

(13) W. P. White, THIS JOURNAL, **36**, 2011 (1914).

(14) Both wires were no. 40, B. & S. gage. The constantan wire had been selected to have a maximum inhomogeneity equivalent to 0.2% of its thermoelectric power against copper, after a test of a large quantity of wire by the method of W. P. White, *Phys. Rev.*, **31**, 135 (1910), p. 142.

(15) Contrary to the findings of H. Stäger, H. Zschokke and J. P. Bohnenblust [*Kolloid-Z.*, **65**, 319 (1933)] oil (Wyrol) attacked this cement at a temperature as low as 70°. To prevent this the bottom of the recess in the steel holder was covered with a zinc oxide–water glass emulsion, which set to a hard glaze that was not affected by Wyrol even at 110°.

(16) J. S. Burlew and R. P. Smith, THIS JOURNAL, **62**, 701 (1940). (a) This was Thermel B, p. 703.

(17) This operation did not affect the thermoelectric power of the thermel any more than the inevitable shift in the temperature gradient from its position during calibration to its position during use. Because this gradient had been kept unidirectional during calibration by the use of the duplex thermostat, the greatest change in the thermoelectric power caused by the shift of the gradient would have been 0.2%, which was the maximum measured inhomogeneity of the constantan wire. If the gradient during calibration had not

metal cylinder that can be seen screwed to the right end of the steel sheath in Fig. 2.

Two separate cells were constructed. The calibration of Cell A was performed in duplicate at mean temperatures of 20, 30, and 40°, with first one limb cold and then the other; but no systematic difference was observed between the two sets of results. Cell B was calibrated at mean temperatures of 5, 35, 65, 95, and 135°. Inasmuch as the differences in the thermoelectric power did not vary regularly with the mean temperature, the thermoelectric power of the thermocouple in each cell was expressed by the same function of the mean temperature t' as had been derived for the reference thermel, but with the constant term changed by the mean observed difference in thermoelectric power. For convenience in use over the limited temperature range 20 to 30°, the quadratic equation for Cell A was transformed into a linear form. The systematic probable error of the calibration equations is estimated to be $\pm 0.1\%$, because of the uncertainty concerning the inhomogeneity of the constantan wire. The relative probable error of the equation for Cell A is $\pm 0.03\%$, and of that for Cell B is $\pm 0.15\%$, which combines the uncertainty of the original calibration of the reference thermel with the uncertainty of the comparison.

Technique

After the piezo-thermometric cell had been filled with the liquid to be studied, mercury was placed in the gooseneck until it came within 2 mm. of the entrance to the bulb. The bomb, containing the cell sealed in it, was filled with Wyrol[10] and the bomb-pipe was half-filled.[18] Pressure was applied to the cell by admitting nitrogen to the pressure distributor.[19] This always had to be done slowly in order to prevent mercury from being forced into the bulb of the cell. A preliminary measurement of $\Delta T/\Delta P$ was made, from which was computed the pressure drop needed to cause the thermocouple to develop a potential of between 15 and 16 μv. After this pressure had been applied, there was a wait of about an hour while the heat of compression leaked away.

When thermal equilibrium had been established within a few hundredths of a degree, the potentiometer dial was set at 15 μv., and the tapping key of the potentiometer was locked down. The release valve was opened suddenly, and at the same time the duplex switch (Fig. 3) was thrown from left to right. In the former position the battery had been connected to a by-pass resistance and the thermocouple had been connected to the galvanometer through the potentiometer coils and a damping resistance, so that the deflection of the galvanometer "spot" from its open-circuit position had been a measure of the temperature difference between the thermostat and the liquid in the cell. Turning the switch to the latter position applied the electromotive force of the potentiometer to the galvanometer. The thermocouple, however, had been cooled by the release of pressure; and since its potential opposed that of the potentiometer, the galvanometer, which first had moved toward its zero position while it was being short-circuited by the one moving arm of the duplex switch, finally was deflected a small amount. By a proper choice of the pressure drop this deflection was made to be always less than 2 cm. in the direction that indicated cooling of the liquid in the cell. The definiteness of the maximum of the galvanometer deflection was enhanced by the fact that the subsequent deflection, caused by the warming up of the cell to the temperature of the thermostat, was opposite the original deflection.

The position of the galvanometer spot before and after the release of pressure was estimated to the nearest 0.2 mm. The difference between the two positions measured[20] the amount by which the potential of the thermocouple exceeded the 15 μv. potential of the potentiometer. Thus the duplex switch not only obviated moving a contact in the galvanometer circuit at the time of a measurement, but also performed the same function as the eliminating switch[21] of a White potentiometer by furnishing a closed-circuit "zero."

As soon as the galvanometer spot began to drift, the duplex switch was placed in the short-circuiting position while pressure was reapplied. Thus the contents of the bomb were restored almost to thermal equilibrium with the thermostat. The potentiometer switch was thrown to the left, whereupon the galvanometer indicated that the cell was only about 0.1° warmer than the thermostat. This difference decreased in about five minutes to less than 0.02°. Ten minutes after the first release of pressure, a second measurement was made. This procedure was repeated for a total of five replicates. Then the temperature of the thermostat was raised, and the same routine was carried out at a new constant temperature.

The procedure of keeping the potentiometer setting the same for all measurements and varying the pressure, increased the precision considerably; for the pressure could be measured much more precisely than the electromotive force of the thermocouple. In effect the uncertainty of the adjustment of the potentiometer coils did not contribute to the observational error, but only to the systematic error. A similar increase in precision was obtained in connection with replicate measurements at a single temperature, by using the same pressure for all of them, so that the galvanometer deflection was the only quantity subject to significant observational variation. These two procedures had the important practical advantage that the mean temperatures for all observations of $(\Delta T/\Delta P)_S$ for a given liquid were a constant amount below the temperature of the thermostat, which simplified the mathematical reduction of the data.

been kept unidirectional, the possible change would have been much larger.

(18) The height of oil in the bomb-pipe increased from about 5 to 15 cm. during a series of experiments at different temperatures, because of the expansion of the oil in the bomb. The corresponding variation of the hydrostatic pressure on the cell, which amounted to ±5 millibars, was insignificant in view of the very small change of the temperature–pressure coefficient with pressure (*v. infra*).

(19) Although the application of pressure decreased the height of the oil column slightly, the decrease of the apparent pressure drop was less than 0.002%.

(20) During the course of a series of measurements the working sensitivity of the galvanometer, which varied gradually with change of room temperature, was measured at the beginning of each set of five measurements, by observing in duplicate the galvanometer deflection corresponding to a potential of 5 μv. Just prior to this observation the working current of the potentiometer was balanced against the standard cell.

[a] These two series of determinations were performed on two different days. Their mean was used as a single point in the least squares computation. [b] This value, which was in considerable disagreement with all the others, was neglected in the derivation of the equation.

Experimental Study of Method

Time between Successive Observations.—As the result of one hundred systematic observations of $(\Delta T/\Delta P)$ it was found that when the time between successive observations was six minutes or less the apparent cooling of the liquid was about 0.1% less than when a longer period elapsed, probably because of lack of thermal equilibrium in the cell. Hence it was concluded that the time between successive observations should be not less than ten minutes; and this rule was followed in all subsequent experiments.

Decrease of $(\partial T/\partial P)_S$ with Pressure.—The adiabatic temperature–pressure coefficient of a liquid decreases with increase of pressure, as was demonstrated by Pushin and Grebenshchikov[22] in the case of a number of organic liquids at pressures of 500 to 3000 bars. An extrapolation of their data for benzene at 90° to the relatively low pressure of 10 bars gives −0.059% per bar for the variation with pressure of $(\partial T/\partial P)_S$. Richards and Wallace[6] found no variation with pressure of $(\partial T/\partial P)_S$ over a range of mean pressures from 8 to 13 bars, probably because the error of an individual measurement was great enough to obscure the variation with pressure over such a small range of pressure.

In the present investigation the pressure variation of $(\partial T/\partial P)_S$ of toluene was measured. Eight sets of five observations each were made with the thermostat at 26.00°, using pressure differences of 12 to 47 bars, as shown in Table I. Not only was the range of mean pressures three times as great as that used by Richards and Wallace; but also the precision of the result was increased by making replicate observations at identically the same mean pressure, instead of using a different pressure for each observation, as they had done.

Because the amount of cooling of the liquid varied with the pressure difference, the mean temperature of the liquid varied by 0.4°. Before the results at different pressures could be compared, they had to be corrected to the same mean temperature, for which 25.70° was chosen, because it was in the middle of the range. The correction of $(\Delta T/\Delta P)$ to 25.70° was made in accordance with the linear temperature variation that was determined for this same sample in the same cell by measurements at 20, 22, 24, 26, 28 and 30°. These corrected values of $(\Delta T/\Delta P)$, which are listed in the sixth column of Table I, were fitted by the method of least squares to a linear equation in which the mean pressure was the independent variable, with this result:

$$(\Delta T/\Delta P) = 2.1877 \times 10^{-2} - 9.6 \times 10^{-6}(P - 1) \quad (2)$$

from which it follows that $(\partial T/\partial P)_S$ decreased 0.044 ± 0.005% per bar of mean pressure. The residuals with respect to this equation are given in the next to the last column of Table I. The probable error of a single observation of $(\Delta T/\Delta P)$ computed from these residuals is $\pm 1.4 \times 10^{-5}$. The last column of Table I lists the values of $(\partial T/\partial P)_S$ corrected to atmospheric pressure (1 bar) and the temperature 25.70°, from which it will be seen that the variation that had characterized the original values of $(\Delta T/\Delta P)$ in the fourth column has been reduced considerably by the correction to a uniform temperature and pressure.

Effect of Medium Surrounding the Cell.—The time required for the center of a sphere of liquid to begin to warm up following a sudden release of pressure will be shorter the smaller the radius of the sphere and the larger the thermal

(22) N. A. Pushin and E. V. Grebenshchikov, *J. Chem. Soc.*, **125**, 2043 (1924).

head between the liquid and the enveloping sphere. Although the glass wall of the thermometric cell furnished the maximum thermal head, because its temperature–pressure coefficient was only about 5% as large as that of the Wyrol that surrounded it, the Wyrol did act as a reservoir of heat after an expansion. When toluene was in the cell, for instance, the thermal head glass-to-toluene was 50% greater than the thermal head glass-to-Wyrol. Therefore it was considered possible that with a sphere as small as that used, the excess heat in the Wyrol might have been great enough so that the temperature at the center of the cell would have begun to change before it was measured.[23]

This possibility was investigated experimentally. Three series of measurements were made with portions of the same sample of toluene in Cell A at 2° intervals from 20 to 30°. Series I and II were performed a week apart with Wyrol in the bomb surrounding the cell. Series III was performed two days before Series II with toluene instead of Wyrol in the bomb. The following linear equation was derived by the method of least squares from the combined results of Series I and II:

$$(\partial T/\partial P)_S = 2.1835 \times 10^{-2} + 9.08 \times 10^{-5}(t' - 25) \quad (3)$$

The residuals with respect to this equation are shown in Fig. 4, from which it will be seen that the

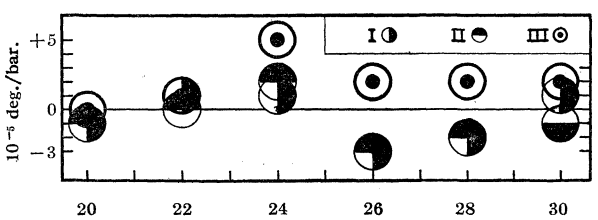

Fig. 4.—Residuals of $(\partial T/\partial P)_S$.

temperature decrease measured when toluene surrounded the cell was a trifle less than that measured when Wyrol surrounded the cell. This difference, which was just about the experimental uncertainty, was opposite that expected if the medium surrounding the cell had affected the measured temperature difference. Hence it was concluded that the use of Wyrol as the pressure-transmitting liquid introduced no error.

(23) Dr. William T. Richards has suggested in a private communication that the effect of radiation on the thermocouple was negligibly small. His opinion is supported by a calculation based on Kirchoff's law and the Stefan–Boltzmann law, which shows that the thermocouple would have been heated less than 0.0001°, if it is assumed that (a) the liquid in the cell transmitted only 0.1% of the black body radiation corresponding to temperatures below 110° and (b) the thermocouple junction absorbed 50% of the radiation incident upon it.

Contamination by Wyrol.—The data in Fig. 4 indicate that the mercury in the gooseneck of the cell acted as a complete barrier to the entrance of Wyrol. The measurements at 30° with Wyrol in the bomb gave results slightly higher than those with toluene in the bomb; whereas if a little Wyrol had slipped past the mercury during the previous twenty-five applications and releases of pressure, it would have lowered $(\partial T/\partial P)_S$.

Precision and Accuracy.—The *a priori* estimates of the probable errors involved in the measurement of the temperature–pressure coefficient of a liquid with the apparatus that has been described are summarized in Table II, which lists the effect on $(\partial T/\partial P)_S$ from each such error.

The data presented in Fig. 4 for $(\partial T/\partial P)_S$ of toluene measured on different days with the same cell illustrate the validity of these estimates of the total observational errors at a single temperature. The root mean square deviation of each value of $(\partial T/\partial P)_S$ from the mean of a pair of duplicates on different days was ±0.02%; the estimate given in Table II is ±0.06%.

TABLE II

ESTIMATED PROBABLE ERROR OF $(\partial T/\partial P)_S$

	Observed quantity	Errors, % Observational	Errors, % Systematic
1.	Pressure difference		
	a. Gage weights	±0.001	±0.001
	b. Piston area	.....	± .05
	c. Height of oil in gage	± .005	.....
	d. Temperature of gage	± .005	.....
2.	Electromotive force		
	a. Potentiometer coils	.....	± .07
	b. Battery current	± .01	.....
	c. Galvanometer deflection (for mean of five replicates)	± .05	.....
3.	Thermoelectric power of thermel	.....	± .18
4.	Temperature of thermostat	± .015	.....
5.	Pressure correction[a]	.....	± .05
	Total	±0.06	±0.21

[a] See p. 688 for a discussion of the uncertainty of the pressure correction at higher temperatures.

Confirmation of the estimates of the other errors, including some of the systematic ones, was sought by making measurements with the same sample of liquid in two different individually calibrated cells at 2° intervals from 20 to 30°. All the values of $(\partial T/\partial P)_S$ both of benzene and of toluene obtained with Cell A were less than those obtained with Cell B. The root mean square deviation of each individual value from the mean

of a pair of duplicates was ±0.10% for benzene and ±0.22% for toluene; whereas the combined value of the estimates of both the observational and systematic probable errors in Table II is ±0.22%.

Samples

Distillation Apparatus.—As the final step in its purification each sample was distilled in an all-glass apparatus that had interchangeable distilling flasks and interchangeable receivers. The round distilling flasks used were of different diameters, but each had a straight tube 3 cm. long and 1.5 cm. in diameter sealed on the bottom. An electric heater was wound on a copper tube that fitted snugly over this extension. Thus boiling took place in this small space, which had a volume of only 6 ml. An inverted cone of sheet copper resting on the upper surface of the distilling flask prevented excessive condensation there. The vacuum-jacketed column, 60 cm. high, which was packed with one-turn glass helices,[24] was surmounted by a reflux condenser. The progress of a distillation was followed by measurement of the refractive index of successive small fractions with an Abbé refractometer. The absolute accuracy of the refractive indices was not known, but the relative precision was ±0.0001.

Benzene.—Some Merck "reagent grade benzene, thiophene-free" was purified by treatment with the following reagents in succession: concentrated sulfuric acid, water, a dilute solution of sodium hydroxide, water, calcium chloride, hot mercury, and phosphorus pentoxide. Then it was fractionated. The refractive index was raised 0.0003 by the purification.

Toluene A.—Sample A, which was purified only slightly in order to give a basis of comparison for the highly purified Samples B and C, was obtained by distillation of 120 ml. of C. P. toluene from the General Chemical Company. After 50 ml. had passed over, a fraction of 6 ml. was preserved. Its refractive index was 0.0007 higher than that of the original material, but 0.0008 lower than that of Samples B and C.

Toluene B.—Some Baker C. P. toluene was purified by treatment with the following reagents in succession: hot mercury, concentrated sulfuric acid, water, a dilute solution of sodium hydroxide, water, calcium chloride, and phosphorus pentoxide. After fractionation, it was refluxed over sodium for two hours, and then fractionated from it. The refractive index was unchanged by this last distillation.

Toluene C.—Some Merck "reagent grade toluene" was purified principally by the preparation of toluenesulfonic acid,[25] from which the toluene was regenerated by distillation with superheated steam. It was treated further with concentrated sulfuric acid, water, a dilute solution of sodium hydroxide, water, and calcium chloride in turn. After having been refluxed over sodium for two hours, it was fractionated from the sodium. A forerun of 3 ml. was discarded, and the other fractions were mixed and refluxed over fresh sodium for an hour, after which the final sample was distilled off in several fractions, all of which had the same refractive index, which was only 0.0001 higher than that of the starting material. It was the same as the index of Sample B.

Effect of Impurities on $(\partial T/\partial P)_S$.—Six series of measurements, consisting of five replicates each, were made at 2° intervals from 20 to 30° with each sample of toluene in Cell A. The mean value for each sample, which was $(\partial T/\partial P)_S$ at 25°, was $(2.1808 \pm 0.0014) \times 10^{-2}$ deg./bar for Sample A, $(2.1827 \pm 0.0007) \times 10^{-2}$ for B, and $(2.1830 \pm 0.0004) \times 10^{-2}$ for C. In other words, Samples B and C were indistinguishable as far as $(\partial T/\partial P)_S$ was concerned although $(\partial T/\partial P)_S$ for the slightly impure sample was 0.1% lower than for the pure ones.

Experimental Data

Definitive measurements of $(\partial T/\partial P)_S$ of benzene and of toluene (Sample C) were made with Cell B at 3° intervals from 8° to the respective b. p., with the results shown in Tables III and IV: where t', the mean temperature of the liquid during an expansion, equals the thermostat temperature minus $\Delta T/2$; ΔP is the instantaneous pressure drop; and ΔT is the accompanying decrease of temperature.

[a] Δ = *calcd.* minus *exptl.*

pressure of 1 bar by means of the pressure coefficient −0.044% per bar that had been found[26] for toluene at 25.7°. This same coefficient was used to correct the measurements at all temperatures, for the pressure variation of $(\partial T/\partial P)_S$ was not measured at other temperatures because of lack of time. A change with temperature of ±50% in the pressure variation would cause an error of only ±0.2% in $(\partial T/\partial P)_S$. It is assumed[27] also that within these limits the same correction applies to benzene. When the mean temperature differed by a few hundredths of a degree from a value of 0.20° less than a whole degree, a correction amounting to 1×10^{-6} deg./bar for each hundredth of a degree was applied to $(\Delta T/\Delta P)$, so that the corrected values of $(\partial T/\partial P)_S$ in the fifth column refer to a mean pressure of 1 bar and a mean temperature 0.20° less than the whole degree next higher than that shown in the first column.

$(\partial T/\partial P)_S$ as a Function of Temperature.—Search for a suitable temperature function was made by analysis of the data for toluene by means of first, second, and third differences according to the plan outlined by Running.[28] Twelve three-parameter functions were tested by evaluating their parameters at the end and middle points and then computing two intermediate points. A cubic equation without a quadratic term and a double logarithmic equation involving the absolute temperature were the only ones that were very promising. These two together with the full cubic equation (four parameters) were investigated more carefully by evaluating their parameters by the method of least squares, using all the points. The probable error of an individual observation based on the residuals did not vary more than 10% for these three equations. The double logarithmic equation was discarded, however, because of a pronounced trend in the signs of the residuals. The data for benzene also were fitted to three- and four-parameter cubic equations by the method of least squares. The probable error of an individual observation was the same for both equations. Therefore, since the three-parameter cubic equation gave as good a general representation of the data for $(\partial T/\partial P)_S$ of both benzene and toluene as did the four-parameter cubic, it was preferred in the interest of simplicity.

computed by means of this equation

$$\left[\frac{d}{dP}\left(\frac{\partial T}{\partial P}\right)_S\right]_T = \frac{T}{(c_p)^2}\left\{c_p\left[\frac{d}{dP}\left(\frac{\partial V}{\partial T}\right)_P\right]_T - \left(\frac{\partial V}{\partial T}\right)_P\left(\frac{\partial c_p}{\partial P}\right)_T\right\} \quad (4)$$

using data from the present investigation for the other terms. At 25° $d(\partial T/\partial P)_S/dP$ is −0.054 ± 0.006% per bar. At higher temperatures the computed value increases numerically to −0.084% at 80°; but inasmuch as this temperature slope is due to a similar slope in $d(\partial V/\partial T)_P/dP$, and inasmuch as this slope was derived from a quadratic equation passed through four points based on measurements at a maximum temperature of 65°, the increase of $d(\partial T/\partial P)_S/dP$ may have been exaggerated.

(26) *Cf.* eq. (2).

(27) This assumption is substantiated partially by a calculation of $d(\partial T/\partial P)_S/dP$ that is made possible by the recently published data of R. E. Gibson and J. F. Kincaid [THIS JOURNAL, **60**, 511 (1938)] for the variation with pressure of the coefficient of thermal expansion of benzene. From the parameters in the equations for the coefficient of thermal expansion at five different pressures from 1 to 1000 bars, given in their Table V, the value of $d(\partial V/\partial T)_P/dP$ has been computed to be -8.6×10^{-7} (cc./g.-deg.)/bar at 25° and a mean pressure of 10 bars. The pressure variation of $(\partial T/\partial P)_S$ has been

(28) T. R. Running, "Empirical Formulas," John Wiley and Sons, Inc., New York, N. Y., 1917.

The equations evaluated by least squares were:

$$[C_6H_6]\quad (\partial T/\partial P)_S = 2.12695 \times 10^{-2} + 1.06806 \times 10^{-5}t + 2.7715 \times 10^{-9}t^3 \quad (5)$$

$$[C_7H_8]\quad (\partial T/\partial P)_S = 1.96840 \times 10^{-2} + 8.6990 \times 10^{-5}t + 2.2285 \times 10^{-9}t^3 \quad (6)$$

The residuals with respect to these equations are listed in the last column of Tables III and IV, respectively. The probable error of an individual observation based on the residuals was $\pm 2.9 \times 10^{-5}$ and $\pm 2.0 \times 10^{-5}$, respectively. These values are less than twice as great as the *a priori* estimates of the total observational probable error given in Table II. Values of $(\partial T/\partial P)_S$ for benzene and toluene computed at 5° intervals from equations (5) and (6) are listed in Table II of the paper[8] on the heat capacity of these liquids.

Comparison of Data.—A comparison of the present data with those of Richards and Wallace[6,29] is given in Table V. The differences between the two sets of data are actually larger than they appear at first, because the present values have been raised 7×10^{-5} on the average by the correction to 1 bar and also because the values of Richards and Wallace refer to the temperature of the thermostat rather than to the mean temperature of the liquid during the expansion. Inasmuch as the liquid cooled during the expansion, the value of $(\partial T/\partial P)_S$ that they reported for a particular temperature is a little too small. If we may judge from the data for benzene at 40° in their Table I, $(\partial T/\partial P)_S$ should be raised 3×10^{-5}. For the purpose of computing the deviations between the two sets of data, given in Table V, the values of Richards and Wallace have been increased by 1×10^{-4}. Except for the results at 20°, the agreement is fairly satisfactory.

(29) Their original values have been changed from the unit "deg./atm." to "deg./bar" by multiplication by the factor 0.98692 atm./bar.

Acknowledgments.—It is a pleasure to acknowledge the encouragement and advice given by Professor Donald H. Andrews during the course of this research. I thank Professor Herbert S. Harned and the other members of the staff of the Department of Chemistry at Yale University for their kindness in making available facilities for research. I am indebted to Mr. H. S. Bittner and Mr. Harry Johns of the Chemistry Shop, Johns Hopkins University, and to Mr. J. M. Berney, Mr. H. G. Cady, Mr. Wm. Duncan and Mr. F. P. Noble of the Chemistry Shop, Yale University, for the interest they took in the careful fabrication of the apparatus.

Summary

An apparatus has been described for the measurement of $(\partial T/\partial P)_S$ of 5 ml. of a liquid, the precision of the observations has been discussed, and the use of the apparatus has been illustrated by data for benzene and toluene at 3° intervals from 8° to the respective boiling points.

Measurement of the Heat Capacity of a Small Volume of Liquid by the Piezo-thermometric Method. II. Coefficient of Thermal Expansion of Benzene and of Toluene Measured with a New Type of Weight Dilatometer

BY JOHN S. BURLEW[1]

In the application of the piezo-thermometric method[2] to the measurement of the heat capacity of a sample of liquid as small as 5 cc., it is necessary to have a means of measuring the coefficient of thermal expansion of this quantity of liquid with a probable error of not more than $\pm 0.3\%$ over a wide range of temperature, without regard to the volatility of the liquid. The weight dilatometer (Fig. 1) devised for the purpose is similar in design to the Meyer–Neubeck pycnometer,[3a] except that in the present dilatometer a fixed weight of liquid is confined by mercury, so that the instrument may be used at any temperature up to the temperature of the boiling point.

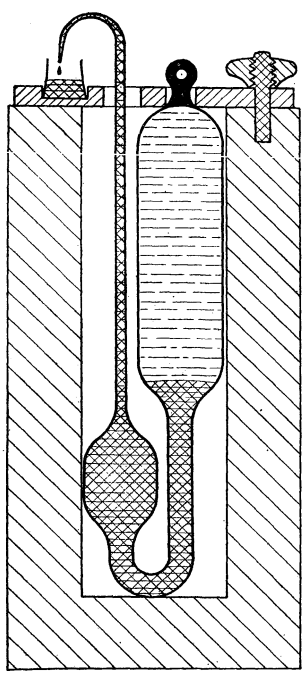

Fig. 1.—Weight dilatometer in steel holder (scale, 2/3).

The principle of this weight dilatometer is that the volume of liquid present at a given temperature can be computed from the weight of mercury contained at a reference temperature and the amount expelled when the dilatometer is heated to the given temperature, the volume of liquid present at the reference temperature being known. The total volume of the dilatometer at any temperature is equal to the sum of the volume of the liquid and the volume of mercury. Expansion of this fundamental relation in terms of the quantities actually measured gives the following equation[4] for the specific volume

$$v_t = \frac{1}{w}\left\{V_\Theta\,[1 + a(t - \Theta)] - \frac{w'_\Theta - w^*_t}{d'_t}\right\} \qquad (1)$$

Dilatometers employing this same principle have been described by Pesce and Hölemann[5] and by Jones and Jelen.[6] Each of them was larger and more elaborate, but furnished results no more precise. The present instrument recently has been adapted[7] to use with solutions.

Weight Dilatometer

Holder.—The dilatometer fitted into a circular hole drilled in a steel cylinder, as shown in Fig. 1. A circular cover plate screwed to the top of the cylinder kept the dilatometer submerged in the mercury with which the hole was filled. The glass ring at the rounded end of the dilatometer projected through a hole in the cover plate, and the capillary neck emerged through a notch cut in its side. The main portion of the dilatometer, which had been blown from 15-mm. pyrex glass tubing, had a volume of 3.5 cc.; the smaller tube and capillary 0.5 cc.; and the bulb 1 cc. The orifice at the end of the capillary neck was less than 0.1 mm. in diameter. A glass cup (6 by 7 mm.) that rested in a small recess cut in the cover plate,[8] caught the overflow of mercury from the capillary neck when the temperature was raised.

Thermostat.—A region of uniform temperature for the dilatometer was provided by an aneroid thermostat:

(2) See paper I of this series, THIS JOURNAL, **62**, 681 (1940).

(3) F. Neubeck, *Z. physik. Chem.*, **1**, 649 (1887); (a) p. 652; (b) pp. 654 and 656.

(4) The symbols used in this paper are as follows: v_t is the specific volume of the liquid under investigation; V_t is the total volume of the dilatometer; V'_t is the volume of mercury in the dilatometer; W_t is the total weight of the contents of the dilatometer; w is the constant weight of liquid in the dilatometer; w'_t is the weight of mercury in the dilatometer; w^*_t is the weight of mercury expelled between a temperature t and the next lower temperature at which an observation was made; d_t is the density of the liquid; d'_t is the density of mercury; and a is the coefficient of thermal expansion of the dilatometer. The subscript t refers to any temperature and the subscript Θ refers to an arbitrary reference temperature.

(8) Figure 1 shows the dilatometer as if it had been rotated through an angle of 90° with respect to the diameter of the cover plate passing through the cup and the wing nut.

a brass cylinder that stood on three legs on the bottom of an oil thermostat. To the top of this cylinder, which was 7 cm. in diameter and 12 cm. high, was soldered a cylindrical extension about 20 cm. long, made from sheet copper, the upper end of which reached just above the surface of the oil. The steel holder for the dilatometer fitted snugly into an axial hole in the brass cylinder. It was raised and lowered by a stiff wire handle that was screwed into its top. The upper end of the aneroid thermostat was closed with a cork. In this way it was not necessary to make any correction for the small length of capillary that was not immersed in the mercury in the holder, for it was at substantially the same temperature as the immersed part.

Filling.—The dilatometer was filled by suction in a test-tube (4 by 18 cm.) provided with two side-arms carrying stopcocks. One was connected to an aspirator or vacuum pump and the other to a calcium chloride tube open to the air. First the dilatometer was hung by its capillary neck from a small cup filled with mercury. By evacuating the tube and then admitting dry air, mercury was forced into the dilatometer.

The dilatometer was turned upside down, and the mercury was shaken into the main portion of the instrument. A sample of the liquid to be studied, freshly boiled and then cooled to about 50° below its boiling point, was placed in a glass cup that rested on the bottom of the filling tube, and the capillary neck of the inverted dilatometer was submerged in it. The liquid was placed in the cup instead of directly in the filling tube in order to decrease the volume needed. The filling tube was evacuated until the liquid began to boil, when evacuation was stopped. Air was admitted slowly to the filling tube, whereupon the liquid rushed into the dilatometer. The lower end of the filling tube was cooled with ice water, so that when the tube was evacuated a second time the last traces of air were removed from the dilatometer by the boiling of the warm liquid in it, without boiling the liquid that remained in the filling cup. When air was readmitted to the filling tube, liquid completely filled the dilatometer, except for a tiny bubble at the top of the bend. This bubble was removed through the capillary stem by gently warming the instrument until a small quantity of mercury had been expelled. The capillary tube was dried on the inside by alternately cooling and heating the dilatometer half a dozen times.

Determination of w.—The dilatometer next was filled completely at a convenient reference temperature (t_Θ) near room temperature. It was placed in warm water until mercury began to be expelled, after which it was cooled to slightly below t_Θ while the nose of the capillary was held under the surface of mercury. Then it was placed in its steel holder in the aneroid thermostat at t_Θ for at least forty minutes; the steel holder previously had been in the thermostat at t_Θ. From the weight of the dilatometer after having been filled at t_Θ in this manner, the amounts of mercury and of liquid contained were computed by means of equations (3) below.

It is possible to measure w and w'_Θ directly at the time of filling the dilatometer (this was done during the calibration), but during routine measurements it is preferable to derive them from the total weight (W_Θ) of the contents of the dilatometer and the total volume (V_Θ). This procedure permits the use of a permanent table of volumes of the dilatometer, and also it does away with one tedious step in the filling of the instrument—namely, catching and weighing the mercury that is expelled when the final air bubble is being removed. The indirect determination of w and of w'_Θ is based on the simultaneous solution of two equations

$$W_\Theta = w + w'_\Theta = (V - V')_\Theta\, d_\Theta + (V'd')_\Theta \quad (2)$$

which gives

$$w = \left\{\left(\frac{d}{d' - d}\right)_\Theta\right\}\left\{(Vd')_\Theta - W_\Theta\right\} \quad (3a)$$

$$w'_\Theta = W_\Theta - w \quad (3b)$$

In one filling of the dilatometer with benzene, w was determined both directly and indirectly, with a difference of 0.4 mg. between the two values, which is good agreement, inasmuch as the direct determination involved four weighings for each of which the probable error was ±0.1 mg.

Measurements.—Although measurements at different temperatures could be made in any order desired, it was convenient to start a series of them with the weight dilatometer at 0° if possible. The dilatometer was filled at 0° by being packed in ice with its nose in a cup of mercury. Handling of the instrument during its transfer to the thermostat that had been set at the next higher temperature was facilitated by chilling it below 0° by pouring strong brine over the ice. After the dilatometer had been in the aneroid thermostat at a constant temperature for one hour, with a receiving cup under the end of the capillary tip, the cup was replaced by an empty one, and the temperature of the thermostat was raised to the next higher temperature; and so on.

Calibration.—The weight dilatometer was calibrated by means of a series of measurements with water at 10° intervals from 10 to 90°. The weight of mercury and water contained at 30° was determined separately, and then the mercury expelled during the successive heating periods was weighed. The specific volume of mercury was computed by the following formula given by Scheel and Blankenstein[9]

$$1/d'_t = 0.0735560(1 + 1.8182 \times 10^{-4}t + 7.8 \times 10^{-9}t^2)\ \text{cm.}^3/\text{g.} \quad (5)$$

The density of water in g./cc. was computed from the density in g./ml. listed in the "Int. Crit. Tables."[10] The values for the volume of the dilatometer at different temperatures, computed according to eq. (1), were fitted to a linear equation in t by the method of least squares, with this result

$$V_t(\text{cm.}^3) = 5.29379 + 5.625 \times 10^{-5}t \quad (6)$$

The relative probable error of V_t based on the residuals with respect to this equation was $\pm 2 \times 10^{-5}$ at the ends of the range, and only $\pm 0.8 \times 10^{-5}$ in the middle. The systematic probable error, however, was $\pm 3 \times 10^{-4}$, because of the uncertainty in the weight of water contained.

The coefficient of thermal expansion of the pyrex glass of the dilatometer as determined by this calibration was $1.063 \pm 0.005 \times 10^{-5}$. This value differs by 7.8% from that of 0.985×10^{-5} reported by Jones and Jelen[6] for their dilatometer; but the difference is not surprising

(9) K. Scheel and F. Blankenstein, *Z. Physik*, **31**, 202 (1925).
(10) "Int. Crit. Tables," Vol. III, pp. 25–26.

in view of the different heat treatments of the two instruments.

Precision and Accuracy

Systematic tests demonstrated that the dilatometer, if left in the thermostat for at least thirty minutes, could be filled at a particular temperature with an error not greater than the error of weighing, namely, ± 0.1 mg.

The question of whether the mercury used as a confining liquid had the same density and coefficient of expansion as that used by Scheel and Blankenstein did not affect the accuracy of the specific volume measurements made with the weight dilatometer, because about the same quantity of the same mercury was used during both the calibration and the volume measurements.

The systematic probable error for the present dilatometer (caused by the uncertainty in the weight of liquid contained compared with the weight of water contained during the calibration) was $\pm 0.01\%$. This uncertainty, which limits the accuracy of the measurements of specific volume, does not affect their relative precision; hence its effect on the accuracy of the coefficient of thermal expansion is negligible.

The maximum relative probable error of the total volume (caused by the uncertainty in the coefficient of expansion of the dilatometer) was $\pm 2 \times 10^{-5}$ cc., and that of the volume of mercury at any particular temperature (caused by the uncertainty[11] in the weight of mercury contained at different temperatures) was $\pm 4 \times 10^{-5}$ cc. Inasmuch as it is the difference of these two volumes that is proportional to the specific volume of liquid, the relative probable error of the latter was $\pm 6/w \times 10^{-5}$ cc./g., which became $\pm 0.0017\%$, when w, the weight of liquid contained, was 3.5 g.

The fourth source of error was the uncertainty in the temperature observations. Its contribution[12] to the total uncertainty in the specific volume is proportional both to the probable error of the temperature and to the coefficient of thermal expansion.

Combination of the errors from these four sources yields the following *a priori* estimates of the total probable error of the specific volume in the middle of the range: $\pm 3.5 \times 10^{-5}$ cc./g.-deg. for benzene and $\pm 4.4 \times 10^{-5}$ cc./g.-deg. for toluene.

The functional relation between the specific volume and the temperature should be derived by the method of least squares under the condition[13] that both these variables are subject to error. The labor of computation may be reduced considerably without violating this condition, if the observations are arranged to be made at equal intervals of temperature and with the probable errors approximately the same (say within a factor of two) for all points. Then the equation can be evaluated from the points distributed symmetrically on each side of the mid-point of temperature, each point being considered of unit weight.

Influence of Number of Observations

The relation of the probable error of the coefficient of thermal expansion to the probable error of the specific volume of a liquid depends considerably on the number of values of the specific volume at different temperatures and on their distribution. In order to find out how many observations with the weight dilatometer were needed to furnish a reliable value of the expansion, the proportional probable error of the coefficient of thermal expansion was computed[14] for different values of n, the number of observations, and of x, the independent variable. The results are given in Table I. Each curve of specific volume was assumed to have its points distributed symmetrically on either side of the mid-point ($x = 0$) from $x = -(n-1)/2$ to $+(n-1)/2$ and was assumed to be represented by a cubic equation.

From Table I it may be seen that over more than half the range of a cubic curve the probable error of the slope is not greater than it is at the mid-point, whereas at the ends of the range it is regularly nearly four times as large. Hence the probable error of the slope at the mid-point, which is very easy to compute, is a useful indicator of the reliability of the slope throughout the course of the curve.

(11) The errors of weighing the separate portions of mercury expelled, which are cumulative, can be minimized by weighing the dilatometer after it has been at the maximum temperature and then adjusting the individual values of w^*. When this is done the probable error in a single value of $(w'_\Theta - w^*_t)$ does not exceed ± 0.5 mg., which is equivalent to an uncertainty of $\pm 4 \times 10^{-5}$ cc. in the volume.

(12) For a liquid with an expansion of 0.001 cc./g.-deg. this contribution is 0.001% for a temperature uncertainty of 0.01°. Hence a weight dilatometer of the dimensions given above is sufficiently precise to make it worthwhile to employ a thermometer having a relative probable error of $\pm 0.005°$ for measurements with organic liquids having coefficients of thermal expansion about 0.0015. In that case the total uncertainty in the specific volume would be a little less than $\pm 2 \times 10^{-5}$ cc./g.-deg. In order to reduce it to one-half this amount, the dilatometer would have to be enlarged to three times its present volume.

12		....	.64	.28	.15	.10	.07
15			....	.47	.26	.16	.12
17				....	.40	.22	.15
20					....	.32	.22
22						....	.28

[a] Assumptions: (1) Coefficient of thermal expansion = 0.001 cc./g.-deg. (2) $v_t = a + bt + ct^2 + dt^3$. (3) Probable error of single observation of sp. vol. = $\pm 2.5 \times 10^{-5}$ cc./g.

Table I shows also that for any given value of x an increase in the number of observations causes a decrease in the probable error of the slope at a diminishing rate. Hence a table such as this helps one decide the number of observations demanded by a certain desired accuracy.

Experimental Data

Measurements of the coefficient of thermal expansion of benzene and of toluene (Sample C) were made with the weight dilatometer using the same samples that were used for the measurement[2] of $(\partial T/\partial P)_S$. The dilatometer was heated in the same oil thermostat used for the piezo-thermometric bomb, and so the temperature uncertainties were the same as previously listed,[2] namely: a probable error of ±0.02 up to 50°; ±0.03 from 50 to 80°; and ±0.02 from 80 to 110°. The weight[15] of liquid contained was computed from a weighing at 25° and the density of the liquid, for which the mean of a series of measurements with a 2-ml. Sprengel–Perkin pycnometer[16] at 1° intervals from 20 to 30° was used. Evidence that the liquids were air-free was furnished by the fact that successful measurements were made less than 1° below the normal b. p.

The specific volume was computed by equation (1) from the observed values of w^*, which are listed in Tables II and III. A cubic equation was fitted by the method of least squares to the values of the specific volume of each liquid. The results

$$[C_6H_6]\ v_t = v_0 + 1.29651 \times 10^{-3}t + 1.7516 \times 10^{-6}t^2 + 5.930 \times 10^{-9}t^3 \quad (7)$$

$$[C_7H_8]\ v_t = v_0 + 1.18497 \times 10^{-3}t + 1.0672 \times 10^{-6}t^2 + 7.366 \times 10^{-9}t^3 \quad (8)$$

are for benzene and toluene, respectively. The residuals with respect to these equations are listed in the last columns of Tables II and III. The probable error of an individual observation, based on the residuals, is $\pm 3.0 \times 10^{-5}$ cc./g. for benzene and $\pm 2.0 \times 10^{-5}$ cc./g. for toluene. Each of these values is somewhat less than the *a priori* estimate given on page 692.

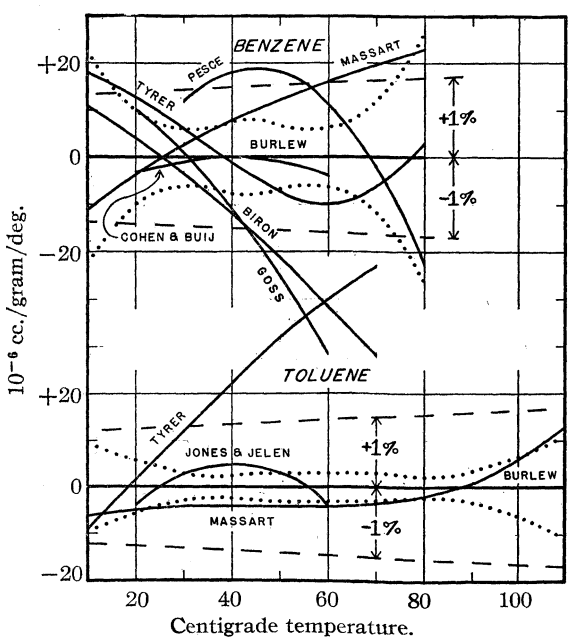

Fig. 2.—Deviations of expansion coefficients.

Differentiation of equations (7) and (8) yielded the following pair of equations for the coefficients of thermal expansion of benzene and of toluene, respectively

$$[C_6H_6]\ 1000\ (\partial V/\partial T)_P = 1.2965 + 3.503 \times 10^{-3}t + 1.779 \times 10^{-5}t^2 \quad (9)$$

$$[C_7H_8]\ 1000\ (\partial V/\partial T)_P = 1.1850 + 2.134 \times 10^{-3}t + 2.210 \times 10^{-5}t^2 \quad (10)$$

The values of the coefficients of thermal expansion, computed from these two equations at 5° intervals, are listed in Table II of the paper[17] on the heat capacity of these liquids.

Comparison of Data for $(\partial V/\partial T)_P$.—The deviations (*other observer* minus *Burlew*) of the results of other investigators from these values are shown in Fig. 2.[18] A summary of the accuracy[19] of their work is given in Table IV, in terms of an estimate of the probable error of $(\partial V/\partial T)_P$ that I have deduced from each author's stated or implied estimate of the probable error of his values of the specific volume. In only three of those investigations (Pesce, Cohen and Buij, and Jones and Jelen) was a sufficient number of observations of specific volume made at regular intervals to permit the

(17) J. S. Burlew, THIS JOURNAL, **62**, 696 (1940).

(18) In each graph of Fig. 2 three times the probable error of the present data is represented by a pair of dotted lines that are symmetrical with respect to the base lines.

(19) A measurement of the coefficient of thermal expansion of a liquid practically is unaffected by systematic errors in the specific volume. Hence its accuracy depends solely on the precision of the measurements of the specific volume.

computation of accurate values of the coefficient of thermal expansion. The deviations of the present data from each of those three are well within the limits of the sum of three times the probable error of each set of data. The results of Massart also agree well with mine, and those of the other four do not disagree by more than the experimental uncertainty except at the ends of the range.

In addition to the data on $(\partial V/\partial T)_P$ that are referred to in Fig. 2, there exist the results of density measurements over considerable ranges of temperature that have not been represented by equations. Although the corresponding coefficients of thermal expansion could not be evaluated accurately, a comparison of total expansions has been made, as shown in Table V. There is good agreement with all except the results of Perkin, whose extremely small expansions are inexplicable. Also the present value for the specific volume of benzene at the boiling point is in close agreement with that of Arbusov.[20] The values of Neubeck[3b] for both benzene and toluene were slightly larger than the present ones.

Density of Toluene at 0 and 25°

An examination of the literature has revealed considerable variance among the values for the density of toluene, which does not seem to have been commented on previously. The several measurements of the density of toluene at 0 and 25° and the measured expansions between these two temperatures are summarized in Table V. The present value of the expansion agrees well with two of the others, inasmuch as the limit of accuracy is ±0.00001, imposed by the uncertainty of ±0.01° in the temperature scale. The several values of the density, however, are at considerable variance, so that a redetermination of the absolute density at both 0 and 25° of several samples of toluene differently prepared clearly is needed.

Tables," Vol. III, pp. 29 and 33. [b] D. Tyrer, *J. Chem. Soc.*, **105**, 2534 (1914), p. 2540. The expansion has been computed from his empirical equation. [c] J. Timmermans and F. Martin, *J. chim. phys.*, **23**, 747 (1926), p. 752. The density at 25° had been interpolated linearly by the authors from measurements at 15 and 30°. [d] K. K. Kelley, THIS JOURNAL, **51**, 2738 (1929). [e] L. Massart, *Bull. soc. chim. Belg.*, **45**, 76 (1936), p. 83. The density at 0° was an arbitrary base point and not a new determination. The expansion has been computed from his empirical equation. [f] E. R. Smith and M. Wojciechowski, *Bull. intern. acad. polon. sci.*, **1936A**, 123.

Summary

A weight dilatometer for the measurement of the coefficient of thermal expansion of 5 cc. of a volatile liquid over a wide range of temperature with a probable error of a few tenths of one per cent. has been described, and its manipulation has been outlined. An analysis has been given of the factors, including the number of observations, that affect the precision of the measurement of the coefficient of thermal expansion. Data for $(\partial V/\partial T)_P$ of benzene and of toluene from 8° to the respective boiling points have been presented and compared with the results of previous investigators. Discrepancies in the current values for the density of toluene at 0 and 25° have been pointed out.

Measurement of the Heat Capacity of a Small Volume of Liquid by the Piezo-Thermometric Method. III. Heat Capacity of Benzene and of Toluene from 8°C. to the Boiling Point

BY JOHN S. BURLEW[1]

As a first application of the piezo-thermometric method of measuring the heat capacity of a small volume of liquid, the heat capacity of benzene and of toluene was determined. Not only did these results furnish an opportunity for comparison with those obtained by other methods by other investigators, but also they extended the data concerning these two liquids.

Method.—The piezo-thermometric method[2] is based on the following thermodynamic equation

$$c_p = T(\partial V/\partial T)_P/(\partial T/\partial P)_S \qquad (1)$$

The heat capacity of each liquid was computed according to equation (1) at each temperature[3] at which a measurement of the adiabatic temperature–pressure coefficient, $(\partial T/\partial P)_S$, had been made, with the results given in Table I. The corrected experimental values of $(\partial T/\partial P)_S$ which are listed in the next to the last column of Tables III and IV of Ref. (2) were employed, in order that no spurious trend might be given to the values of c_p by the use of calculated values of $(\partial T/\partial P)_S$. The coefficients of thermal expansion, $(\partial V/\partial T)_P$, were computed from the equations[4a] that had been obtained by differentiation of the empirical equations used to express the results of measurements of the specific volumes of these two liquids made at 3° intervals from 8° to the respective boiling points. For the computation of the absolute temperature T in equation (1) the ice point was taken as 273.2° K.

Precision.—The uncertainty of a value of c_p determined according to equation (1) is a combination of the uncertainties that are contributed by each of the factors on the right-hand side of that equation. Those for $(\partial T/\partial P)_S$ have been summarized in Table II of Ref. 2. As explained elsewhere[5] the observational uncertainty in $(\partial V/\partial T)_P$ depends on the number of observations of specific volume and also varies over the temperature range. Combination of these several uncertainties gave for the estimated observational probable error of c_p of benzene and of toluene ± 0.25%

(1) Sterling Fellow, 1934–1936; present address: Geophysical Laboratory, Washington, D. C.

(2) For a discussion of this method see the first paper of this series, THIS JOURNAL, **62**, 681 (1940).

(3) These measurements had been made at 3° intervals; but the precision was so great over the whole range of temperature that now it is considered that measurements at ten to fifteen uniformly distributed temperatures would have been sufficient to yield results for $(\partial T/\partial P)_S$ comparable in precision to those obtained for $(\partial V/\partial T)_P$ by twice that number of measurements of the specific volume.

(4) J. S. Burlew, THIS JOURNAL, **62**, 690 (1940); (a) equations (9) and (10).

(5) Ref. (4), p. 692. Table I of Ref. (4) shows the extent of the variation of the probable error with temperature for a particular number of observations. The estimates of the probable error of $(\partial V/\partial T)_P$ for benzene and toluene are only 60 to 80% as large as the table indicates for n = 23 and 32, respectively, because $(\partial V/\partial T)_P$ of both liquids is greater than 0.001 cc./g.-deg.

at the middle of the range, somewhat less on either side of the middle, and about twice as much at the ends[6] of the range. The estimated systematic probable error of c_p was $\pm 0.20\%$ over the entire range.

c_p as a Function of Temperature.—The curves obtained by plotting as functions of the temperature the values of c_p listed in Table I are slightly S-shaped, the change of curvature being more pronounced for toluene than for benzene. It was proved by means of a calculation of the specific volume from computed values of the heat capacity that this change of curvature was greater than could be accounted for on the assumption that errors in the measurements of specific volume gave rise to false values of $(\partial V/\partial T)_P$.

Before equations were derived for these curves, it was necessary[7] to weight the individual values of c_p, because the probable error was not constant. The weights listed under p in Table I were taken in proportion to the reciprocal of the square of the estimated probable error of each point. The cubic equations based on the weighted points are

$$[C_6H_6]\ c_p = 1.6673 + 2.047 \times 10^{-3}t + 3.051 \times 10^{-5}t^2 - 2.196 \times 10^{-7}t^3 \quad (2)$$

$$[C_7H_8]\ c_p = 1.6534 + 1.119 \times 10^{-3}t + 4.294 \times 10^{-5}t^2 - 2.204 \times 10^{-7}t^3 \quad (3)$$

The residuals with respect to these equations are listed in Table I. The probable error of an individual observation in the middle of the range, computed from these residuals, is $\pm 0.08\%$ in the case of benzene and $\pm 0.05\%$ in the case of toluene. Both of these values are considerably smaller than the *a priori* estimate given above, which is to be expected, because the values of $(\partial V/\partial T)_P$ used in computing c_p had been smoothed by the process of differentiation. When the unit of c_p is changed from the joule to the defined 15°-calorie,[8] equations (2) and (3) become

$$[C_6H_6]\ c_p = 0.3984 + 4.89 \times 10^{-4}t + 7.29 \times 10^{-6}t^2 - 5.25 \times 10^{-8}t^3 \quad (4)$$

$$[C_7H_8]\ c_p = 0.3951 + 2.68 \times 10^{-4}t + 1.026 \times 10^{-5}t^2 - 5.27 \times 10^{-8}t^3 \quad (5)$$

Comparison of Data.—Values of c_p at 5°, intervals, computed from equations (4) and (5), are listed in Table II. They are compared with previous data[9] in Fig. 1, which shows the deviations (*other observer* minus *Burlew*) in millical. of those data that extend over any considerable temperature range. Table III summarizes the most pertinent information concerning the types of measurements that had been carried out in arriving at those values. In nearly all cases the estimated probable error listed in the last column is based on the original author's estimate of the accuracy of his measurements. In Fig. 1 the circles distributed along the two zero base lines indicate the individual values of c_p that are listed

(6) Unless it is feasible to make measurements of specific volume over a wider range of temperature than it is desired to evaluate the coefficient of thermal expansion, one must be resigned to have the probable error of c_p determined by the piezo-thermometric method two to three times as great at the ends of the range as in the middle.

(7) W. E. Deming, *Phil. Mag.*, **11**, 146 (1931). When cubic equations for c_p are derived using equal weights, the individual parameters are somewhat different, but the interpolated values of c_p are not much different from those computed according to equations (2) and (3), respectively. The greatest differences occur at the ends. In the case of benzene, the value at 10° is lowered 0.2 millical. and that at 80° is raised 0.6 millical. by the weighting; whereas in the case of toluene the effect is opposite, the value at 10° being raised 0.3 millical. and that at 110° being lowered 0.3 millical.

(8) Calorie$_{15}$ = 4.1850 absolute joules. F. R. Bichowsky and F. D. Rossini, "The Thermochemistry of the Chemical Substances," Reinhold Publishing Corp., New York, N. Y., 1936, p. 9.

(9) Whenever necessary and possible the data have been corrected to the defined 15°-calorie. In addition it has been necessary to recompute the data of von Reis and of Mills and MacRae, because the equations they published had been derived without regard to all their data. The new equations, evaluated by the method of least squares from all the original data, are

$$[C_6H_6\text{—von Reis}]\ c_p = 0.3853 + 9.0 \times 10^{-4}t \quad (6)$$

$$[C_7H_8\text{—von Reis}]\ c_p = 0.3985 + 6.7 \times 10^{-4}t \quad (7)$$

$$[C_6H_6\text{—Mills and MacRae}]\ c_p = 0.39593 + 5.72 \times 10^{-4}t \quad (8)$$

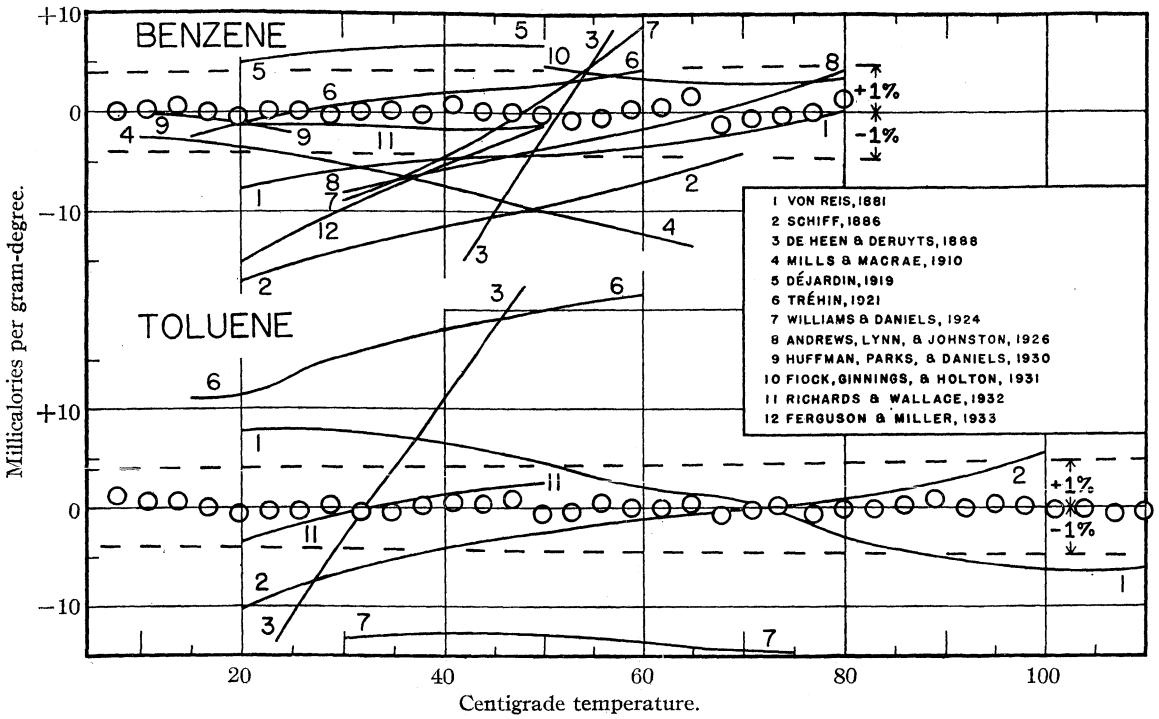

Fig. 1.—Deviations of heat capacities.

[b] The temperature interval through which the liquid was heated or cooled during a single experiment.

in Table I. The radius of each circle is 1 millical., which is approximately the estimated probable error of a single observation in the middle two-thirds of the range.

The present data differ by less than 1% from the mean of all the previous measurements[10] shown in Fig. 1 (neglecting the results of deHeen and Deruyts); but there are great differences among the results of the various investigators, for which no reason is apparent. Although some samples may have been more pure than others, there probably was no gross impurity present in any, for all had been especially purified. What impurities did remain probably would have changed c_p by not more than 0.5%.

The comparison with the work of the early investigators von Reis, Schiff, and deHeen and Deruyts is important, because it furnishes an estimate of the worth of their values of the heat capacity of the many liquids that they alone investigated. The results of deHeen and Deruyts appear worth-

(10) The close agreement between the present results and those of Richards and Wallace is partly accidental, because some of the difference between their values of $(\partial T/\partial P)_S$ and the present ones happened to be balanced by an opposite difference between the present measurements of $(\partial V/\partial T)_P$ and the values that they had taken from the "Int. Crit. Tables."

less. Those of von Reis and of Schiff[11] are within ±2% or ±3% of the truth, if their results for benzene and toluene are fair samples of their work.

In addition to the measurements over a considerable range of temperature recorded in Fig. 1, there have been a considerable number of others. Some[12] of the early ones consisted of only a few measurements by the method of mixtures. Others[13] were just incidental to the investigation of c_p of solutions. Still other measurements[14] made at isolated temperatures involved either single experiments of unverified precision or samples of unknown purity. All these miscellaneous data have been compared with the present results; but the details are scarcely worth recording. Just as those different results show considerable variance among themselves, so the present ones agree with some of them and disagree with others.

Although equation (3) is not suitable for extrapolation to low temperatures, the present data for toluene are consistent with those of Battelli[15] and of Kelley[16] at low temperatures, as can be seen when the several sets of data are plotted on the same graph. Kelley's value at 11.3°, which was the upper limit of temperature in his measurements, is only 2 millical. (0.5%) lower than the present one.

Minimum in c_p of Benzene.—Williams and Daniels,[17] shortly after the publication of the data referred to in Fig. 1, published the results of further experiments with the same calorimeter. They found that the c_p *vs.* t curve of dry samples of benzene exhibited at about 20° a minimum with slight curvature, which they considered indicative of molecular changes in the liquid. A sample saturated with moisture at 6° (0.035% H_2O), however, showed only a marked decrease in slope in the vicinity of 20°. Unfortunately they were not able to trace the course of the curve very far on the low-temperature side of the minimum. The present results, which extend 12° below 20°, give no indication of a minimum. The curve is slightly S-shaped, as mentioned above, which means that the slope is a little less at the low-temperature end than in the middle; but the decrease is not nearly so marked as was found by Williams and Daniels for even a moist sample.

Le Blanc and Möbius,[18] using a heating interval of only 0.1° with a Nernst vacuum calorimeter, made measurements of c_p both above and below the m. p. of a highly purified sample of 75 g. of benzene. Their values at 30.15 and 25.15° (each the mean of two determinations) were 2 and 3 millical., respectively, less than those computed from equation (4). At 14.90° the mean of their twelve determinations was only 1 millical. (0.25%) greater than that computed from equation (4). This value they considered a minimum on the c_p *vs.* t curve, because the mean of five determinations at 6.95° was 6 millical. higher than it and the mean of eighteen determinations at 5.75° was 5 millical. higher. The presence of the minimum they ascribed to the persistence of a state of partial order above the m. p. According to the present data c_p continues to decrease regularly with decreasing temperature down to the limit of the measurements at 7.8°. The present value at this temperature is 11 millical. less than the value found by Le Blanc and Möbius at 6.95°.

Cohen and Buij[19] made triplicate measurements of c_p of carefully purified benzene at 4° intervals from 8 to 24°, in a search for irregularities in the c_p *vs.* t curve. Their conclusion that the curve is linear in this temperature interval is supported by the present data. Their values of c_p were not absolute ones, but were relative to the value 0.4078 cal./g. at 20°, given by Williams and Daniels,[17] which is 0.0028 cal. lower than that found in the present investigation. If the straight line used by Cohen and Buij to express their data is shifted so that it passes through the present value at 20°, their results at other temperatures between 8 and 24° differ from those computed

(11) Schiff's conclusion (*Ann.*, **234**, 300 (1886), p. 327), sometimes referred to as "Schiff's Law," that the specific heat of the different members of a homologous series can be represented by a single straight line or by a few parallel straight lines, is not valid for the two homologs benzene and toluene, as can be seen from Table I. In the "Int. Crit. Tables," nevertheless, twenty-five paraffin esters of the fatty acids are listed on the authority of Schiff as having a heat capacity at 20° of 1.921 j./g., with an uncertainty of only ±0.5%.

from equation (4) by not more than 0.2 millical. (0.05%), which is excellent agreement with respect to the temperature coefficient of c_p.

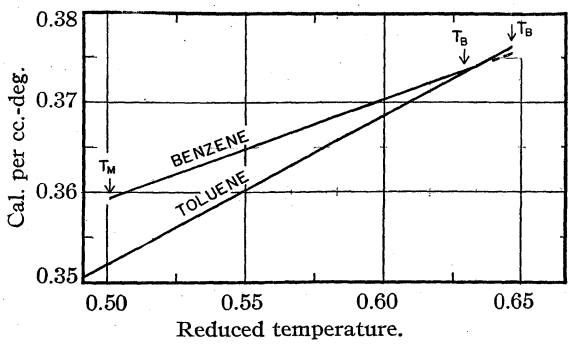

Fig. 2.—Heat capacity per unit volume.

Heat Capacity per Unit Volume

Williams and Daniels[20] suggested on the basis of their data that "the heat capacity per cubic centimeter of unassociated liquids is a constant, approximately 0.35 calorie per degree at room temperature and slightly more than this at higher temperatures." The present data are especially suitable for a test of this suggestion. The values[21] of c_p in cal. per cc., computed at each temperature at which a measurement of $(\partial T/\partial P)_S$ had been made, varied much less with the temperature than the corresponding values of c_p in cal. per gram; but they were by no means constant for either liquid over the whole temperature range nor were they the same for both liquids at the same temperatures. The variation with temperature was expressed by these two linear equations

$$[C_6H_6]\ c_p\ (\text{cal./cc.-deg.}) = 0.3579 + 1.97 \times 10^{-4}t \quad (9)$$

$$[C_7H_8]\ c_p\ (\text{cal./cc.-deg.}) = 0.3453 + 2.79 \times 10^{-4}t \quad (10)$$

The fit of these equations was better than that of linear equations for c_p in cal. per gram. Thus the probable error of an individual observation based on the residuals was 4% less for equation (9) than for the corresponding one for c_p in cal. per gram and 28% less for equation (10). The straight lines represented by equations (9) and (10) approach each other at higher temperatures, but they do not intersect within the normal liquid range.

When the temperature variable in equations (9) and (10) is changed to the reduced temperature (that is, the absolute temperature divided by the absolute temperature of the critical point), the relative slopes of the lines are scarcely changed, but the line for toluene is shifted to the left, so that the two lines intersect as shown in Fig. 2. The reduced temperature of the point of intersection (0.635) is in good agreement with the conclusion of Schiff[22] that at six-tenths of the critical temperature equal volumes of homologous liquids (in his case 27 esters of fatty acids) have equal heat capacities.

Alleged Allotropy of Benzene

It is desirable to emphasize that the data presented in this series of three papers contradict the several suggestions that have been made concerning irregularities in the variation of the physical properties of benzene with temperature. Not only was no minimum observed in the c_p *vs.* t curve, as discussed above, but also comparison of the observations of $(\partial T/\partial P)_S$ and of the specific volume of benzene with those of toluene show the former to vary just as regularly in the neighborhood of 40° as the latter. This conclusion, which is in opposition to the suggestion that Menzies and Lacoss[23] made after an examination of the data of others for several physical properties, agrees with the measurements by Pesce[24] of the specific volume and the refractive index and with those of the specific volume by Cohen and Buij,[19] all of which had been made for the purpose of testing the suggestion of Menzies and Lacoss.

Acknowledgment.—It is a pleasure to thank my wife, Grace Schaum Burlew, for assistance in the computation of these data and in the preparation of the manuscript.

Summary

Values of the heat capacity of benzene and of toluene, computed from $(\partial V/\partial T)_P$ and $(\partial T/\partial P)_S$ measured with 5-cc. samples at 3° intervals from 8° to the respective boiling points, have been shown to agree with results by other investigators. No evidence has been found to support the suggestion that benzene is allotropic.

A Direct Method of Calibration of a Copper–Constantan Thermel for Measurement of Temperature Differences at a Series of Temperatures

BY JOHN S. BURLEW[1] AND RODNEY P. SMITH

The suitability of a thermel for differential temperature measurements has long been recognized,[2a] but heretofore the advantage of a differential method of calibration has been neglected. Because of inhomogeneity, the accuracy of an actual thermel is not, like that of an "ideal" thermel, independent of the method of calibration. The requirement for the highest accuracy—namely, that the temperature gradients be of the same order of magnitude and occur at the same places during calibration as during use—is approached most closely by the direct differential method of calibration described in the present paper.

A thermel that is to be used for the measurement of individual temperatures is calibrated regularly according to any one of several procedures[3] that permits the expression of the total e. m. f. as a function $E(t)$ of the temperature of one junction, when the other junction is kept at a fixed reference temperature. Inhomogeneity of a thermel calibrated in this way (to which we shall refer as "the integral method of calibration") introduces an error[2b] that is approximately a fixed proportion of the total e. m. f., because both vary directly as the temperature. Usually it is possible, however, to increase[4] the accuracy of temperature measurements with such a thermel by having the temperature gradients during calibration occur at the same places along the wires as during use.

A thermel that is to be used for the measurement of temperature differences also may be calibrated by the integral method; but the error from inhomogeneity will be considerably greater than if the same thermel were used for single temperature measurements. The error is magnified because, first, the e. m. f. that corresponds to the difference in temperature is the difference between two large e. m. f.'s with each of which is associated an error due to inhomogeneity; and, second, the temperature gradients during calibration are much steeper and occur along different portions of the wires than those during subsequent use.

This magnification of the error from inhomogeneity is particularly important with a copper–constantan thermel, for even the best constantan wire, especially in the smaller sizes,[5] is not completely homogeneous. An effect of this sort interfered with the calibration of a thermel of No. 40 copper and constantan wires intended for use in the piezo-thermometric method[6] of measuring the heat capacity of a small volume of liquid. It was overcome by the direct method of calibration that we describe in this paper.

A thermel is arranged during calibration by this method in a manner similar to that during subsequent use, which not only diminishes the error from inhomogeneity, but also often simplifies the experimental set-up. A further advantage of this method is that the e. m. f.'s measured during calibration approach in magnitude those during the later use of the thermel. Consequently the electrical measurements may be performed with greater convenience and accuracy. It was for this reason that a 26-junction thermel used recently for the measurement[7] of boiling point elevations was calibrated by the differential method.

Differential Method

The Function μ.—The direct differential method of calibration that we have used involves the measurement of the e. m. f. (ΔE) of a thermel whose junctions are at two temperatures (t_1 and t_2) and the simultaneous measurement of the temperature difference ($\Delta t = t_2 - t_1$). The results of the calibration are expressed conveniently in terms of a function that we call μ, which is the quotient of these two measured quantities. Provided that the temperature differences remain approximately constant, a series of μ's obtained during calibration can be expressed as a quadratic function of the mean temperature of the junctions

$$\mu \equiv \frac{\Delta E}{t_2 - t_1} = \alpha + \beta t_m + \gamma t_m^2 \left[t_m = \frac{t_1 + t_2}{2} \right] \quad (1)$$

in which α, β and γ are empirical parameters.

(7) Rodney P. Smith, THIS JOURNAL, **61**, 497 (1939).

The function μ is the slope of a secant that cuts the curve representing the function $E(t)$. The thermoelectric power (dE/dt) is the tangent to this same curve; but because of the shape of the curve for a copper–constantan thermel, the tangent at a particular temperature t_m is not quite parallel to the secant whose mid-abscissa is t_m. This curve is represented accurately over fairly large ranges of t by

$$E = at + bt^2 + ct^3 \quad (2)$$

It can be shown algebraically by a combination of equations (1) and (2) that

$$\mu - \frac{dE}{dt} = c\left[\frac{t_2 - t_1}{2}\right]^2 = \frac{\gamma}{12}(\Delta t)^2 \quad (3)$$

Hence a value of μ that applies to one temperature difference Δ_1 may be transformed into one to apply to any other temperature difference Δ_k by this equation

$$\mu_{\Delta_k} - \mu_{\Delta_1} = \frac{\gamma}{12}[(\Delta_k)^2 - (\Delta_1)^2] \quad (4)$$

in which γ is the parameter in equation (1). For a copper–constantan thermel γ is about 1 (10^{-6}) (*cf.* equation (9)), and so this transformation term is not large. By the combination of equations (1) and (4), a temperature difference at any mean temperature within the range of the calibration may be computed directly from the measured e. m. f. of the differential thermel.

Relation of μ to the Integral Method.—Application of the function μ is not limited to a thermel calibrated by the differential method. If a homogeneous thermel that has been calibrated by the integral method is used for the measurement of a temperature difference, μ can be employed to compute that difference directly, which is simpler than the usual computation of the separate temperatures of the two junctions by a series of approximations. If the parameters in equation (2) have been evaluated as a result of the calibration by the integral method, it follows from equation (3) that the parameters in equation (1) can be derived from them as follows

$$\alpha = a + c\left[\frac{\Delta t}{2}\right]^2; \quad \beta = 2b; \quad \text{and } \gamma = 3c \quad (5)$$

If the total e. m. f. has been expressed by the exponential equation[8]

$$E = At + B(1 - e^{Ct}) \quad (6)$$

the parameters of equation (1) are given to a high degree of approximation by these relations

$$\alpha = (A - BC); \quad \beta = -BC^2; \quad \text{and } \gamma = -\frac{5}{6}BC^3 \quad (7)$$

Experimental Procedure

In the calibration of a thermel by the differential method, we used a duplex oil thermostat having two similar halves mounted in a wooden cabinet (60 × 110 × 55 cm., supported on legs 40 cm. high) with a wooden partition between them. Each half was a separate thermostat that could be heated and stirred independently. Each thermostat tank, which was a cylinder of galvanized iron (45 × 45 cm.), had an overflow pipe 4 cm. from the top in order to keep the level of the automobile "flushing oil" constant. A stirrer-propeller that rotated in a tube about 10 cm. in diameter was directly driven by a high-speed motor mounted on the cabinet. Tap water could be circulated through a cooling coil of copper tubing in the upper part of each propeller tube. The oil-baths were heated electrically by commercial resistance units of the type that are used in radiant heaters, screwed into porcelain sockets mounted on the underside of a wooden cover resting on top of the tanks. The main heaters were controlled by lamp-banks, and an intermittent heater in each tank was controlled through a magnetic relay by a conventional mercury-in-glass thermoregulator immersed in the oil-bath.

A region of constant temperature in each oil-bath was provided by a well containing mercury, the top of which was 9 cm. below the surface of the oil. The well was constructed from iron pipe fittings (inside dimensions, about 4 × 25 cm.), the bottom part being a flanged nipple filled with lead.

Above the wooden cover resting on the oil tanks, the thermostat cabinet had a separate cover with a removable center. The thermel to be calibrated straddled the partition between the oil tanks, its mid-section clamped to a copper plate and its limbs immersed in the two mercury wells. The mid-portion of the constantan wire was kept at nearly the mean temperature of the junctions, both by having the mid-section of the case of the thermel constructed from a metal tube[9] that dipped into the oil in both halves of the thermostat, and by having this part placed beneath the upper cover of the thermostat. Then, by observing similar precautions during the use of the thermel, it could be assured that the temperature gradients along the constantan wire would be of approximately the same magnitude and would occur at about the same places as during calibration. The wires from the thermel passed through a shielded slot in the upper cover to a shielded copper connection box mounted on top of the thermostat cabinet. From there an all-copper circuit led through a shielded conduit to the potentiometer.

The temperature of each half of the duplex thermostat was measured in turn with a platinum resistance thermometer,[10] that dipped into the mercury well through holes in the covers. The thermometer was kept in each

(9) *Cf.* W. P. White, THIS JOURNAL, **36**, 2303 (1914). We have found that the assembly of a thermel is facilitated by the use of copper pipe and the copper solder-joint fittings that have come into use recently for household plumbing. These fittings enable one to enclose the thermel wires by easy stages without making the case undesirably bulky. A copper straight-coupling makes an especially good socket in which to cement the glass tube that forms the lower end of a limb of the thermel.

(10) An alternative arrangement would be the use of a pair of resistance thermometers connected differentially, as described by Laby and Hercus, *Trans. Roy. Soc.* (*London*), **227**, 63 (1928).

side long enough to show that the temperature there was constant, after which it was returned to the first side to make certain that its temperature had not changed. During all three sets of observations the e. m. f. of the thermel was measured at regular intervals.

The temperature within either well of the thermostat in the temperature range 20 to 140° had a maximum variation of ±0.005° over a period of about one-half hour—although often the variation was only ±0.001°. The observed variation in the e. m. f. of the thermel gave a direct measure of the constancy of the temperature difference between the two halves of the thermostat. In a series of measurements during the calibration of a particular thermel at five mean temperatures from 20 to 65°, the average maximum fluctuation in the temperature difference of 10° was ±0.002°. At higher temperatures (up to 125°) the maximum fluctuation was about twice this amount. The latter variation represented an uncertainty of ±0.05% in the measured e. m. f., which was about the same magnitude as the uncertainty in the temperature difference as measured with the resistance thermometer.

The quotient of the e. m. f. divided by the temperature difference was a value of μ at a particular mean temperature t_m. A series of eight or ten such measurements was made, using a temperature difference between the junctions of approximately 10° at different mean temperatures. From the resulting μ's and t_m's the parameters in equation (1) were evaluated by the method of least squares.

Experimental Comparison of Methods

The differential and integral methods of calibration were compared by direct experiment using two copper–constantan thermels that had been constructed from No. 30 constantan and No. 36 copper wires. The maximum inhomogeneity of the constantan was less than 0.05% of its thermoelectric power against copper, as determined by the method described by White.[2c]

Calibration of Thermel A.—Thermel A was calibrated according to the integral method by measurement of the e. m. f. produced when one junction was kept at 0° and the other was heated to different temperatures between 40 and 130°. Temperatures were measured with a platinum resistance thermometer (Leeds and Northrup), the fundamental interval of which we redetermined prior to the calibration, measuring the resistance with the same Mueller-type bridge (Leeds and Northrup) that we used during the temperature measurements. The calibration measurements were made at 10° intervals with first one junction at 0° and then the other. Each value of the e. m. f. was divided by the corresponding temperature; and then the two sets of values of E/t were fitted to separate quadratic equations in t by the method of least squares,[11] with equal weight assigned to each variable. Residuals were computed for each set of data with respect to the equation derived from it and also with respect to the equation obtained by taking the mean values of the respective parameters of the two equations. The probable error (P. E.) of a single observation corresponding to the residuals of the mean equation was only slightly larger than that corresponding to the residuals of each individual equation—4% larger in one case and 16% in the other. For as few as ten observations these differences are without practical significance; and so the mean equation is used to represent the e. m. f. of the thermel

$$E = 38.3162\,t + 4.56212\,(10^{-2})t^2 - 3.3208\,(10^{-5})\,t^3 \quad (8)$$

The P. E. of this function,[12] based on the residuals, is 0.003% or less in the range 40 to 130°. This low P. E. and the agreement between the reversed calibrations indicate that the inhomogeneity of this thermel was very small.

Calibration of Thermel B.—Thermel B was calibrated according to the differential method in the duplex thermostat already described by measuring the e. m. f. that was produced by at emperature difference of about 10° at different mean temperatures at 15° intervals from 5 to 125°. Each junction of the thermel was the cold junction during half the measurements. The temperature differences were measured with the same resistance thermometer used in the calibration of Thermel A. The separate values of μ were fitted to a quadratic equation in t_m by the method of least squares,[11] with infinite weight assigned to the values of the mean temperature. The resulting function

$$\mu_{10} = 42.6744 + 7.6183\,(10^{-2})\,(t_m - 65) - 9.745\,(10^{-5})\,(t_m - 65)^2 \quad (9)$$

has a P. E.[12] of 0.03% or less in the range 10 to 110°.

Mode of Comparison.—For the comparison of the two methods of calibration, both thermels were placed in the duplex thermostat at the same time. The temperatures of the two sides of the thermostat were maintained 10° apart at each of six mean temperatures from 30 to 105°. The temperature of the colder side was measured with the platinum resistance thermometer that had been used in the calibrations. The same ends of the thermels were always on this side. Two sets of observations at each temperature were made twenty minutes to an hour apart.

TABLE I

MEASUREMENT OF TEMPERATURE DIFFERENCES WITH THERMEL A

Nominal mean temp., °C.	t_1, °C.	E_A μv.	E_1 μv.	E_2 μv.	t_2, °C.	$(\Delta t)_A = (t_2 - t_1)$, °C.
30	25.009	405.62	986.26	1391.88	34.911	9.902
	25.011	405.66	986.35	1392.01	34.915	9.904
45	40.106	412.64	1607.95	2020.59	49.880	9.774
	40.102	413.37	1607.79	2021.16	49.893	9.791
60	55.100	435.30	2244.17	2679.47	65.121	10.021
	55.099	434.47	2244.13	2678.60	65.101	10.002
75	69.917	446.48	2890.61	3337.09	79.930	10.013
	69.919	446.48	2890.71	3337.19	79.932	10.013
90	85.292	462.41	3579.34	4041.75	95.400	10.108
	85.291	462.76	3579.30	4042.06	95.407	10.116
105	100.088	509.31	4258.71	4768.02	110.963	10.875
	100.078	509.51	4258.24	4767.75	110.957	10.879

Data.—In Table I under "t_1" is listed the cold temperature measured with the resistance thermometer, and under "E_A" is listed the e. m. f. of Thermel A. The temperature difference corresponding to this e. m. f. difference was found by computing the temperature (t_2) of the hot side of the thermel in the following manner. First the e. m. f. (E_1) corresponding to t_1 was computed from equation (8). To it was added E_A to give E_2. Then the temperature (t_2) corresponding to E_A was computed from equation (8) by successive approximations.

TABLE II

MEASUREMENT OF TEMPERATURE DIFFERENCES WITH THERMEL B

Nominal mean temp., °C.	t_1, °C.	E_B μv.	t_m, °C.	μ μv./°C.	$(\Delta t)_B = E_B/\mu$, °C.	Difference $(\Delta t)_A - (\Delta t)_B$, °C.

In Table II under "E_B" is listed the e. m. f. of Thermel B. The temperature difference was found by a series of approximations, usually three. First a value was assumed for the mean temperature, and the corresponding value of μ was computed from equation (9). The first approximation to the temperature difference was found by dividing E_B by μ. Half of this difference was added to the measured cold temperature to obtain a second approximation for the mean temperature. The cycle was repeated until the same value of the mean temperature was obtained twice in succession. It is this final value of "t_m" together with the corresponding "μ" that is listed in Table II.

Conclusion.—The agreement between the values of Δt that were obtained with the two thermels is excellent, inasmuch as the estimated relative probable error of a single measurement of the temperature difference with either thermel was ±0.008°. The maximum difference between the two sets of values, as shown in the last column of Table II, is 0.005°, and the average difference without regard to sign is 0.002°.

Summary

The computations involved in the measurement with a thermel of temperature differences at a series of mean temperatures (t_m) are simplified by the introduction of the function

$$\mu \equiv \Delta E/(t_2 - t_1) = \alpha + \beta t_m + \gamma t_m^2$$

A direct differential method of calibration, whereby the parameters of this equation are evaluated, minimizes the error from inhomogeneity. For the demonstration of the experimental validity of this method, a copper–constantan thermel that had been calibrated by it was compared with one that had been calibrated by the ordinary integral method: in a series of temperature differences measured with the two thermels the maximum divergence was 0.005°, which was less than the experimental uncertainty.

The Interpretation of Simple Electrophoretic Patterns

BY L. G. LONGSWORTH AND D. A. MACINNES

Introduction.—An electrophoresis experiment with a single protein may be represented diagrammatically as follows. Initially boundaries are formed at the level a′-a, of Fig. 1, in the two sides of the cell, between the protein solution P and the buffer solution B. After displacement of the boundaries from behind the horizontal glass plates of the cell, passage of a current causes one of the boundaries, a, to descend through a volume V_d to a new position d, as in Fig. 2, and the other,

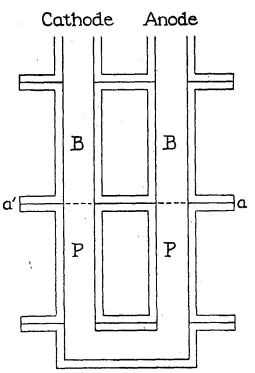

Fig. 1.

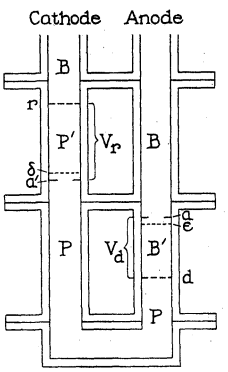

Fig. 2.

Figs. 1 and 2.—Diagrams of the electrophoresis cell illustrating the formation and relative position of the boundaries.

a′, to rise through a volume V_r to the position r of the same figure. Under ideal conditions, approximated with a dilute solution of a protein in a buffer of sufficient capacity, the volumes V_d and V_r are equal and a knowledge of their value permits a precise computation of the mobility of the protein. In general, however, the volume V_r is greater than V_d and an analysis of the concentration changes resulting from the electrolysis is necessary in order to obtain mobilities from the experimental results. It is the purpose of this paper to describe electrophoretic experiments on ovalbumin, at 0°, in which these concentration changes have been determined, and to outline an analysis of the data for the purpose of obtaining accurate mobilities.

Methods.—The recent development of methods for studying and recording refractive index gradients, initiated by Tiselius,[1] has made possible the precise study of electrophoretic boundaries. From "electrophoretic patterns" thus obtained concentration changes during electrophoresis may be computed. The available procedures are the scale method of Lamm,[2] the diagonal schlieren method of Philpot[3] and Svensson[4] and the schlieren scanning method developed in this Laboratory[5,6] and used in the present research.

In outline the schlieren scanning method is illustrated in Fig. 3. An image at P of the illuminated slit S-S is formed by the schlieren lens D. The camera lens O is focused on the electrophoresis cell E and forms an image (full sized in our apparatus) on the screen at G-G. Now if the fluid in the cell is homogeneous this image will be uniformly illuminated. On the other hand, if there is a boundary, B, between, for instance, a protein-bearing solution and a buffer, there will be a region in which the refractive index varies with the height in the cell, and light which would normally pass to P is deflected downward, since the solution with the greater refractive index is on the bottom. If the opaque schlieren diaphragm Q is raised to a point p where it intercepts the most deflected light, a dark band will

appear on the screen, conjugate to the region of steepest gradient in the boundary B. Such a band appears in the image G-G at p′.

However, a boundary between two solutions does not consist of a single geometric plane, but of a region in which the composition varies from that of one solution to that of the other. The refractive index, n, in such a region changes continuously with the height, h, of the liquid in the cell. The gradient, dn/dh, of refractive index, for each boundary, will thus, theoretically at least, vary from zero to a maximum, and back to zero. In Fig. 3 the variation of the gradient, dn/dh, of the boundary B in the cell E, is represented by the density of the shading. The pencil

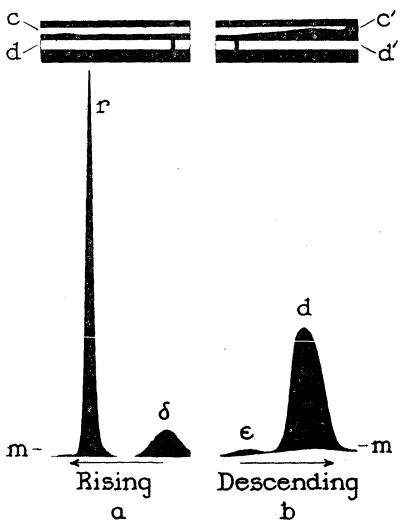

Fig. 4.—Electrophoretic patterns of a 1.36% solution of ovalbumin in a 0.1 N sodium acetate buffer at pH 3.92 and 0°. Scanning exposure made after electrolysis for 13,000 seconds at 5.39 volts per cm.

of light passing through the layer having the maximum value of the gradient will be most bent from the normal path and will be the first to be intercepted when the schlieren diaphragm Q is raised. On lifting this diaphragm still further, *i. e.*, to the level q, less refracted pencils of light will also be intercepted and the schlieren band in the image G-G will widen. This obviously can be continued until the whole field has been covered. In the schlieren scanning method this process is made continuous and is recorded photographically. The image of the cell at G-G is masked by a narrow vertical slit and a photographic plate A is moved in the direction of the arrow at a constant rate across this slit. Actuated by the same mechanism, the schlieren diaphragm Q is given a steady movement upward. The resulting (positive) photographic record for a typical single boundary is indicated by the area e-f-g. The displacement of the diaphragm Q from the position P is proportional to the gradient at levels in the cell E conjugate to the edges of the schlieren bands. Thus the contour of the area e-f-g indicates both the position and the magnitude, of the refractive index gradients existing in the boundary. Since the photographic plate A was in position a at the time the schlieren diaphragm was at p, a section of the band p′ appears at f when the plate has been moved to a′. It will be seen that the usual schlieren bands are narrow sections through the area e-f-g. By a system of gears the ratio of the rates of motion of the schlieren diaphragm Q to that of the plate A is given a constant value, such as one to three, and this ratio can be varied by changing the gears. For establishing the base line of the schlieren patterns the position of the diaphragm Q may be read accurately with a micrometer.

Experimental Results and Discussion.—The type of phenomenon to be discussed in this paper is illustrated in Fig. 4, which represents electrophoretic patterns of a 1.36% solution of ovalbumin at pH 3.92 in a 0.1 normal sodium acetate buffer.[7]

In order to interpret these patterns in terms of concentrations and mobilities, information must be available about (a) the base line of the diagram and (b) the starting position of the boundaries. The base line is obtained as shown at c-c′ of Fig. 4 by a scanning exposure of the cell immediately after the formation of the boundaries but before the latter have been shifted into view from behind the horizontal glass plates. The procedure consists in setting the schlieren diaphragm, Q of Fig. 3, just below P, the exact position of the diaphragm being given by the reading, m of a micrometer, and then scanning until the diaphragm is somewhat above P. The lower edges of the strips c and c′ of Fig. 4 are thus the schlieren patterns of the windows of the cell and thermostat, deviations of these edges from the horizontal indicating imperfections in the windows. The upper edges of the strips c and c′

(7) The ovalbumin used in this research was prepared from fresh hen's eggs. Although three times recrystallized, it was not electrophoretically homogeneous. At most pH values the main component is accompanied by a second component migrating somewhat more slowly, as shown in Fig. 2 of reference (5) and in Fig. 6 of this paper. Similar patterns have been obtained with samples of ovalbumin from four different laboratories. A study of egg white now in progress indicates that the slow component is present in the starting material. Ovalbumin appears homogeneous in the patterns reproduced in Fig. 4, because the pH-mobility curves of the two components apparently intersect in the neighborhood of the isoelectric point. At pH 3.92 the protein may be considered electrically homogeneous, thereby simplifying the interpretation of the patterns.

correspond to a reading, m, of the micrometer. The equivalent position on the patterns a and b, Fig. 4, is at m-m. Consequently when the upper edges of the strips c-c′ are brought into coincidence with the line m-m the lower edges of these strips constitute the base line for the patterns. In order to obtain the position of the freshly formed boundaries after they have been shifted into view, the schlieren bands shown at d-d′ in Fig. 4 are recorded on the photographic plate. As Guggenheim[8] has suggested, the diffusion process smooths out the slight irregularities in the distribution of concentrations resulting from the formation and shifting of the boundaries. As illustrated by the finite width of the bands in the strip d-d′, the boundaries are not infinitely sharp. However, the positions of the mid-points of these bands may be taken as the positions at zero time from which mobilities can be computed.

It will be seen in Fig. 4 that two peaks or maxima are evident in the patterns of both the rising and descending boundaries but that the patterns are far from being mirror images of each other. This may, possibly, be an extreme case but is all the more useful in illustrating deviations from ideal behavior and in testing the validity of the interpretation to be given below.

The deviations, or so-called "boundary anomalies," illustrated by these patterns are as follows. (1) The rising boundary r is much sharper than that, d, descending into the protein solution. (2) The boundary r has swept through a larger volume V_r, than that, V_d, of the boundary d. (3) The total shaded area of Fig. 4a is equal to that of Fig. 4b, but the partial area A_r under the rising boundary r is less than that, A_d, for the descending boundary d. Since these areas, as will be shown, are proportional to the concentration changes at the boundaries it is apparent that the change is less at the rising boundary than at the descending one. Also (4), the concentration distribution in a boundary is not, in general, symmetrical about the maximum as is shown by the shapes of the peaks d and r.

These deviations were explained qualitatively by the authors[9] as follows. In practice the protein solution is prepared by dialysis against a buffer solution. A difference, due to the Donnan equilibrium, of salt composition exists between the two solutions when dialysis is complete. Moreover, the protein solution contains conducting constituents, the protein ions, that are not present in the buffer solution. When passage of a current causes a boundary between two such solutions to move from a to d of Fig. 2, for example, there is found in the intervening volume V_d a buffer solution of composition [B′]. This composition has been adjusted, in general, to a value different from that of B.[10] The boundary ϵ, which moves very slowly, thus forms between two solutions of the same buffer, but at different concentrations,[11] and is quite evident in Fig. 4. With the boundary r moving upward into the buffer solution, there is a similar but more complicated adjustment of the composition of the protein solution which replaces the buffer as the boundary rises. The resulting concentration boundary δ, between the solutions P and P′, Fig. 2, also moves very slowly under the influence of the current. The δ boundary, also shown in Fig. 4, is much more visible than the ϵ boundary because the former involves a gradient of protein concentration whereas the latter does not.

Since the specific conductance, κ_P, of the protein solution P has been found experimentally to be less than that, κ_B', of the adjusted buffer solution, the electric field is greater in the protein solution than in the buffer and variations of this field thus exist at the descending boundary d. The protein ions in the dilute uppermost layers of the boundary d are therefore in weaker fields than are those in the concentrated layers and thus tend to lag behind, causing the boundary to become diffuse, as is shown in Fig. 4b. In the case of the boundary r rising into the buffer solution $\kappa_P' < \kappa_B$ so that the dilute, slowly moving protein ions tend to be overtaken by the faster concentrated ones, with the result that this boundary tends to remain sharp, as is illustrated by Fig. 4a. Due to these field gradients at the boundaries, and in some instances to *p*H gradients also, the distribution through a boundary may be unsymmetrical about the ordinate passing through the maximum of the refractive index gradient curve. This lack of symmetry, shown clearly by the boundary d of Fig. 4b, has been studied by Tiselius and Horsfall.[12] Assuming a proportionality between refractive index and protein concentration it is apparent that in such cases the position of the maximum gradient is not identical with that of the ordinate which divides the area under the

(10) This adjustment is understood for some simple cases (Kohlrausch, *Ann. Physik*, **62**, 209 (1897); Weber, "Die partiellen Differential-Gleichungen der mathematischen Physik," 5te Aufl., Braunschweig, 1910, **1**, 195–203, 503–527; Longsworth, THIS JOURNAL, **52**, 1897 (1930); Henry and Brittain, *Trans. Faraday Soc.*, **29**, 798 (1933)) but the theory for the more complicated systems frequently encountered in practice has not been developed.

curve into two equal parts. The position of the latter ordinate is the better value to use in mobility computations since it is approximately the position the boundary would have if it retained its original sharpness. The precise location of an unsymmetrical boundary requires an integration of the concentration–distance curve. Computations for the cases considered in this paper show that the position of the ordinate dividing the gradient curve into equal parts differs from the true value by at most 1%, whereas the position of the maximum ordinate may be in error by 19%.

It is important in this connection to be clear as to what is meant by the mobility, u, of a protein. It is the distance moved per second in a unit electric field by an average particle in the body of the protein solution. The movement of the particle through this distance corresponds to the transport of uA [P] grams of protein through a plane (to be discussed below) in the body of the protein solution, A being the cross-sectional area of the channel and [P] the concentration of protein in grams per milliliter. If the electric field, F, differs from unity and the transport continues for t seconds the total quantity, p, of protein transported through a reference plane is $p = uA[\mathrm{P}]Ft$, from which $u = p/FAt[\mathrm{P}]$. Since the field strength, F, in the body of the protein solution is $i/\kappa_{\mathrm{P}}A$ this expression becomes

$$u = p\kappa_{\mathrm{P}}/[\mathrm{P}]it \qquad (1)$$

in which i is the current. The quantity p is determined analytically in the Hittorf or "transport" method, whereas in the moving boundary method it is determined by following the motion of a boundary between the solution and the buffer. If the passage of electricity causes a boundary to descend from a to d, of Fig. 2, it sweeps through a volume $A(a - d) = V_{\mathrm{d}}$. Thus the amount of protein passing any plane in the unmodified solution is $A(a - d)[\mathrm{P}] = V_{\mathrm{d}}[\mathrm{P}]$. Equation 1 thus becomes

$$u_{\mathrm{d}} = \frac{A(a-d)[\mathrm{P}]}{[\mathrm{P}]}\frac{\kappa_{\mathrm{P}}}{it} = \frac{V_{\mathrm{d}}\kappa_{\mathrm{P}}}{it} \qquad (2)$$

in which u_{d} indicates the mobility computed from data on the descending boundary.

The computation of mobilities from data on the rising boundary is, however, complicated by the change of protein concentration at the δ boundary. Assuming, in essential agreement with experiment, that the latter remains stationary, the quantity, p, of protein migrating upward through a plane in the body of the solution on the passage of it coulombs is $(r - a')A$ [P′] $= V_{\mathrm{r}}$[P′] in which [P′] is the concentration of protein in the adjusted solution between the δ and r boundaries. Introducing this value of p into equation 1 we obtain

$$u_{\mathrm{r}} = \frac{[\mathrm{P}']}{[\mathrm{P}]}\frac{V_{\mathrm{r}}\kappa_{\mathrm{P}}}{it} \qquad (3)$$

which differs from equation 2 in that it contains the concentration ratio [P′]/[P]. Since it is one of the main conclusions of this paper that, correctly interpreted, the data on rising and descending boundaries yield the same value of the mobility, *i. e.*, $u_{\mathrm{d}} = u_{\mathrm{r}}$, it is important to establish values of the ratio [P′]/[P]. This requires an investigation, which is given below, of the changes of protein and salt concentrations in the channel of the apparatus during electrolysis.

Strictly, the reference plane from which mobilities are measured should be fixed with respect to the solvent. Since the observed boundary displacements refer to a plane fixed with respect to the apparatus they should be corrected for the displacement the solvent experiences as a result of electrolysis (see reference 11, page 203) otherwise the mobilities found will depend, among other things, upon the nature of the electrode reaction. This computation is greatly facilitated if one electrode chamber is closed since only the volume changes occurring on this side of the protein solution can affect the position of the boundaries. In the experiments reported in this paper the anode chamber was closed and the volume change, ΔV, was equal to

$$\Delta V = f(T_{-}\varphi_{\mathrm{NaAc}} - \varphi_{\mathrm{NaCl}} + V_{\mathrm{AgCl}} - V_{\mathrm{Ag}}) - [\mathrm{P}]V_{\mathrm{d}}\bar{\varphi}_{\mathrm{P}}$$

in which V_{d} is the volume swept through by the descending boundary, for example, on the passage of f Faradays, T_{-} the anion transference number of sodium acetate, φ and V are the apparent molal and molal volumes, respectively, of the materials indicated by the subscripts, and $\bar{\varphi}_{\mathrm{P}}$ is the apparent specific volume of the protein. On the basis of the available data

$$\Delta V = 19.03f - 0.749[\mathrm{P}]V_{\mathrm{d}}$$

A positive value for this volume change represents an expansion of the solution in the closed side and consequently the observed V_{d} is too large by an amount ΔV. The values of V_{d} and V_{r} recorded in Table I have been corrected for this volume change. The corrections for the descending boundary are 2.1, 1.5 and 0.5% at protein concentrations of 0.64, 1.36 and 2.74%,

respectively, and are thus by no means negligible. The validity of the correction is difficult to prove in the case of the electrophoresis of proteins but has been amply demonstrated for strong electrolytes.[11]

We have observed repeatedly, within a small experimental error, that (1) the total area of an electrophoretic pattern is independent of the time during the electrolysis at which a pattern may be obtained, *i. e.*, the area is independent of the mode of variation of the refractive index through the boundaries and (2) the total areas of the patterns for the two sides of the channel are identical. These observations are consistent with the fact that the total area of a pattern is given by the integral $\int_B^P (dn/dh)dh$, in which n is the refractive index at the level h in the cell, the limits of integration being the same for both sides of the channel and independent of the time of electrolysis. Thus the results of planimeter measurements on enlarged images of Figs. 4a and b, in arbitrary units, yielded $A_\epsilon = 18$, $A_d = 354$, $A_\delta = 72$ and $A_r = 302$, from which the sum of the areas for the descending boundaries, $A_\epsilon + A_d$, is 372, whereas the sum, $A_\delta + A_r$, for the rising boundaries has the closely agreeing value of 374.

From the discussion given above it is evident that the partial area A_ϵ of Fig. 4 is due to a gradient of buffer concentration. Since the solution P retains its original composition, in which the buffer electrolyte concentration differs but little from that of solution B, another variation of salt concentration, opposite in sign to that at the ϵ boundary, must exist in the boundary d. Consequently the area A_d must be increased by an amount A_ϵ in order to measure the change of protein concentration at the boundary d. Conductance measurements of the B′ and P′ solutions, to be described later in this paper, indicate that the δ boundary also contains a gradient of buffer salts. Since the same quantity of electrolyte enters the channel from the electrode vessel on one side as leaves the channel on the other side, it follows that the increment of buffer electrolytes in the B′ solution must be compensated by a corresponding decrement in the P′ solution. The concentrations of salts [B] and protein [P] as functions of the height can thus be represented schematically, as is shown in Fig. 5. The increment of buffer salts in the B′ solution is proportional to $A_\epsilon V_d$ while the corresponding and equal decrement in the P′ solution is proportional to $A'_\epsilon V_r$ in which A'_ϵ is that portion of the area A_δ due to the electrolyte gradient in the δ boundary. Therefore $A'_\epsilon = A_\epsilon V_d/V_r$. Moreover, since an electrolyte gradient, equal in magnitude but opposite in sign to that in the δ boundary, must also exist in the boundary r, the area A_r must be increased by an amount $A_\epsilon V_d/V_r$ in order to measure the change of protein concentration at this boundary. The ratio [P′]/[P] of equation 3 thus takes the value $(A_r + A_\epsilon V_d/V_r)/(A_d + A_\epsilon)$ and equation 3 becomes

$$u_r = \frac{V_r \kappa_P}{it} \times \frac{A_r + A_\epsilon V_d/V_r}{A_d + A_\epsilon} \qquad (3a)$$

A small error may arise from the use of equation 3a due to the fact that account has not been taken of slight pH changes at the boundaries.

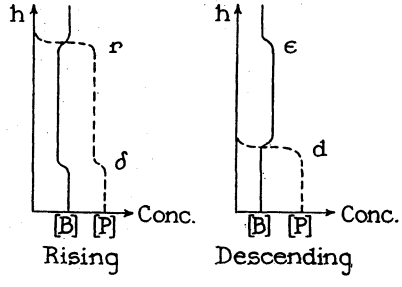

Fig. 5.—Schematic diagram of the changes of buffer electrolyte (———) and protein (– – –) concentrations at each of the electrophoretic boundaries.

The data necessary for the computation, and the resulting mobilities, at three concentrations of ovalbumin are recorded in Table I. The figures in the second column include data obtained from Fig. 4 and at the other concentrations

from similar electrophoretic patterns. The mobilities u_d given in line 13 have been computed with the aid of equation 2 whereas the values u_r in line 12 were obtained from equation 3a. It will be noted that they agree reasonably closely, as would be expected if our interpretation is correct. Line 11 contains values of u_r^* computed from the relation $\kappa_P V_r/it$, in which the change of protein concentration at the δ boundary, *i. e.*, [P']/[P], has been ignored. The large error which may arise from this procedure may be seen by comparing the figures of lines 11 and 12. The percentage deviations reach a maximum of 37% in our experiments.[13]

It will be observed that the mobilities of ovalbumin, computed as described above and recorded in lines 12 and 13 of Table I, change but slightly with the protein concentration and much of this change disappears if the mobilities are multiplied by the relative viscosity, η (line 10), the product $u_d\eta$ increasing but slightly with the protein concentration. This observation is important since it indicates that mobility measurements may aid in the identification of components in an electrophoretic pattern.

The Delta and Epsilon Boundaries.—Although the interpretation, given in the foregoing pages, of patterns of the type shown in Fig. 4, appears to be satisfactory, two questions may arise in the mind of the reader. Do gradients of buffer electrolyte really exist in the boundaries? And has the possibility that the δ and ϵ boundaries may be due, in part, to a slowly moving protein constituent been completely eliminated?

To answer the first of these questions the procedure was as follows. After the electrophoresis in which the patterns shown in Fig. 4 were obtained, the contents of each section of the cell were isolated and the specific conductances at 0° were measured. The results, before and after electrolysis, are given in Table II. In the lower cathode and upper anode sections of the cell, Fig. 2, no boundaries were present and no significant change of conductance occurred, showing, as would be expected, that the compositions of the solutions B and P are unchanged by the passage of current. In the upper cathode section, however, where the adjusted protein solution P' has partially replaced the buffer solution B originally present, the specific conductance had decreased 5.1%. A corresponding *increase* in the lower anode section accompanied the partial replacement of the protein solution P by the adjusted buffer solution B'. The conductance of the solution P', between the boundaries δ and r, can be readily estimated. The height of the upper cathode section is known, as well as the positions of the r and δ boundaries. In addition data are available, in Table II, on the conductances of the B and P solutions, and of the mixture of these with the P' solution. These, assuming simple proportionality, are sufficient data for computing the conductance of the latter solution, which is given as "P' solution, computed" in the table. A change of equivalent conductance from $\kappa_P = 0.00343$ to $\kappa_{P'} = 0.00322$ is therefore indicated at the δ boundary. Since the conductances of these solutions are due mainly to the buffer ions and are roughly proportional to their concentrations, this indicates that there is a decrease of concentration of buffer electrolyte in passing from solution P to solution P' across the δ boundary in accord with Fig. 5. It is of interest, however, that the ratio $\kappa_{P'}/\kappa_P (= 0.939)$ differs appreciably from that [P']/[P] (= 0.853) computed from refractive index measurements, showing that the P' solution is not obtained from the P solution simply by dilution with water as required by the theory of electrophoretic boundaries discussed by Henry and Brittain.[14] The theory, however, was developed for a ternary ionic system, *i. e.*, protein ions and the anions and cations of a binary buffer salt. At the *p*H of the experiments and with the buffer solution

(13) This result indicates that mobility measurements involving observations of rising boundaries, without considering the δ effect, may be in error. Thus Landsteiner, Longsworth and van der Scheer (*Science*, **88**, 83 (1938)) used a mean value, $(u_d + u_r^*)/2$, which is about 2.5% higher, for the data of their Table I for example, than the correct value, u_d. It should be noted, however, that this correction does not affect the order of the mobilities, and consequently the conclusions of that paper remain unchanged. In a recent electrophoretic study of hemoglobin Davis and Cohn (THIS JOURNAL, **61**, 2092 (1939)) observed a mobility increase of 27% on increasing the protein concentration from 0.17 to 1.33%. They computed their results from observations on the rising boundary and it seems probable that most of this apparent mobility variation is due to neglect of the correction for the concentration change at the δ boundary.

(14) Henry and Brittain, *Trans. Faraday Soc.*, **29**, 798 (1933).

used (0.1 N NaAc + 0.5 N HAc) it is probable that the effects of the hydrogen ion constituent and of the undissociated acid cannot be neglected.

In this and other laboratories the δ and ϵ boundaries were first thought to be due to slowly migrating protein or carbohydrate constituents.[15] Attempts to isolate such materials were unsuccessful, however. Although the explanation, outlined in this paper, of the boundaries was soon evident[9] the possibility of a small concentration of electrophoretically inert material was not entirely eliminated. The work of Henry and Brittain, mentioned above, suggested a method by which the δ and ϵ boundaries might be suppressed under certain conditions if no inert material were present. In the case of the electrophoresis of ovalbumin in the neutral range, where the contribution of the hydrogen ion conductance to the system is negligible, the conductance ratio $\kappa_{P'}/\kappa_P$ is in fair agreement with the ratio [P']/[P] determined refractometrically. Thus in the electrophoresis experiment (the patterns for which are shown in Fig. 6) of a 1.36% solution of ovalbumin in a phosphate buffer at 6.80 the conductance, $\kappa_{P'}/\kappa_P$, and protein concentration, [P']/[P], ratios were found to have nearly the same value, *i. e.*, 0.935 and 0.923, respectively. Under these conditions the concentrations of the constituents of the P′ solution are such as would result from dilution of the P solution with water. Thus in this case if the boundaries were initially formed between the buffer and the solution P′, obtained by diluting solution P by the factor 1/0.935, there should be no δ and ϵ boundaries left behind when the protein boundaries migrate away from their original positions. This idea was tested experimentally with the result shown in Fig. 7. It will be seen that the δ and ϵ boundaries, quite evident in Fig. 6, have been eliminated. This would appear to be conclusive evidence of the nature of the δ and ϵ boundaries, as outlined above, and of the absence of inert constituents in the sample of ovalbumin.

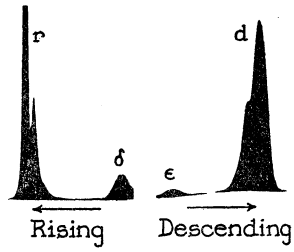

Fig. 6.—Electrophoretic patterns of a 1.36% solution of ovalbumin in a 0.1 μ sodium phosphate buffer at pH 6.80 and 0°. Scanning exposure made after electrolysis for 6000 seconds at 7.23 volts per cm.

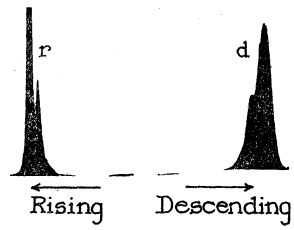

Fig. 7.—Same as for Fig. 6 except that the dialyzed ovalbumin solution was diluted in order to eliminate the δ and ϵ boundaries.

Summary

Electrophoretic studies of ovalbumin, at 0° and at pH 3.92, have been made by the moving boundary method. The research was undertaken in order to establish the conditions under which accurate values of protein mobilities may be found from moving boundary data. This involved investigation of the nature of the δ and ϵ boundaries, and of the concentration distributions in the rising and descending protein boundaries. The results indicate that, although in general more diffuse, the descending boundaries yield correct values of the mobility. The rising boundaries may give results that are greatly in error unless additional data are available from which corrections may be made, in which case the two types of boundary yield the same value of the mobility. Contrary to some recent conclusions, the mobilities have been found to vary but slightly with the protein concentration, if a small viscosity correction is made, within the composition limits studied. There is evidence that gradients of buffer concentration exist, in general, in all the boundaries. The correctness of the interpretation has been indicated by showing that, in certain cases, the δ and ϵ boundaries may be suppressed.

Vapor–Liquid Equilibrium. V. Carbon Tetrachloride–Benzene Mixtures[1]

BY GEORGE SCATCHARD, S. E. WOOD AND J. M. MOCHEL

These measurements on carbon tetrachloride–benzene mixtures complete the cycle of binary systems with the components: carbon tetrachloride, benzene and cyclohexane. They permit an interesting comparison of these three systems and a prediction of the behavior of ternary systems of these components.

The purification of materials was the same as in III and IV and the measurements were made as in IV, with nitrogen as the confining gas. The leakage through the stoppers was so reduced by moistening them with the liquid in the still and seating them very tightly that the temperature increase was only 0.0002–0.0004° per minute at 40° and not over 0.0001° per minute at 70°. The vapor pressures of the pure substances agreed with the equations given in IV as well as did the measurements from which the equations were obtained. Apparently no phosgene was formed during these measurements as not even its odor was detected.

The electrical heating permits a fairly precise measurement of the rate of boiling at atmospheric pressure and so makes possible an estimate of the difference in pressure necessary to keep the vapors streaming from the boiler and to the condenser, which is more accurate than the estimate made in I. Since the rate of heating is almost independent of the boiling temperature, the rate of boiling may be taken to be so, also. At atmospheric pressure 2–2.2 cc. of benzene distilled per minute. This corresponds to a pressure drop along a tube 9 cm. long and 0.5 cm. in diameter of 0.003 mm. at 760 mm. pressure, and of 0.013 mm. at 120 mm. pressure. These pressure drops are smaller than those estimated in I, because the rate of distillation is smaller than we estimated, and they are also much smaller than the errors in measuring the pressures.

The density measurements showed systematic errors of the same magnitude as those reported in IV, probably caused by the evaporation of the first component weighed out in the preparation of the standards. Since they correspond to less than 0.02% in the composition, the equation for the relation between density and composition was determined by applying an average correction to the measurements. Table I contains the uncorrected densities and their deviations from the equation

$$d = (0.87370 + 0.71056z_1)/(1 + 0.00061)z_1z_2 \quad (1)$$

$$z_1 = 1 - z_2 = 1/(1 + w_2d_1/w_1d_2) \quad (2)$$

in which d is the density of the solution, d_1 and d_2 the densities of the components, w_1 and w_2 their weights in the solution, and z_1 and z_2 their volume fractions. The last column gives $100V^M/V^0 = 100(V - V^0)/V^0$, in which V^0 is the volume of the unmixed components, V is the volume of the solution, and V^M is the increase of volume on mixing. From equation 1 it follows that

$$V^M/V^0 = 0.00061\ z_1z_2 \quad (3)$$

Vapor–liquid equilibrium measurements were made at intervals of approximately one-eighth in the mole fraction of the liquid at 40 and 70° and for an approximately equimolal mixture at 30, 50 and 60°. The measurements at 40° are shown in Fig. 1, in which the curves are determined from equations 4 and 5 and the circles are the individual experimental points. The top curve with the plain circles gives the equilibrium pressure as ordinate and the liquid composition, expressed as mole fraction of carbon tetrachloride, as abscissa. The curve just below it with the

(1) Paper IV in this series appeared in THIS JOURNAL, **61**, 3206 (1939).

flagged circles gives the equilibrium pressure *versus* the vapor composition, and the two lower curves are the derived partial pressures. The broken lines represent the Raoult's law total and partial pressures *versus* the liquid composition. The measurements are reported in detail in Table II as mole

fraction of carbon tetrachloride in the liquid, and in the vapor, equilibrium pressure, and the derived excess free energy of mixing. After each of the last three is given the deviation of the corresponding quantity from that calculated by the following equations together with these vapor pressures of the pure components at 30, 40, 50, 60 and 70° from IV: benzene—119.16, 182.70, 271.34, 391.66, 551.03; carbon tetrachloride—141.55, 213.34, 312.04, 444.28, 617.43.

$$\mu^E{}_1 = RT \ln Py_1/P_1x_1 + (\beta_1 - V_1)(P - P_1)$$
$$= (1.25141 - 0.0014837\,T)(1 + 0.14z_1)V_1z_2^2 \quad (4)$$
$$\mu^E{}_2 = RT \ln Py_2/P_2x_2 + (\beta_2 - V_2)(P - P_2)$$
$$= (1.25141 - 0.0014837T)(0.93 + 0.14z_1)V_2z_1^2 \quad (5)$$
$$F^E{}_x = (1.25141 - 0.0014837T)(1 + 0.07z_1)V^0{}_xz_1z_2 \quad (6)$$
$$H^M{}_x = 1.25141\,(1 + 0.07z_1)V^0{}_xz_1z_2 \quad (7)$$

in which $V^0{}_x = x_1V_1 + x_2V_2 = V^0/(N_1 + N_2)$, x is the mole fraction in the liquid, y is that in the vapor, and the subscript $_1$ refers to carbon tetrachloride, V_1 and V_2 are the molal volumes at

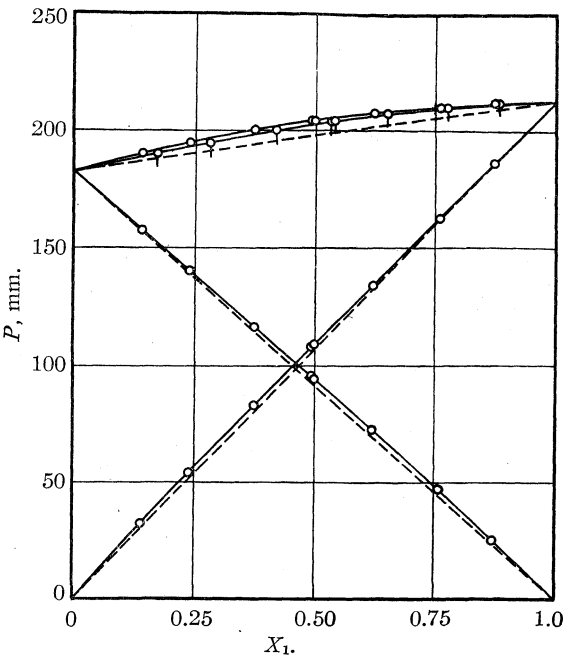

Fig. 1.—Vapor pressure *vs.* mole fraction for carbon tetrachloride–benzene at 40°.

25°, and β_1 and β_2 are the limits at zero pressure of the differences between the molal volumes of the vapors and those of perfect gases at the same temperature and pressure. The values of β used for benzene, carbon tetrachloride and cyclohexane, respectively, are −1839, −1864 and −2031 cc. per mole at 40° and −1287, −1310 and −1426 cc. per mole at 70°. The calculated results from which the curves in Fig. 1 and the deviations in Table II are calculated are from equation 6 for $F^E{}_x$ and from the combined equations 4 and 5 for P and y. The constants are chosen to give the average of $F^E{}_x$ at 40 and 70° and a linear variation of $F^E{}_x$ with temperature. The average deviation is 0.06% in y and 0.015% in P, which is about the same as for carbon tetrachloride–cyclohexane mixtures.

To calculate the thermodynamic functions for mixing at constant total volume, we have made use of the following expressions for the coefficients of thermal expansion and compressibility in reciprocal degrees centigrade or reciprocal atmospheres

$$\alpha_0 = 1.228 \times 10^{-3}(1 - 0.0024z_2)$$
$$\beta_0 = 1.10 \times 10^{-4}(1 - 0.1z_2)$$
$$\alpha_0/\beta_0 = 11.16(1 + 0.108z_2)$$
$$\mathrm{d} \ln \beta/\mathrm{d}T = 0.0076$$

and $V_0 = 97.104/(1 + 0.086z_2)$. Then

$$(A^E{}_v - F^E{}_p)_x = 4.05 \times 10^{-5}(97.104)z_1^2z_2^2/(1 - 0.1z_2)(1 + 0.086z_2) \quad (9)$$
$$(S^E{}_v - S^E{}_p)_x = -(16.40 \times 10^{-5})(97.104)(1 + 0.108z_2)z_1z_2/(1 + 0.086z_2) + 0.0076(A^E{}_v - F^E{}_p)_x \quad (10)$$
$$(E^M{}_v - H^M{}_p)_x = T(S^E{}_v - S^E{}_p)_x + (A^E{}_v - F^E{}_p)_x \quad (11)$$

In Fig. 2 are shown F^E_{px} at 25 and at 70° from equation 6, H^M_{px} from equation 7, and E^M_{vx} from H^M_{px} and equation 11. The value for A^E_{vx} at 25° is so near that of F^E_{px} that they could not be distinguished on a scale many times as large as this one. For the equimolal mixture at 25°, F^E_{px} (or A^E_{vx}) is 19.5, H^M_{px} is 30.2 and E^M_{vx} is 29.0 cal./mole. The correction to $(E^M_{vx} - A^E_{vx})$ caused by deviations from random distribution is calculated from Kirkwood's equation[1] as −0.18 cal./mole, which is very small relative to the measured +9.5 cal./mole. V^M_x/β is 3.27 cal./mole, which is scarcely more than a tenth of E^M_{vx}.

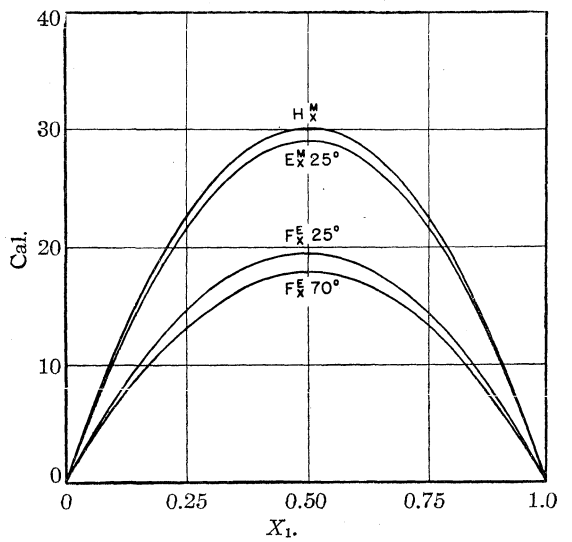

Fig. 2.—Various thermodynamic functions for carbon tetrachloride–benzene.

The results are made a little clearer if they are translated back to the measured pressure, for the effect on the vapor composition is very small. For equimolal solutions we find a pressure 2.75% greater than the average of the pressures of the components at 70°, and 3.15% greater at 40°. This decrease of 0.40% would be only 0.22% if the solutions were regular and 0.24% if the entropy of mixing at constant total volume were zero. A decrease of 0.16% in 30° is left unexplained. The deviations from random distribution, calculated by Kirkwood's equation, increase the unexplained deviations by 0.003%.

The cohesive energy densities at 25°, a_{11} and a_{22}, are calculated as −72.96 cal./mole for carbon tetrachloride and −84.11 for benzene. By quadratic combination they lead to 9.21 cal./mole for E^M_{vx}, or about one-third of the measured 29.0. However, the mutual energy per unit volume

$$a_{12} = \left(\frac{E^M/V^0}{z_1 z_2} + a_{11} + a_{22}\right)\Big/2$$

is −77.91, which is only 0.54% less than $\sqrt{a_{11}a_{22}}$. As in the other systems, the quadratic combination of constants leads to fairly good agreement in the calculation of a_{12}, but the percentage error in $(2a_{12} - a_{11} - a_{22})$ is very large.

This system has been studied by many observers, but we shall compare our measurements with only a few. Hubbard[2] found values of V^M/V^0 at 25° which correspond very closely to ours. At 50° he finds V^M/V^0 about four times as great as calculated by our equation for 25°, which indicates that the discrepancy between V^M/β and E^M decreases rapidly as the temperature increases. Hirobe's measurements[3] of the heat of mixing at 25° are about 15% smaller, and those of Vold[4] are about 30% smaller than those we calculate from our equilibrium measurements. Vold's measurements are also higher in benzene-rich solutions and lower in benzene-poor solutions than a symmetrical curve. The curvature in F^E *versus* T necessary to give agreement with either set of the heat measurements is probably within the error of our measurements, but we see no basis for a choice between the two sets. The measurements by Zawidski[5] of the vapor pressure at 49.99° are 2–5 mm. lower than those calculated from our equations. The vapor pressures of the pure components are also lower, and his ratio of pressure to ideal pressure agrees very well with ours in solutions rich in benzene, and is higher than ours for solutions poor in benzene. His vapor compositions differ from ours on the average by 0.2%, which is about the spread in his measurements, and his vapor is always richer in that component which is in excess in the liquid. The vapor pressure measurements at 50.15° by Tahvonen[6] are in excellent agreement with ours.

Table III contains various properties of equimolal mixtures of each of the three systems of this cycle. If the deviations from ideality are measured by the percentage increase in pressure, $100(P - P_I)/P_I$, the benzene–cyclohexane system shows much the largest deviation, and carbon tetrachloride mixtures with benzene deviate a little more than those with cyclohexane. The

thermodynamic functions show the same relations, except that the heat of mixing and the excess entropy at constant pressure interchange the last two systems. This indicates that that property which determines these deviations is intermediate for carbon tetrachloride between the values for the two hydrocarbons and nearer to that for cyclohexane. We also see that the value for benzene–cyclohexane is much greater than the sum of the other two. The square roots of these deviation measures are, however, approximately additive. This relation between the square roots is that predicted by quadratic combination, and the cohesive energy density of carbon tetrachloride does lie between those of the two hydrocarbons and nearer to that of cyclohexane than to that of benzene. The simple theory of non-polar mixtures states that it is the square of the difference between the square roots of the cohesive energy densities which determines the deviations from ideality rather than any difference in molecular structure or nature of the atoms. So it should be quite possible for substances which are very different chemically to give nearly ideal solutions. The quantitative calculations for the energy densities give, however, only about a fifth of the measured values.

The volume increase on mixing is greater than that calculated from the energy of mixing by simple theory for the mixtures containing cyclohexane, but it is very much smaller for carbon tetrachloride–benzene mixtures. However, the measurements of Hubbard indicate that the volume increase becomes rapidly larger as the temperature increases.

For the two systems with large increase of volume, the excess entropy of mixing at constant total volume is considerably smaller than that at constant pressure, but it is still important in all three cases. It was suggested in III[7] that the entropy increase in the benzene–cyclohexane system might be due to an abnormally small entropy in one of the liquids, probably caused by incomplete randomness of orientation which becomes complete in the mixtures. If this explanation were correct, the excess entropy of the first system should equal the sum of that for the other two if there were no lack of randomness in the more symmetrical carbon tetrachloride, and would in general be less than this sum by twice the effect for carbon tetrachloride. From Table III we see that the excess entropy for benzene–cyclohexane is almost four times as great as the sum for the other two systems. Barring the very improbable case of a large negative entropy in one of the mixtures giving compensation, the study of the two systems with carbon tetrachloride shows that most of the excess entropy cannot arise from an abnormally low entropy in either of the components.

To consider ternary mixtures we will assign the subscripts $_1$ to benzene, $_2$ to cyclohexane, and $_3$ to carbon tetrachloride. If the excess free energies of the binary mixtures are given by expressions of the type $F^E_{12} = V^0B_{12}z_1z_2$, the expression for the free energies of ternary systems should be the sum of those for the binary systems: $F^E = V^0(B_{12}z_1z_2 + B_{13}z_1z_3 + B_{23}z_2z_3)$. If the expression for binary systems contains a triple product of the type $C_{112}z_1^2z_2$, however, we may expect for ternary mixtures a term $C_{123}z_1z_2z_3$ which cannot be determined by measurements on binary mixtures. Of the three systems under discussion, benzene–cyclohexane mixtures deviate from the symmetrical expression only enough to give a maximum discrepancy of about 0.4% in the pressure; benzene–carbon tetrachloride mixtures give a maximum discrepancy of about 0.1%, and cyclohexane–carbon tetrachloride mixtures give none within the accuracy of our measurements. We may then expect an error of about the average, which is less than two parts per thousand, if we ignore the term in $z_1z_2z_3$ and adjust our expression to merge into each of those for a binary liquid as the third component

(7) G. Scatchard, S. E. Wood and J. M. Mochel, *J. Phys. Chem.*, **43**, 119 (1939).

disappears. Our expressions for the binary mixtures are

$$F_{12}/V^0 = z_1z_2(B_{12} + D_{12}z_2^2)$$
$$F_{23}/V^0 = z_1z_3(B_{13} + C_{13}z_3)$$
$$F_{23}/V^0 = z_2z_3B_{23}$$

For ternary mixtures we must eliminate the unsymmetrical method of writing the first two by replacing z_2 by its equivalent $(1 - z_1 + z_2)/2 = (2z_2 + z_3)/2$ and z_3 by $(z_2 + 2z_3)/2$. This gives the following expressions, in which the volume fraction of each component is eliminated in the expression for the potential of that component.

$$F^E/V^0 = B_{12}z_1z_2 + D_{12}(z_1z_2^3 + z_1z_2^2z_3 + z_1z_2z_3^2/4) + B_{13}z_1z_3 + C_{13}(z_1z_2z_3/2 + z_1z_3^2) + B_{23}z_2z_3$$

$$\mu^E_1/V_1 = B_{12}(z_2^2 + z_2z_3) + B_{13}(z_2z_3 + z_3^2) - B_{23}z_2z_3 + D_{12}(3z_2^4 - 2z_2^3 + 6z_2^3z_3 - 2z_2^2z_3 + 15z_2^2z_3^2/4 - z_2z_3^2/2 + 3z_2z_3^3/4) + C_{13}(z_2^2z_3 - z_2z_3/2 + 3z_2z_3^2 - z_3^2 + 2z_3^3)$$

$$\mu^E_2/V_2 = B_{12}(z_1^2 + z_1z_3) - B_{13}z_1z_3 + B_{23}(z_1z_3 + z_3^2) + D_{12}(3z_1^4 - 6z_1^3 + 6z_1^3z_3 + 3z_1^2 - 8z_1^2z_3 + 15z_1^2z_3^2/4 + 2z_1z_3 - 5z_1z_3^2/2 + 3z_1z_3^3/4) + C_{13}(z_1^2z_3 - z_1z_3/2 - z_1z_3^2)$$

$$\mu^E_3/V_3 = -B_{12}z_1z_2 + B_{13}(z_1^2 + z_1z_2) + B_{23}(z_1z_2 + z_2^2) + D_{12}(-3z_1^3z_2/4 + z_1^2z_2 + 3z_1^2z_2^2/2 - z_1z_2/4 - z_1z_2^2 - 3z_1z_2^3/4) + C_{13}(-2z_1^3 + 2z_1^2 - 3z_1^2z_2 + 3z_1z_2/2 - z_1z_2^2).$$

These equations readily may be extended to include the cases where any or all of the constants C_{12}, C_{13}, C_{23}, D_{12}, D_{13}, D_{23} are not zero by the appropriate interchange of coefficients, and to H^E or S^E instead of F^E. The values of the parameters for our system are: $V_1 = 89.400$, $V_2 = 108.754$, $V_3 = 97.104$, $B_{12} = (6.943 - 0.013233\ T)$, $B_{13} = (1.3335 - 0.0022916\ T)$, $B_{23} = (1.25141 - 0.0014837\ T)$, $D_{12} = 0.084\ B_{12}$, $C_{13} = 0.07\ B_{13}$. The units are cc./mole for the volumes and cal./cc. for the other parameters.

Applying these expressions to mixtures containing equal mole fractions of benzene and cyclohexane at 25° we find that, as the fraction of carbon tetrachloride increases from zero to unity, $\log Py_i/P_ix_i$ increases by 0.009 for benzene, decreases by 0.011 for cyclohexane and increases by 0.002 for carbon tetrachloride. As a result the total pressure is almost linear, and it varies only from 109.1 to 113.8 mm. The vapor pressures of benzene and cyclohexane are 94.98 and 97.45 mm., respectively, and the pressures of equimolal binary mixtures with carbon tetrachloride deviate 3.35 and 2.86% from Raoult's law. Therefore, the cross sections at constant mole fraction of carbon tetrachloride are nearly symmetrical and flatten out rapidly as the fraction of carbon tetrachloride increases. At one half mole fraction carbon tetrachloride, the excess over the average of the end-points has already decreased from 12.9 to 3.1 mm.

Summary

The vapor–liquid equilibrium pressure and compositions of benzene–carbon tetrachloride mixtures have been measured at 40 and 70° over the whole composition range, and at 30, 50 and 60° for approximately equimolal mixtures. The densities have been determined at 25°.

These measurements have been expressed analytically, and corresponding equations have been derived for the thermodynamic functions, including the energy and entropy of mixing at constant total volume.

These equations show a slight asymmetry, and a moderate deviation from regularity, which, on account of the nearly additive volumes, is almost the same at constant total volume as at constant pressure.

These results are compared with those obtained previously for mixtures of each of the components with cyclohexane, and approximate equations are derived for the ternary system: benzene–cyclohexane–carbon tetrachloride.

Preparation and Properties of Diborane Diphosphine

BY E. LEE GAMBLE AND PAUL GILMONT

Of the compounds formed by the hydrides of boron, diborane diammine $B_2H_6 \cdot 2NH_3$, has been investigated most extensively. This compound was first prepared by Stock,[1] and from its properties he concluded that it was a salt, $(NH_4)_2(B_2H_4)$, derived from the dibasic acid, $H_2(B_2H_4)$. Schlesinger and Burg[2] have reported that the low temperature reaction of metallic sodium on a solution of diborane diammine in liquid ammonia, gave results that could be explained only on the basis of a monobasic salt being formed. Therefore, they believed that the structure of diborane diammine is best represented by the formula, $NH_4(BH_3NH_2BH_3)$. When $B_2H_6 \cdot 2NH_3$ is heated rapidly to 200°, a volatile cyclic compound, $B_3N_3H_6$, is formed,[3] the six-membered ring having alternate boron and nitrogen atoms.

The similarities and differences between phosphine and ammonia led us to investigate the action of phosphine on diborane and the nature of the product so obtained.

Two volumes of phosphine react with one volume of diborane to form a white unstable compound of empirical composition $B_2H_6 \cdot 2PH_3$ or $BH_3 \cdot PH_3$.[4] The reaction takes place slowly in the gas phase at temperatures above −30°, and fairly rapidly in the liquid phase above −110°. The product, diborane diphosphine, dissociates above −30° into diborane and phosphine, the dissociation pressure at 0° being about 200 mm. No evidence for the corresponding dissociation of diborane diammine has ever been reported.

Diborane diphosphine is formed from the gas phase as long, white, crystalline needles, and from the liquid phase as a microcrystalline mass. It is spontaneously inflammable in air, and rapidly decomposed by water with the formation of hydrogen, phosphine and boric acid. On heating rapidly to 200°, large quantities of hydrogen and a non-volatile, unidentified residue are formed, but no volatile product corresponding to $B_3N_3H_6$, which is formed under comparable conditions, has been isolated.

The compound dissolves with difficulty in liquid ammonia at its melting point without apparent reaction. A true phosphonium salt, PH_4Br, slowly dissolves under the same conditions with complete evolution of the phosphine in the compound, and the formation of ammonium bromide. If the solution of diborane diphosphine in liquid ammonia or the solid compound in liquid ammonia is warmed to approximately −60°, phosphine is slowly evolved. The rate of evolution increases with increasing temperature, the maximum evolution at 0° taking place within twenty minutes. The maximum evolution of phosphine corresponds to between 52 and 58% of the total, an average of seven determinations being 55.5%. The resulting solution evolves no more phosphine even on standing for months dissolved in liquid ammonia at room temperature. When the solvent ammonia is pumped off, a white solid remains, whose composition is approximated by the formula $B_2H_6 \cdot PH_3 \cdot NH_3$.

Gaseous ammonia has been found to react slowly with diborane diphosphine with the displacement of 21 to 75% of the phosphine in the compound, depending chiefly on the temperature and the time of reaction. An interpretation of the above reaction may involve the fact that at temperatures much above −30°, the quantity of diborane formed by the dissociation of diborane diphosphine, $B_2H_6 \cdot 2PH_3 \rightleftarrows B_2H_6 + 2PH_3$, is sufficient to cause one to expect direct action between diborane and ammonia.[5]

(4) While this work was in progress, Schlesinger and Burg[2] reported in a footnote the formation of this compound, but no details have been published. However, Professor Schlesinger has been kind enough to inform us of the results of his work with Dr. Burg. These results are given in the following footnote of this paper.

(5) Professor Schlesinger's private communication states that he and Dr. Burg have found that at −40°, gaseous ammonia reacts with diborane diphosphine with the displacement of 50% of the phosphine. They believe that two compounds containing diborane, phosphine and ammonia exist, namely, $B_2H_6 \cdot PH_3 \cdot NH_3$ and $B_2H_6 \cdot PH_3 \cdot 2NH_3$. The latter compound is quite unstable, losing one mole of ammonia at −30°. Trimethylamine displaces 100% of the phosphine from diborane diphosphine, with the formation of borine trimethylamine and phosphine. They have also noted that phosphine reacts with borine carbonyl with the formation of carbon monoxide and diborane diphosphine.

The product formed by the reaction of liquid ammonia on diborane diphosphine is a white pasty solid the stability of which is much greater than that of diborane diphosphine itself. It evolves hydrogen slowly over a period of time, either in the solid state or in solution in liquid ammonia, in which it is readily soluble. It burns with difficulty in air, and dissolves readily in water to form a clear solution. This solution evolves hydrogen, 10% of the hydrogen attached to boron being liberated in six hours, but no phosphine is liberated during this time. If the formula of diborane phosphine ammine is expressed as a phosphonium salt, $PH_4(BH_3NH_2BH_3)$, it would be expected that both liquid ammonia and water would liberate phosphine from the compound. Therefore, the ammonium salt, $NH_4(BH_3PH_2BH_3)$, seems more probable.

When diborane phosphine ammine was heated rapidly to 200°, $B_3N_3H_6$ was formed in yields of 30%, calculated on the nitrogen content. No volatile compounds containing phosphorus were detected.

Hydrogen chloride reacts with diborane diphosphine to form chlorinated derivatives, displacing hydrogen in volume equivalent to the hydrogen chloride introduced. Under controlled conditions, the following reaction takes place

$$B_2H_6\cdot 2PH_3 + 2HCl = B_2H_4Cl_2\cdot 2PH_3 + 2H_2$$

The product so formed is a clear, water-white, viscous, non-volatile liquid, which may further react with hydrogen chloride. The product with an empirical composition $B_2H_2Cl_4\cdot 2PH_3$ is usually formed as a white, crystalline solid, melting with decomposition near 68°. By the use of high pressures of hydrogen chloride above 0°, it can be converted to $BCl_3\cdot PH_3$.[6]

Four possible formulas have been considered for the compound formed by diborane and phosphine: [I], $(PH_4)_2B_2H_4$, corresponding to the formula $(NH_4)_2B_2H_4$ for the diammine suggested by Stock and Wiberg,[7] appears to be inadequate to account for the properties of the compound. [II], $BH_3\cdot PH_3$. If the simple monomer, borine phosphine, were capable of existence in the gas phase for a few minutes at room temperature, it could be detected easily by gas analysis. The results of numerous analyses have given no indication that borine phosphine exists as a stable gas; however, this does not preclude the possibility of its existence in the solid state. The monomeric form for the solid gives the simplest explanation for the reaction with hydrogen chloride, inasmuch as only when two, four and six moles of hydrogen chloride are introduced (for each mole of diborane in the compound) do the products appear to be homogeneous. The reactions with ammonia cannot be accounted for on the basis of the monomeric form, unless it is converted to the dimeric form by the ammonia, which is entirely possible. [III], $PH_4(BH_3PH_2BH_3)$, corresponding to $NH_4(BH_3NH_2BH_3)$ for the diammine, can be used to account for the reactions of the compound formed by diborane and phosphine. The salt-like nature of this compound is, however, not well defined, inasmuch as it will dissolve in liquid ammonia at −75° without the liberation of phosphine. [IV], $B_2H_6\cdot 2PH_3$ is unsatisfactory from many points of view, but it implies the mode of formation and decomposition of the compound and does not emphasize any salt-like character of the compound. It seems probable that without a more extended study of the other hydrides of boron, especially B_4H_{10} and B_5H_9, more definite conclusions may not be drawn concerning the salts or addition compounds formed from diborane.

Experimental

Description of Apparatus.—The apparatus was adapted from the type used by Stock and his co-workers[7] and Schlesinger and his co-workers.[8] The use of stopcocks instead of mercury valves was found to be permissible in situations where the grease was exposed to diborane at low pressures for short periods of time.

Analytical Methods.—The reactants were measured in a calibrated globe and distilled into the reaction tubes with liquid nitrogen. After the reaction had taken place the excess gases were pumped off from the reaction tube into a gas buret by means of a Toepler pump. Wherever possible, these gases were separated by fractional condensation before entering the buret. Diborane was determined by the increase in volume on hydrolysis or the volume of residual hydrogen. Phosphine was determined by the decrease in volume on treatment with 0.1 *N* silver nitrate solution.

Preparation of Diborane.—Diborane was prepared by the method of Schlesinger and Burg[9] as modified by Stock and Sütterlin.[10] Hydrogen saturated with boron tri-

(6) A. Besson, *Compt. rend.*, **110**, 516 (1890), originally prepared this compound by the reaction of equal volumes of gaseous boron trichloride and phosphine below 20°.

bromide at 25° was passed through an electric arc 7 cm. in length at a pressure of 10 mm., and a rate of 500 cc. per minute.[11] The arc produced by a 10,000 volt, 500 volt-ampere transformer proved to be 50% more efficient for the ultimate yield of diborane than the arc produced by a 25,000 volt, 1000 volt-ampere transformer. Yields of 16 cc. of gaseous diborane per cc. of liquid boron bromide (measured at 0°) were obtained. About 85% of the BBr_3 used passed through the arc unchanged.

Preparation of Diborane Diphosphine.—When a mixture of diborane and phosphine was kept at a temperature of −20 to 0°, the pressure slowly decreased over a period of eight to fourteen hours, and long, white, crystalline needles were formed filling the void of the reaction tube. With the reaction tube cooled to −78°, the gases which did not take part in the reaction were pumped out and analyzed. The composition of the residue in the reaction tube, determined by fourteen experiments, is described by the formula $B_2H_6 \cdot (2.00 \pm 0.04)PH_3$. In a typical preparation, 15.0 cc. of diborane and 39.2 cc. of phosphine with an initial pressure of 1.8 atmospheres at 0° produced in six hours a yield of 92% of diborane diphosphine. Neglecting 1.3 cc. of hydrogen formed during this time, the composition of the product was $B_2H_6 \cdot 2.02PH_3$.

The degree to which the reaction takes place is influenced mostly by pressure, an increase from 0.6 to 6.0 atmospheres increasing the yield of product from 72 to 98%. The rate of reaction is also markedly influenced by pressure; at 0° after two to three hours the pressure in the reaction tube is quite independent of the original pressure of the reactants. High concentrations of phosphine and long time of reaction are favorable factors for high yields. The extent of secondary decomposition is increased by high temperatures and long periods of reaction.

Liquid diborane does not react with liquid phosphine at an appreciable rate much below −110°, but above that temperature liquid phosphine reacts within two or three hours with either gaseous or liquid diborane. When insufficient pressure of phosphine is left to maintain the liquid phase, the reaction apparently ceases. For this reason, the temperature should be kept as low as possible to reduce the vapor pressure of the phosphine, and the quantity of unreactive material in the gas phase without reducing the rate of reaction to too great a degree. Using a tube of 6 cc. volume, containing 25.9 cc. of diborane and 60.8 cc. of phosphine at −100°, a yield of 98% in three hours reaction time was obtained. The composition of the product is described by the formula $B_2H_6 \cdot 2.01PH_3$.

Of the two sets of conditions which have been used to prepare diborane diphosphine, the low temperature reaction is the more desirable, because of the increased rate and the elimination of any side reactions in which hydrogen is formed.

Diborane diphosphine dissociates to form one volume of diborane and two volumes of phosphine. An equilibrium exists which can be approached from either side.

$$B_2H_6 \cdot 2PH_3 \rightleftharpoons B_2H_6 + 2PH_3$$

At 0°, this pressure is about 200 mm. Other pressure measurements include: at +25°, 1400 mm.; at −11°, 71 mm.; and at −21°, 11 mm. Since the time required for equilibrium to be established is unusually long, and considerable quantities of hydrogen are formed by secondary decomposition during this time, the precision of the measurements of pressure is quite low.[12]

Pyrolysis of Diborane Diphosphine.—A mixture of 63.6 cc. of PH_3 and 33.9 cc. of B_2H_6 was stored overnight at 0° to form diborane diphosphine in equilibrium with its gaseous constituents. An electric sleeve furnace preheated to 200° and calibrated to maintain that temperature was placed around the reaction tube for fifteen minutes. The tube was cooled to −195°, and 76.7 cc. of hydrogen pumped out. Warming to −77°, 10.5 cc. of a mixture of diborane and phosphine was pumped off. On warming to room temperature, no more gas was evolved. The residue in the tube was a yellowish-white, greasy-looking solid covering the walls of the tube. Under comparable conditions, the pyrolysis of diborane diammine produces up to 40% of $B_3N_3H_6$.

Diborane Diphosphine and Ammonia.—While the solid diborane diphosphine dissolves with difficulty[13] in liquid ammonia at −75° with no apparent reaction, at higher temperatures the rate of solution is quite rapid, and phosphine is evolved. The evolution of phosphine was followed by cooling the tube to −78° and pumping off the phosphine together with some ammonia. At the end of the experiment, the solvent ammonia was pumped off completely. The results of the reaction are shown in Table I. The quantities of diborane diphosphine and ammonia used are expressed as cc. of gas. The fraction of the total phosphine given off in the reaction is expressed as per cent. evolved. The ratio of the sum of the ammonia introduced plus the phosphine calculated to be left in the compound, to the diborane in the compound, is shown in the eighth column. The last column shows the volume of hydrogen evolved; this is a measure of the secondary decomposition during the reaction.

The reaction of gaseous ammonia and diborane diphosphine is in all probability complicated by the decomposition of diborane diphosphine into diborane and phosphine, and thus by the possibility of direct reaction taking place between diborane and ammonia in the gas phase. It is also possible that the formation of phosphine in excess of 50% in the reaction with liquid ammonia is due to this reaction. Part B of Table I shows the results of the gas phase reaction.

Diborane Phosphine Ammine.—The product of the reaction of liquid ammonia on diborane diphosphine is best expressed as $B_2H_6 \cdot PH_3 \cdot NH_3$ although the analysis is not exact. The sum of the phosphine plus the ammonia bears the correct relation to the formula.

Pyrolysis of Diborane Phosphine Ammine.—A sample containing 24.1 cc. of diborane, 22.0 cc. of phosphine and

(11) All volumes referred to in this paper are at standard conditions of temperature and pressure.

(12) The slowness with which this equilibrium is established may very well be due to the reaction involving the borine molecule ($B_2H_6 \rightleftharpoons 2BH_3$) as has been suggested by Schlesinger and Burg[2] for the formation of diborane diammine.

(13) At a temperature just above the melting point of ammonia, 0.079 g. of diborane diphosphine (18.4 cc. B_2H_6 and 37.1 cc. PH_3 as gases) dissolve appreciably in 0.285 g. of liquid ammonia (375.8 cc. of gas) in twenty-nine hours. Solution is complete in forty-eight hours.

TABLE I

REACTION OF AMMONIA AND DIBORANE DIPHOSPHINE

				20	3 mo.	63	2.01	7.6

21.3 cc. of ammonia was heated in a sealed tube to 200° for fifteen minutes; 90.4 cc. of hydrogen and 2.1 cc. of $B_3N_3H_6$ were formed, while 1.5 cc. of phosphine, 0.2 cc. of B_2H_6 and 0.5 cc. of NH_3 were left unreacted. The vapor pressure of the $B_3N_3H_6$ was 79 mm. at 0° as compared with the reported value of 85 mm. at 0°. Thus, about 30% of the nitrogen in the diborane phosphine ammine was converted to the cyclic compound.

Reaction of Hydrogen Chloride on Diborane Diphosphine.—The results of the reaction of hydrogen chloride on solid diborane diphosphine are shown in Table II. The volume of the reactants is shown in the second, third and fourth columns, while the hydrogen produced and the hydrogen chloride introduced are shown in the last two columns.

Soon after one mole of hydrogen chloride is introduced into diborane diphosphine, the product begins to liquefy. When liquefaction is complete the product has the empirical composition $B_2H_4Cl_2 \cdot 2PH_3$. On addition of more hydrogen chloride, a mixture of solid and liquid is obtained, and when the composition is $B_2H_2Cl_4 \cdot 2PH_3$, it is completely solid. On further reaction with hydrogen chloride, the product can be converted completely into $BCl_3 \cdot PH_3$. When $BCl_3 \cdot PH_3$ is treated with diborane, a liquid containing boron, hydrogen, chlorine and phosphorus is obtained, but its composition could not be established definitely. When a tube containing $B_2H_2Cl_4 \cdot 2PH_3$ is heated rapidly the solid melts about 68° with decomposition. On warming the tube to 100° for an hour, a liquid is formed, and crystals of $BCl_3 \cdot PH_3$ sublime

TABLE II

REACTION OF HYDROGEN CHLORIDE ON DIBORANE DIPHOSPHINE

Expt.	B_2H_6, cc.	PH_3, cc.	HCl, cc.	Temp., °C.	Time, hr.	Press., atm.	$\frac{HCl}{B_2H_6}$	$\frac{H_2 \text{ evolved}}{B_2H_6}$
1	17.7	34.3	38.2	− 26	12	0.2	2.02	1.95
			89.7	− 20	6	0.3		2.92

					15	3.5		2.50
				0	72	0	4.00	4.00

to the top of the tube. Small amounts of hydrogen are formed at the same time.

Density of $BCl_3 \cdot PH_3$ in the Gas Phase.—40.3 cc. of $BCl_3 \cdot PH_3$ weighs 0.1230 g. The calculated weight of this volume of gas, if complete dissociation is assumed, and the product acted as a perfect gas, would be 0.1340 g.

Decomposition Pressure of $BCl_3 \cdot PH_3$.—The pressure of $BCl_3 \cdot PH_3$ was determined between −11 and +25°, the results being expressed by the equation $\log p = 11.137 - 2810/T$. The maximum deviation of the observed from the calculated pressures does not exceed 0.5 mm.

Reaction of Hydrogen Bromide on Diborane Diphosphine.—Hydrogen bromide reacts in much the same way as hydrogen chloride, the reaction of liquid hydrogen bromide at −78° taking place very rapidly.

Summary

1. Diborane and phosphine react to form a white unstable solid. The reaction takes place in the gas phase above −30° and in the liquid phase above −110°. The properties of the substance were studied and its probable structure discussed.

2. The action of ammonia on diborane diphosphine has been investigated over a temperature range of −75 to +25°. Liquid ammonia has been found to displace from 52 to 58% and gaseous ammonia up to 75% of the phosphine in diborane diphosphine.

3. The action of hydrogen chloride and hydrogen bromide on diborane diphosphine was found to result in the splitting out of hydrogen attached to boron. The compounds $B_2H_4Cl_2 \cdot 2PH_3$, $B_2H_2Cl_4 \cdot 2PH_3$ and $BCl_3 \cdot PH_3$ have been obtained by this reaction.

4. Attempts to prepare a volatile compound $B_3P_3H_6$, the analog of the cyclic compound $B_3N_3H_6$, were unsuccessful.

Dipole Moment, Induction and Resonance in Tetra-, Penta- and Hexa-substituted Benzenes

BY CHARLES P. SMYTH AND GEORGE L. LEWIS

The dipole moments of a great many poly-substituted benzenes have been measured by numerous investigators, but the loan by Dr. S. O. Morgan of the Bell Telephone Laboratories of fourteen such compounds, only one of which had been previously measured, has given us an unusual opportunity for the study of a large number of closely related compounds obtained from a single source. In the cases of most of the poly-substituted benzenes, departures of the moments from the values calculated as the resultants of the moments produced by the individual substituents have been attributed to mutual repulsion between adjacent atoms, which has since been shown by X-ray and electron diffraction to produce little distortion in most cases, and to mutual induction between adjacent groups, which calculation has shown to be sufficient to account for the observed discrepancies. More recently, the development of our ideas of resonance has brought the explanation not only of differences in moment between mono-substituted aromatic and aliphatic hydrocarbons, but also of a few seeming discrepancies in the moments of poly-substituted benzenes not previously accounted for. Although Groves and Sugden[1] have refined the method of calculating the inductive effect of a dipole upon the various atoms of the molecule containing it, the calculation retains the fundamental uncertainty inherent in the treatment of a distribution of charges as a single dipole located at a point and in the decision as to the proper location of this point. This uncertainty is serious only in calculating the inductive effects of the dipole upon the immediately adjacent atoms, but it is just these effects which make up the major part of the inductive shifts produced by the dipole. Although reasonable and, at times, very satisfactory results have been obtained on the basis of plausible assumptions in both the more and the less refined calculations, the inductive effect will be treated here in an empirical manner, rendered convenient by the number of but slightly differing compounds under examination.

Consideration of the moments obtained in the present work, like that of nearly all poly-substituted benzenes previously treated, loses a certain amount of precision because of the solvent effect, as the low volatility of the substances has

(1) Groves and Sugden, *J. Chem. Soc.*, 1992 (1937).

necessitated their measurement in benzene solution. However, as the dipoles in the fourteen molecules considered here lie in the plane of the benzene ring and as the maximum polarizabilities of the molecules, with a slight deviation in the case of pentachloroethylbenzene, must also lie in this plane and should not vary a great deal with the direction in this plane, the moments observed in benzene solution should be somewhat lower than the gas values,[2] but the small lowering should be relatively much the same for the different molecules, which should, therefore, have rather closely comparable moment values. The difference in solvent effect between these poly-substituted benzenes and those of mono-substituted benzenes should probably be greater than the differences among the solvent effects of the poly-substituted benzenes. However, the moments of mono- and disubstituted benzenes measured in solution will be used in discussing those of the tetra-, penta-, and hexa-substituted molecules. In general accord with what has been said in regard to the lowering of the moment by solvent effect in the more highly substituted benzenes, it may be mentioned that the moments found by Groves and Sugden[3] for the following vapors are higher than those listed by Fuchs and Wolf[4] for the substances in solution by the amount ($\times 10^{18}$) given after each: *m*-$C_6H_4Cl_2$, 0.19; *o*-$ClC_6H_4NO_2$, 0.29; *m*-$ClC_6H_4NO_2$, 0.30; *p*-$ClC_6H_4NO_2$, 0.23. The value reported by Groves and Sugden for *o*-$C_6H_4Cl_2$ vapor is 0.11 lower than the often-measured solution value, 2.27, while, on the basis of the theoretical considerations qualitatively applied and the experimental values just cited as well as the 0.15 lower value of monochlorobenzene in solution, 1.55, than in the vapor, the vapor value might be expected to be higher than that in solution. This single seeming discrepancy does not invalidate our method of approach, but does show the element of uncertainty involved in the comparison of values from different sources.

The solution values of the mono-substituted benzenes, 1.55 for chlorobenzene and 4.00 for nitrobenzene, to be used in the discussion are 0.15 and 0.21 lower than the gas values. The average moment value 0.34 calculated for toluene from the differences between the molar refraction for the D sodium line and the polarizations measured[5] for the pure liquid from -90 to $+90°$ is indistinguishable from the vapor value 0.35 obtained from the variation of polarization with temperature.[6] If, however, the moment is calculated for the vapor from the differences between the molar refraction and the polarization, a constant value 0.45 is obtained, which, probably, represents the upper limit assignable to the toluene moment. The value 0.35 will be used in the calculations of the present paper.

Experimental Data

As previously indicated, the substituted benzenes were obtained through the kindness of Dr. S. O. Morgan of the Bell Telephone Laboratories and were used without further purification. The benzene used as solvent was purified in the usual manner.[7] The dielectric constants of the solutions were measured at a frequency of 520 kilocycles with a crystal-controlled heterodyne beat apparatus described elsewhere[5] and the densities were measured with an Ostwald–Sprengel pycnometer in the manner previously described.[8] The dielectric constants ϵ and densities d of the solutions containing mole fractions c_2 of solute are given in Table I together with the polarizations P_2 calculated from them and the value P_1 for the solvent. The value of P_∞ for each substance at 25° given in Table II was obtained by extrapolation of the P_2 values to infinite dilution. The dipole moment μ was calculated in the usual manner from the difference between P_∞ and the molar refraction MR_D listed in Table II. As the substances were solid at room temperature, the molar refractions were calculated as additive quantities from the refraction data in "Landolt–Börnstein." The accuracy of these calculated values is equal to that obtainable experimentally in moderately dilute solutions and greater than that obtainable in the most concentrated solutions that could be prepared from the least soluble substances under examination. The smallness of the differences found between P_∞ and MR_D for the symmetrical trichloromesitylene and dichlorodurene give evidence of the accuracy of the MR_D values. The two small moment values calculated from these differences and listed in parentheses are, of course, indistinguishable from zero and indicate zero moments just as do similar small values obtained for liquid carbon tetrachloride and benzene. The somewhat larger moment values of 2,4,6-trichlorotoluene and pentachlorobenzene have probable errors of about 15% and 5%, respectively, because of uncertainty as to atomic polarization, and the remaining values, all higher, have probable errors of about 1%, with the exception of that for the difficultly soluble pentachlorotoluene, which has a probable error of about 5%. In Table II all the substances are named as substituted benzenes, the order of listing being the same as in Table I.

1,2,3,4-Tetramethyl-5,6-dinitrobenzene	58.2	1035	6.86

Discussion of Results

In discussing the dipole moments in Table II, we are primarily concerned with the effects of the methyl, chloro, and nitro groups upon one another and upon the benzene ring to which they are attached. Unless otherwise indicated, the moment values quoted are taken from the summary of Fuchs and Wolf already referred to.[4]

It is well known that the methyl group is classed with the halogens in its orienting effect

upon substitution in the benzene ring. The small moment of toluene has been attributed by some investigators to the C–H bond moments of the methyl group, it being assumed tacitly and without reason that the aromatic C–H bond moment is zero. The orienting effect of the methyl group shows that it produces some alteration in the distribution of charge in the ring, which should contribute to the moment. That this moment contribution acts in the direction of the C–C bond between the ring and the methyl group, as would be expected, is shown by the fact that the allocation of the entire dipole moment to this axis leads to good agreement between the calculated and the observed moments when additional groups are substituted on the ring. The small moment of the para aromatic H–C bond is included in the value used for each monosubstituted benzene moment and cancels out when these moments are added and subtracted. The fact that the length of the C–C bond between the ring and the methyl group in mesitylene and hexamethylbenzene cannot be distinguished from that of an ordinary aliphatic C–C bond,[9] is consistent with the absence of any very profound disturbance of structure as shown by the smallness of the dipole moment.

The moment values 0.5 and 0.4 determined in solution for *o*- and *m*-xylene respectively differ by no more than the probable errors in their measurement from the values 0.61 and 0.35 calculated by assigning a moment 0.35 to each axis of the ring-to-methyl bonds. The observed moment of *p*-chlorotoluene 1.90 is identical with the value calculated as the sum of the toluene moment 0.35 and the chlorobenzene moment 1.55, the observed value 1.78 for *m*-chlorotoluene agrees well with the resultant 1.75 of the two vectors 0.35 and 1.55, with an angle 120° between them, and the moment of the ortho compound 1.35 is but slightly lower than the value 1.41 calculated with an angle 60° between the two vectors. The agreement between the observed and calculated values of the three bromotoluenes is equally good.

While the *p*- and *m*-dichlorobenzene moments agree well with the calculated values the moment of the ortho compound determined in solution is 15% lower than the resultant of two dipoles of moment 1.55 with an angle 60° between them. This lowering must be attributed to mutual induction since the widening of the angle between the dipoles because of mutual repulsion has been shown by electron diffraction measurements[10] to be only of the order of 1°. It is well known that the moment of monochlorobenzene is lowered through resonance with contributions from structures in which a positively charged chlorine is connected to the ring by a double bond and a negative charge occurs on the para or on one of the two ortho carbons. It would be expected that substitution of additional chlorines on the ring would lessen the occurrence of the double bond between any particular chlorine and the ring and thus increase the dipole moment associated with the bond. The shortening of the carbon–chlorine bond by its partial double bond character has been observed by means of electron diffraction,[10] but the possible variation in this shortening with variation in the degree of double bond character which might be expected to accompany variation in the number of chlorines was not apparent here as it was in the case of the chloroethylenes.[11] The fair agreement between the observed and calculated values of *m*-dichlorobenzene, in which the effect of mutual induction is small shows that any increase of moment caused by decrease in double bond character must be small.

The agreement between the observed and calculated values of the chlorotoluenes and the fact that chloromesitylene has the same moment 1.55 as chlorobenzene while bromomesitylene and bromodurene[12] have moments 1.52 and 1.55, respectively, as compared to 1.52 for bromobenzene, show that the effects of the methyl groups upon the structures contributing to that of chlorobenzene as well as the inductive effect between the halogen and the adjacent methyl are too small to be detected in the moments.

This absence of effect of the methylbenzene upon the chlorobenzene moment is further evidenced by the moments in Table II. In pentamethylchlorobenzene, the moments due to the 2,3-methyl groups should cancel those due to the 5,6-methyl groups, leaving a moment equal to that of *p*-chlorotoluene. The observed value 1.85 is in satisfactory agreement with the observed value of *p*-chlorotoluene 1.90, which has been found identical with the calculated value. Similar treatment of pentachlorotoluene and penta-

(12) Birtles and Hampson, *J. Chem. Soc.*, 10 (1937).

chloroethylbenzene would have the moments due to the 2,3-chlorines cancelling those due to the 5,6-chlorines leaving moments equal to those of *p*-chlorotoluene and *p*-chloroethylbenzene, which should be almost identical in value. The observed values 1.55 and 1.50 are considerably lower than that of *p*-chlorotoluene because of induction between the chlorines. Indeed, it is surprising that they are not still lower. This will be clearer after consideration of the moments of tri-, tetra- and pentachlorobenzenes. The previously determined moment of 1,2,4-trichlorobenzene is 1.25. In the absence of inductive effects, the moments due to the 1,4-chlorines should cancel each other leaving a moment equal to that of chlorobenzene 1.55, but the moment of *o*-dichlorobenzene 2.27, 15% lower than the calculated value, has given evidence of strong mutual induction. If the resultant of the 1,2-chlorine moments is taken equal to that of *o*-dichlorobenzene and acting in the line bisecting a 60° angle between the bonds of the 1,2-chlorines, and the usual moment 1.55 is assigned to the 4-chlorine, the resultant moment of the molecule is calculated to be 1.21 in excellent agreement with the observed value 1.25. In 1,2,3,5-tetrachlorobenzene, the 2- and the 5-chlorine moments should, in the absence of induction, cancel one another, while the 1- and 3-chlorine moments should result in a moment equal to that of one, 1.55. However, the three adjacent chlorines give approximately double the opportunity for lowering of moment by induction that is given by two adjacent chlorines and the moment is lowered from 1.55 to 0.65.

At first glance, it would appear that the moment of pentachlorobenzene in Table II should be the same as that of the 1,2,3,5-tetrachlorobenzene, the pair of chlorine moments on one side of the ring cancelling the pair on the opposite side leaving the moment of the central 3-chlorine to determine that of the molecule. However, the 2- and 4-chlorine moments are reduced by the inductive effects of the 1- and 5-chlorines and, consequently, exert a somewhat reduced inductive effect upon the central 3-chlorine, which, therefore, gives a higher moment to the molecule than that found for 1,2,3,5-tetrachlorobenzene. As pentachlorobenzene differs from the two preceding compounds in Table II only in lacking a methyl or ethyl group, one would expect the moments of these latter compounds to be about $0.88 + 0.35 = 1.23$, but they are about 0.3 higher.

The moment of 1,2,3,4-tetrachlorobenzene in Table II can be treated as made up of two vectors with a 120° angle between them and a value equal to that of *o*-dichlorobenzene 2.27, which is reduced 0.41 by the induction between the two chlorines. The resultant of the two vectors 2.27 is, of course, 2.27, but their value will be reduced by the induction between the 2- and 3-chlorines. A reduction of 0.4 gives close agreement with the observed moment 1.90. The apparently small and actually zero moments found for the symmetrical molecules of trichloromesitylene or 1,3,5-trimethyl-2,4,6-trichlorobenzene, and dichlorodurene, or 1,2,4,5-tetramethyl-3,6-dichlorobenzene, indicate that the atomic polarizations of these poly-substituted benzenes are small, probably not over 2 cc. The moment value of 2,4,6-trichlorotoluene, which should be the same as that of toluene in the absence of mutual effects between the methyl group and the chlorines, is higher than that of toluene by an amount which may easily arise from the small atomic polarization.

In the molecule of trichloropseudocumene, or 1,2,5-trimethyl-3,4,6-trichlorobenzene, absence of induction would leave a moment equal to that of *p*-chlorotoluene 1.90. The observed value 1.83 is slightly lower than this, though not distinguishable from the moment of pentamethylchlorobenzene. One would expect the moment to be reduced more than 0.07 by the induction between the 3- and 4-chlorines. Indeed, if the resultant of these two chlorine moments is taken as equal to the moment of *o*-dichlorobenzene 2.27, the moment calculated for the molecule is 1.54, 0.3 lower than the observed as in the cases of methyl- and ethylpentachlorobenzene.

The moment of tetrachloro-*o*-xylene should be equal to the sum of the moments of 1,2,3,4-tetrachlorobenzene 1.90 and *o*-xylene, 0.5 observed, 0.61 calculated. If the calculated value of *o*-xylene is used, the sum obtained is 0.13 lower than the observed value 2.64. The moment of 4,5-dichloro-*o*-xylene should similarly be equal to the sum of the moments of *o*-dichlorobenzene and *o*-xylene, $2.27 + 0.61 = 2.88$. The observed value is higher than this by 0.13. In other words, the tetrachloro-*o*-xylene and the 4,5-dichloro-*o*-xylene moments differ from each other by just the difference between the moments of

1,2,3,4-tetrachlorobenzene and *o*-dichlorobenzene, as they should, but both are slightly higher than the calculated values. Similarly, the moment of 4,5-dibromo-*o*-xylene[13] 2.86 is higher than the value calculated as the sum of the moments of *o*-dibromobenzene and *o*-xylene, 2.00 + 0.61 = 2.61, but the observed moment of 4-bromo-*o*-xylene[13] 2.07 is identical with the calculated value. In 3,4,5-trichloro-*o*-xylene, the moment due to the three chlorines may be calculated roughly by adding 1.55 to the previously mentioned moment of 1,2,3,5-tetrachlorobenzene 0.65. Resolution of the resultant value 2.20 and the moments due to the two methyl groups gives an approximate value 2.74, which is higher than the observed value 2.46 by no more than its possible error. Dichloroprehnitene, or 1,2,3,4-tetramethyl-5,6-dichlorobenzene, should have the same moment as 4,5-dichloro-*o*-xylene. The observed value is 0.08 lower than this latter and only 0.05 higher than the calculated value. As there was originally some uncertainty as to the composition of a substance subsequently found to be 4,6-dichloro-*m*-xylene, the data on it are omitted from Tables I and II. The moment value observed for it, 2.30, is 0.40 higher than the value calculated as the resultant of the individual methyl and chlorine moments.

In the absence of complicating effects, the moment of dinitroprehnitene, or 1,2,3,4-tetramethyl-5,6-dinitrobenzene, should be equal to that of *o*-dinitrobenzene 6.00 plus the resultant 0.61 calculated for two methyl groups ortho to each other. The observed value 6.86 is slightly higher than this calculated value 6.61, although, for a reason to be discussed presently, one might expect it to be slightly lower. Birtles and Hampson[12] have shown that the moments of nitrodurene and aminodurene are lower than those of the corresponding benzene derivatives and close to those of the corresponding alkyl compounds. The moments of aniline and nitrobenzene, through resonance, receive contributions from highly polar structures in which the nitrogen is linked to the ring by a double bond, with the two other atoms of the group lying in the plane of the ring. Birtles and Hampson conclude that the steric repulsion of the adjacent methyl groups in the durenes tends to prevent the atoms attached to the nitrogen from lying in the plane of the ring and, therefore, reduces the contributions from the highly polar structures. No such reduction is evident, at first glance, in the moment of dinitroprehnitene. The moment of *o*-dinitrobenzene is lowered about 13% below its calculated value, as is also the moment of *o*-chloronitrobenzene, while the moment of *o*-dichlorobenzene is lowered 15% below its calculated value. This difference in lowering is far less than in the case of nitroform and chloroform, in the former of which the lowering below the calculated value is 15% as compared to 44% in the latter.[14] As consideration of the dimensions of the nitro and the methyl groups leads to the conclusion that steric repulsion between the two coplanar nitro groups in *o*-dinitrobenzene would be much greater than that between a methyl group and a nitro group in the plane of the ring, it would appear that the 13% reduction of the moment of *o*-dinitrobenzene below the calculated value may be due, to a considerable extent, to the reduction by steric repulsion of the contribution from the coplanar, highly polar structure. Unless the steric repulsion between the two nitro groups were so great that the addition of a methyl group on each side did not increase the steric effect, one would expect a further lowering of the nitro moments in dinitroprehnitene, which is not observed. Further evidence of the lowering of the nitro moment by the proximity of methyl groups is given by the moment of nitromesitylene 3.65 as compared to 4.00 for nitrobenzene and 3.39 for nitrodurene. A slight lowering is also suggested by the fact that the observed moment of *o*-nitrotoluene 3.66 is lower than the calculated value 3.84, while the observed value of *m*-nitrotoluene 4.17 agrees with the calculated 4.18, and the observed value of the para compound 4.44 is higher than the calculated 4.35. The repulsive effect probably should be less in nitromesitylene than in nitrodurene, where the *o*-methyl groups are pushed somewhat toward the nitro group by the methyls on the next carbons, and obviously should be much less in *o*-nitrotoluene, where, however, the apparent lowering may be due, at least in part, to experimental error.

It is evident that the agreement between the observed and calculated values for these polysubstituted benzenes is fairly good, although the observed values tend to be a little higher than the calculated when the latter are unaffected by in-

(13) Sidgwick and Springall, *J. Chem. Soc.*, 1532 (1936).

(14) Lewis and Smyth, THIS JOURNAL, **61**, 3067 (1939).

duction. The toluene moment 0.35 used for the methyl group would seem the most logical value, but, as pointed out previously, it is not impossible that this moment should be as high as 0.45. If this higher value is used for the methyl group moment, some of the calculated values become higher than the observed and the difference between the two is no longer always in the same direction. The moments of pentachlorotoluene and pentachloroethylbenzene, 1.55 and 1.50, still remain appreciably higher than the value 1.33 calculated by adding the methyl group moment 0.45 to the moment of pentachlorobenzene. The discrepancy might be explained by a small lowering of the moment of pentachlorobenzene through a slight bending of the chlorine bonds by steric repulsion between the chlorines. The replacement of the one hydrogen by the larger methyl or ethyl would prevent or even slightly reverse this bending but no such effect is apparent in the relation of the moment of tetrachloro-*o*-xylene to that of 1,2,3,4-tetrachlorobenzene, where it should occur to a slightly smaller extent. Similar discrepancies have been noted in the cases of trichloropseudocumene and of the slightly doubtful 4,6-dichloro-*m*-xylene. It is possible that the somewhat better agreement obtained with the higher value 0.45 for the methyl group moment is not due to incorrectness of the toluene moment 0.35, but is due to reinforcement of the methyl moment by interaction through the ring with the other substituent groups. It may be concluded, however, that, in view of experimental errors and of possible small variations in the effect of solvent upon the moment values, the differences between the observed and calculated values of the moments are too small to give definite evidence of any effects of resonance in the methyl- and chlorine-substituted benzenes other than those occurring in the mono-substituted compounds.

The effects of resonance are so great in nitrobenzene with its large moment that their influence upon the chlorobenzene resonance is apparent in the moment value of *p*-chloronitrobenzene 2.78 found for the vapor,[3] which is 0.26 higher than the value calculated as the difference between the vapor values for chlorobenzene and nitrobenzene. The contribution of one of the polar forms due to each substituent is increased by the presence of the other as in the familiar case of *p*-nitroaniline, where the effect is much greater. The observed value for *m*-chloronitrobenzene vapor[3] 3.69 agrees with the calculated 3.68, as does that of *m*-dichlorobenzene previously noted, and the same is approximately true of the solution value of *m*-nitroaniline in the literature, while resonance again increases the moment of *o*-nitroaniline. Although, as previously concluded, the data in this paper fail to establish definitely the existence of the interaction of resonance effects of methyl and chlorine groups upon the ring, they suggest the possibility of a small increase in moment through the mutual effects of para-substitution upon resonance.

In conclusion, the writers wish to express their gratitude to Dr. B. S. Biggs of the Bell Telephone Laboratories, who prepared the compounds here discussed, and to Dr. S. O. Morgan of the same Laboratories, through whose kindness they were made available for our measurements.

Summary

The dipole moments of fourteen tetra-, penta-, and hexa-substituted benzenes with chlorine and the methyl and nitro groups as substituents have been measured in dilute solutions in benzene. The values are compared with those calculated as the vector sums of the moments of mono-substituted benzenes and the effect of induction between groups is taken care of by using the moment of a di-, tri-, or tetra-substituted molecule as a single vector. On the whole, satisfactory agreement is obtained between the observed and the calculated results. The alteration in the moment due to one group produced by the resonance effects of another group is evident in *p*-chloronitrobenzene, but is too small to detect with certainty in these results where methyl and methyl, methyl and chlorine, or chlorine and chlorine are the groups involved, although an indication of a possible small increase in moment due to such effects is given.

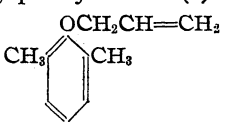
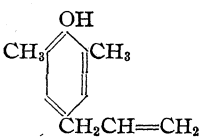
The Claisen Rearrangement. II. A Kinetic Study of the Rearrangement of Allyl 2,6-Dimethylphenyl Ether in Diphenyl Ether Solution

BY D. STANLEY TARBELL AND JOHN F. KINCAID

A recent study[1] of the kinetics of the rearrangement of allyl *p*-tolyl ether in diphenyl ether solution indicated that the reaction is first order and proceeds by some mechanism which does not require catalysis by acids or bases. The case studied involves migration of the allyl group to the free ortho position and might be expected to be a unimolecular reaction. If both ortho positions of an allyl phenyl ether are blocked, however, the allyl group enters the para position on rearrangement, and the reaction might be expected to involve a bimolecular mechanism. We wish to report a study of the rate of rearrangement of a compound of this type, allyl 2,6-dimethylphenyl ether (I).



I



II

The rate of conversion of this compound to 2,6-dimethyl-4-allylphenol (II) in one molar solution in diphenyl ether has been studied at three temperatures, 185.8, 171.6, and 156.9°. At the two higher temperatures the rate of reaction of the pure liquid has been measured, and at 171.6° the effect of dimethylaniline and acetic acid has been studied, as well as the rate in solutions more concentrated and more dilute than one molar.

The structure of the rearrangement product II was proved by the fact that it was identical with the product obtained from direct C-alkylation of 2,6-dimethylphenol with allyl bromide. With allyl bromide and sodium ethylate in alcohol, 2,6-dimethylphenol yielded a mixture of approximately 85% of the ether I and 15% of the C-alkylation product II. In a trial run with allyl bromide and sodium in benzene, the product consisted of 55% of the ether and 45% of the C-alkylation product.

It was found that the phenylurethan of the rearrangement product II could be prepared readily using a trace of dry hydrogen chloride as catalyst; aluminum chloride and bases are also known to catalyze the formation of phenylurethans from phenols.[2]

The isolation of the rearrangement products described in the experimental part was carried out in order to determine whether side reactions occurred during the reaction. The results of the fractionation showed that 95% of the product was pure 2,6-dimethyl-4-allylphenol when the rearrangement of the pure liquid was carried out at 171.6° in the absence of air. Five per cent. of a non-volatile product was formed which was probably a polymer. Since polymerization reactions should be slower in solution than in the pure liquid, it is concluded that the rearrangement in solution is greater than 95% quantitative.

The first order rate constants obtainable from these data by the usual equation, given in Tables I to III, show that the kinetics of the rearrangement are strictly first order. If the slow step in the reaction mechanism were bimolecular, the first order constants for 80% reaction would be only about one-half as great as the initial values, whereas inspection of the table reveals that the constants for the two most dilute solutions do not change greatly with the percentage reaction, while those for the most concentrated solution actually increase with percentage reaction. This increase is very marked for the pure liquid, the rate constant for 77% reaction being 11.85×10^{-5} sec.$^{-1}$ compared to 7.75×10^{-5} sec.$^{-1}$ for 16% reaction. It should be mentioned that these rate constants are not an accurate measure of the specific rate of the rearrangement in the two cases since they were computed from an equation integrated with the condition that k remain constant as the reaction proceeds. Actually the rate of the rearrangement is about three times the initial rate after 80% reaction in the pure liquid. This behavior is similar to that previously noted for allyl *p*-tolyl ether.[1] Although the reaction takes place considerably faster in the pure liquid than it does in solution, the initial values of the rate constants are almost the same. This constancy of the initial values is further proof that the reaction is first order.

27.0	27.8	30.4	33.1	...	

[a] The first row gives the time in sec., the second gives the percentage reaction, and the third gives the rate constants in reciprocal seconds times 10^5.

The effect of dimethylaniline on the rate was studied in order to determine whether the slow step in the mechanism involved the transfer of a proton. If this were the case, then dimethylaniline should considerably accelerate the rate since it is a far better proton acceptor than diphenyl ether. From Table I it is seen that the addition of 10% of dimethylaniline increases the rate by about 15%. This relatively small increase is interpreted as indicating that a prototropic change is not the slow step in the reaction, although it does not preclude the possibility that such a change is involved somewhere in the mechanism. This 15% increase is, however, to be compared with only a 3% increase for a similar experiment carried out with allyl *p*-tolyl ether.[1]

TABLE III[a]

FIRST ORDER RATE CONSTANTS AT 156.9°

14.13% I and 85.87% diphenyl ether					
5,920	8,440	11,680	22,780	43,420	
12.00	16.78	21.35	43.36	65.80	mean
2.16	2.18	2.06	2.50	2.47	2.27

[a] The first row gives the time in sec., the second gives the percentage reaction, and the third gives the rate constants in reciprocal seconds times 10^5.

The two series of runs in the presence of acetic acid indicate that the reaction is speeded up to some extent by the presence of acids. Thus the rate constant for a 1% solution of acetic acid is 28%, and that for a 2% solution is 42%, greater than that for the reaction in the absence of acids. This effect, although not very great, appears to be definitely beyond any possible experimental error. On the other hand, it appears definite that the reaction as it takes place in the pure liquid or in solution in pure diphenyl ether is not a catalyzed reaction since a much greater increase in the rate would be expected if the reaction could occur *only* in the presence of acids.

The mean rate constants for the 14% solutions at the three temperatures were used to compute the activation energy for the reaction from the Arrhenius equation

$$k = A \exp(-\Delta E/RT) \qquad (1)$$

we obtain $A = 0.583 \times 10^{11}$ sec.$^{-1}$, and $\Delta E =$ 30.3 kcal. per mole. The entropy of activation for the reaction, $\Delta S^{\pm}$, may be obtained from the constant A by means of the equation[3] for the absolute rate of any reaction

$$k = (kt/h)\,\kappa \exp(\Delta S^{\pm}/R) \exp(-\Delta E^{\pm}/RT)$$

Here k is Boltzmann's constant, h is Planck's constant, κ is the transmission coefficient, and $\Delta S^{\pm}$ and $\Delta E^{\pm}$ are the entropy and energy of activation, respectively. By making the usual assumption that κ equals unity, we find that $\Delta S^{\pm}$

(3) H. Eyring, *J. Chem. Phys.*, **3**, 107 (1935).

$= -10.1$ E. U. at 171.6°. This value is to be compared to $\Delta S^{\ddagger} = -9.5$ E. U. for the rearrangement of allyl *p*-tolyl ether.[4] The fact that the entropies of activation for the rearrangement to the ortho and para positions differ by only 0.6 E. U. suggests strongly that the slow step is the same in each case.

Two mechanisms were discussed[1] as possibilities for the rearrangement to the ortho position. The first, the cyclic mechanism, is one in which the γ carbon atom on the allyl group starts to form a bond with the atom in the ring simultaneously with the breaking of the carbon–oxygen bond. The second mechanism proposed, the dissociation mechanism, is one in which the slow step is the breaking of the carbon–oxygen bond, the allyl group being split off as a radical or positive ion. The chemical evidence favors the cyclic mechanism for the rearrangement to the ortho position. This mechanism requires inversion of the allyl group during rearrangement, and this has been observed repeatedly.[5] That the allyl group is never free during the rearrangement to the ortho position is indicated by the work of Hurd and Schmerling,[6] who showed that mixed products are not formed when a mixture of cinnamyl phenyl ether and allyl β-naphthyl ether is rearranged. On the other hand, the chemical evidence favors the dissociation mechanism for the rearrangement to the para position. Thus it has been shown[7] that inversion does not usually occur during the migration of the allyl group to the para position. The chemical evidence for the incorrectness of the cyclic mechanism for the rearrangement to the para position is supported by the use of Fisher-Hirschfelder atomic models. They show that, even in the most favorable orientation, there is still an internuclear distance of more than 4 Å. between the para and γ carbon atoms. Not only is this too great to be favorable for bond formation but the angle is not suitable, being about 120° away from the stable configuration in the plane of the ring.

Thus the chemical evidence appears to indicate that the mechanisms of the migrations to the ortho and para positions are different, while the kinetic studies lead to the conclusion that they are the same. It must, however, be remembered that rate measurements, by themselves, can give information *only* about the slow step in the reaction.

(4) The value previously found for $\Delta S^{\ddagger}$ for the rearrangement of allyl *p*-tolyl ether[1] was −8.1 E. U. However, for purposes of comparison with the present case this must be corrected by $-R \ln 2$ (−1.4 E. U.) due to the fact that there are two ortho positions in the ring available for substitution.

Experimental

The technique of carrying out the measurements and analyzing the reaction mixture already has been described.[1]

Allyl 2,6-Dimethylphenyl Ether (I).—Eastman Kodak Co. 2,6-dimethylaniline was purified through the crystalline formyl derivative[8] and 2,6-dimethylphenol prepared from the purified amine by the method of Bamberger.[9] To a solution of 19.5 g. of sodium in 350 cc. of alcohol, 103.5 g. of recrystallized 2,6-dimethylphenol (m. p. 47–48°) was added, followed by dropwise addition of 121 g. of allyl bromide, while heating the solution on the steam-bath. The reaction mixture, which formed a solid precipitate immediately, was heated on the steam-bath for three hours, and poured into 1.5 liters of water. The product was isolated by extraction with 400 cc. of low boiling petroleum ether in two portions; the extract was washed twice with 100-cc. portions of 20% sodium hydroxide solution, dried, the solvent removed, and the product distilled in nitrogen through a modified Widmer column. The main fraction of 63.9 g. had the boiling point of 67–68° at 2 mm., bath temperature 100–105°; d^{25}_4 0.9422, $n^{25}D$ 1.5048. *Anal.*[10] Calcd. for $C_{11}H_{14}O$: C, 81.44; H, 8.69. Found: C, 81.53; H, 8.70. Analysis by the usual method showed that this sample contained 0.4% of 2,6-dimethyl-4-allylphenol (II).

2,6-Dimethyl-4-allylphenol (II).—The sodium hydroxide wash solution of the preceding paragraph yielded on acidification and extraction 34 g. of oil, which was separated by fractionation into two fractions: 10.8 g. of 2,6-dimethylphenol, b. p. 103–115° at 22 mm., and 10 g. of the C-alkylation product, 2,6-dimethyl-4-allylphenol, b. p. 131–138° at 21 mm. The phenylurethan prepared as described below, melted at 139–140.5° after two crystallizations from ligroin, and gave no depression when mixed with the phenylurethan of II produced by rearrangement.

When 8.45 g. of 2,6-dimethylphenol was alkylated with the equivalent amount of sodium and allyl bromide in benzene solution, 2.8 g. of the O-alkylation product I was obtained, and 2.1 g. of the C-alkylation product II.

Isolation of the Products of the Rearrangement.—Forty-three grams of the ether (I) was heated for seven hours at 171.6° in sealed tubes.

The product II (41.3 g.) was distilled in a nitrogen atmosphere through a modified Widmer at a distillation rate of about six drops per minute. At 2 mm. pressure, the boiling point of fractions 2, 3 and 4 varied between 90.5 and 91.4°.

These fractions were analyzed in duplicate for active hydrogen by the usual method, and the molecular weights per active hydrogen are shown in Table IV. The fact

(8) Busch, *ibid.*, **32**, 1008 (1899).

(9) Bamberger, *ibid.*, **36**, 2036 (1903).

(10) Analyses by Dr. L. Weisler.

TABLE IV

Fraction	% Total material	Mol. wt.[a]
1	2.8	
2	55.2	162.8
3	25.5	164.3
4	5.8	162.9
5	9.0	
Total	98.3	

[a] Mol. wt. of 2,6-dimethyl-4-allyl phenol, 162.2.

that these fractions have the expected molecular weight per active hydrogen indicates that they are composed of pure rearrangement product. That fraction 1 was composed almost entirely of the unrearranged ether (I) and its rearrangement product (II) was shown by analyses of samples taken before and after this fraction had been heated for five hours more at the same temperature. The molecular weight per active hydrogen was 296 before and 169.5 after further heating. If fraction 1 is considered to be a mixture of I and its rearrangement product only, these figures are equivalent to a percentage composition of 55% II and 96% II before and after the second heating. These data make it appear probable that no appreciable amount of material formed by side reactions was present in the low boiling fraction.

Fraction 6, the residue left in the still pot, was distilled from a 5-cc. Claisen flask at reduced pressure; 40% of the material distilled at the expected boiling point, but the remainder of this fraction, 5.4% of the original 41.3 g., did not distil. It was evidently polymeric. The portion which distilled had a molecular weight per active hydrogen which agreed with that for (II) to within 0.2%.

The material not accounted for in Table IV, 1.7%, was held up in the still, and by washing out the apparatus with ether a small amount of material was recovered which boiled at the correct place for the rearrangement product. The amount available was insufficient for analysis.

Therefore the only product except the rearrangement product and unreacted ether which could be found was 5.4% of polymeric material in fraction 5. Since polymerization reactions would be expected to be somewhat less rapid in solution than in the pure liquid, it seems certain that the reaction in solution is greater than 95% quantitative. The pure 2,6-dimethyl-4-allylphenol (fractions 2, 3 and 4) has the following properties: b. p. 90.5–91.4° at 2 mm.; d^{25}_4 0.9870; $n^{25}D$ 1.5370.

The **phenylurethan** was prepared from 1 cc. of the phenol and 0.6 cc. of phenyl isocyanate by passing dry hydrogen chloride over the surface of the solution and heating the mixture on the steam-bath for ten minutes. The product, which crystallized on cooling, was recrystallized twice from ligroin, m. p. 141–142.5°, and gave no depression when mixed with samples from the 2,6-dimethyl-4-allylphenol prepared by direct C-alkylation of 2,6-dimethylphenol.

Anal. Calcd. for $C_{18}H_{19}O_2N$: C, 76.84; H, 6.81. Found: C, 76.79; H, 6.78.

Summary

1. Allyl 2,6-dimethylphenyl ether and 2,6-dimethyl-4-allylphenol have been prepared and characterized.

2. The rate of rearrangement of allyl 2,6-dimethylphenyl ether has been measured at 156.9, 171.6 and 185.8°, in the pure liquid at the two upper temperatures, and in diphenyl ether solution at all three temperatures. Measurements covering a four-fold range in concentration in solution showed the reaction to be first order, and the initial values of the rate constants for the pure liquid are the same as those in solution.

3. The reaction rate is not appreciably affected by 10% of dimethylaniline, but 1% and 2% of acetic acid lead to increases in the rate constant of 28% and 42%, respectively.

4. The energy of activation for the reaction is 30.3 kcal. per mole, and the entropy of activation is −10.1 E. U. From a comparison of this value of $\Delta S^{\ddagger}$ with that for the rearrangement to the ortho position, it is concluded that the slow step is the same in each case.

5. The rearrangement has been shown to be at least 95% quantitative in solution.

6. Appreciable amounts of the C-alkylation product are observed in the reaction of allyl bromide and 2,6-dimethylphenol even when the reaction is carried out in alcohol solution in the presence of sodium ethylate.

Structure of Cannabidiol. II. Absorption Spectra Compared with those of Various Dihydric Phenols

BY ROGER ADAMS, C. K. CAIN AND HANS WOLFF

IN COLLABORATION WITH THE TREASURY DEPARTMENT, NARCOTICS LABORATORY, WASHINGTON, D. C.

The isolation of a new substance, cannabidiol, from the red oil of Minnesota wild hemp was recently described.[1] It proved to be an optically active, resinous, dihydric phenol from which two crystalline derivatives, the *bis*-3,5-dinitrobenzoate and the *bis-m*-nitrobenzenesulfonate, could be obtained. A pure dimethyl ether also was prepared. Oxidation of cannabidiol with formation of *n*-caproic acid indicated the likelihood of the presence of an *n*-amyl group in the phenolic nucleus.

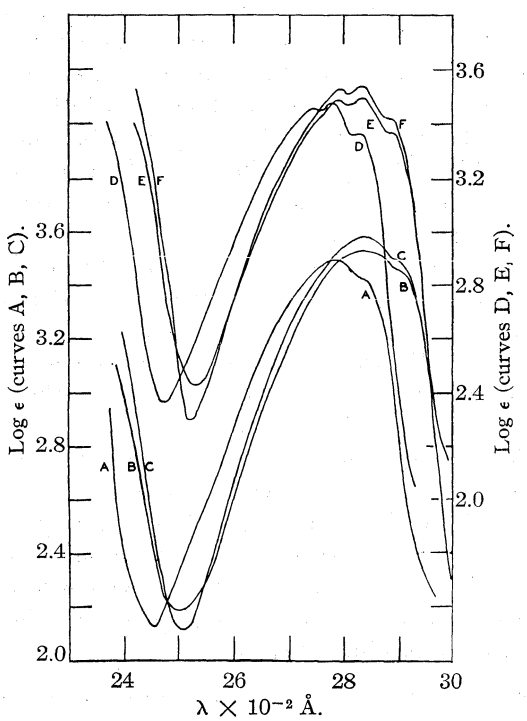

Fig. 1.—A, Catechol; B, 4-methylcatechol; C, 4-*n*-amylcatechol; D, catechol dimethyl ether; E, 4-methylcatechol dimethyl ether; F, 4-*n*-amylcatechol dimethyl ether.

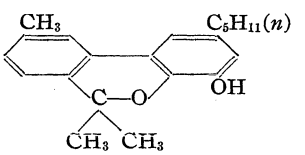
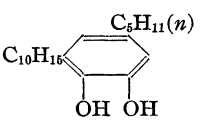
The analyses of cannabidiol and its derivatives revealed the probable formula as $C_{21}H_{30}O_2$, whose similarity to that of cannabinol, $C_{21}H_{26}O_2$, is striking. With the structure of cannabinol (I) satisfactorily established,[2] except for the positions of the hydroxyl and *n*-amyl groups, an analogous structure for cannabidiol might be anticipated, since these two natural products come from essentially the same source.



I



II

Consequently, a tentative formula (II) for cannabidiol was suggested with the postulation that the $C_{10}H_{15}$–group was probably a menthyl residue containing two double bonds.

Information concerning the orientation of the two hydroxyls in the cannabidiol molecule is not readily obtained chemically but through absorption spectra the relationship should be possible to determine. With this end in view a comparison has been made of the ultraviolet absorption spectra of cannabidiol and cannabidiol dimethyl ether with those of catechol, 4-methylcatechol and 4-*n*-amylcatechol and their dimethyl ethers, and with those of resorcinol, 5-methylresorcinol and 5-*n*-amylresorcinol and the corresponding dimethyl ethers.

From Fig. 1 it is apparent that the catechols have one broad peak and one that is much narrower. The introduction of alkyl groups into the catechol molecule in the 4-position causes a shift of the peaks of the spectra toward longer wave lengths with a simultaneous increase in the extinction coefficients at these wave lengths. The dimethyl ethers of these compounds show spectra having three distinct peaks and the variations with introduction of the alkyl groups are similar to those in the unmethylated compounds.

In Fig. 2 are given the spectra of resorcinol and its derivatives. They all show two distinct peaks of about the same breadth. In marked contrast to the catechol derivatives, the introduction of alkyl groups in the 5-position causes a slight shift in the peaks of the spectra toward lower wave lengths and the molecular extinction coefficients at these wave lengths are decreased. The same

(1) Adams, Hunt and Clark, THIS JOURNAL, **62**, 196 (1940).

(2) Cahn, *J. Chem. Soc.*, 986 (1930); 630 (1931); 1342 (1932); 1400 (1933).

general effects are found in the spectra of the dimethyl ethers.

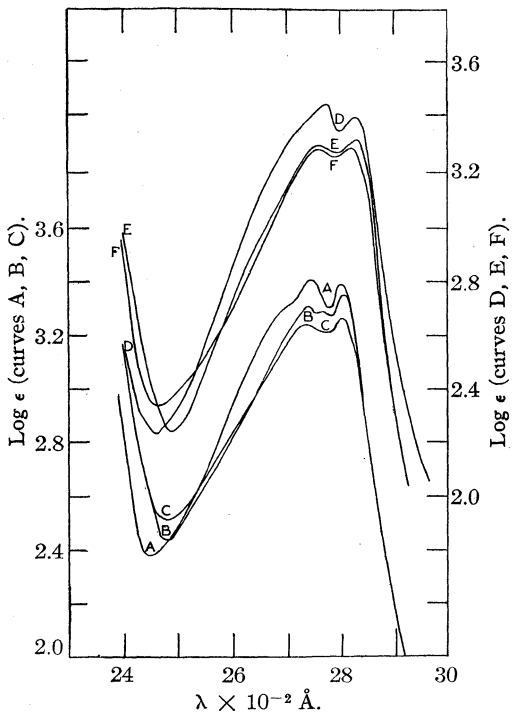


Fig. 2.—A, Resorcinol dimethyl ether; B, 5-methylresorcinol dimethyl ether; C, 5-*n*-amylresorcinol dimethyl ether; D, resorcinol; E, 5-methylresorcinol; F, 5-*n*-amylresorcinol.

A comparison of the spectra of cannabidiol, 5-*n*-amylresorcinol and 4-*n*-amylcatechol shows the striking similarity of the curves of cannabidiol and 5-*n*-amylresorcinol. The peaks in the curve for cannabidiol are shifted toward lower wave lengths and lower extinction coefficients, as was shown to be the effect on the spectra of resorcinol when alkyl groups are introduced. The dimethyl ethers of these three compounds give spectra similarly related.

Confirmation of the deduction that cannabidiol probably is a resorcinol derivative was obtained by infrared absorption spectra (Fig. 4). These were kindly carried out for us by Dr. W. H. Rodebush and Mr. G. W. McMillan of this Laboratory, to whom we are deeply indebted. The spectra of cannabidiol and 5-*n*-amylresorcinol have only single peaks at essentially the same wave length, while that of 4-*n*-amylcatechol shows two distinct peaks at different wave lengths from those shown in the other two spectra.

On the basis of these results, structure II for cannabidiol must be incorrect; it may now be assigned structure III which represents the molecule as a resorcinol derivative. The location of the

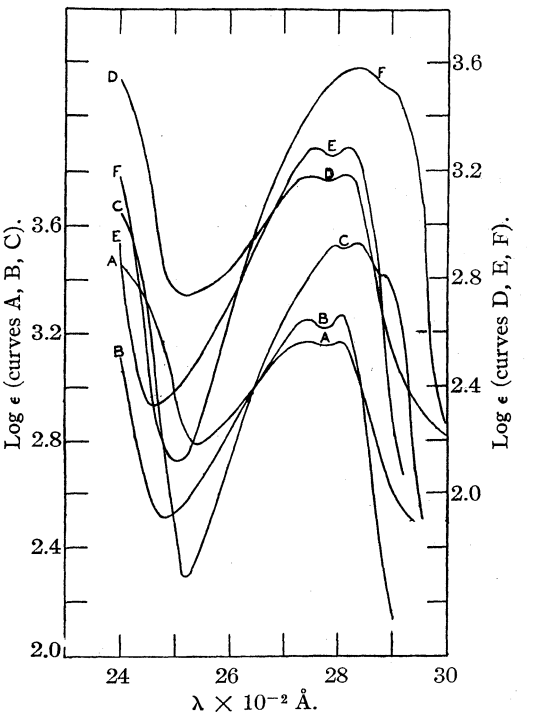

Fig. 3.—A, Cannabidiol dimethyl ether; B, 5-*n*-amylresorcinol dimethyl ether; C, 4-*n*-amylcatechol dimethyl ether; D, cannabidiol; E, 5-*n*-amylresorcinol; F, 4-*n*-amylcatechol.

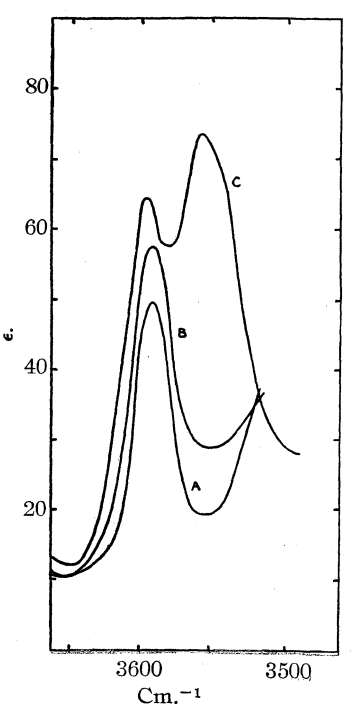

Fig. 4.—A, Cannabidiol; B, 5-*n*-amylresorcinol; C, 5-*n*-amylcatechol.

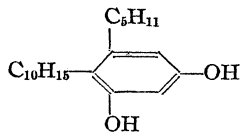

III

$C_{10}H_{15}$–radical and of the *n*-amyl group in relation to the hydroxyl groups in structure III is purely arbitrary.

Attempts to determine the presence of a resorcinol or catechol orientation of hydroxyls in cannabidiol by means of a variety of color reactions such as have been used in the past for testing for resorcinol, catechol, and red oil, proved negative. No satisfactory correlation was apparent between the color reactions of cannabidiol and 5-*n*-amylresorcinol nor between cannabidiol and 5-*n*-amylcatechol.

Experimental

A Bausch and Lomb medium quartz spectrograph and a Moll type recording densitometer were used for the ultraviolet absorption spectra of solutions of the compounds in ether. The infrared absorption spectra were taken of carbon tetrachloride solutions.

Cannabidiol and cannabidiol dimethyl ether were prepared as previously described.[1]

1,2-Dimethoxy-4-methylbenzene.—This was prepared by the Clemmensen reduction of veratric aldehyde as described by King and l'Ecuyer.[3] The product used boiled at 112° (20 mm.); m. p. 23° (cor.); $n^{25}D$ 1.5250.

1,2-Dihydroxy-4-methylbenzene (4-Methylcatechol).—A mixture of 9 g. of 1,2-dimethoxy-4-methylbenzene and 37 cc. of 48% hydrobromic acid was refluxed for six hours. Water was added followed by sodium bicarbonate until neutral. The compound was ether extracted, the ether solution in turn extracted with 10% aqueous sodium hydroxide, and the alkaline solution which became deeply colored was acidified immediately with dil. sulfuric acid. Subsequent extraction with ether and evaporation of the solvent gave a product which had a b. p. 141–143° (20 mm.). This liquid solidified and was crystallized from a mixture of benzene and petroleum ether (b. p. 40–60°), m. p. 65–66°. Finally it was redistilled before determining the absorption spectra; yield 4.5 g.

1,2-Dihydroxy-4-*n*-pentanoylbenzene.—This was prepared by a method previously described.[4] The observed m. p. 99–100° (cor.) differed slightly from that given by the above authors.[4]

1,2-Dihydroxy-4-*n*-amylbenzene (4-*n*-Amylcatechol).—Miller, Hartung, Rock and Crossley report only a 40% yield by the Clemmensen reduction of 1,2-dihydroxy-4-*n*-pentanoylbenzene, but a 90% yield by a palladium–hydrogen reduction. It has been found that the Clemmensen reduction of the ketone by the modification of Martin[5] gave a 72% yield; b. p. 153–155° (4–5 mm.); $n^{20}D$ 1.5258. The product crystallized in rosets on cooling in ice.

1,2-Dimethoxy-4-*n*-amylbenzene (4-*n*-Amylcatechol Dimethyl Ether).—To a mixture of a solution of 3.6 g. of 4-*n*-amylcatechol in 100 cc. of methanol and 6 g. of dimethyl sulfate was added slowly a 10% ethanolic sodium hydroxide solution until the reaction remained neutral. Another 6 g. of dimethyl sulfate was introduced and the procedure repeated. Most of the color in the solution had disappeared when methylation was complete. The mixture was extracted with ether and the ether solution was washed with aqueous alkali; b. p. 124–126° (4–5 mm.); $n^{20}D$ 1.5084; d^{20}_4 0.9856.

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 75.00; H, 9.62. Found: C, 75.29; H, 9.85.

The resorcinol and orcinol used were purified grades of commercial products. The methyl ethers were prepared in the usual way.

Olivetol dimethyl ether and olivetol were made by the method of Asahina,[6] though more recently the procedure of Suter and Weston[7] for the preparation of these compounds proved to be more satisfactory.

Summary

The ultraviolet and infrared absorption spectra of cannabidiol resemble closely that of olivetol, 1,3-dihydroxy-5-*n*-amylbenzene, and do not resemble that of 4-*n*-amylcatechol. It therefore was concluded that cannabidiol is a resorcinol derivative.

A comparison of the absorption spectra of resorcinol with its 5-methyl and 5-*n*-amyl derivatives indicates that introduction of the alkyl groups causes a slight shift in the peaks toward lower wave lengths and the molecular extinction coefficients at these wave lengths are decreased.

A comparison of catechol and its 4-methyl and 4-*n*-amyl derivatives indicates that introduction of the alkyl groups causes a shift in the peaks toward longer wave lengths and an increase in the extinction coefficients at these wave lengths.

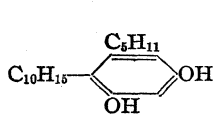
Structure of Cannabidiol. III. Reduction and Cleavage

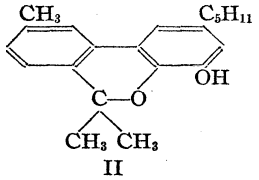
BY ROGER ADAMS, MADISON HUNT AND J. H. CLARK[1]

IN COLLABORATION WITH THE TREASURY DEPARTMENT, NARCOTICS LABORATORY, WASHINGTON, D. C.

On the basis of absorption spectra,[2] cannabidiol (I) appears to be a resorcinol and not a catechol derivative as was first assumed after a consideration of the structure proposed by Cahn[3] for the closely related compound cannabinol (II).



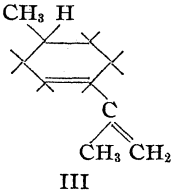
I



II

The C_5H_{11}–group previously has been shown to be normal. New chemical evidence is now submitted to demonstrate that cannabidiol is a resorcinol derivative. Information also has been discovered pertaining to the position of the amyl group in the resorcinol nucleus and to the chemical characteristics and the mode of attachment of the $C_{10}H_{15}$–grouping.

Earlier experiments on catalytic reduction of cannabidiol were variable and hence unsatisfactory for quantitative deductions. These results probably were due primarily to the fact that the cannabidiol used contained traces either of 3,5-dinitrobenzamide or ethyl 3,5-dinitrobenzoate. When pure, cannabidiol reduces rapidly in glacial acetic acid with platinum oxide catalyst and hydrogen at room temperature and 2–3 atm. pressure. Two moles of hydrogen are absorbed before the reduction stops. The product has all of the characteristic color reactions of the original molecule and contains two active hydrogens. It was concluded, therefore, that the amylresorcinol nucleus remained unaffected, and that the reduction had occurred in the $C_{10}H_{15}$–residue with the establishment of the presence therein of two double bonds. In view of the rapidity of hydrogenation under mild conditions, it appears unlikely that the unsaturation consists of one double bond and a three-, four- or five-membered ring such as was suggested as a possibility in the first paper in this series. With these facts in hand and keeping in mind the cannabinol formula, the $C_{10}H_{15}$–group may be postulated as a menthyl residue containing two double bonds (III) which have been assigned the positions indicated fortuitously.



III

The tetrahydrocannabidiol is an essentially colorless, viscous, optically active oil. No crystalline derivatives have as yet been isolated. The product probably is not a pure individual, for reduction of two double bonds in an optically active nucleus is likely to lead to diastereoisomeric tetrahydro derivatives.

Dehydrogenation of cannabidiol was also attempted. The product was optically inactive and analyzed satisfactorily for a biphenyl molecule. No solid derivatives, however, were obtained. In view of the possibility of disproportionation and the small amounts of material taken, these experiments may be used merely as a further indication of the presence of a menthyl group containing two double bonds, which may dehydrogenate, possibly with rearrangement, to a cymyl group. The description of these experiments will be postponed to a later paper.

A reaction of cannabidiol which proved to be very informative was its pyrolytic cleavage with pyridine hydrochloride. When heated to 210–230° for three hours, a mixture of cannabidiol and pyridine hydrochloride decomposes and cymene distils. Cymene was proven beyond a doubt by its analysis, physical and chemical properties. Isolation of cymene confirms the previous evidence that the $C_{10}H_{15}$–residue is a menthyl containing two double bonds. From the residual mixture after pyrolysis, was isolated olivetol, 1,3-dihydroxy-5-*n*-amylbenzene, proved by comparison of it and its *bis*-3,5-dinitrobenzoate with au-

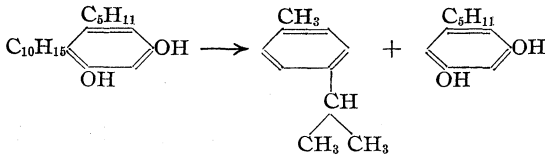
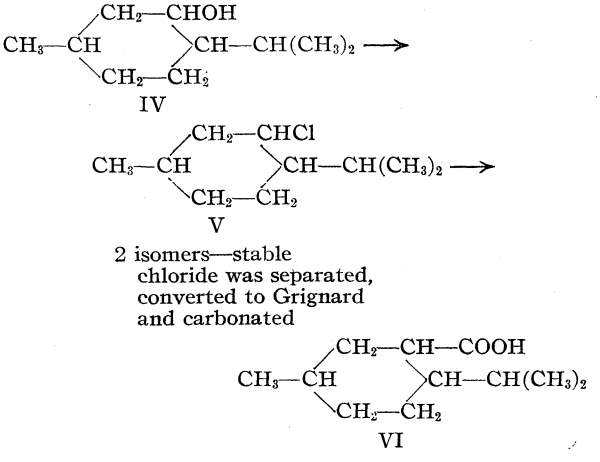
thentic samples of these products. The equation may be written as follows



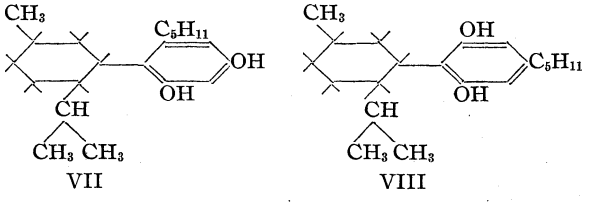
The isolation of olivetol establishes the orientation of the two hydroxyls and the *n*-amyl groups in cannabidiol. The mechanism of this cleavage is not clear and the limited quantity of cannabidiol available excluded further study. It may consist in the primary addition of hydrogen chloride, the hydrogen sufficing to complete the olivetol molecule and the chlorine forming $C_{10}H_{15}Cl$. This latter then is dehydrohalogenated to an olefin linkage which with the other two already present conjugate to a benzene system. On the other hand, the pyridine hydrochloride may function merely as a catalyst in the cleavage. The olivetol then would be formed by removal of a hydrogen from a carbon adjacent to that to which it is attached in the $C_{10}H_{15}$–residue. A new double bond simultaneously would be introduced in the $C_{10}H_{15}$–group thus leading to the completed molecule $C_{10}H_{14}$. Sulfamic acid in place of pyridine hydrochloride gave traces of cymene but the cleavage reaction did not appear to take place readily under these conditions.

Numerous experiments on the oxidation of cannabidiol to obtain one of the two possible olivetol carboxylic acids and thus to establish the position of the $C_{10}H_{15}$–group were unsuccessful. However, oxidation of the tetrahydrocannabidiol gave evidence as to the carbon of the dihydrocymyl residue (III) which was attached to the olivetol. Permanganate in acetone oxidation resulted in a mixture from which sodium bicarbonate solution extracted organic acids. It was obvious by the odor that caproic acid and possibly other low molecular weight aliphatic acids were present. This mixture was converted into the corresponding acid chlorides and then to the anilides. By crystallizing the anilides from benzene a single pure substance was isolated with a melting point of 152–152.5°. Analysis showed $C_{17}H_{25}ON$ and thus the molecule coincided with that of a menthanecarboxylic acid anilide $C_{10}H_{19}CONHC_6H_5$. Of the various theoretically-possible menthane carboxylic acids, one is described, the anilide of which melts at about the same point as that obtained in the above oxidation experiment.[4] This was synthesized by Kurssanow's method. It proved by mixed melting point to be identical with the cannabidiol product. Since the synthetic acid was prepared from *l*-menthol (IV–VI), the configuration of one or more of the asymmetric carbons in tetrahydrocannabidiol probably is similar to the corresponding asymmetric carbons in *l*-menthol



It would appear likely that this acid is the same as that obtained by Bergel[5] from oxidation of reduced red oil. He reported that the anilide of his acid melted at 148.5° (uncor.) but did not identify it. The analyses for this product averaged quite close to the calculated for menthane carboxylic acid anilide (Calcd.: C, 78.72; H, 9.72; N, 5.40. Found: C, 78.56; H, 9.68; N, 6.05).

Significant is the fact that isolation of menthane carboxylic acid anilide establishes the linkage of the $C_{10}H_{15}$–group to the olivetol residue as on the carbon adjacent to that holding the isopropyl group. Consequently, tetrahydrocannabidiol may be formulated as VII or VIII.



Cannabidiol then must be considered as one of these two molecules with two double bonds in the left-hand cycle, the positions of which are now being investigated.

Experimental

Cleavage of Cannabidiol to Cymene and Olivetol.—A mixture of 10 g. of cannabidiol and 12 g. of pyridine hydrochloride was heated for three hours at 210–230°. During the heating a liquid distilled. It was taken up in a little ether, extracted with dilute hydrochloric acid and then with water. After drying with anhydrous magnesium sulfate, the ether was removed by distillation and the product distilled. It boiled very sharply at 176° (cor.) (745 mm.); $n^{20}D$ 1.4900; d^{20}_4 0.8561; yield 2.6 g.

Anal. Calcd. for $C_{10}H_{14}$: C, 89.53; H, 10.51. Found: C, 89.55; H, 10.50.

The same constants were found for an authentic sample of *p*-cymene.

The residue in the reaction flask was treated with a little water and extracted several times with ether. The ether layer was separated, washed with dilute hydrochloric acid and then extracted twice with 10% aqueous sodium hydroxide. The aqueous extracts were acidified with hydrochloric acid and extracted several times with ether. After drying the ether layer with anhydrous magnesium sulfate, the ether was removed and the product distilled. It boiled at 170–175° (2 mm.); yield 3.2 g. The oil was warmed with water and on cooling a white crystalline material, m. p. 41°, was obtained. The crystalline product showed no melting point depression when mixed with an authentic sample of olivetol hydrate, 1,3-dihydroxy-5-*n*-amylbenzene hydrate. Upon drying the hydrate at 50° (2 mm.), anhydrous olivetol was obtained.

Anal. Calcd. for $C_{11}H_{16}O_2 \cdot H_2O$: C, 66.64; H, 9.15. Found: C, 66.69; H, 8.98.

For further identification of the olivetol from the cleavage reaction, it was converted to the *bis*-3,5-dinitrobenzoate by the use of 3,5-dinitrobenzoyl chloride and pyridine. The product was purified from ethanol or ether; white crystals, m. p. 127–128° (cor.).

Anal. Calcd. for $C_{25}H_{20}O_{12}N_4$: C, 52.90; H, 3.54; N, 9.84. Found: C, 52.87, 52.98; H, 3.59, 3.87; N, 10.08.

An identical product was obtained in a similar manner from synthetic olivetol.

Tetrahydrocannabidiol.—A solution of 4.86 g. of cannabidiol in 150 cc. of glacial acetic acid was reduced with hydrogen at 2–3 atm. pressure at room temperature using 0.1 g. of platinum oxide. Hydrogen corresponding to 2.06 moles per mole of cannabidiol was absorbed in fifteen minutes, after which no pressure change was noted in an additional thirty minutes.

The acetic acid was removed *in vacuo* and the tetrahydrocannabidiol, a pale yellowish highly viscous resin, was distilled, b. p. 188–190° (2.5 mm.) (bath temperature 200–215°, $n^{20}D$ 1.5298; yield 4.05 g.).

Rotation. 0.0582 g. made up to 5 cc. with 95% ethanol at 25° gave αD −0.33; *l*, 1; $[\alpha]^{25}D$ −28°.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.18; H, 10.76. Found: C, 78.97; H, 10.52.

Oxidation of Tetrahydrocannabidiol.—To a solution of 2.75 g. of tetrahydrocannabidiol in 100 cc. of acetone was added over a three-hour period a solution of 9.5 g. of potassium permanganate in 500 cc. of acetone at room temperature. During the first ninety minutes of addition, reaction was instantaneous. The flask became warm. The reaction was much slower during the latter part of the addition and unreacted permanganate remained an hour after addition was complete.

The mixture was made slightly acid and the manganese dioxide and excess permanganate were destroyed with sodium bisulfite. After dilution with 500 cc. of water, most of the acetone was removed by distillation. It was then extracted with ether and the ether in turn extracted with aqueous sodium bicarbonate. The bicarbonate layer was acidified and extracted with ether. After removal of the ether the crude bicarbonate-soluble portion amounted to 0.87 g. and the bicarbonate-insoluble, 1.52 g.

The bicarbonate-soluble material, which had an odor of lower fatty acids, was treated with 1.6 g. of thionyl chloride and refluxed overnight on a steam cone. The excess thionyl chloride was evaporated, the resulting mixture dissolved in 10 cc. of benzene, and 4 g. of aniline added. Solid material separated at once. The mixture was heated on the steam cone for two hours, poured into dilute hydrochloric acid solution and extracted with benzene. A product gradually crystallized and was purified by further crystallization from benzene; white crystals, m. p. 152–152.5° (cor.).

Anal. Calcd. for $C_{17}H_{25}ON$: C, 78.72; H, 9.72; N, 5.40. Found: C, 78.79; H, 9.81; N, 5.37.

A mixed melting point with the anilide of *p*-menthane carboxylic acid prepared by the method of Kurssanow[4] showed no depression.

Summary

Cleavage of cannabidiol with pyridine hydrochloride resulted in formation of *p*-cymene and olivetol, demonstrating that cannabidiol probably is a dihydrocymyl group attached to an olivetol residue.

Reduction of cannabidiol resulted in the rapid absorption of two moles of hydrogen with formation of a tetrahydro derivative which showed the same color reactions as cannabidiol. From this experiment it was deduced that the olivetol nucleus was unattacked and confirmed the fact that two double bonds were present in the $C_{10}H_{15}$– grouping.

Oxidation of tetrahydrocannabidiol led to the isolation of a menthane carboxylic acid identical with that which previously has been synthesized from *l*-menthol. The linkage of the $C_{10}H_{15}$–residue thus is established as on the carbon adjacent to that holding the isopropyl group.

Evidence is presented that cannabidiol is a dihydrocymyl olivetol.

Studies on the Chemistry of the Fatty Acids. V. The Preparation of Methyl Ricinoleate and Ricinoleic Acid by Fractional Crystallization Procedures

BY J. B. BROWN AND NAOMA D. GREEN

Ricinoleic acid, $C_{18}H_{34}O_3$, occurs in castor oil to the extent of 80–86% of the total fatty acids.[1,2] The valuable medicinal and commercial properties of this oil are due in large part to this unsaturated hydroxy acid which occurs in the oil as tri-ricinolein and as mixed triglycerides with oleic, linoleic and stearic acids. According to Goldsobel[3] and others[4,5,6,7] ricinoleic acid is 12-hydroxy-*cis*-9-10-octadecenoic acid. Although numerous attempts have been made in the past to prepare the pure acid for use in preparation of derivatives and to study its properties, few, if any, pure preparations, especially of the acid, are described; in most cases analytical criteria of purity are quite inadequate. Methods of preparation up until 1931 have been reviewed by Rider.[8] They have included cold-pressing of the acids of castor oil, and crystallization of the barium soaps of the resultant acids from alcohol; direct alcoholysis of castor oil with methyl alcohol and distillation of the methyl esters; removal of olein, linolein, dihydroxystearin and unsaponifiable from the original oil by repeated extraction with benzine, the final product being 98.5% ricinoleic acid and various combinations of procedures. Rider prepared the pure acid by chilling the fatty acids of castor oil, dissolved in an equal volume of 95% alcohol, to −15° when the solid acids precipitated. The liquid acids were then converted into methyl esters, acetylated with acetic anhydride and the acetylated esters fractionally distilled at 4 mm. The pure acetyl ester was thus isolated. It was converted into ricinoleic acid by saponification. The acid melted at 4–5°. The melting point was the only criterion of purity reported. A more recent preparation by Straus, Heinze and Salzmann[9] employs Rider's method of removing the saturated fatty acids and in addition crystallization of the lead soaps from ether and preparation of the benzoyl methyl ester.

The object of the present work was to apply low-temperature fractional crystallization methods, previously developed in this Laboratory for the purification of oleic, linoleic and linolenic acids,[10] to the preparation of ricinoleic acid and its methyl ester. Since it has long been known that the free acid cannot be distilled without decomposition even at very low pressures, the preparation of pure methyl ricinoleate was first attempted. A specimen of castor oil was converted into methyl esters by direct alcoholysis. The distilled esters were fractionally crystallized from acetone or from methyl alcohol. Fractions were isolated in good yield which analyzed as methyl ricinoleate of high purity. Four such preparations are described. Attempts to prepare pure ricinoleic acid from the pure ester were unsuccessful because the product could not be distilled and because during saponification, even in the cold, the acid was partly dehydrated with the formation of octadecadienoic acids. A specimen of ricinoleic acid of 95% purity was prepared by cold saponification of the crude methyl esters, followed by direct fractional crystallization of the acids from acetone.

Experimental Part

Equipment.—For low temperature work the special equipment described in our previous work was used, namely, a room in which a temperature of −20 to −25° was continuously maintained and a well insulated dry-ice–alcohol apparatus designed to accommodate a 2-liter Erlenmeyer flask. In the latter part of this work, a similarly constructed bath for a 4-liter Erlenmeyer flask was used. All filtrations were carried out by suction in the −20° room.

Procedures. A. Preparation of Pure Methyl Ricinoleate.—(1) One kilogram of castor oil (iodine number 87.9; saponification number 179.7) was esterified with 1500 cc. of methyl alcohol containing 2% dry hydrogen chloride by refluxing on a hot water-bath for twenty-four hours. The crude esters were then distilled at a pressure of 2–3 mm., the boiling point range being 185 to 212°; yield 810 g.

Eighty grams of the esters was dissolved in 4 liters of C. P. acetone in 2-liter Erlenmeyer flasks (more concen-

[a] Purity based on acetyl number. [b] Haller, *Compt. rend. acad. sci.*, **144**, 462 (1907). [c] Leathes, "The Fats," Longmans, Green and Co., New York, N. Y., 1925. [d] At 20°. [e] At 27°.

trated solutions, 4, 8 and 10% were tried and found to give too bulky precipitates for efficient fractionation). No precipitate formed at −20° after standing seventy-two hours. The solution was therefore cooled with constant stirring to −50° at which point a small precipitate (approx. 1%) was removed by suction on a large Buchner funnel (−20°). This fraction was solid at room temperature and probably contained most of the saturated esters. The filtrate was further cooled with vigorous stirring to −60 to −62° and the precipitate at this temperature separated by filtration as above. Solvent was then removed from the precipitate by warming under reduced pressure. The residual product was distilled at 3.6 to 4 mm. pressure in an all-glass apparatus. It was water-white; yield 62 g. Constants on this sample, no. 1, together with those of other specimens of methyl ricinoleate prepared are given in Table I.

(2) In an attempt to find a solvent in which more concentrated solutions could be handled, 400 g. of the original methyl esters was dissolved in 4000 cc. C. P. methyl alcohol and allowed to stand overnight at −20°. The precipitate was filtered off and the filtrate was further cooled with continuous stirring to −40° and a second small precipitate removed. Upon cooling to lower temperatures, it was found that this solution was too concentrated for further fractionation; so it was diluted with an equal volume of methyl alcohol making the solution approximately 5%. A large precipitate came down at −65° and was filtered off. This specimen was treated in a manner similar to the first. The yield of the distilled ester, specimen 2, was 328 g.

(3) Six hundred and forty grams of original esters was dissolved in 32 liters of C. P. acetone in eight 4-liter flasks and treated as sample (1) with the following differences.

The precipitation was carried out in 4-liter flasks in the dry ice–alcohol bath and it was found (perhaps due to slight supercooling with somewhat less efficient stirring in the larger volume of solution) that precipitation corresponding to that in (1) occurred at −55 and −65° instead of −50 and −60° as before. After filtering at −65°, the precipitate was allowed to melt, made up to approximately 2% solution and recrystallized at −65°.

The yield of distilled specimen (3) was 283 g.

(4) An additional sample of methyl ricinoleate was prepared in the same manner as sample (3) except that the recrystallization at −65° was from a 4% solution in acetone instead of 2%.

Analytical data on the four specimens are given in Table I. Molecular weights were determined by saponification; iodine numbers by the Wijs method with one hour reaction time. Acetyl numbers were determined essentially by the method of West and co-workers.[11] The acetyl value was defined as the number of mg. of acetyl radical taken up by 1 g. of sample. In our work we have allowed one and a half hours reaction time and one-half hour decomposition time.

The analytical data in Table I, especially the iodine and acetyl numbers, show the four specimens to be methyl ricinoleate of high purity. The molecular weights by saponification are also in excellent agreement with the theory in specimens (1) and (4). They are not so satisfactory in (2) and (3), which may be due to side reactions with alkali. We have repeatedly obtained low results for molecular weight by the saponification method. In fact it has been difficult with some specimens to obtain checks on this account. From these experiments it may be concluded that it is possible to prepare methyl ricinoleate of high purity by the low temperature crystallization methods described above, either methyl alcohol or acetone being satisfactory solvents.

B. Preparation of Ricinoleic Acid.—It would seem that the preparation of pure ricinoleic acid from the pure ester would be a comparatively simple procedure, but in actual attempts to saponify the ester the resultant acids gave constants which were far from satisfactory. In three such experiments the pure ester was saponified with boiling alcoholic potash, most of the alcohol distilled off, and the soaps decomposed with hot hydrochloric acid. The temperatures of most of these operations were kept below 60°. The resultant acids were analyzed directly or crystallized from ether or acetone at very low temperature. Attempts to distil the acid even at 0.5–1.5 mm. pressure gave products with iodine numbers of 92–113. The undistilled product invariably gave molecular weights by titration 20 to 30 units high, up to 330 (theory 298). Also high iodine

(11) West, Hoagland and Curtis, *J. Biol. Chem.*, **104**, 627 (1934); Hafner, Swinney and West, *ibid.*, **116**, 691 (1936).

numbers were obtained.[12] These high values, however, are not due to abnormal reaction with the Wijs reagent used but to the formation of octadecadienoic acids by the dehydration of methyl ricinoleate or soap during the saponification and subsequent treatment. High molecular weights on the other hand are caused by formation of polyricinoleic acids, to incomplete saponification, or to the presence of residual solvent which is difficult to remove without distillation. Since hot saponification caused definite alteration in the product, two attempts at cold saponification were tried in which the ester was treated with a large excess of alcoholic potash at 0–4° for 101 and 285 hours, respectively. The products again had iodine numbers and mean molecular weights which were indicative of incomplete saponification.

These experiments made it obvious that cold saponification of the pure ester was not complete and hot saponification did not give a pure acid and that the product would have to be fractionally crystallized to remove poly acids and dienoic acids formed in the process. Since fractional crystallization was necessary, obviously it was practical to start with more crude ester which had not been so highly purified. Accordingly a number of samples of less pure methyl ricinoleate were mixed and saponified with hot alcoholic potash. The resultant acids, 359 g., were then dissolved in 7180 cc. of C. P. acetone. No precipitation occurred at −20° and the solution was cooled to −70°. A copious precipitate was removed by filtration and an acid recovered by warming under reduced pressure, taking care to keep the temperature below 60°. Apparently this procedure was successful in removing the last traces of solvent, because the product gave a molecular weight by titration in neutral alcohol of 298 (theory 298.3). The other constants were iodine number (Wijs) 88.52 (theory 85.1), acetyl number 137.9 (theory 144.2), m. p. 5.5°. (The literature reports various melting points from 4–5° (Leathes) to 17°); n^{20} 1.4697 (Straus, Heinze and Salzmann, report 1.4716); $\alpha^{26}D$ (acetone) +7.15°; sp. gr. 27.4°, 0.940. The thiocyanogen number of this specimen of acid was 85.34 (theory 85.09). On the basis of acetyl number, the product was 95.6% ricinoleic acid. On the basis of iodine number and assuming the mixture to consist of ricinoleic and octadecadienoic acids, the purity was 97%.

In the above experiments we have given only a résumé of many of our attempts to prepare ricinoleic acid from its methyl ester and details only in our most successful preparation. We conclude that it is a comparatively simple procedure to prepare the ester in high purity and in very good yield, but, even with pure ester available, it is quite difficult to prepare an acid of satisfactory purity. Ricinoleic acid, itself, appears to be even more difficult to prepare than oleic acid, not because of difficulty of separation from other acids but because of its own reactivity.

(12) *Cf.* Caldwell and Piontkowski, THIS JOURNAL, **56**, 2086 (1934).

Summary

1. Low temperature fractional crystallization procedures have been applied successfully to the preparation of methyl ricinoleate from castor oil.

2. Saponification of methyl ricinoleate and isolation of the resultant acid does not yield a pure ricinoleic acid.

3. Analytical constants of pure methyl ricinoleate and of 95.6% ricinoleic acid are given.

N^1,N^4-Nicotinyl Derivatives of Sulfanilamide

BY T. C. DANIELS AND HARRY IWAMOTO

A comparatively large number of N^1 and N^4 acyl derivatives[1] of sulfanilamide have been described and several have been reported to be of pharmacologic interest in the treatment of bacterial infections.[2,3,4] The pharmacologic properties of nicotinic acid and of sulfanilamide suggested the desirability of preparing the nicotinyl derivatives. One of us in 1937 prepared the N^4-nicotinylsulfanilamide. Crossley, Northey and Hultquist[3] have described the N^1-nicotinylsulfanilamide and reported a melting point of 256–257.5°. Our N^4 product had the same melting point and we therefore became interested in ascertaining whether rearrangement had occurred or the melting point of the two derivatives was a coincidence. Partial rearrangement of certain of the N^1-acylsulfanilamides had been observed by Crossley, Northey and Hultquist.[3]

We have prepared the N^4-nicotinyl derivative by two general methods: (1) by the action of nicotinyl chloride[5] on sulfanilamide in anhydrous pyridine, and (2) by treating the anilide of nicotinic acid with chlorosulfonic acid followed by ammonia. The products obtained by the above methods give the same melting point and mixed melting point (257–258°). They do not titrate to a phenolphthalein end-point.

We prepared the N^1-nicotinylsulfanilamide from N^4-acetylsulfanilamide by the method of Crossley, Northey and Hultquist.[3] This product melts at the same temperature as the N^4-nicotinyl derivative (257–258°) but because of its greater acidity titrates quantitatively to a phenolphthalein end-point. A 50% mixture with the N^4-nicotinyl derivative melts at 233–235°. The N^1-derivative after melting can still be titrated quantitatively with sodium hydroxide to a phenolphthalein end-point, which shows that rearrangement does not occur during the melting.

All of the N^4-acyl derivatives of sulfanilamide thus far described, with the exception of the nicotinyl, have a considerably higher melting point than the corresponding N^1 compounds.[2,3]

.....	Nicotinyl	277.3	...	99.9	257–258

[a] Prepared by the method of Crossley, Northey and Hultquist.[3] [b] Product exists in two forms, one of which melts sharply at 222, the other at 248°.

Pharmacology.—Although the work of Fourneau, *et al.*,[6] indicated that the introduction of acyl groups on the N^4 nitrogen of sulfanilamide greatly reduces the antistreptoccic activity, compounds of this class have since been described which have equal or greater effectiveness.[2,4] The N^4-nicotinylsulfanilamide has been studied by Leake, Karr, Finnegan and Murayama.[7] The preliminary work has indicated an effectiveness greater than that of sulfanilamide in the treatment of experimental hemolytic streptococcal infections and equal to sulfapyridine in experimental pneumococcal infections. The toxicity is much less than that of sulfanilamide or of sulfapyridine. Studies are now in progress on the N^1,N^4-dinicotinylsulfanilamide and on the N^1-acetyl-N^4-nicotinylsulfanilamide. The details of the pharmacologic investigation will be published elsewhere.

Experimental Part

N^4-Nicotinylsulfanilamide.—(1) To 14.2 g. (0.1 mole) of nicotinyl chloride and 17.2 g. (0.1 mole) of sulfanilamide was added 18.0 g. of anhydrous pyridine. The mixture was refluxed on a water-bath for one hour, cooled and several volumes of cold water added. The precipitate was collected on a filter and washed thoroughly with water followed by recrystallization from 50% alcohol; yield 50 to 75%.

(2) To 58.3 g. (0.5 mole) of chlorosulfonic acid in a three-necked flask, equipped with a mechanical stirrer and reflux condenser cooled to 0°, was added 9.9 g. (0.05 mole) of nicotinylanilide in divided portions with continuous agitation. The temperature during the addition was kept below 15°, then gradually raised to 60° on a water-bath

(6) Fourneau, *et al.*, *Compt. rend. soc. biol.*, **122**, 258 (1936).

(7) Leake, Karr and Murayama, unpublished report.

and maintained at this temperature for two hours. The reaction mixture was cooled and treated directly with an excess of cold 28% ammonia solution, adding the ammonia in divided portions with continuous stirring. The stirring was continued for approximately one hour and the precipitate collected and washed several times with water followed by recrystallization from 50% alcohol; yield 40 to 50%. The melting point was identical with that of the product from (1) and gave the same mixed melting point.

N^1-Acetyl-N^4-nicotinylsulfanilamide.—To 25 cc. of acetic anhydride was added gradually 2.8 g. (0.01 mole) of N^4-nicotinylsulfanilamide. The mixture was refluxed for one hour and cooled in an ice-bath. The precipitate was collected and washed with water, then dissolved in sodium hydroxide (*p*H 8), decolorized with activated charcoal and precipitated by the addition of dilute hydrochloric acid to *p*H of 5. The precipitate was filtered, washed and dried; yield approximately 50%.

N^1,N^4-Dinicotinylsulfanilamide.—To 5.5 g. (0.02 mole) of N^4-nicotinylsulfanilamide and 5.7 g. (0.04 mole) of nicotinyl chloride was added 20 cc. of anhydrous pyridine and the product refluxed for one hour. Several volumes of water were added to the cooled reaction product and the solution acidified with dilute hydrochloric acid to a *p*H of 5. The precipitate was collected and washed with several portions of water, redissolved with sodium hydroxide to a *p*H of 8, filtered and reprecipitated by the addition of dilute hydrochloric acid to a *p*H of 5. The product was again washed and dried; yield approximately 40%. The product melts sharply at 222°, resolidifies on heating and melts again at 248°. Titration with sodium hydroxide of the form melting at 248° gives the same equivalent weight as before melting.

Summary

1. The N^4-nicotinylsulfanilamide and N^1,N^4-dinicotinylsulfanilamide are described.

2. The melting points of N^1 and N^4-nicotinylsulfanilamide are the same.

3. The preliminary pharmacologic investigation indicates that the N^4-nicotinylsulfanilamide is effective in the treatment of experimental hemolytic streptococcus infections and also certain types of pneumococcus infections. The toxicity of the N^4-nicotinylsulfanilamide is lower than either sulfanilamide or sulfapyridine.

α-Furfurylpropylamine and Di-α-furfuryl Tertiary Amines

BY J. E. ZANETTI AND J. T. BASHOUR

α-Furfurylpropylamine has now been synthesized by the same general method as previously used with other secondary α-furfuryl amines.[1] It is a colorless oil with a faint fishy odor boiling at 80–81° under 20 mm. pressure, d^{25}_{25} 0.947, $n^{20}D$ 1.4679. Its hydrochloride melts at 138–140°.

Anal. Calcd. for $C_8H_{13}ON$: N, 10.1. Found: N, 10.2.

Very little has been done in the field of tertiary α-furfuryl amines and only one tertiary amine containing two furfuryl groups has been reported, namely, the tri-α-furfurylamine synthesized by Zanetti and Beckmann.[2] Von Braun and Kohler[3] synthesized several tertiary furfurylamines which, however, contained only one α-furfuryl group and Von Braun and Braunsdorf[4] made an analog of novocaine containing one α-furfuryl group on the tertiary nitrogen.

In our synthesis of secondary α-furfurylamines,[5] tertiary amines were suspected in the small amount of high boiling residue accompanying each preparation. However, in the synthesis of these amines, unfavorable yields are obtained unless the purified secondary amines be made to react with furfuryl bromide.

These tertiary amines are either high boiling liquids or solids and are miscible with most organic solvents. Their properties and the analyses are given in Table I. They are colorless when pure but turn yellow on standing. They have only faint ammoniacal odors. With hydrochloric acid in ether solution they form stable hydrochlorides. As in the case of the secondary furfurylamines, excess of hydrochloric acid must not be used as dark decomposition products will readily form.

Experimental Part

In a flask provided with an air condenser the furfuryl bromide in ether solution is allowed to stand for one to three hours over crushed potassium hydroxide and then the secondary amine is added with agitation. With intermittent shak-

[b] By immersion in preheated baths.

ing the solution rapidly clouds and reaches the boiling point within several minutes to an hour (difurfurylphenylamine developed a dark red color but did not boil). At times excessive heat evolution must be reduced by use of an ice-bath. After twelve hours, the ether is removed and the mixture carried through fractional distillation at reduced pressure in an atmosphere of nitrogen, until successive fractions showed no difference in refractive index. Yields were uniformly about 80% of the theoretical.

The authors are indebted to Mr. Saul Gottlieb for the microanalysis of these compounds.

Summary

1. Six tertiary di-α-furfurylamines were synthesized by the action of furfuryl bromide on secondary α-furfurylamines and their properties reported.

Further work on these amines is being continued in these Laboratories.

Sulfonamide Derivatives of Arylureas

BY EDWARD H. COX

The para sulfonamide derivative of phenylurea is in reality a derivative of sulfanilamide. This relationship has prompted the work of preparing some of the arylureasulfonamides with the anticipation that they might possess therapeutic activity comparable to that of sulfanilamide.

The parent substance in the series, *p*-phenylureasulfonamide is then N^4-carbamylsulfanilamide. This compound has been prepared recently by Kolloff[1] and given the name *p*-uraminobenzenesulfonamide. The reaction for its preparation is an application of that reported by Buck and Ferry[2] and involves the action of nitrourea on sulfanilamide in alcohol. The therapeutic activity of the compound was not reported.

In the present work it has been found that the arylureas or their acetyl derivatives can be sulfonated by means of chlorosulfonic acid. The resulting sulfonyl chlorides can then be transformed into the amides or substituted amides. The yields are consistently high throughout the series of reactions.

Some of the N^4-acyl derivatives of sulfanilamide show as high a therapeutic activity[3] as sulfanilamide itself and this is believed to be due to deacylation in the organism with the resultant freeing of the sulfanilamide. In the present case the carbamyl group apparently is not removed *in vivo* and therefore the arylureasulfonamides show no activity in experimental streptococcal infection in mice.[4]

Since it is proposed to continue the work on this series with certain modifications, the author considered it of interest to record the preparation and properties of these arylurea derivatives.

(4) The author wishes to thank Dr. Perrin H. Long of The Johns Hopkins Medical School for carrying out the biological tests.

Experimental

The sulfonation of the arylureas and the acetylarylureas presents no difficulties. The resulting sulfonyl chloride derivatives of the arylureas are, however, difficult to purify and no analytical data are listed for them. On the other hand, the acetylarylureasulfonyl chlorides are not difficult to purify and are produced in good yields. The chlorides are converted into the amides by treatment with ammonia or diethylamine. The removal of the acetyl group from the acetylarylureasulfonamides is effected by treating them with boiling hydrochloric acid solution. Mechanical stirring is used in all the reactions carried out, and the temperatures recorded are those for the reaction mixtures.

Acetylation of the Arylureas.—The arylureas are acetylated according to the method of Walther and Wolodowski.[5] To 70 g. of the urea, dissolved or suspended in 200 cc. of pyridine, is added slowly 60 g. of acetyl chloride. During the addition, the reaction mixture is stirred and cooled to 10° below zero. The reaction mixture is then warmed to 30° for one-half hour, poured into cold dilute hydrochloric acid solution, filtered, and washed. Without further purification, the acetylated product is dried and sulfonated. The yields are from 80–90%.[6]

Sulfonation of the Arylureas and the Acetylarylureas.—The procedure is that given in "Organic Syntheses,"[7] except that the temperature during sulfonation of the arylurea is maintained between 0–10°. Higher temperatures tend to darken the reaction product and lower the yields. To 170 cc. of chlorosulfonic acid is added with stirring 70 g. of the arylurea and after the addition the reaction mixture is heated to 50° for one to two hours. The sulfonyl chlorides are filtered, washed and dried before conversion into the amides. Calculated upon air dried aliquots, the yields are 60–70%.

The procedure for the sulfonation of the acetylarylureas is the same as indicated above for the arylureas. The temperature at which the sulfonation is carried out is 10–15° and the amount of the acetylarylureas employed is 90 g. The yields of the crude acetylarylureasulfonyl chlorides are 75–85%. They are crystallized from hot benzene or toluene.

Amide Derivatives.—Fifty grams of the sulfonyl chloride derivatives of the arylureas or the acetylarylureas is treated with 150 cc. of 28% ammonia or 150 cc. of 30% diethylamine. The mixtures are stirred and warmed on a water-bath for one-half hour and then set aside to cool. In some cases the diethylamides remain as oils which are made to solidify by trituration with alcohol. The unsubstituted amides crystallize from hot water or diluted alcohol, while the diethylamides crystallize from a mixture of ethyl acetate and benzene.

Removal of the acetyl group from the acetylarylureasulfonamides is accomplished by treatment with boiling 5 *N* hydrochloric acid solution. The time of hydrolysis, for 40 g. of the various acetyl compounds, using twice the calculated amount of acid and stirring, varies from one-half to two hours. When pure samples of these resulting amides are mixed with the corresponding ones prepared by direct sulfonation and subsequent amidation of the arylureas, no depression in melting points is observed.

The melting points and analytical data are given in tabular review.

Summary

The preparation and properties of a series of sulfonamide derivatives of some of the arylureas, as well as the intermediate derivatives, are described.

The parent substance, *p*-acetylphenylureasulfonamide (N^4-carbamylsulfanilamide), shows no activity in experimental streptococcal infection in mice.

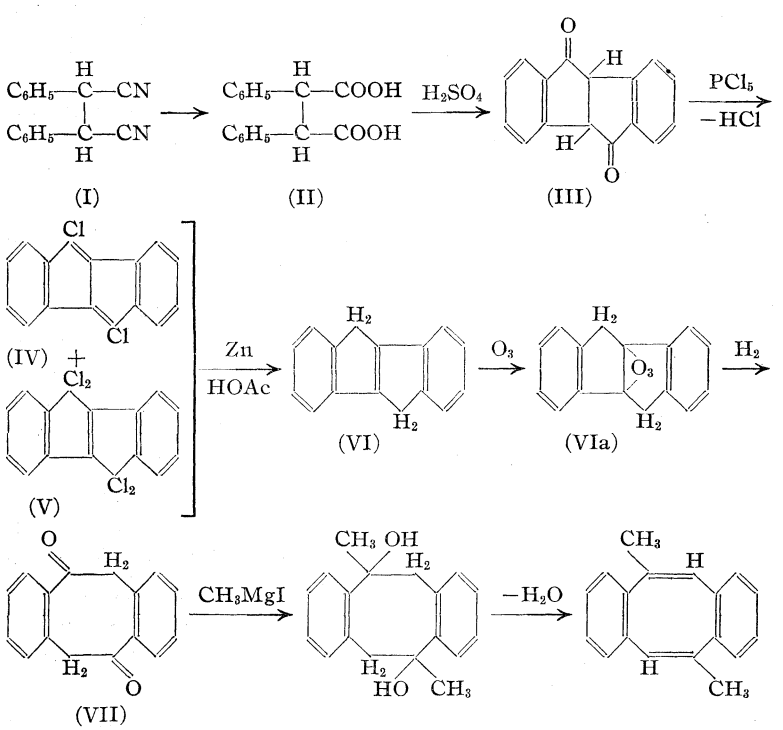
An Attempt to Synthesize a Substituted Cycloöctatetraene[1]

BY STANLEY WAWZONEK

Willstätter[2] has reported the synthesis of cyclooctatetraene. In view of the results obtained by Hurd and Drake[3] in their study of the pyrolysis of bis-quaternary ammonium hydroxides related to 1,2- and 1,3-butenes, and the striking similarity[4] in chemical and physical properties between styrene and its derivatives and the supposed cycloöctatetraene and its derivatives, the structure of the latter compound is questionable.

In the hope that a substituted cycloöctatetraene might be synthesized in an easier manner than cycloöctatetraene itself,[4] the following synthesis[5] of *sym*-dibenzocycloöctatetraene was attempted, and carried out successfully through the formation of the *sym*-dibenzocycloöctanedione-5,11 (VII).



In spite of the failure to complete the synthesis, it was thought that the properties and reactions of the cyclic diketone (VII) were of sufficient interest to be reported.

sym-Dibenzocycloöctanedione-5,11 (VII) is a white solid, difficultly soluble in aqueous alkali and easily soluble in alcoholic alkali to give a yellow solution. To determine the nature of this salt, an alkaline solution was treated with dimethyl sulfate and found to give a product that analyzed for a hydrated dimethyl ether. Since the ether would not brominate and could be cleaved by hydrobromic acid to the diketone (VII), its structure is that given by formula (VIII). The sodium salt is therefore a derivative of the hydrated form of the diketone (IX), a structure which is supported in part by the failure of the salt to react with benzenediazonium sulfate in alkaline solution.

All attempts to cause the diketone (VII) to react with butyl nitrite, *p*-nitrosodimethylaniline, bromine or selenium dioxide were either unsuccessful or gave oily products. That active methylene groups were present in the compound was shown by the formation of a dibenzal compound (X) from benzaldehyde in alcoholic alkali, and by the formation of a substituted quinoline (XI) from isatin in alkali.

The presence of two carbonyl groups was shown by the formation of a dioxime (XII) and a dichlorodiphosphinic acid (XIII) from phosphorus pentachloride. In the Grignard machine the cyclic diketone (VII) showed only one carbonyl group. The Grignard product in turn showed only one active hydrogen. Difficulty in dehydration of the Grignard product indicated that the compound was a dihydropyran (XIV). The formation of such a compound is analogous to the previously reported[6] formation of 2,4,4,6-tetraphenyl-

2-ethyl-dihydropyran in the reaction between 1,3-dibenzoyl-2,2-diphenylpropane and ethylmagnesium bromide.

With ammonia, ammonia derivatives and reducing agents, the behavior of the diketone (VII) was similar to that of open chained 1,5-diketones in that substituted tetrahydropyridines and glycols, respectively, were formed. The product, (XV) obtained from ammonia, was soluble in dilute hydrochloric acid, and could be converted either by nitrous acid or by melting into the diketone (VII). The compound (XVI) obtained from semicarbazide, upon heating alone or in the presence of powdered potassium hydroxide, gave a mixture of diphensuccindene-10 (VI) and diphensuccindane (XVII). Because of stereochemical reasons, the characteristic loss of water to form pyridines observed with ammonia addition products of open chained 1,5-diketones is impossible with ammonia derivatives of *sym*-dibenzocycloöctanedione-5,11. The glycol (XVIII), formed by the reduction of the diketone (VII) with either amalgamated zinc and hydrochloric acid or zinc and alkali, could be cleaved with lead tetraacetate to the diketone (VII). Treatment of the glycol (XVIII) with either sulfuric or hydriodic acid in acetic acid solution gave a highly insoluble polymer melting above 350°.

That enolic forms were possible was shown in the formation of a mono- and a diacetate by refluxing the diketone (VII) with acetic anhydride in the presence of anhydrous potassium acetate and sulfuric acid, respectively.

The structure of the monoacetate (XIX) was demonstrated by hydrolysis with alkali to the diketone (VII), and oxidation with chromic anhydride to *o,o'*-desoxybenzoindicarboxylic acid (XX). Treatment with bromine in acetic acid caused substitution and the formation of a monobromomonoacetate of structure (XXI), since the product failed to react on refluxing with anhydrous potassium acetate in acetic acid. Further treatment of the monobromomonoacetate (XXI) with bromine in chloroform gave a compound which was not obtained in a pure state, but which contained a smaller percentage of carbon than the starting material. Hydrolysis of the impure product with aqueous alcoholic ammonia gave an orange colored compound which was probably the *sym*-dibenzo-cycloöctanetrione-5,6,11 (XXII), since it formed a bright red hydrated phenazine (XXIII). No reaction could be brought about between the triketone (XXII) and either hydrogen peroxide in alkaline solution, or acetic anhydride in the presence of sulfuric acid or potassium acetate.

The diacetate (XXIV) could be obtained from the monoacetate (XIX) and was hydrolyzed to the cyclic diketone (VII) by alkali. Treatment with bromine in acetic acid gave a monobromodiacetate (XXV), which likewise could be obtained by acetylating the monobromomonoacetate (XXI). No reaction took place between the monobromodiacetate (XXV) and bromine or potassium acetate in acetic acid.

Experimental[7]

α,β-Diphenylsuccinic Acid (II).—The following procedure is a modification of Lapworth and McRae's[8] original directions. A suspension of α,β-diphenylsuccinonitrile (I) (117 g.) in a mixture of concentrated sulfuric acid (333 ml.), water (333 ml.) and glacial acetic acid (166 ml.) was refluxed for eleven hours. The resulting gray suspension was diluted with water, filtered and the acid thus obtained was purified through its potassium salt; yield, 116 g. The product, which was used as such in the next step, melted at 220° when crystallized from acetic acid.

9,12-Dichlorodiphensuccindadiene-9,11 (IV) and 9,9,-12,12-Tetrachlorodiphensuccindene-10 (V).—Brand's original directions[5] were changed in the following manner. Diphensuccindanedione-9,12[9] (III) (24 g.) was heated slowly with phosphorus pentachloride (48 g.) until a clear solution was obtained. The resulting red liquid after cooling was treated with glacial acetic acid (400 ml.) and allowed to stand for twenty-six days. Attempts to accelerate the loss of hydrogen chloride by heating or other means gave less clean-cut reactions. The 9,12-dichlorodiphensuccindadiene-9,11 (IV) that separated out during this time was filtered; yield, 19 g. The filtrate, on pouring into water and extracting with ether, gave a mixture of the red dichlorodiene (IV) and a yellow compound, which, from its analysis and reaction, was 9,9,12,12-tetrachlorodiphensuccindene-10 (V). The red dichlorodiene (IV) obtained in the first step was contaminated by this yellow compound. One gram of starting material (III) was also recovered. 9,9,12,12-Tetrachlorodiphensuccindene-10 (V) crystallized once from a (60–68°) petroleum ether–benzene mixture and once from acetic acid formed yellow prisms melting at 178–179°.

Anal. Calcd. for $C_{16}H_8Cl_4$: C, 56.14; H, 2.34. Found: C, 55.79; H, 2.40.

Diphensuccindene-10 (VI).—9,9,12,12-Tetrachlorodiphensuccindene-10 (V) (0.2 g.) in boiling acetic acid (10 ml.) was treated with zinc dust until the solution became colorless. Upon pouring into water and extracting with ether a white solid (0.08 g.) was obtained melting at 197–204°. When crystallized from ethyl acetate, the solid melted at 204–208° and gave no depression when mixed with diphensuccindene-10 (VI) obtained from 9,12-dichlorodiphensuccindadiene-9,11 (IV).[4]

***sym*-Dibenzocycloöctanedione-5,11 (VII).**—Crude diphensuccindene-10 (VI) (6.06 g.) suspended in pure ethyl acetate (210 ml.) was treated with 12% ozone at −40° until all the diphensuccindene-10 (VI) had gone into solution. Warming to room temperature precipitated the white ozonide (VIa) melting at 191–193° with decomposition but exploding when heated rapidly. The suspension of the ozonide was mixed with 5% Pd·$BaSO_4$ catalyst (0.3 g.) and ethyl acetate (50 ml.) and reduced at room temperature with hydrogen at thirty-five pounds (2.3 atm.) pressure for twenty-four hours. From the resulting solution, after removing the catalyst and unreacted ozonide by centrifuging, and then removing the solvent, there was obtained the white crystalline *sym*-dibenzocycloöctanedione-5,11 (VII) (1.95 g.) melting at 202–204°. The unreacted ozonide and catalyst obtained by centrifuging gave upon further treatment in ethyl acetate (100 ml.) with hydrogen at 1000 pounds pressure and 120° for three hours, an oil from which more of the diketone (VII) (0.29 g.) was isolated. The residual oil, taken up in ether and washed with sodium carbonate, gave upon vacuum distillation an additional 0.35 g. of the diketone (VII); total yield, 2.5 g. The acidic by-products were not investigated further. *sym*-Dibenzocycloöctanedione-5,11 (VII), after four crystallizations from benzene, gave white needles melting at 203.5–204.5°.

Anal. Calcd. for $C_{16}H_{12}O_2$: C, 81.36; H, 5.08. Found: C, 81.30; H, 5.02.

The cyclic diketone (VII) is difficultly soluble in aqueous alkali but easily in alcoholic aqueous alkali to give a pale yellow solution. The yellow solution upon heating turns orange. Upon cooling the original hue returns. Acidification of the solution gives the diketone (VII) back unchanged.

No color change was observed when the diketone (VII) was treated in alcoholic alkali with benzenediazonium sulfate.

The dioxime (XII), obtained by refluxing the diketone (VII) in alcohol for four hours with an excess of hydroxylamine hydrochloride neutralized by sodium carbonate, was crystallized twice from ethanol. It formed white needles melting at 240–243° with decomposition.

Anal. Calcd. for $C_{16}H_{14}O_2N_2$: C, 72.18; H, 5.26; N, 10.53. Found: C, 71.96; H, 5.43; N, 10.50.

Methylation of the Diketone.—The diketone (VII) (0.25 g.) in methanol (4 ml.) was treated alternately with 20% potassium hydroxide and dimethyl sulfate until the solution when basic showed no yellow color. Ether extraction gave a white solid (VIII) (0.25 g.) which, after two crystallizations from ethanol, formed prisms, m. p. 143–144°.

Anal. Calcd. for $C_{16}H_{12}O(OCH_3)_2$: C, 76.60; H, 6.38; OCH_3, 21.67. Found: C, 76.16; H, 6.32; OCH_3, 21.32, 21.29.

The dimethyl ether (VIII) would not brominate but could be cleaved by hydrobromic acid in acetic acid to the diketone (VII).

Dibenzal Derivative of the Diketone (X).—A solution of the diketone (VII) (0.1 g.) in a mixture of ethanol (5 ml.), benzaldehyde (0.5 ml.) and saturated alcoholic potassium hydroxide solution (0.5 ml.) was allowed to stand at room temperature for eight days and then poured into water. Acidification followed by extraction with

(9) Roser, *Ann.*, **247**, 153 (1888).

ether gave a white solid (X) (0.035 g.) which melted at 244–246° after two crystallizations from toluene.

Anal. Calcd. for $C_{30}H_{20}O_2$: C, 87.37; H, 4.85. Found: C, 86.86; H, 4.23.

Reaction of the Diketone with Isatin.—A mixture of the cyclic diketone (VII) (0.24 g.) and isatin (0.29 g.) in 20% potassium hydroxide solution (5 ml.) was heated for forty-eight hours and the resulting solution then cooled to 0°. Acidification with acetic acid of the insoluble potassium salt formed followed by extraction with ether gave a white solid (XI) (0.115 g.) soluble in both acids and bases. Crystallization twice from ethanol and once from ethyl acetate gave very fine, white crystals which melted at 297° with gas evolution.

Anal. Calcd. for $C_{24}H_{15}O_3N$: C, 78.90; H, 4.10; neut. eq., 365. Found: C, 78.29; H, 4.69; neut. eq., 351, 349.

Reaction of the Diketone with Phosphorus Pentachloride.—A mixture of the diketone (VII) (0.24 g.) and phosphorus pentachloride (1 g.) was heated until completely liquid, cooled and then poured into water. Extraction with ether gave a white solid (XIII) (0.277 g.) which contained both phosphorus and chlorine and melted at 123–126° with gas evolution. Three crystallizations from (60–68°) petroleum ether gave white needles which melted at 123–126° with gas evolution. The residue from melting no longer contained chlorine.

Anal. Calcd. for $C_{16}H_{16}Cl_2P_2O_6$: C, 43.93; H, 3.66. Found: C, 44.14; H, 3.23.

Reaction of the Diketone with Methylmagnesium Iodide.—A solution of the diketone (VII) (0.47 g.) and excess methylmagnesium iodide in ether (10 ml.) and benzene (10 ml.) was refluxed for two hours. Decomposition with ammonium chloride followed by extraction with ether gave the tetrahydropyran (XIV) (0.35 g.) which formed white cubes after two crystallizations from benzene. It melted at 213–215°.

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 80.95; H, 6.35. Found: C, 81.24; H, 6.06.

In the Grignard machine the diketone (VII) showed only one carbonyl group.

The Grignard product (XIV) in the Grignard machine liberated only one mole of gas. No dehydration of the Grignard product was observed after six hours of refluxing with a few drops of concentrated sulfuric acid in acetic acid.

Reaction of the Diketone with Ammonia.—A solution of the diketone (VII) (0.12 g.) in concentrated ammonium hydroxide (5 ml.) and ethanol (5 ml.) was refluxed for thirty minutes and poured into water. Extraction with ether gave a white solid (XV) (0.06 g.) soluble in dilute hydrochloric acid. After two crystallizations from benzene and one from a (60–68°) petroleum ether–ether mixture the substituted tetrahydropyridine (XV) melted, if heated rapidly, at 167° with gas evolution, then solidified and melted again at 202–203.5°.

Anal. Calcd. for $C_{16}H_{15}O_2N$: C, 75.88; H, 5.93. Found: C, 75.39; H, 5.55.

The ammonia addition product (XV) when treated with nitrous acid or when heated above its melting point, gave the diketone (VII).

Reaction of the Diketone with Semicarbazide.—A solution of the diketone (VII) (0.12 g.), semicarbazide hydrochloride (0.25 g.) and sodium carbonate (0.06 g.) in ethanol (5 ml.) and water (1 ml.) was refluxed for two hours and the crystalline precipitate (XVI) formed, filtered; yield, 0.105 g., m. p. 207–208° with decomposition. A sample recrystallized twice from methyl cellosolve melted at 210° with decomposition.

Anal. Calcd. for $C_{17}H_{17}O_3N_3$: C, 65.60; H, 5.47. Found: C, 65.50; H, 5.69.

Decomposition of the Semicarbazide Addition Product.—A mixture of the semicarbazide addition product (XVI) (0.35 g.) and powdered potassium hydroxide (0.04 g.) upon heating in a sublimer at atmospheric pressure gave a mixture (0.11 g.) separable by fractional crystallization into diphensuccindene-10 (VI) and diphensuccindane[5] (XVII). A similar behavior was observed when the addition product was heated without potassium hydroxide.

Reduction of the Diketone.—The diketone (VII) (0.24 g.) was refluxed with amalgamated zinc (5 g.) in a mixture of water (5 ml.), concentrated hydrochloric acid (5 ml.) and acetic acid (10 ml.) for seven hours. The glycol (XVIII) (0.125 g.) obtained, after two crystallizations from benzene and one from (60–68°) petroleum ether, gave fine, white needles which melted at 148.5–149°.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.67; H, 5.88. Found: C, 80.99; H, 6.00.

A similar result was obtained by refluxing the diketone (VII) (0.12 g.) in 20% potassium hydroxide (14 ml.) and ethanol (4 ml.) with excess zinc dust until the solution was colorless. Acidification followed by extraction with ether gave the glycol (XVIII) (0.082 g.).

The glycol (XVII) when treated with either sulfuric or hydriodic acid in acetic acid gave a very insoluble yellow compound melting above 350°.

Cleavage of the Glycol.—A mixture of the glycol (XVIII) (0.23 g.) and lead tetraacetate (0.5 g.) in dry benzene (10 ml.) was allowed to stand for six hours at 50° and poured into dilute hydrochloric acid. Extraction with ether gave the cyclic diketone (VII) (0.14 g.).

Monoacetate of the Diketone.—A solution of the diketone (VII) (1.17 g.) in acetic anhydride (15 ml.) was refluxed with anhydrous potassium acetate (0.25 g.) for thirty minutes and then poured into water. Extraction with ether gave a white solid (XIX) (0.85 g.), m. p. 137–140°. Crystallization from ethanol gave white plates melting at 138–139°.

Anal. Calcd. for $C_{18}H_{14}O_3$: C, 77.69; H, 5.04. Found: C, 77.78; H, 5.08.

Alkaline hydrolysis of the monoacetate (XIX) gave the diketone (VII).

Oxidation of the Monoacetate.—A solution of the monoacetate (XIX) (0.14 g.) in acetic acid (10 ml.) was heated with chromic anhydride (0.16 g.) in water (0.2 ml.) at 50–60° for one hour, then poured into water and extracted with ether. A carbonate extraction of the ether layer gave a white solid (0.035 g.) which after crystallization from acetic acid first softened at 180° then melted at 215–220° with all the solid phase disappearing at 245°. This behavior was similar to that of *o,o'*-desoxybenzo-

indicarboxylic acid (XX) prepared according to the directions of Ephraim.[10]

Bromination of the Monoacetate.—A solution of the monoacetate (XIX) (0.28 g.) in glacial acetic acid (10 ml.) was treated with bromine (0.3 g.) in acetic acid (3 ml.) and allowed to stand at room temperature for twelve hours. The white crystals (XXI) (0.2 g.) formed were filtered and recrystallized twice from benzene, m. p. 219–223° with gas evolution. An additional 0.065 g. of the monobromomonoacetate (XXI) could be obtained from the filtrate.

Anal. Calcd. for $C_{18}H_{13}O_3Br$: C, 60.50; H, 3.65. Found: C, 60,10; H, 3.62.

The monobromomonoacetate (XXI) was not affected by refluxing in acetic acid with anhydrous potassium acetate.

Further treatment of the monobromomonoacetate (XXI) (0.25 g.) with bromine (0.5 ml.) in chloroform (10 ml.) at room temperature for thirty-six hours gave a white compound (0.12 g.) that melted at 173–178° with gas evolution. This compound could not be purified.

Anal. Calcd. for $C_{18}H_{13}O_3Br$ (XXI): C, 60.50; H, 3.65. Calcd. for $C_{16}H_{10}O_2Br_2$: C, 48.73; H, 2.54. Found: C, 52.63; H, 3.46.

***sym*-Dibenzocycloöctanetrione-5,6,11.**—The above impure bromo compound (m. p. 173–8°) (0.244 g.) was refluxed with concentrated ammonium hydroxide (2 ml.) and ethanol (7 ml.) for ten minutes and then poured into water. Extraction with ether and chloroform gave an orange solid (XXII) which was purified by sublimation under reduced pressure; yield 0.033 g., m. p. 245–250°. Two crystallizations from ethyl acetate followed by a sublimation at atmospheric pressure gave orange needles melting at 254–256°.

Anal. Calcd. for $C_{16}H_{10}O_3$: C, 76.80; H, 4.00. Found: C, 76.88; H, 3.47.

The triketone (XXII) was not affected by refluxing in acetic anhydride with potassium acetate or sulfuric acid and was stable toward alkaline peroxide.

The hydrated phenazine (XXIII) was obtained by refluxing the triketone (XXII) in absolute ethanol with phenylenediamine and a few drops of acetic acid for five hours. Two crystallizations from ethyl acetate gave bright red needles melting at 283–285°.

(10) Ephraim, *Ber.*, **24**, 2820 (1891).

Anal. Calcd. for $C_{22}H_{16}O_2N_2$: C, 77.64; H, 4.71. Found: C, 77.16; H, 4.57.

Diacetate of the Diketone.—A solution of the diketone (VII) (0.708 g.) in acetic anhydride (10 ml.) was refluxed with one drop of concentrated sulfuric acid for thirty minutes and then poured into water. Extraction with ether gave the diacetate (XXIV) (0.525 g.) melting at 145–148°. Three crystallizations from ethanol gave white plates melting at 150–151°.

Anal. Calcd. for $C_{20}H_{16}O_7$: C, 75.00; H, 5.00. Found: C, 74.98; H, 4.97.

The diacetate (XXIV) could also be obtained from the monoacetate (XIX). Alkaline hydrolysis of the diacetate (XXIV) gave the diketone (VII).

Bromination of the Diacetate.—A solution of the diacetate (XXIV) (0.32 g.) in acetic acid (10 ml.) was treated with bromine (0.4 g.) in acetic acid (4 ml.) and allowed to stand at room temperature for five hours. The crystalline plates (XXV) (0.24 g.) formed were filtered, m. p. 225–229°. An additional 0.055 g. was obtained from the filtrate. Two crystallizations did not change the melting point. A mixture with the monobromomonoacetate (XXI) showed a depression in melting point.

Anal. Calcd. for $C_{20}H_{15}O_4Br$: C, 60.76; H, 3.79. Found: C, 60.66; H, 3.92.

The same monobromodiacetate (XXV) was obtained by refluxing the monobromomonoacetate (XXI) in acetic anhydride with a drop of sulfuric acid.

The monobromodiacetate (XXV) was not affected by refluxing in acetic acid with either anhydrous potassium acetate or excess bromine.

Acknowledgment.—The author wishes to thank Professor C. F. Koelsch for his advice and interest during the course of this research.

Summary

1. The preparation of *sym*-dibenzocycloöctanedione-5,11 from diphensuccindene-10 is described.

2. The properties and reactions of *sym*-dibenzocycloöctanedione-5,11 resemble those of open chained 1,5-diketones.

Identification of Organic Compounds. II. Piperidyl Derivatives of Aromatic Halogenonitro Compounds[1]

BY MARGARET K. SEIKEL[2,3]

The work of this Laboratory on the systematic identification of organic compounds has been extended to the development of standard procedures for the preparation of derivatives of aromatic halogenonitro compounds by means of their reaction with piperidine. This paper reports the results of a study of thirty-seven members of this class. In addition to the application of standard procedures, it includes other observations which are of assistance in identifying the compounds as well as the optimum conditions for preparation and the characterization of all their possible piperidyl derivatives.

As a reagent for the preparation of derivatives of compounds with reactive halogen atoms, piperidine possesses many advantages over other bases such as ammonia, aromatic amines, alkali alkoxides[4] or morpholine.[5] Its main advantage lies in its far greater reactivity, a fact shown quantitatively by workers such as Franzen and Bockhacker[6] and Harradence and Lions.[5] Moreover the main reaction products tend to be more readily crystallized and in general contain fewer by-products.

In preparing piperidyl derivatives no single method applicable to all halogenonitro compounds can be used, both because of the spread in the reactivities of halogen atoms in variously substituted compounds and because of the fact that in certain cases two or more halogen atoms can be replaced successively by careful control of conditions. However, two fairly general reactions have been developed: *i. e.*, procedure A in which the compound is refluxed with piperidine for one hour and procedure B in which an alcohol solution is heated fifteen minutes on the steam-bath. Procedure A yielded derivatives in 65% and identifiable compounds in 79% of the thirty-seven cases studied, the difference in the percentages representing recoveries of original material. The corresponding figures for procedure B are 46 and 74%, respectively.

Initial evidence for the reactivity of the compounds was gained by observing the phenomena occurring on adding piperidine to the solid. Such observations are often valuable in suggesting the identity of an unknown halogenonitro compound. The mildest conditions of time, temperature and solvent for the complete replacement of each halogen atom were determined so that a qualitative comparison of the reactivities of these halogen atoms might be made.

In certain cases replacement of a nitro group in preference to a halogen atom occurs, as Mangini and Deliddo and Le Fèvre and Turner have already shown for the ortho dinitro compounds 19[7,8] and 13.[4] Such replacement is often evidenced by the initial red or red-orange color of the solution of the compound in piperidine and by the failure of any piperidine hydrohalide to precipitate even though the solution boils. The nitro group splits out as nitrosopiperidine for the residual clear yellow oil gives the diphenylamine test for nitrosamines. The presence of this compound in the reaction mixture seems to exert a catalytic effect in continued piperidination because dipiperidination of 13 and 19 occurs more readily than dipiperidination of 15 and 22, which yield the same derivatives, respectively. Although 27 also possesses two nitro groups ortho to each other, successive replacement of the chlorine atoms is the chief result of the reaction.[9] Compound 26 whose structure is intermediate between those of 13 and 27 resembles each of them to a certain extent so that derivatives formed by replacement of one nitro group or of two chlorine atoms were isolated.[10] The somewhat similar

(7) These numbers refer to those assigned the compounds in Tables I and II.

(8) Mangini and Deliddo, *Gazz. chim. ital.*, **63**, 625 (1933).

(9) Some nitro replacement is evidenced by the following facts: nitroso piperidine was detected even in the mildest reactions, crude samples of the dipiperidyl derivative always possessed low broad melting points and the piperidine hydrochloride yield was never higher than 80% for two chlorine atoms replaced.

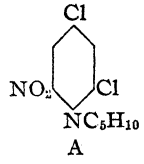
(10) Replacement of chlorine (in preference to nitro) by piperidyl in 26 and 27 is contrary to the results reported for the reaction of these compounds with ammonia; see MacLeod, Pfund and Kilpatrick, THIS JOURNAL, **44**, 2268 (1922), Körner, *Gazz. chim. ital.*, **4**, 353 (1874), and Blanksma, *Rec. trav. chim.*, **27**, 47 (1908).

trinitro compound, 21, however, shows only replacement of the 2-nitro group. Which of the two ortho nitro groups is replaced does not seem to follow any rule as far as can be determined from the compounds under observation. In fact, their reactivities are often so nearly alike that the main reaction product is definitely contaminated with a product resulting from replacement of the other nitro group.[11] Para nitro groups also may be replaced as evidenced by 25.

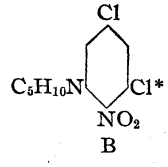
Preparation of all the theoretically possible piperidyl derivatives of each compound was successful in every case with the exception of the monopiperidyl derivative of 32 and the tripiperidyl derivatives of 30 and 33. The derivatives are for the most part readily crystallizable solids melting between 30 and 225°. Some have already been reported as shown in Table I; others, shown in Table II, are new.

The structures of fifteen of the twenty-two new compounds as well as of one already reported may be considered established either by proof, by formation due to replacement of all the halogen in the original compound or replacement of all the halogen atoms which are ortho or para to a nitro group[12] or by evidence as to whether a chlorine atom or a nitro group has been replaced. The structures of the remaining seven compounds as well as of one already reported (the monopiperidyl derivative of 16) are open to some doubt. Footnotes in Table II indicate the assumed structures, whose tentative assignment is based on such facts as the proved structures of amino derivatives of the same halogenonitrobenzenes, the greater reactivity toward amines of halogen ortho to nitro in contrast to halogen para to nitro, and the tendency of the known symmetrical derivatives to be higher melting and more insoluble.

The structures newly established in this work include the following. The identity of the mono- and dipiperidyl derivatives of 19 and 22 limits their structures to N-(3-chloro-6-nitrophenyl)-piperidine and 1-nitro-2,4-di-N-piperidylbenzene. Similarly, 21 and 24 produce the same derivative, indicating that the 2-nitro in 21 is reactive. The monopiperidyl derivative of 26, which forms by replacement of a nitro group, might be either A or B

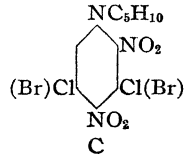


A

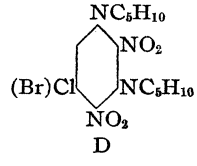


B

It appears to be A as the molecule contains no further reactive chlorine; the Cl* in formula B should be reactive. Also B is believed to be the structure of the monopiperidyl derivative of 30, a compound which melts 15° lower and contains another reactive chlorine atom. The question of the order of replacement of the halogen atoms in the symmetrical trihalogenodinitrobenzenes 16 and 17 has finally been definitely established, at least in respect to the replacement of bromine in 17 by piperidyl. The monopiperidyl derivatives of 16 and 17 already reported have been assigned structure C.[4,13]

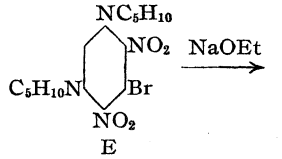


C

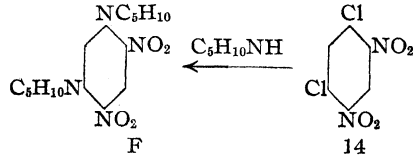


D

The dipiperidyl derivatives have never been prepared before although analogous compounds have been obtained with other amines.[13,14] Borsche's work[13] seemed to show indirectly that the di derivatives were of type D. However, E is definitely the structure of the bromodipiperidyl compound since by reduction with sodium ethylate, similar to the work of Jackson on the establishment of the structures of the two diethoxy derivatives of 17,[15] F is produced which is the known dipiperidyl derivative of 14.



E



F 14

(11) For example, the crude mono- and dipiperidyl derivatives of 19 melt low and over a wide range and the maximum yield of piperidine hydrochloride obtained in the preparation of the latter was 80% no matter how extended the time of reaction. That the presence of nitrosopiperidine in the reaction mixture is not the cause of this reduced yield is proved by the fact that the symmetrical compound 13 produces 100% piperidine hydrochloride yields. Such facts indicate that some replacement of the 4-nitro group accompanies the main replacement of the 3-nitro group.

(12) The complete non-reactivity of halogen atoms meta to nitro groups toward all reagents has been well established.

(13) Borsche and Trautner, *Ann.*, **447**, 1–18 (1926).

(14) Hüffer, *Rec. trav. chim.*, **40**, 451–476 (1921).

(15) Jackson and Warren, *Am. Chem. J.*, **13** 164–193 (1891); Jackson and Koch, *ibid.*, **21**, 510–528 (1899).

This work also proves that C is the structure of the monopiperidyl of 17. The structures of the derivatives of the chloro analog 16 may be assumed to be C and E, respectively, an assumption supported by the similarity in properties, although a reduction such as described above could not be carried out.

The meta substituted compound 20 is characteristically different from all the compounds studied, for it dissolves in piperidine without change in temperature but with the formation of a black-red color. The deep color is believed to be caused by the formation of a molecular addition product since addition of water to a newly mixed solution reprecipitates the original.[16] However, no crystalline addition compound could be isolated. The reaction of *sym*-trinitrobenzene was investigated and found to give analogous results although in this case an unstable mole for mole addition complex could be crystallized.[17] In both cases further deep-seated reactions occur between the nitrobenzene and excess piperidine if allowed to stand or if heated; from the resultant brown powders with indefinite melting points no pure products could be isolated readily.

Experimental

All melting points reported in this paper were taken by the method described in Mulliken's "Identification of Pure Organic Compounds," Vol. I, page 218, on a 360° melting point thermometer immersed in sulfuric acid to the 0° point. All melting points are uncorrected.

Procedure A.—To 0.5 g. of the halogenonitro compound add 1.5 ml. (1.0 ml. for bromo compounds) of piperidine.[18] Observe phenomena such as sputtering (stir to prevent local overheating), boiling, color formation and the time elapsing before piperidine hydrohalide precipitates; these are partially dependent on the quantities used. Reflux the resultant solution or mixture in an oil-bath for one hour, cool, add water and filter. If the product separates as an oil, the following crystallization methods should be tried in order[19]: (a) ice the mixture for an hour with scratching (with few exceptions this method is sufficient); (b) decant the aqueous layer containing excess piperidine and piperidine hydrohalide and wash the oil several times with water; (c) freeze in dry-ice. If no crystallization is then obtained, abandon the experiment. The yields are 90–100% and the crude product will melt sharply provided that the chlorine replacement is complete and decomposition products due to excessive reactivity are not present.

Recrystallize from 85% alcohol using excess if the melting point is low. Certain high melting insoluble compounds require 95% alcohol, acetone, or glacial acetic acid; such cases are mentioned in the footnotes of Table II.

The by-product piperidine hydrohalide yield, an index of the completeness of the reaction, can be determined qualitatively by evaporating the aqueous filtrate of the crude product and weighing the residue. If a nitro group is replaced, this residue is a reddish, acetone-soluble gum, giving a nitrosamine test with diphenylamine reagent.

Procedure B.—Dissolve 0.5 g. of the compound in 5 ml. of boiling alcohol (more if necessary), add 1.5 ml. (1.0 ml. for bromo compounds) of piperidine and heat for fifteen minutes on the steam-bath. If the product does not separate on cooling or icing, force it out with water, crystallizing any oil obtained as described above. If water has not been added before filtering, wash the precipitate with water to remove possible contaminating piperidine hydrohalide. The yields are only 70–90%, but the crystallization from alcohol effects purification.

Modified Procedures.—In most cases the standard procedures do not represent the readiest method of obtaining the derivatives of any one compound, nor can all the theoretically possible derivatives of each compound be prepared by these means. Therefore, modified procedures have been developed. For the most part these consist of applying conditions A or B with a change in the time of heating. These times are noted in Tables I and II; for example, A-2h means that conditions A should be applied for two hours (m is used to represent minutes) and B-0m means that as soon as the piperidine is added to the hot alcohol solution of the compound, the mixture is allowed to cool. The exact number of minutes is critical only in cases where the first of two reactive

(16) Although no addition compounds of 20 and amines have been reported, *m*-dinitrobenzene and certain of its derivatives are known to yield them; see Pfeiffer, "Organische Molekülverbindungen," 1927, p. 360.

(17) Romburgh, *Rec. trav. chim.*, **14**, 68 (1895), obtained the color but could not crystallize the compound.

(18) Monsanto catalytic piperidine with a reboiling range of 104–107° was used for this investigation; see Cook, THIS JOURNAL, **59**, 2661 (1937).

(19) The more laborious crystallization aids suggested by Le Fèvre and Turner,[4] are unnecessary. In fact the ability to dissolve readily in dilute hydrochloric acid is confined to those piperidyl derivatives with few ring substituents.

Best purified by dissolving in 95% alcohol and adding water dropwise so that the oil crystallizes as it forms.

chlorine atoms is being replaced; otherwise it represents the minimum time required for complete halogen replacement as evidenced by piperidine hydrohalide yields. Other procedures are as follows: C, mix the two reactants and add water after the specified time, this representing the simplest method of obtaining a derivative; D, add ice-cold piperidine to the solid compound also iced, continue icing until the initial violent reaction has moderated and then allow the mixture to stand in a water-bath maintained at room temperature, stirring frequently, until the spontaneous evolution of heat ceases (one to two hours); E, dissolve the compound in the least amount of cold alcohol (20–40 ml. for 0.5 g.), add piperidine and after the specified time at room temperature add water to precipitate the product. To prepare monopiperidyl derivatives in cases where dipiperidination is rapid, the amount of piperidine must be limited to the exactly calculated two mols; such procedures are prefixed by 2M. Calculated quantities may be used in other cases to conserve piperidine.

Structure Proofs. Monopiperidyl Derivatives of 1-Chloro-2,3,5-trinitrobenzene (21) and 1,2-Dichloro-3,5-dinitrobenzene (24).—By replacement of a nitro group in 21 a piperidyl derivative was obtained which did not lower the melting point of the monopiperidyl derivative of 24 (which was formed by replacement of a chlorine). Therefore the derivatives must be N-(2-chloro-4,6-dinitrophenyl)-piperidine.

Derivatives of 1-Chloro-3,4-dinitrobenzene (19) and 1,3-Dichloro-4-nitrobenzene (22).—The mono- and dipiperidyl derivatives of 19, formed, respectively, by replacement of one nitro group and a nitro group plus a chlorine, do not lower the melting points of the corresponding derivatives of 22 formed by successive replacements of the chlorines. Therefore, the 3-nitro must be

[a] As in Table I. [b] Value reported is mean of two determinations; average deviation of analyses from means is 0.4%. [c] Fraenkel and Landau product recrystallized from 85% alcohol until air evaporation of the alcohol solution deposited crystals and not an oil. *Anal.* Calcd. for $C_6H_3ClN_2O_4$: Cl, 17.5. Found: Cl, 17.5, 17.4. [d] Dry-ice required for crystallization. [e] See discussion in Experimental Section. [f] Bader, *Ber.*, **24**, 1655 (1891), and de Kock, *Rec. trav. chim.*, **20**, 112 (1901). The 3,5-dinitroaniline necessary for the preparation was obtained preferably from 3,5-dinitrobenzoyl chloride, Blanksma and Verberg, *ibid.*, **53**, 988 (1934). [g] In the diazotization of 2,6-dichloro-4-nitraniline and the replacement of the diazo group by a nitro group according to Körner and Contardi, *Chem. Abs.*, **8**, 1761–1762 (1914), and Holleman,[k] the 5% yield of the desired 1,3-dichloro-2,5-dinitrobenzene (25) was accompanied by a 6% yield of 21, the latter being less volatile in superheated steam. It was identified by its melting point, its analysis (Calcd. for $C_6H_2ClN_3O_6$: Cl, 14.3. Found: Cl, 14.5, 14.5) and its piperidyl derivative. [h] Complete replacement of the halogen or nitro group occurs at once, *i. e.*, under conditions E-lm. [i] Roberts and Turner, *J. Chem. Soc.*, 2011 (1925). [j] Holleman, *Rec. trav. chim.*, **23**, 366 (1904). [k] Holleman and Den Hollander, *Rec. trav. chim.*, **39**, 435–480 (1920). [l] A very slow replacement of chlorine occurs, for a trace of piperidine hydrochloride was present in the reaction mixture of procedure A, but its yield amounted to only 10% even after heating four hours. [m] Ullmann and Sané, *Ber.*, **44**, 3734 (1911). [n] See Table I for other derivatives, etc. [o] Structure assumed by analogy with mono-amino derivative, Körner and Contardi, *Chem. Abs.*, **8**, 1762 (1914). [p] Blanksma, *Rec. trav. chim.*, **27**, 46 (1908). [q] Isolated in maximum yield of 15% by recrystallizing once or twice from a large volume of 85% alcohol the oil or gummy solid obtained from conditions E-24h. [r] Isolated in maximum yield of 10% by treating the oil obtained under conditions C-10m with boiling 85 or 95% alcohol until the last few bits of oil crystallized in the hot solution and by allowing the solution to cool slowly. In one case the monopiperidyl derivative separated in a 10% yield from the filtrate after the dipiperidyl derivative had been removed. [s] Page and Heasman, *J. Chem. Soc.*, 3247–3255 (1923). [t] Glacial acetic acid is preferable for recrystallization. [u] Compare with the melting point given by Groves, Turner and Sharp, *J. Chem. Soc.*, 521 (1929). [v] Beilstein and Kurbatow, *Ann.*, **192**, 228–240 (1878). [w] Carten, Ph.D. Thesis, Massachusetts Institute of Technology, 1939, pp. 116–118. [x] Structure assumed by analogy with the mono-amino derivative.[p] [y] The crude product precipitates with piperidine of crystallization and melts around 125°; this is removed by heating for one hour at 110° or by repeated recrystallizations. [z] Structure assumed; compare with derivatives of 33. [aa] Isolated in a 70% yield by recrystallization of the oily product obtained under conditions 2M-A-20m; dry-ice cooling necessary to initiate crystallization even when pure. [bb] Reference 14. [cc] Acetone is preferable for recrystallization. [dd] No monopiperidyl derivative could be obtained; reactions even under the mildest conditions and with only two moles of piperidine produced gums from which only the dipiperidyl derivative

could be isolated in a crystalline state. [ee] By heating the 143° compound for one hour at 125–130° or by remelting it. The 147° compound reverts to the 143° compound on recrystallization. [ff] Structure assumed by analogy with 17. See discussion. [gg] Jackson, *Ber.*, **8**, 1172–1173 (1875). [hh] Structure assumed by analogy with diamino derivative, Körner, *Gazz. chim. ital.*, **4**, 425 (1874). [ii] Fraenkel and Landau material. [jj] If the product is recrystallized from 65% alcohol, a seed must be preserved to initiate crystallization; if it is recrystallized from 60% acetone and seeded by the crust which forms on the edge during icing, it must be filtered ice-cold as in the presence of acetone at room temperature the crystals return to oil. [kk] Compare Lellmann and Pekrun, *Ann.*, **259**, 40–61 (1890). [ll] Recrystallized from absolute alcohol. [mm] Norris and Taylor, THIS JOURNAL, **46**, 756 (1924). [nn] Taken floating in water.

replaced first in 19 and the 3-chloro in 22, followed by the 1-chloro in both. The properties of these derivatives (melting point and color) disagree with those already reported. Mangini[8] only obtained the monopiperidyl derivative of 19 as an oil whose hydrochloride melted at 147–150° (a crude sample of the latter prepared in this work melted at 145–149°). The dipiperidyl derivative of 22 has been described twice by Le Fèvre and co-workers[4,20] as red-orange, m. p. 67–68°; these properties as well as the method of preparation are more consistent with those given in Table II for the monopiperidyl derivative.

Monopiperidyl Derivative of 1,3-Dichloro-4,5-dinitrobenzene (26).—Analysis showed that piperidyl had replaced nitro. When 20 mg. of this derivative was subjected to the treatment A-4h, it was quantitatively recovered in pure form, m. p. 56–57° [57–58°], and did not lower the melting point of the analyzed sample; the filtrate contained only the merest traces of ionized chlorine. Therefore, this derivative contains no replaceable chlorine and must possess Structure A. Under the same conditions the monopiperidyl derivative of 30, m. p. 41–42°, and believed to possess structure B, yielded the dipiperidyl derivative which melted at 89–89.5° after one recrystallization [88.5–89.5°] and did not lower the melting point of an analyzed sample.

Mono- and Dipiperidyl Derivatives of 1,3,5-Tribromo-2,4-dinitrobenzene (17).—The structures of these derivatives were proved to be C and E, respectively, by the following reduction of the dipiperidyl derivative with sodium ethylate to F. The dipiperidyl derivative (0.5 g., 0.0012 mole) was dissolved by heating in 50 ml. of absolute alcohol and treated with 0.27 g. of sodium (10 × 0.0012 mole) dissolved in 10 ml. of absolute alcohol. The yellow solution was refluxed on the steam-bath for fifteen minutes, the color changing very slowly at first and then rapidly to orange, red and finally dark red. The dark red solution was evaporated almost to dryness by air, leached with water (which dissolved the red by-product) and filtered. The mustard colored crude (yield 50%, m. p. 120–126°) was recrystallized once or twice from 85% alcohol using Norite decolorizing carbon, m. p. 130–130.5°. Shorter reaction times, even ten minutes, produced very little reduction and, coupled with other observations, this seems to indicate that the red by-product catalyzes the reduction. Longer reaction times did not change the yields or the melting point. The identity of this product as 1,3-dinitro-4,6-di-N-piperidylbenzene was proved by a mixed melting point with authentic material, m. p. 130–131° (obtained by the action of piperidine on 14) and by analysis.

Anal. Calcd. for $C_{16}H_{22}N_4O_4$: N, 16.7. Found: N, 16.7, 16.9.

(20) Le Fèvre, Saunders and Turner, *J. Chem. Soc.*, 1171 (1927).

Dipiperidyl Derivative of 1,3,5-Trichloro-2,4-dinitrobenzene (16).—An attempt to reduce this compound to F with sodium ethylate and hence prove its structure failed. When it was subjected to the same treatment as its bromo analog (see under 17), the color change shifted only to orange-yellow after refluxing for one-half hour and a sample of the product melted at 150–165°. The ethylate concentration was tripled and the refluxing continued until the dark red color formed (three-quarter hour more). The 70% yield of product, m. p. 167–170°, crystallized from 80% acetic acid in orange-yellow needles, m. p. 173–174°. It contained no chlorine and is believed to be 1-ethoxy-2,6-dinitro-3,5-di-N-piperidylbenzene.

Anal. Calcd. for $C_{18}H_{26}N_4O_5$: N, 14.8. Found: N, 14.8, 14.9.

Lack of material prevented further investigation. The formation of this ethoxy derivative may indicate that the compound has structure D instead of E as its bromo analog, but undoubtedly the chlorine atom is more resistant to reduction than the bromine atom.

Addition Compounds with Piperidine. 1,3,5-Trinitrobenzene.—When *sym*-trinitrobenzene, m. p. 119–121, and piperidine are mixed mole for mole, a thick black-red solution forms at first with slight if any change in temperature. This thickens at once and becomes crystalline, the dark dull red product melting at 60–62° with gas evolution between 110–120°. The formation of this addition compound occurs so readily that if a few crystals of trinitrobenzene are floated on a 0.05% aqueous piperidine solution, the solution slowly acquires a very slight pink tinge. However, it is unstable in two directions. First, it decomposes into the original components whenever exposed to air, the surface fading to a light pink; solvents, while dissolving enough to produce a red solution, decompose it for the most part. Therefore it cannot be recrystallized and can be preserved only by stoppering tightly with a minimum of space. In an atmosphere saturated with piperidine it deliquesces. Second, deep-seated reactions occur slowly so that a well-stoppered sample cannot be kept for more than an hour or two before the melting point begins to drop and broaden; in three or four days the material becomes a black liquid. In fact even if the addition product were decomposed immediately

after forming, the recovered trinitrobenzene was light raspberry colored, although even two days of standing had little effect on the melting point of the recovered material. The identification of any further products was not undertaken as the material obtained from long standing or from heating the trinitrobenzene in excess piperidine consisted of brown crystallized gums, completely soluble in concentrated hydrochloric acid but not responding to any simple method of purification.

1-Chloro-3,5-dinitrobenzene (20).—This exhibited the same color phenomena with piperidine as *sym*-trinitrobenzene, but no crystalline addition product could be prepared although various ratios of piperidine to chloronitrobenzene were tried and the thick red liquids cooled in dry-ice until they hardened to glasses. This addition product does not form as readily, for although 20 deliquesces in saturated piperidine vapor, it will not produce color with aqueous piperidine. The same deep-seated reactions occur, but no pure product could be isolated from the brown powders by fractional precipitation from either the concentrated hydrochloric acid solution or from acetone solution.

Relative Reactivities.—A qualitative determination of the relative reactivities of the various compounds was made both very roughly by observing the phenomena occurring when piperidine is added to the solids and more accurately by determining the mildest conditions for complete replacement of each halogen atom as well as by certain comparative experiments not discussed. The following list is in order of decreasing reactivity in respect to monopiperidination only: A. Compounds producing sputtering as simultaneous precipitation of the piperidine hydrohalide and boiling of the red or orange liquid occurs (sp) or boiling of the red or orange solution without salt precipitation (b), (1) reactions instantaneous in cold alcohol solution [10 (sp), 7 (sp), 8 (sp), 14 (sp), 28 (sp), 24 (sp), 9 (sp), 21 (b) and 13 (b)], (2) reactions not instantaneous in cold alcohol solution, 19 (b), 25 (b), 27 (sp), [16 (sp) and 31 (sp)], 26 (b, sp), 32 (sp); B. Compounds forming clear yellow solutions from which piperidine hydrohalide precipitates in the cold in a few minutes (Xm) generally accompanied by liberation of heat, [36(0m), 37(0m) and 18(0m)], 15(0m), 17(0-1m), 22(1m), 29(1-2m), 30($2^1/_2$m), 12(5m), 33(15m); C. Compounds dissolving in piperidine with absorption of heat and producing clear yellow solutions, 2, 11, 1, 6, 5, 23, [3, 4, 34 and 35].

Summary

1. Two standard procedures for the preparation of piperidyl derivatives of aromatic halogenonitro compounds have been developed.

2. All possible piperidyl derivatives of the compounds studied have been isolated and the most favorable conditions for their preparation determined.

3. The structures of certain derivatives have been proved.

The Deepening of Color of Sodium Nitrophenolate Solutions with Elevation of Temperature

BY TENNEY L. DAVIS AND JOSEPH L. RICHMOND

The yellow color of solutions of the salts of *m*-nitrophenol is of significance in discussions of theories of color and constitution. Satisfactory quinoid formulas may be written for the colored salts of *o*- and *p*-nitrophenol, as Armstrong[1] pointed out, and the parent substances may be supposed to exist in tautomeric quinoid forms. Hantzsch[2] accepted the view of Armstrong and suggested formulas for the colored salts of *m*-nitrophenol. Later he[3] succeeded in preparing colored and colorless esters of *o*- and *p*-nitrophenol, but not of the *m*-compound, and concluded that the free *m*-quinone is not capable of existence; or, as we should say, that *m*-nitrophenol is not capable of tautomerizing to a quinoid form, but that the colored salts of *m*-nitrophenol are nevertheless quinoid, the *m*-

quinone structure being stable in electronegative radicals present in an electrolyte along with positive ions of the metal. Hantzsch's *m*-quinoid formulas have not met with general acceptance, for they represent atomic arrangements which are thought to be unstable. The problem has been complicated further by the absence from the literature of any clear cut definition of quinones and of an understanding or an agreement as to what the structure of *m*-quinones, if they exist, would be.[4]

Hirsch[5] reported that solutions of the sodium salts of *o*- and *p*-nitrophenol become more deeply colored when they are warmed, and stated wrongly that the colors of the solutions on cooling revert only slowly to the original shades. We find that the changes of color intensity are as rapid as the changes of temperature, and we find, contrary to the observation of Hirsch, that solutions of sodium *m*-nitrophenolate behave in the same general way as those of the *o*- and *p*-compounds. The change appears to be solely a change in color intensity, for the color of a short column of warm solution matches perfectly with the color of a longer column of cold solution.[6]

The colors of solutions of the three sodium nitrophenolates are sensibly the same to the eye. Measurements of the thermotropic color intensifications have shown that the three substances differ from one another in respect to this property no more than substances of similar but not wholly identical structure would be expected to differ.

(4) The common practice in textbooks appears to be to describe the production of *p*-benzoquinone by the oxidation of hydroquinone, to discuss the peculiar chemical and structural properties of this substance, and then to use these properties as a basis for outlining, but not for defining, the class of quinones. The definition of quinones as oxidation products of benzene derivatives is not satisfactory; quinone dioxime, an undoubted quinone, is oxidized by strong nitric acid to yield *p*-dinitrobenzene. For a number of years T. L. D. has been accustomed in his classes to define quinones as substances in which two atoms attached to an aromatic ring (or ring system) are the terminal atoms of a conjugate system through the aromatic ring (or ring system). (An aromatic ring is conceived and defined as a six-membered carbon ring, each carbon atom of which has one residual valence.) This definition is believed to include all substances which are recognized to be quinones, and to exclude all those which are not now classed as such. It has the advantage that it unifies the reactions of quinones, in which the side chain conjugated into the ring acts in many cases to make the ring accessible to reagents which do not affect the ring of other aromatic substances. It excludes the possibility of *m*-quinones, but leaves open for study the question of what structures result when two hydrogen atoms are removed from *m*-diphenols.

(5) Hirsch, *Ber.*, **36**, 1893 (1903).

(6) Hantzsch, *ibid.*, **39**, 1084 (1906), reported observations on the colors of the dry salts, that they intensified on warming and after cooling later faded again. Goddard, *J. Chem. Soc.*, 54 (1922), found that the hydrated sodium salts of the nitrophenols lose water to form the anhydrous compounds which are darker in color, and that these on standing in the air take up water to form the lighter hydrated salts.

The results of our experiments with 0.1 *N* solutions of the sodium nitrophenolates are plotted in Fig. 1, where each curve summarizes the results from two or from three runs, and the spread of the data indicates the approximation or error with which we have been able to match the colors.

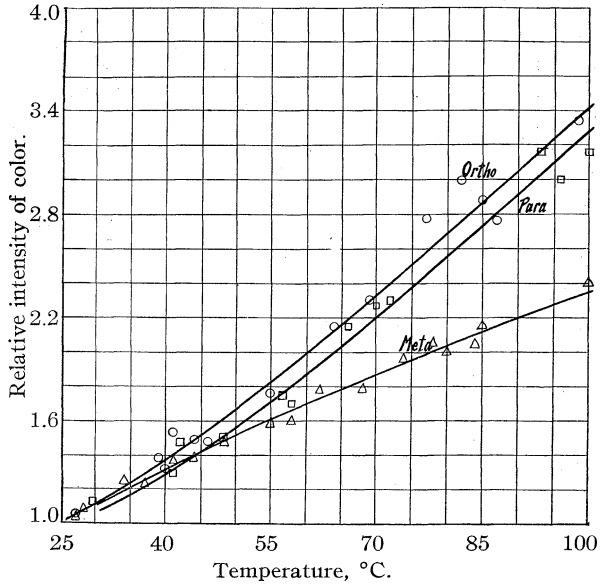

Fig. 1.—Intensity of color of warm 0.1 *N* sodium nitrophenolate solutions compared with the color of the same solutions at 25°: ○, ortho; □, para; △, meta.

The curves for the *o*- and *p*-compounds are close together; the color of the solution of the ortho compound is about 3.4 times as intense at 100° as at 25°; that of the para compound about 3.3 times. The curve for the *m*-compound slopes upward less sharply but is of the same general form as the curves for its isomers; the color of 0.1 *N* sodium *m*-nitrophenolate is about 2.3 times as intense at 100° as at 25°. In other experiments to determine the effect of alkalinity, sodium carbonate was added to 0.1 *N* *m*-nitrophenol solution in amounts corresponding to 0.02, 0.2, 1.0 and 2.0 *N* concentration of sodium ion. The results, plotted in Fig. 2, show that the thermotropic color intensification is lessened by increasing amounts of alkali, hence, since the alkali may be presumed to reduce the ionization of the salt, that the effect is due to a property of the ion.

An hypothesis to account for the behavior of the three nitrophenolates must assign similar structures to the ions of all of them, and will have additional plausibility if it relates the structure of the *m*-nitrophenolate ion to the known

facts relative to the existence, or non-existence, of *m*-quinone.

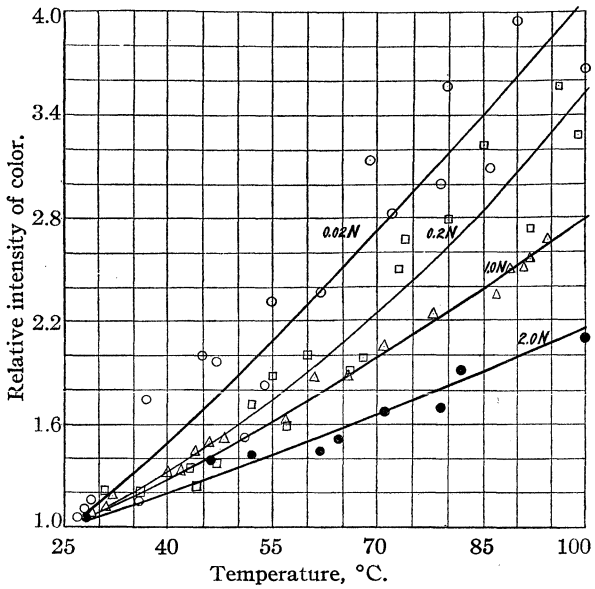

Fig. 2.—Effect of sodium carbonate upon thermotropic color intensification of 0.1 *N* *m*-nitrophenol solutions: ○, 0.02 *N* sodium carbonate; □, 0.2 *N*; △, 1.0 *N*; ●, 2.0 *N*.

Experimental Results

A colorimeter was constructed in which two beams of light from a single source were made to pass respectively through two tubes, one of which contained a column of solution at room temperature the length of which could be varied while the other contained a column of constant length enclosed in a jacket through which water was circulated into which steam or warm water or cold water was injected as required. The temperature of the second column of solution was determined by means of a thermocouple which, it was found, did not interfere with the optical path. The light after passing through the two tubes was reflected upon a single target as two semicircular spots so placed as to form a complete circle with each other. The length of the column of liquid at room temperature was then adjusted until the two halves of the circular spot were indistinguishable. The runs were started with the same solution in both tubes in columns of equal length. The temperature of the jacketed column was then raised a convenient amount. When the potentiometer readings showed that the temperature had become constant, the length of the column in the other tube was adjusted until the colors matched and the ratio of the length of the cold column to the length of the warm column was recorded as the relative intensity of the color of the solution at the temperature in question as compared with the color at room temperature. Similar readings were made at intervals while the temperature was raised to about 100°, then while the temperature was lowered to that of tap water, and the relative color intensities were calculated in comparison with the color at 25°. There was no perceptible lag in the intensification of the color on warming or in the fading of the color on cooling; the relative intensities of color were found to be the same whether measured while going up or while going down the temperature scale. At each concentration two or generally three runs were made, and the results were plotted in a single curve. The results at the even temperatures read from such curves, for 0.1, 0.02, 0.01 and 0.005 *N* solutions of the three nitrophenolates are summarized in Table I. From these data it is evident that the difference between the isomers is less in the more dilute solutions.

In another series of experiments sodium carbonate in amounts corresponding to 0.02, 0.2, 1.0 and 2.0 *N* concentration was added to 0.1 *N* solutions of *m*-nitrophenol, and the thermotropic color intensifications of these solutions, containing, respectively, one-fifth, twice, ten times, and twenty times the equivalent amount of sodium ion, were determined. The data lay closest to smooth curves in the experiments in which the more sodium carbonate was used. Other experiments were carried out with 0.01 *N* solutions of *m*-nitrophenol containing one-fifth, twice, ten times and twenty times the equivalent amount of

sodium ion, and with 0.001 *N* solutions containing ten and twenty times the equivalent, respectively. The results read from the curves are summarized in Table II. The data from the experiments with the more dilute solutions are probably the least precise because of the difficulty of matching the fainter colors.

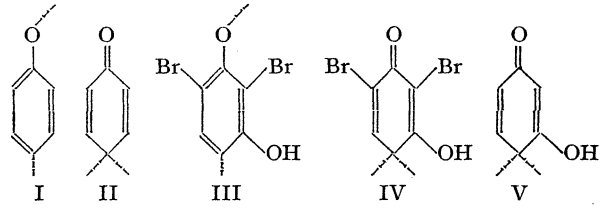
m-Nitrophenol, prepared by the method of Adams and Wilson,[7] was purified by vacuum distillation and finally by sublimation in vacuum, almost white crystals melting sharply at 96°. The sodium salt, prepared in the usual way and recrystallized from alcohol and from water, consisted of orange colored small crystals containing two molecules of water of crystallization. *Anal.* Sodium found, 11.4, 11.5. Calcd. for $C_6H_4O_3NNa \cdot 2H_2O$: Na, 11.6.

Sodium *o*-nitrophenolate, recrystallized from alcohol and from water, consisted of anhydrous bright red needles. *Anal.* Sodium found, 14.6, 14.5. Calcd. for $C_6H_4O_3N$-Na: Na, 14.3.

Sodium *p*-nitrophenolate crystallized from water in bright canary-yellow crystals containing two molecules of water of crystallization. *Anal.* Sodium found, 11.6.

Interpretation of Results

The work of Hunter and his co-workers[8] has shown that the oxidation of phenol occurs through the intermediate production of a radical having formulas I and II below (which formulas we regard as equivalent), while that of Davis and Hill[9] has shown that tribromoresorcinol similarly passes through the stage represented by formulas III and IV. Davis and Harrington[10] have shown that the quinyl radical, formula IV, is probably intermediate in many of the reactions of tribromoresorcinol, being formed by the spontaneous splitting off of hydrogen bromide from the tautomeric form of that substance. This formula



I II III IV V

corresponds to the removal of two hydrogen atoms from dibromoresorcinol and may be regarded, if the language is permitted, as representing dibromo-*m*-quinone. The comportment of *m*-diphenols in general, on oxidation and in other reactions, may be interpreted by supposing the intermediate existence of such *m*-quinones, and formula V may be taken as representing *m*-quinone itself; which is thus a *p*-quinyl radical, probably incapable of an independent existence but ready, according to the environment in which it exists momentarily, to form resorcinol by reduction, hydroxy-*p*-quinone by oxidation, or by doubling-up under conditions which are neither oxidizing nor reducing to form dihydroxydiphenoquinone. If *m*-quinone may hydrate, formula VI, as *o*- and *p*-quinone presumably hydrate, formulas VII and VIII, then the hydrated quinones will exhibit similar unsaturated and resonating structures and will supply a common basis for discussions of color and constitution. The fact that formula VI represents one of the tauto-

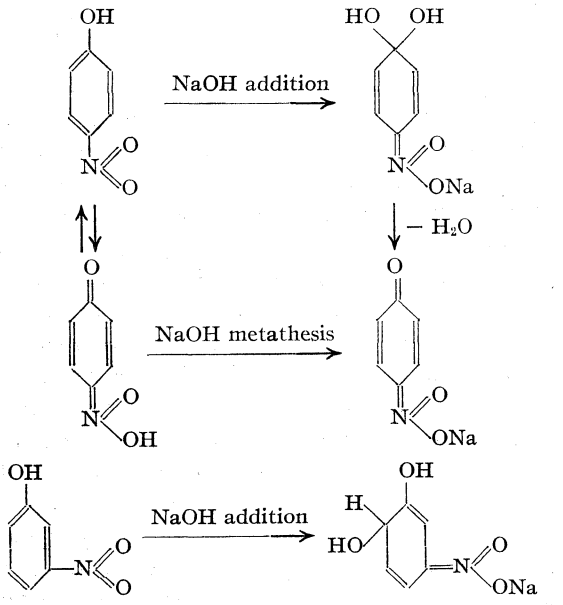
VI VII VIII

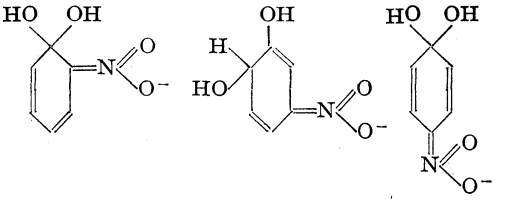
meric forms of 1,2,4-trihydroxybenzene suggests that the latter substance may perhaps be procurable from resorcinol by oxidation under appropriate conditions. For our present purpose however it is not necessary to suppose that the simple quinones hydrate. The formulas are illustrative. Our hypothesis supposes only that quinoid (not quinone) ions may exist which correspond to the three hydrated quinones.

o- and *p*-nitrophenol are both capable of tautomerizing, and may form sodium salts by the replacement of hydrogen atoms in the tautomers. *m*-Nitrophenol cannot do this. The same sodium salts of *o*- and *p*-nitrophenol, however, may be formed by a different mechanism; it is possible that the sodium hydroxide may add to the benzene derivative to form a quinoid compound[11] from which water may subsequently split off. But there is no evidence that the water does split off in aqueous solution. The colored ions may in fact be hydrated. *m*-Nitrophenol likewise may



(11) The addition of alkali to nitro compounds in this manner, the alkali metal to the nitro group and the rest of the adding molecule to the *p*-position of the ring, has been shown to be probable in many instances, particularly by the work of Jackson and his collaborators in their investigations of the reactions of picryl chloride and of trinitroanisole and trinitrophenetole with sodium alcoholates, *Am. Chem. J.*, **20**, 448 (1898); **23**, 294 (1901).

combine directly with sodium hydroxide to form a *p*-quinoid compound (a hydrated *m*-quinone) from which, however, water cannot split off, and, as far as the formation of hydrated salts, and of colored hydrated ions, is concerned, all three of the nitrophenols are alike. We suppose therefore that the colored ions of the three nitrophenolates are the hydrated quinoid ions indicated. By this



hypothesis the structure assigned to the *m*-nitrophenolate ion has the same relationship to the structure of *m*-quinone as that of the *p*-nitrophenolate ion has to the structure of *p*-quinone. The three nitrophenolate ions are supposed to be of similar structure and hence are expected to behave in similar manners. We are not prepared to offer an hypothesis to explain how the quinoid structure accounts for the thermotropic intensification of the colors of the solutions, except by the general supposition that the increase of temperature increases the resonance of the conjugate system of the ions, for we suppose that it is not the quinoid structure merely, but the possibilities of resonance which that structure provides, which make the basis for the quinone theory of color and constitution. The resonating system of the ions extends only into the rings, but not through them and beyond as in many of the dyestuffs, and this circumstance, in some way, may perhaps be associated with the phenomenon of color intensification.

Summary

The colors of warm solutions of the three sodium nitrophenolates have been measured by comparison with the colors of the same solutions at 25°. The thermotropic color intensifications of the three isomers appear to conform to the same general law, but the effect is least in the case of the *m*-compound.

The effect of various concentrations of sodium carbonate in solutions of *m*-nitrophenol has been studied. Alkali retards the color intensification, confirming the opinion that the effect is due to a property of the ion.

An hypothesis has been offered which assigns similar hydrated quinoid structures to the *o*-,

m-, and *p*-nitrophenolate ions, and is, at the same time, in harmony with the known facts concerning *m*-quinone and the oxidation of *m*-diphenols.

Cyanates of Silicon, Phosphorus and Boron. Instability of Certain Ternary Boron Compounds

BY GEORGE S. FORBES AND HERBERT H. ANDERSON

Reynolds[1] prepared stable silicon thiocyanate (b. p. 314°) from silicon tetrachloride and lead thiocyanate in benzene. Two years later, Cocksedge,[2] upon treating boron bromide with silver thiocyanate, obtained boron thiocyanate as a white crystalline solid which grew dark even at 100°. Both offered some evidence that sulfur, not nitrogen, was linked to the non-metallic element. Dixon[3] reported the isolation of phosphorous thiocyanate from lead thiocyanate and phosphorus trichloride in commercial benzene as "a reddish-yellow, clear, dense oil which gave the reactions for thiocyanate, thiocarbimide and phosphorus." At 170° the contents of the flask "suddenly changed, without evolution of gas, to a sticky black solid which presently became hard and brittle." Dixon thought that this might be a polymer of $P(NCS)_3$, but was unable to substantiate his opinion.

It occurred to us to inquire whether these weakly electronegative elements would form stable cyanates, or isocyanates or both. Preparations were undertaken to obtain evidence bearing upon this issue.

Silicon Isocyanate and Cyanate

Preparation.—Eighty grams of silicon chloride was added with vigorous shaking, over a period of fifteen minutes to 250 cc. of pure benzene in which 290 g. of finely powdered silver (iso)cyanate was suspended. The flask was then heated on the steam-bath for half an hour. After filtration, and several washings with benzene, the solvent was distilled off at atmospheric pressure. The yield of crude liquid product, 72 g., was 78% referred to cyanate. Potassium and lead cyanates were much less reactive and led to much smaller yields even after forty hours of refluxing. A second preparation, starting with excess of silicon chloride, afforded a yield of 86%. After expulsion of silicon tetrachloride and benzene, the colorless liquid product was distilled under 25 mm. pressure. The boiling point rose sharply at the end, and the residue, a very pale yellow liquid, was found to be 2.5% of the whole.

(1) Reynolds, *J. Chem. Soc.*, **89**, 397 (1906).
(2) Cocksedge, *ibid.*, **93**, 2177 (1908).
(3) Dixon, *ibid.*, **79**, 541 (1901).

Anal. Weighed portions of each fraction were converted into silica by hydrolysis, evaporation and ignition to constant weight all in the same crucible. The results follow.

Fraction of b. p. 185.6°, silicon found 14.22, 14.27, 14.46, 14.47%, average 14.35%.

Fraction of b. p. 247.2°, silicon found 14.06 and 14.56%, average 14.31%.

Calculated for $Si(NCO)_4$ and $Si(OCN)_4$, 14.32%.

The molecular weight of each fraction was determined in Dumas bulbs of about 50 cc. capacity, with the usual precautions.

186° fraction, mol. wt. found 202.5, 205.7, average 204.1.

247° fraction, mol. wt. found 211.9.

Calculated for $Si(NCO)_4$ and $Si(OCN)_4$, 196.1.

In addition, the molecular weight of the 186° fraction was determined by the freezing point method in benzene solution to be 204.1 and 194.4, average 199.2. Not enough of the higher boiling fraction for this determination remained.

Properties.—The boiling points were measured at various pressures by a dynamic method described, among others, by Mack and France.[4] Rubber connections were avoided by fused joints. The thermometers for these and other definitive measurements were standardized in the same apparatus with water, aniline and benzoic acid as primary standards, also with bromobenzene and benzoyl chloride. The plot of $\log_{10} p$ (mm.) for each liquid, against $1/T$ was a satisfactory straight line, and the logarithmic equations predicted the data within three millimeters, assuming the correctness of the temperatures. Densities at 20° were determined only by weighing the contents of a pipet. The index of refraction (white light), also at 20°, was measured with an

Abbe refractometer with thermostated prism. Table I summarizes the data obtained.

The above identification of the two silicon cyanates rested mainly upon analogies with ethyl isocyanate and cyanate, respectively. The structures of the latter were established by Anschütz[5] and Ponomareff[6] who showed that hydrolysis of the first yielded diethylurea and carbon dioxide, hydrolysis of the second urethan. The difference between their boiling points, 60 and 160°, respectively, agrees with that of the two silicon cyanates. Further evidence was available from their respective behavior when hydrolyzed. The reaction of the low-boiling liquid, presumably

$$Si(NCO)_4 + 4H_2O \longrightarrow H_4SiO_4 + 4HNCO$$

was vigorous, and the silica was largely coagulated due to its formation in acid solution. But the reaction of the high-boiling liquid, presumably

$$Si(OCN)_4 + 12H_2O = H_4SiO_4 + 4NH_4HCO_3$$

was slow, and silica was obtained in the form of a sol, which proved extremely hard to dehydrate.

The prospect of a decisive proof of the structures of our silicon cyanates, as well as those of boron and phosphorus by purely chemical methods, appears less bright than by Raman spectra or electron diffraction data. It is hoped that such studies may be undertaken, at a later date, in this Laboratory.

Phosphorous Isocyanate

Preparation.—Ninety grams of phosphorus trichloride reacted with 230 g. of silver (iso)cyanate in 300 cc. of warm benzene. After filtration and expulsion of the solvent, 62 g. of liquid remained, nearly 80% of the theoretical yield based on cyanate. After several distillations a colorless liquid was obtained boiling at 167° (uncorrected) under 755 mm. There was a higher boiling fraction of about 2% which decomposed yielding a dark residue. This residue, observed in each of two runs, was hydrolyzed by water.

Anal.—The redistilled product contained no chloride. Weighed samples were hydrolyzed to phosphorous and (iso)cyanic acids. A known volume of standard iodine solution was added, and the solution made about 3 *N* in hydrochloric acid. After an hour on the steam-bath, the oxidation of phosphorous to phosphoric acid was assumed to be complete. The excess of iodine was then titrated with standard thiosulfate. Phosphorus found, 20.02 and 20.11%. Calculated, 19.75%. The molecular weight of the vapor, by the Dumas method, was 159.0 and 158.6. Calculated for $P(NCO)_3$, 157.1.

Properties.—Our data for the more important physical properties were as follows: boiling point at 760 mm., 169.3 ± 0.3°; melting point, −2 ± 0.5°; vapor pressure, $\log_{10} p$ (mm.) = 8.7455 − 2595/T; λ_v = 11,900 cal.; λ_v/T = 26.8 cal./deg.; density 1.439 g./cc.; refractive index (white light) n, 1.5352.

Our identification of the product as isocyanate rests largely upon its normal boiling point, 169.3°, which is even lower than that of phosphorus tribromide, 172.9°, and far below that which would be predicted for a normal cyanate, judging from corresponding ethyl and silicon compounds. The Trouton constant, also, agrees with that of silicon isocyanate in a clean-cut fashion.

The purest product displayed some unexpected phase relationships. The distillate boiling at 169.3° stood for two weeks at room temperature without visible change. Upon supercooling it to −20°, a white solid appeared having a melting point of −2°. The resulting liquid, held at room temperature for three days, turned into a white solid, melting at about 80°, and insoluble in benzene, ether, chloroform and carbon tetrachloride. Sidgwick[7] has summarized various investigations upon polymers of cyanic acid. Cyanuric acid, soluble in ordinary solvents, can be converted to cyanic acid, which repolymerizes to cyanelide, a solid insoluble in the same solvents. Without attempting to press the analogy too far, we consider the behavior of our phosphorous isocyanate rather similar to the above. Our insoluble solid melting at 80° yielded a liquid boiling at 169.3° like the original liquid, but another sample held at room temperature yielded once more the supposed polymer, melting this time at 95°. Possibly the polymerization was more nearly complete than in the solid melting at 80°.

Boron Cyanate

Preparation.—Forty grams of silver (iso)cyanate, 8 g. of boron bromide and 125 cc. of warm benzene were shaken in a flask. The resulting solution contained about one-quarter of the expected boron cyanate and extraction of the solid residue with benzene removed but little more. A large box was provided with a glass cover, a built-in steam coil, and holes in the sides with wristlets having elastic bands to fit snugly over the operator's gloves. Air was expelled by tank nitrogen, and a slow current maintained during filtration, evaporation to a small volume, drying of the crystals, and sampling. Hydrolysis of the solid was negligible under these conditions.

Anal. The white solid decomposed with evolution of carbon dioxide in water and in dilute sulfuric acid, thus

(5) Anschütz, *Ann.*, **359**, 210 (1908).

(6) Ponomareff, *Ber.*, **15**, 513 (1882).

(7) Sidgwick, "Organic Chemistry of Nitrogen," revised by Taylor and Baker, Clarendon Press, Oxford, 1937, pp. 322–326 and 331.

indicating presence of cyanate. No bromide was detected in the resulting solution. Four samples, ranging from 0.1071 to 0.3592 g., were weighed under dry nitrogen and hydrolyzed in dilute sulfuric acid.

$$2B(OCN)_3 + 3H_2SO_4 + 12H_2O \longrightarrow 2H_3BO_3 + 3(NH_4)_2SO_4 + 6CO_2$$

After expulsion of carbon dioxide, standard sodium hydroxide was added to a methyl red end-point. Enough mannite was added to yield a 10% solution, and titration followed to a phenolphthalein end-point. In a blank experiment with an equal weight and concentration of ammonium sulfate the proper correction for its buffering action was evaluated. Boron found was 8.12, 7.94, 7.87 and 8.05%, average 7.99%; the calculated value is 7.91%.

Properties.—Boron cyanate, like boron thiocyanate, was isolated from benzene in tiny crystals. Its solubility in benzene, ether, chloroform or dioxane is roughly 2 g. per 100 cc. Anhydrous ethanol dissolves it with rapid decomposition. Bromine is unreactive at 25° and at 200°. An attempt was made to sublime it in a good vacuum, with cautious heating, but the substance merely became brown to black in color. The fact that our product had no melting point, and could not even be sublimed, suggested that its structure was analogous to that of boron thiocyanate as established by Cocksedge.[2]

Instability of Certain Ternary Boron Compounds

Before preparing the cyanates, efforts were made to obtain boron chlorobromides, analogous to the silicon chlorobromides previously studied by one of us.[8] Besson[9] had reported the existence of boron bromoiodides, but his evidence that the scanty products were single definite compounds left much to be desired. On the other hand, Poggiale[10] obtained only boron chloride from boron bromide treated with chlorine. Gustavson[11] and Tarible[12] employing carbon tetrachloride and arsenic trichloride, respectively, reported the same outcome. Amorphous boron, from boric oxide and magnesium, was treated with bromine vapor at 800°. The resulting boron bromide was purified by distillation. We employed a three-necked flask with stirrer, separatory funnel and a column leading to a condenser. In successive experiments boron bromide was treated separately with sulfur monochloride, stannic chloride and titanium tetrachloride. The vapors, upon leaving the heated zone, were cooled by dry ice. Sulfur monochloride yielded only boron chloride mixed with unchanged boron bromide, and the flask contained sulfur monobromide. Titanium tetrachloride and stannic chloride reacted quantitatively with boron bromide. Next, hydrogen chloride was bubbled through boron bromide at 65° and the mixed vapors passed through a tube heated to 800° over a length of 70 cm., but boron bromide and chloride, only, were recovered. It was hoped that silicon dichlorodibromide might yield boron dichlorobromide, but boron trichloride was the only low-boiling product obtained at 800°, with a yield of 10%.

In addition, simple products only were obtained from the following reactions: (1) boron with mixed chlorine and oxygen, the temperature of the reaction zone being gradually lowered from 800 to 650°; (2) boron with mixed chlorine and bromine at 800°; (3) boron bromide and oxygen at 800°; and (4) boron bromide and antimony trifluoride at 90°.

Summary

1. Silver (iso)cyanate reacts with silicon tetrachloride, phosphorus trichloride and boron bromide in benzene far more completely than does potassium cyanate or lead cyanate.

2. Ninety-eight per cent. of the product obtained from silicon tetrachloride appears to be $Si(NCO)_4$, m. p. 26.0° and b. p. 185.6°; the remainder was $Si(OCN)_4$, m. p. 34.5° and b. p. 247.2°. Our identification rests mainly upon analogies with ethyl isocyanate and cyanate. Various physical properties were quantitatively investigated.

3. Phosphorus trichloride yielded $P(NCO)_3$ as the only volatile product, m. p. −2.0°, b. p. 169.3°. Samples once frozen, on standing at room temperature, were converted into a solid insoluble in ordinary organic solvents which reverted to the original (soluble) liquid on heating.

4. Boron trichloride yielded a white solid of low solubility which decomposed on moderate heating. Its analysis, as well as its properties, indicated that it was $B(OCN)_3$.

5. Boron chlorobromides, fluorobromides, oxychloride and oxybromide were not obtained in a series of experiments in which both reactants and temperatures were widely varied.

The Mercurous Bromide Electrode

BY W. D. LARSON

There are available in the recent literature only a few measurements from which the standard potential of the mercury–mercurous bromide electrode can be calculated. Gerke[1] measured the cell

$$H_2/HBr/Hg_2Br_2/Hg \qquad (1)$$

at an acid molality of 0.10015. Ishikawa and Ueda[2] measured cell (1) at a molality of 0.1012.

In the present study are presented data on the cell

$$Ag/AgBr,\ KBr,\ Hg_2Br_2/Hg \qquad (2)$$

at 20, 25, and 30°. These data allow the calculation of the standard potential of the mercury–mercurous bromide electrode, since the corresponding value for the silver–silver bromide electrode is well known at the various temperatures.[3] Harned[3e] has pointed out that $E^0 = 0.07115 \pm 0.00015$ v. includes the results of all the investigators listed in reference (3). The value of Harned and Donelson,[3e] namely, $E^0 = 0.07131 - 4.99 \times 10^{-4}(t - 25) - 3.45 \times 10^{-6}(t - 25)^2$ has been chosen for the calculation of the standard potentials reported in this paper.

Experimental

The cell vessels were of a modified H type arranged so that solutions free from air (and saturated with nitrogen) could be used in them. There was a stopcock between the two electrodes. Measurements were made with the stopcock open, but it was kept closed at all other times.

Mercury was purified by spraying through a tower of diluted nitric acid, and washing with water. It was then distilled in a slow current of air, and redistilled *in vacuo*.

Mercurous bromide was prepared by precipitation from approximately 0.1 *N* solutions of potassium bromide and mercurous nitrate. Br^- was kept in excess. Especial care was taken that no chloride was present in the potassium bromide; it was prepared from a chlorate and chloride-free preparation of potassium bromate by decomposition with heat followed by three crystallizations from "conductivity" water. The mercurous nitrate solution was made up without the addition of nitric acid.[4] Preliminary experiments showed that constant and reproducible e. m. f. readings could be obtained with aged mercurous bromide. Preparations of the salt allowed to stand in the dark under water for at least one week after thorough rinsing gave e. m. f. readings which were constant within a few hours after the cells were made up. The thickness of the layer of mercurous bromide on the mercury in the electrode made no difference in the values obtained.

The silver–silver bromide electrodes were prepared according to the directions of Keston[3b] for the thermal type electrodes. In order to compare an electrolytic type electrode, several silver–silver bromide electrodes were prepared according to Carmody[5] for silver–silver chloride electrodes. Electrodes prepared by these two methods had potentials which differed by about 0.1 mv. on the average. The greatest variation observed was 0.4 mv.

Electromotive force measurements were made with a L. & N. type K potentiometer and either a type R or a type 2520-c L. & N. galvanometer. An Eppley unsaturated Weston cell certified by the manufacturers was the standard of e. m. f. The cells were kept in a water thermostat. Temperature control at 25° was within 0.04° and within 0.06° at 20 and 30°. The temperatures were determined by reference to a mercury in glass thermometer certified by the Bureau of Standards, and were known to be accurate to within 0.05°.

Cells were measured for not less than five days, and some were kept for over a month. Any cell which showed wide variations in e. m. f. after the first few days was discarded.

Concentrations of the electrolyte, KBr, varied from 0.02 to 0.15 molar. No differences in e. m. f. due to concentration of the bromide were observed.

Results

The Standard Potential.—The measurement of eleven cells containing silver–silver bromide electrodes prepared electrolytically gave a mean value of 0.06831 v. at 25°. The average error was 0.15 mv. The greatest deviation from the mean value amounted to 0.38 mv. for these cells. For the cells containing thermally prepared silver–silver bromide electrodes, the e. m. f. was 0.06839 v. at 25°. The average error and greatest individual deviation from the mean for these latter cells were 0.11 mv. and 0.18 mv., respectively. Table I summarizes the results obtained at 20, 25, and 30°.

TABLE I

THE VALUES OF THE E. M. F. OF CELL (2) AT VARIOUS TEMPERATURES

Temp., °C.	E. m. f., volts	Number of cells	Type of AgBr electrode
20	0.06630 ± 0.00014	5	Thermal
25	.06831 ± .00015	11	Electrolytic
25	.06839 ± .00011	9	Thermal
30	.07048 ± .00012	5	Thermal

(1) Gerke, *J. Phys. Chem.*, **31**, 886 (1927).

(2) Ishikawa and Ueda, *J. Chem. Soc. Japan*, **51**, 59 (1930).

(3) (a) Jones and Baeckstrom, THIS JOURNAL, **56**, 1524 (1934); (b) Keston, *ibid.*, **57**, 1671 (1935); (c) Harned, Keston and Donelson, *ibid.*, **58**, 989 (1936); (d) Owen and Foering, *ibid.*, **58**, 1575 (1936); (e) Harned and Donelson, *ibid.*, **59**, 1280 (1937).

(4) Kolthoff and Larson, *ibid.*, **56**, 1881 (1934).

(5) Carmody, *ibid.*, **54** 188 (1932).

The cells with thermal type silver–silver bromide electrodes gave better agreement among themselves than those containing electrolytically prepared electrodes. For this reason the calculations are based on the cells made with thermal silver bromide electrodes.

At 20, 25, and 30°, the standard potential of the mercury–mercurous bromide electrode has the values 0.14001, 0.13970, and 0.13921 v., respectively. These figures are obtained by adding the standard potentials of the silver–silver bromide electrode as reported at these temperatures by Harned and Donelson[3e] to the observed electromotive forces. These results may be expressed by the equation

$$E^0 = 0.13970 - 8.1 \times 10^{-5}(t - 25) - 3.6 \times 10^{-6}(t - 25)^2 \quad (3)$$

Values calculated by means of this equation agree with the experimental ones to less than 0.1 mv.

The value 0.1397 v. at 25° obtained in this study may be compared with 0.1396 v. reported by Gerke[1] and 0.1395 v. which may be calculated from the measurements of Ishikawa and Ueda[2] if one uses the activity coefficient for 0.1 molal hydrobromic acid given by Harned, Keston and Donelson.[3c] Latimer[6] gives 0.1397 v., based also on the measurement of Ishikawa and Ueda. It seems likely that a somewhat different activity coefficient may have been used by Latimer in this computation. In addition, there is the value 0.1385 v. given by Gerke in the "I. C. T."[7] This value apparently is based on Gerke's own measurement.[1] Finally, there are the values of the author[8] from measurements of cell (1) over a wide concentration range at 25°. When these results are recalculated using the activity coefficients of Harned, Keston and Donelson, one obtains 0.1389 v. as the standard potential at 25°.

Since the cells measured in this study were not as sensitive to oxygen or to light as are cells containing mercurous bromide in an acid solution, and in view of the agreement between the result obtained in this study and the value calculated from thermal measurements (see Latimer[6]), it seems reasonable that the most reliable value for the standard potential is 0.1397 v.

The Entropy of Mercurous Bromide.—From the value of the temperature coefficient of the standard electrode potential, which may be computed from eq. (3) by differentiation, one may calculate the standard entropy change for the reaction $2Hg + 2H^+ + 2Br^- \rightarrow Hg_2Br_2 + H_2$, using the familiar equation

$$\Delta S^0_{298} = nF(dE/dT) = 2 \times 23070 \times 0.000081 = 3.7 \text{ e. u.}$$

ΔS^0_{298} is also given by

$$\Delta S^0_{298} = S^0_{H_2} + S^0_{Hg_2Br_2} - 2S^0_{Hg} - 2S^0_{H^+} - 2S^0_{Br^-}$$

Using the values for the entropy of the substances involved which are given by Latimer,[6] the value of $S^0_{Hg_2Br_2}$ is found to be 48.9 e. u. at 25°.

To be compared with this is the value 52.8 given by Latimer. This value is based on the measurement of Ishikawa and Ueda[2] and on the thermal data of Kelley.[9] The temperature coefficients obtained in this study agree very well with those of Ishikawa and Ueda. Since Kelley also used the entropies of liquid mercury and of liquid bromine in computing the entropy of mercurous bromide, it is well to compare the entropy calculated on the basis of the reaction $2Ag + Hg_2Br_2 \rightarrow 2AgBr + 2Hg$ which is the cell reaction of cell (2). The e. m. f. of cell (2) is given by $E = 0.06839 + 0.000418(t - 25)$ over the range 20–30°. From this, the value of the temperature coefficient is 0.000418, giving for the standard entropy change of the reaction $2Ag + Hg_2Br_2 \rightarrow 2AgBr + 2Hg$, 19.3 e. u. If this value is combined with the entropies of AgBr, Hg, and Ag given by Latimer, one finds that the standard entropy of mercurous bromide is 48.5 e. u. This is in excellent agreement with the value calculated using the values given by Latimer for the entropy of Br^-, H_2, and Hg. This result would seem to indicate that the discrepancy may be due to the value of the entropy of liquid bromine used by Kelley.

Summary

1. The standard potential of the mercury–mercurous bromide electrode was determined by measurements of the cell Ag / AgBr, KBr, Hg_2Br_2 / Hg. The standard potential of the mercury–mercurous bromide electrode is 0.1397 v. at 25°.

2. From temperature coefficient measurements the standard entropy of mercurous bromide was computed. The standard entropy of solid mercurous bromide computed was 48.7 cal. deg.$^{-1}$ mole^{-1}.

A Study of Some Reactions between Dry Inorganic Salts. V. Reactions below the Fusion Point[1]

BY HAROLD L. LINK WITH LYMAN J. WOOD

It has been demonstrated[2] that when the sixty reciprocal pairs of the alkali halides were fused and the molten masses quenched the resultant mixtures contained, in almost every case, respectively, the heavy cation united with the heavy anion and the light cation united with the light anion. This pair of salts which has been called the stable pair might, for some purposes, be more conveniently called the pair of balanced mass. In only three cases was any evidence found for incomplete reaction of the reciprocal (unstable) pair when reacting to form the stable pair of balanced mass. When the chlorides, bromides and iodides of sodium, potassium, rubidium and cesium (reactions 1–18 of the series described above) were heated for long periods of time under the fusion point several stable pairs of balanced mass were found to be partially converted to the reciprocal pairs.[3] It was shown in this last paper that some of these reversals resulted in a chemical equilibrium which appeared to follow the mass law. Not much reaction was found to occur in the solid state unless the reaction temperature was within 100° of the fusion temperature.

The purpose of this paper is to report further studies on (1) the relationship between temperature and reaction in the solid state, (2) a study of the remaining 42 reactions of the alkali halide reactions (numbers 19 to 60), and (3) a further study of chemical equilibrium in the solid state.

Apparatus, Materials and Methods.—The salt mixtures were heated in the same furnace and in the same manner as previously described.[3] The X-ray apparatus used for analyzing the mixtures after heating was the one used by Thomas and Wood.[2] The lithium, sodium and potassium salts were Analytical Reagent quality. Rubidium and cesium chlorides, bromides and iodides were C. P. stock supplies from the Maywood Chemical Company. The fluorides of both rubidium and cesium were prepared by dissolving the respective carbonates in hydrofluoric acid. The pure salts were fused and kept over phosphorus pentoxide until needed. The lithium salts were fused in an atmosphere of carbon dioxide.

In order to study further the relationship between the extent of the reaction in the solid state at a given temperature and the melting range it was first necessary to determine the melting ranges for the various salt pairs. This was accomplished by heating the salt pairs in a small wire wound electric furnace and measuring the temperature with a thermocouple which had been calibrated by comparison with the melting points of ten pure chemicals which covered the range of temperatures involved in this investigation. No effort was made to obtain highly accurate results since such were not necessary. Approximately the same results were obtained regardless of whether the reciprocal or stable pair was heated.

Experimental Results

After the melting ranges of the first 18 reactions had been determined several salt pairs which were known to react with each other were heated for thirty-six hour periods at various temperatures. It was found in general that if the reaction temperature was more than 200° under the melting range very little reaction occurred while if the reaction temperature was within 100° of the melting range the extent of the reaction was quite considerable. Results obtained for reaction 4 (NaI–KCl) and reaction 7 (NaI–KBr) showed[3] that reaction in the solid state may be quite rapid if the reaction temperature is only a few degrees under the fusion temperature.

With these general rules in mind the remaining 42 reactions of this series (reactions 19–60 as numbered by Thomas and Wood[2]) were divided into 6 groups and heated for thirty-six hour periods at the various reaction temperatures described in Table I. In this way it was found possible to make most of the reaction temperatures within approximately 100° of the respective melting ranges. The difference was a little more than 100° for a few of the reactions heated at 550°. With the exception of cesium fluoride the accepted cube edges for the various alkali halides, with which the values in Table I are to be compared, have been listed in the above-mentioned papers[2,3] and are not repeated here. The accepted cube edge value for cesium fluoride is 6.008 Å. For convenience the reactions described in Table I have been divided into two groups, *viz.*, reactions 19–42 which include all

of the reaction mixtures containing lithium salts and reactions 43–60 which do not involve lithium salts. When the stable or balanced pairs of this last group of reactions were heated at the reaction temperatures indicated in Table I, no evidence for any reversal to the reciprocal pair was obtained. On the other hand, when the reciprocal pairs were heated all of them were converted partially or completely to the stable pairs. Evidence for incomplete reaction was obtained for reactions 45, 46, 49, 52, 53, 54, 55, 57, 58, 59 and 60. It was found possible to calculate the extent of the reaction for the reciprocal pairs of reactions 52 and 54 because of the formation of solid solutions. The cube edge of 6.493 Å. reported for reaction 52 corresponds to a solid solution of 26.5 mole per cent. potassium chloride and 73.5 mole per cent. rubidium chloride. The cube edge value of 6.816 Å. reported for reaction 54 corresponds to a solid solution of 15.2 mole per cent. potassium bromide and 84.8 mole per cent. rubidium bromide. The reciprocal pairs of reactions 43, 44, 47, 48, 50, 51 and 56 appeared to go to completion in the direction of the stable pairs. Only in the case of reaction 56 would solid solutions be expected to form if reaction were incomplete.[2,3] The X-ray diffraction patterns obtained corresponded to those of pure rubidium iodide and potassium fluoride and are to be taken as evidence that the reciprocal

pair has been completely converted to the stable pair. In the other cases the same conclusion is based on the absence of any diffraction patterns corresponding to the reciprocal pairs.

The 24 reactions numbered 19–42 are of considerable interest since all of the reaction mixtures contain lithium salts. In the studies above the fusion point it was found that the stable pair always contained the highest melting compound in the case of each reaction except the reaction mixtures containing lithium salts. In the case of the lithium reactions, only the stable pairs of reactions 21, 22, 25, 26, 29 and 30 contained the highest melting compounds. Referring to Table I it will be seen that no evidence was obtained for any reversal of the stable pairs of reactions 19–30. In six of these reactions the stable pair contains the highest melting compound and in six the reciprocal pair. The only common factor that has been discovered is that each stable pair contains lithium fluoride.

The reciprocal pairs of the other twelve reactions (31–42) all contain the highest melting compound and the stable pairs of most of the reactions showed some reversal to the reciprocal pair when heated at the temperatures indicated in Table I. No evidence of any reversal of stable pairs for reactions 32, 33, 34 and 40 was observed.

Reaction No. 11.—In a previous study[3] of reaction number 11 at 480° (under the fusion temperature) it was found that when either the reciprocal or stable pair was heated an equilibrium was formed as represented by the equation

$$CsCl + KBr \rightleftarrows CsBr + KCl$$

and that when the composition of the reacting mixture was changed the equilibrium shifted in accordance with the demands of the mass law. Further studies of this reaction have been made at 440, 400 and 360°. The observations, though not yet fully completed, indicate that the reaction proceeds to equilibrium at each temperature and that the composition of the equilibrium mixture changes with the composition of the reaction mixture in accordance with the demands of the mass law. Efforts to calculate ΔH for reaction 11 by means of van't Hoff's reaction isochor after the manner of Tubandt and Reinhold[4] when working with the solid reactions occurring between the pairs Ag_2S–CuI and Ag_2S–Cu_2Se gave values for ΔH of the correct sign but several times as large as was to be expected from the best available experimental values. A detailed description of these and other similar studies is being made the subject of a future report.

In Table II are to be found the results of solid solution studies made necessary by the investigation of reaction 11 described above. Table III shows in detail the X-ray diffraction data for a CsCl–CsBr solid solution formed at 360°. Other

similar data are summarized in Table II. Particular attention should be called to the results obtained from heating an equimolar mixture of potassium chloride, potassium bromide and cesium chloride (Table II). When potassium chloride and potassium bromide are heated together at 400° no solid solution results. However, when cesium chloride is heated with potassium chloride and potassium bromide at 400°, a solid solution of potassium chloride and potassium bromide results. The cube edge obtained for this solid solution indicates that only the potassium chloride formed by the interaction of the cesium chloride and potassium bromide dissolves in the residual potassium bromide. The cesium bromide in the CsCl–CsBr solid solution is less than when an equimolar mixture of cesium chloride and potassium bromide is heated and very nearly the same as when 2 moles of potassium chloride and 1 mole of cesium bromide are heated together (Table IV). Within the limits of experimental error, the extent of the reaction is, in each case, in agreement with the demands of the mass law.

Summary

Reactions occurring between the alkali halides in the solid state have been studied. Salt pairs corresponding to all sixty of the possible reactions have been heated for long periods of time below the fusion point and the resulting mixtures analyzed by the method of X-ray crystal analysis. The reaction mixtures of the forty-two reactions included in this report contained lithium salts or fluorides or both, the remaining eighteen reactions having been previously reported.[3]

1. Twelve of the reaction mixtures contained both lithium salts and fluorides. The highest melting component was contained in the stable pair in six cases and in the reciprocal pair in six cases. In each case lithium fluoride was a member of the stable pair. No evidence was found for the reversal of any of the stable pairs to the corresponding reciprocal pairs.

2. Twelve of the reaction mixtures contained lithium salts but no fluorides. The highest melting component was contained in the reciprocal pair in each case. Eight of these stable pairs showed some tendency toward reversal to the reciprocal pair and four did not.

3. Eighteen of the reaction mixtures contained fluorides but no lithium salts. The highest melting component was contained in the stable pair in each case and no evidence was obtained for the reversal of any of the stable pairs to the reciprocal.

4. Evidence for partial or complete conversion of the reciprocal to the stable pair was obtained for forty of the forty-two reactions.

5. It was found that in general there was very little reaction in the solid state if the reaction temperature was more than 200° below the melting range and that there was likely to be considerable reaction if the reaction temperature was within 100° of the melting range.

Carbon Suboxide in the Friedel–Crafts Reaction. I

BY JOHN H. BILLMAN,[1] GEORGE E. TRIPP AND R. VINCENT CASH

It was first shown by Hurd[2] that ketene would react with aromatic hydrocarbons or aromatic ethers in the presence of aluminum chloride to form primarily simple ketones according to the equation

$$C_6H_6 + H_2C{=}C{=}O \xrightarrow{AlCl_3} C_6H_5{-}\overset{\overset{O}{\|}}{C}{-}CH_3 \quad (1)$$

Since Hurd's discovery, several investigators[3] have studied ketene more extensively in an endeavor to increase the yield of the expected ketone or to identify the other products formed in some of the reactions. Recently Boese[4] has found that diketene also would react in a manner similar to ketene, for with benzene and aluminum chloride he was able to prepare benzoylacetone.

As the above ketenes are the only two ketenes that have been tried in a Friedel–Crafts reaction, we felt that it would be of value to extend this type of reaction using carbon suboxide as the ketene, for in carbon suboxide there is a duoketene structure which should offer double the possibility for reaction and thereby lead to the formation of an entirely different series of products than could be obtained from any other simple ketene.

If carbon suboxide should react with benzene in the presence of aluminum chloride exactly as does ketene, then one would expect to obtain dibenzoylmethane. However, if only one of the two ketene functional groups participated in the Friedel–Crafts reaction, then benzoylacetic acid, or acetophenone by decarboxylation of the latter, would be anticipated.

$$C_6H_6 + O{=}C{=}C{=}C{=}O \xrightarrow{AlCl_3} C_6H_5COCH_2COOH \quad (2)$$

$$C_6H_5COCH_2COOH \longrightarrow C_6H_5COCH_3 + CO_2 \quad (3)$$

Except for a large amount of polymerized carbon suboxide, the only product identified in the reaction after hydrolysis by dilute acids was acetophenone. This ketone must have come by way of benzoylacetic acid, which is known[5] to undergo decarboxylation in the presence of dilute acids, whereas dibenzoylmethane is stable in this medium.

Despite the fact that all of the runs were carried out at nearly ice temperature, polymerization of carbon suboxide could not be prevented. As it has been shown that in certain instances anhydrous stannic chloride causes less polymerization than aluminum chloride,[6] the former condensing agent also was used. However, no difference in the results could be observed.

Whereas previous workers have reported the liberation of hydrogen chloride during the condensation of ketenes with aromatic hydrocarbons, in the presence of aluminum chloride, we were unable to detect any of the gas. Only upon refluxing the mixtures was hydrogen chloride evolved.

Further work is being done in this Laboratory on carbon suboxide in the Friedel–Crafts reaction.

Experimental

Preparation of Carbon Suboxide.—The carbon suboxide used in our experiments was prepared by a method similar to that used by Hurd[7] in which diacetyltartaric anhydride was pyrolyzed by heating in an electric furnace to 625°. The gas, as it formed, was collected in a trap cooled to −78° by solid carbon dioxide and acetone. Before using the liquid carbon suboxide it was first distilled to free it from the dark colored impurities that also collected in the trap. The carbon suboxide, as it distilled over, was run directly into a calibrated receiver containing dry benzene cooled to approximately 4°. At the completion of the distillation, a measured volume of the benzene solution was removed and treated with an excess of aniline. From the amount of malonanilide formed, the amount of carbon suboxide in solution was determined.

Procedure.—Seven and five-tenths grams (0.12 mole) of carbon suboxide dissolved in 400 cc. of benzene, as prepared above, was added to 200 cc. of benzene and cooled to approximately 4°. Forty grams (0.27 mole) of aluminum chloride was then added slowly with vigorous stirring. A deep reddish-brown precipitate formed immediately. After all of the aluminum chloride had been added it was found that there was no noticeable odor of carbon suboxide in the reaction flask. The mixture was then refluxed, at which time large amounts of hydrogen chloride were evolved. Hydrolysis was accomplished by the addition of ice and water and the mixture allowed to stand over-

night. When hydrolysis was complete the mixture was worked up in the usual manner. A small amount of an oil with the odor of acetophenone was found after evaporation of the benzene layer. A similar product was obtained by steam distillation of the water layer. This oil solidified at approximately 19° and formed a semicarbazone melting at 195–196°, which corresponds to that of acetophenone. An authentic sample of the semicarbazone of acetophenone also melted at 195–196°; a mixed melting point evidenced no lowering of this value.

Summary

1. It has been shown that carbon suboxide will undergo a Friedel–Crafts reaction with benzene.
2. We conclude that benzoylacetic acid was formed as an intermediate in the reaction.
3. Acetophenone was isolated from the reaction mixture.

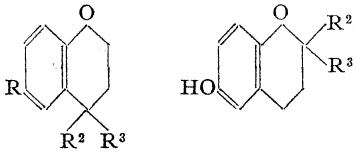
Polymethylbenzenes. XXV. The Reaction between Dimethylacrylic Acid and the Trimethylbenzenes[1]

BY LEE IRVIN SMITH AND WILLIAM W. PRICHARD[2]

The work described in this paper was begun as an attempt to synthesize some 4,4-disubstituted chromans (I) or hydrocoumarins (III) in which the 6-position was occupied by a hydrogen atom or hydroxyl group.



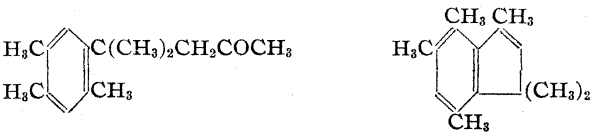
I, R = H or OH; R^2 and R^3 = alkyl

II

III

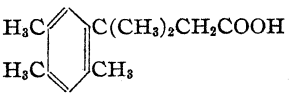
Such compounds were of interest because of their relationship to the tocopherols (vitamin E) which are analogous 2,2-dialkyl chromans, II. Very few examples of 4,4-disubstituted chromans are known,[3] and there is only a single example (III) of the synthesis of a 4,4-disubstituted hydrocoumarin.[4]

The difficulty in the synthesis of these substances appeared to be the introduction of the quaternary carbon atom,[5,6] hence attention was turned to methods for closing the chroman and hydrocoumarin rings after introduction of the quaternary carbon atom. The necessary intermediates, however, proved impossible to prepare. Appropriate alkylation of malonic ester failed because dimethyl - *o* - hydroxyphenylcarbinol[7,8] could not be converted to the chloride. Likewise unsuccessful were all attempts to obtain any crystalline products when mesityl oxide in the presence of aluminum chloride was condensed with any of a number of substituted phenols and hydroquinones or their ethers,[3a,9] and it appeared that the unsaturated ketone could be condensed successfully only with hydrocarbons.[7] It was known that β-[2,4,5-trimethylphenyl]-propionic acid could be converted into a quinone and then to a 6-hydroxyhydrocoumarin[10] and the analogous propionic acid, completely substituted in the β-position, should be accessible through the ketone IV resulting from the condensation of pseudocumene and mesityl oxide. The result of this condensation, however, was an indene V, although in view of the rearrangements described below the orientation of the methyl groups in the benzene ring of this compound is not certain.



IV

V



VI

The possibility remained that the condensation of pseudocumene with β,β-dimethylacrylic acid might lead to the acid VI, in which case the series of reactions could be carried out as planned. The product of this condensation was a mixture of

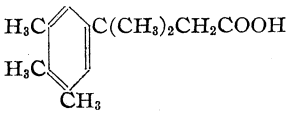
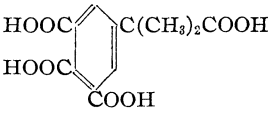
acids from which there was isolated 50–60% of a pure acid which melted at 111–112° and which had the composition required by formula VI.

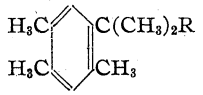
However, investigation of this acid soon showed that it could not be the substance VI, but must be an isomer having the structure VII. Oxidation to a known benzenetetracarboxylic acid failed because the quaternary carbon atom was resistant to oxidation,[11] and the oxidation product was an unknown tricarboxyphenylisobutyric acid, VIII. It was necessary, therefore, to use other methods in determining the orientation of the substituents, and as a first approach VI was synthesized from 5-acetopseudocumene by the method Hoffman[7] used in synthesizing β-phenylisovaleric acid.



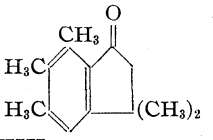
VII



VIII



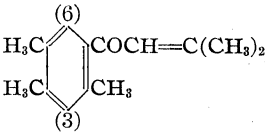
IX, R = OH
X, R = Cl
XI, R = $CH(COOC_2H_5)_2$
XII, R = $CH(COOH)_2$



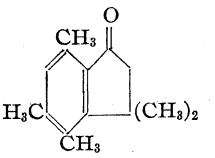
XIII
XIV, Oxime of XIII

Methylmagnesium iodide was added to 5-acetopseudocumene to give the carbinol IX; the ketone is enolized to the extent of 25% by the Grignard reagent[12] and consequently the product contained much of the starting material. Since the carbinol could not be crystallized, and the risk of dehydration precluded distillation, this product was subjected to the action of hydrochloric acid at 0° and the mixture containing the chloride X was used to alkylate sodium malonic ester. The product of this reaction was saponified and a malonic acid (XII) was isolated in 5–10% yield. This malonic acid melted with decomposition to give a monobasic acid VI isomeric with, but different from, the acid VII.

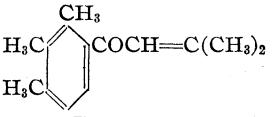
The acid VII, in contact with sulfuric acid, was readily converted to the hydrindone XIII, which gave an oxime XIV with ease. Since acetyl chloride condensed readily with pseudocumene in the 5-position, it seemed likely that any other acid chloride would attack the same position. Accordingly β,β-dimethylacrylic acid chloride was condensed with pseudocumene in the presence of aluminum chloride. The product XV was obtained in good yield, and shown to have this structure by oxidation to pyromellitic acid.



XV

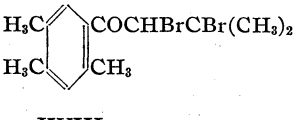


XVI

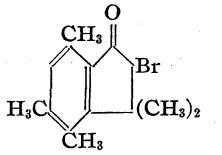


XVII

The ketone XV was then cyclized by aluminum chloride[13] to the hydrindone XVI, in quantitative yield. This hydrindone XVI was an *isomer* of XIII, and since the acyl group in XV was known to be in position 5, cyclization of XV must have involved position 6 in this compound. Consequently the condensation of pseudocumene with β,β-dimethylacrylic acid could not have involved the 6-position of the aromatic nucleus, for this would also have led ultimately to the indone XVI. Since the synthetic acid VI was different from VII, neither could this condensation have involved the 5-position. Condensation in the 3-position of pseudocumene would lead to an acid which could not be converted to a hydrindone. Hence it followed that VII could not be a derivative of pseudocumene; nor could it be a derivative of mesitylene, for the acid analogous to VI and VII, derived from mesitylene, likewise would not be convertible to a hydrindone. The only possibility remaining was that VII was a derivative of hemimellitene. The ketone XV gave a dibromide XVIII, identical with the product obtained by condensing α,β-dibromoisovaleryl chloride with pseudocumene. This dibromide XVIII was cyclized by aluminum chloride, giving the bromohydrindone XIX.



XVIII



XIX

Condensation of 1,2,3-trimethylbenzene with dimethylacrylic *acid chloride* under the same conditions used in the synthesis of XV, produced the ketone XVII. Oxidation of XVII gave benzene-1,2,3,4-tetracarboxylic acid, proving the orienta-

(11) Tiemann and Kruger, *Ber.*, **26**, 2685 (1893); Bogert and Applebaum, THIS JOURNAL, **60**, 930 (1938).

(13) Kohler, *Am. Chem. J.*, **42**, 376 (1909).

tion of the groups in the ketone. Cyclization of XVII with aluminum chloride gave the hydrindone XIII, identical with the product obtained by cyclizing VII. The structure of VII, therefore, must be β-[3,4,5-trimethylphenyl]-propionic acid. The only weakness in this argument is the fact that aluminum chloride was used in cyclizing the ketone XVII, and a rearrangement in this step was possible. Against this is the fact that the ketone XV gave an isomeric hydrindone on similar treatment and hence if rearrangement had occurred in either case both ketones should have given the same hydrindone, *i. e.*, the one stable in the presence of aluminum chloride. Moreover, the cyclizations gave pure hydrindones, while if rearrangement had occurred, a mixture would have been more likely.

As a further proof of the structure of VII, hemimellitene and β,β-dimethylacrylic *acid* were condensed under conditions identical with those used in the condensation of pseudocumene. The result was a single acid, obtained in almost quantitative yield, identical in every way with VII. Thus the interesting fact emerges that hemimellitene condenses with an acid chloride in the 4-position, while the product obtained by adding the hydrocarbon to the conjugated system in dimethylacrylic acid has the acid residue in the 5-position. These results are in agreement with those of Nightingale[14] and Perry[15] who found that *t*-butyl chloride condensed with *m*-xylene in the 5-position, while acetyl chloride condensed in the 4-position. The β-phenylisovaleric acids may be regarded as *t*-butyl derivatives, and hence they should behave toward aluminum chloride in a manner similar to that of the hydrocarbons themselves, and Nightingale, as well as Perry, have shown that 4-*t*-butyl-*m*-xylene rearranges readily in the presence of aluminum chloride to give 5-*t*-butyl-*m*-xylene. The formation of VII, a 1,2,3,5-tetrasubstituted benzene, in the presence of aluminum chloride is also in accord with experience obtained in methylating xylene and other hydrocarbons in the presence of aluminum chloride; in these reactions, little if any 1,2,3-trimethyl- and 1,2,3,4-tetramethyl-benzenes are formed.[16] With these facts in mind, it was of interest to subject the 1,2,4,5-acid VI (m. p. 77–79°) to the action of aluminum chloride. The product was a mixture having the same melting point range as that of the mixture of acids obtained by condensation of pseudocumene with β,β-dimethylacrylic acid; because of the small amount of material available, it was not possible to isolate the 1,2,3,5-acid VII from this mixture in an entirely pure state. However, the impure acid obtained in this way (m. p. 101–107°) when mixed with pure VII (m. p. 111–112°) melted at 104–108°. It was thus established that aluminum chloride would bring about rearrangement of acid VI, and that the product, if not quite entirely VII, contained a large proportion of it. While not strictly comparable to the rearrangement of VI, migrations of this type have been noted by v. Auwers in connection with his studies on the Fries rearrangement.[17] Thus the acetates of pseudocumenol-5 and -6, of mesitol and of hemimellitenol-4 all give 4-hydroxy-5-acetohemimellitene, the first three with rearrangement of the methyl groups, and the last with no such rearrangement.

It was not possible to determine all of the constituents of the mixture of acids obtained when pseudocumene was condensed with dimethylacrylic acid. Saponification of the lower boiling fractions of the ester made from the crude acid product gave a mixture of acids melting at 68–90°. It is likely that these are dimethylphenylisovaleric acids, since a part of the pseudocumene used was always converted into durene. Hence some xylenes must also have been formed, and as no xylenes could be obtained from the alkali-insoluble portion of the product, these must have condensed with the acrylic acid. Several crystallizations of the residue from which most of the acid VII had been removed gave an acid melting at 85–89°, but repeated crystallization failed to give a product with a sharper melting point.

p-Xylene condensed readily with dimethylacrylic acid to give a dimethylphenylisovaleric acid. If no migration of methyl groups occurred, this acid could have but one structure, that in which the methyl groups are in positions 2 and 5. But in view of the rearrangement of the butyl xylenes and of acid VI in the presence of aluminum chloride, this product may well be the 3,5-dimethyl compound. The orientation of the methyl groups in this compound was not established, but the acid was readily cyclized to a hydrindone.

Mesitylene also condensed with dimethylacrylic acid. The product was a mixture, from which a pure dimethylphenylisovaleric acid was isolated in poor yield. This acid likewise was readily cyclized to a hydrindone. It is interesting that acid VII, the acid from *p*-xylene and the acid from mesitylene all melt at about 110–112°, yet a mixture of any two of them exhibits a marked depression in melting point.

Experimental Part[18]

β-[3,4,5-Trimethylphenyl]-isovaleric Acid, VII.—Dimethylacrylic acid (10 g., 0.1 mole) was dissolved in pseudocumene (44 g., 0.36 mole). The solution was cooled (−10°) and stirred, and aluminum chloride (26.6 g., 0.2 mole) was added at such a rate that the temperature did not exceed −10°. The mixture became viscous and dark red, and there was a slight evolution of hydrochloric acid. Stirring at −10° was continued for two hours after all the catalyst was added; the mixture was then poured over a large amount of iced hydrochloric acid. The organic layer was removed and the aqueous layer was extracted three times with ether (30 cc. each time). These extracts were combined with the organic layer and were washed thoroughly with water and then were extracted with carbonate (10%) until the aqueous washings were strongly alkaline. The alkaline solution was warmed gently to remove dissolved ether and then was made strongly acid with hydrochloric acid. The oil which separated soon solidified; the crude acid so obtained weighed 20.8 g. and melted at 84–96°. Repeated recrystallization from dilute alcohol or dilute acetic acid gave a product melting at 111–112° (VII), but the losses were great and it was much better to esterify the crude product and fractionate the ester.

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.36; H, 9.09; n. e., 220. Found: C, 75.72, 76.79; H, 8.73, 8.96; n. e., 217.7, 217.9, 216.2.

The carbonate insoluble portion of the reaction mixture was fractionated under 11 mm. pressure. There resulted 26 g. of a liquid boiling at 52–53° (pseudocumene) and a residue (4 g.) of a white solid (durene, m. p. and mixed m. p., 76–78°).

Methyl Ester.—The crude acid VII (63.5 g., m. p. 99–102°) was refluxed for two hours in methanol (300 cc.) containing sulfuric acid (10 cc.). The reaction mixture was diluted with water (600 cc.). The ester layer was removed and the aqueous layer extracted three times with benzene (30 cc. each time). The combined organic layers were washed with water, then twice with carbonate (10%) and again with water. The benzene was removed under reduced pressure on the water-bath and the residual oil was fractionated under 4 mm. pressure through a 30-inch (76-cm.) Fenske column. The products were: A, 4.0 g., b. p. 111–118.5°; B, 8.7 g., b. p., 118.5–123°; C, 3.0 g., b. p. 124–129°; D, 41.5 g., b. p. 129–130°; E, 6.0 g., residue. Hydrolysis of fraction D gave crude acid VII, m. p. 103–107°. After two crystallizations from dilute alcohol, the acid weighed 28 g. and melted at 111–112°. A portion of this purified acid (10.4 g.) was re-esterified, giving 13.3 g. of methyl ester, practically all of which boiled at 130–130.5° under 6 mm. pressure.

Anal. Calcd. for $C_{15}H_{22}O_2$: C, 76.87; H, 9.16. Found: C, 76.92, H, 9.40.

Hydrolysis of fraction B (2 cc.) gave 2.0 g. of a crude acid which melted at 68–90°. Crystallization of this acid from dilute ethanol gave a product melting at 85–90°; several more crystallizations did not give a product with a higher melting point. A mixture of this acid and the pure acid VII melted at 79–87°.

Acid VII from Hemimellitene.—Dimethylacrylic acid (2.5 g.) and hemimellitene (6 g.) were condensed at −10° with aluminum chloride (6.65 g.) as described above. The crude product, isolated as described above, weighed 5.4 g. and melted at 106–107°; when mixed with the pure acid VII from pseudocumene, the substance melted at 109–110°. One crystallization of this product from dilute ethanol gave a product melting at 111–112°; it was not necessary to convert the acid made from hemimellitene into the ester in order to purify it, and from the yield and purity of the crude product, it is apparent that this condensation gives a single substance, VII.

3,4,5-Tricarboxyphenylisobutyric Acid, VIII.—The acid VII (1.0 g.) was refluxed with potassium permanganate (11.1 g.) in water (210 cc.) containing potassium hydroxide (20 cc., 20%) for eighteen hours. Ethanol was added to decolorize excess permanganate, the precipitated manganese dioxide was filtered off and the filtrate was concentrated to 20 cc. and made faintly acid with acetic acid. Barium chloride (saturated solution) was added to the hot solution until no more precipitate formed. The barium salt was removed and dissolved in hydrochloric acid (4 *N*, 8 cc.). The barium was precipitated with sulfuric acid (6 *N*), care being taken to avoid an excess of the acid. The barium sulfate was removed and the acid VIII was isolated from the filtrate. After crystallization from 6 *N* hydrochloric acid, the substance melted at 192–194°. It did not correspond in melting point with any of the known tri- or tetracarboxybenzenes. Repetition of the oxidation, refluxing for thirty hours, gave the same product.

Anal. Calcd. for $C_{13}H_{21}O_8$: C, 52.70; H, 4.02. Found: C, 52.78, 52.24, 52.99; H, 4.99, 5.27, 4.84.

A small amount of the acid was esterified with diazomethane in ether, but the methyl ester was an oil which could not be crystallized.

β-[2,4,5-Trimethylphenyl]-isovaleric Acid, VI.—5-Acetopseudocumene (16.2 g., 0.1 mole) was added to a solution of methylmagnesium iodide (magnesium 2.5 g., methyl iodide 16 g.) in ether (60 cc.) under nitrogen. The mixture was refluxed for an hour and then decomposed with iced ammonium chloride solution. The product was removed by several ether extractions and the ether solution was washed with water, then with dilute bicarbonate and again with water and dried over sodium sulfate. Removal of the ether under vacuum left a light yellow oil (18 g.) which could not be crystallized. It was a mixture of acetopseudocumene and the carbinol IX. This oil was dissolved in petroleum ether (20 cc., b. p. 38–40°) and the solution was saturated with dry hydrogen chloride at 0°; a layer of water separated. After standing for thirty minutes,

(18) Microanalyses by J. W. Opie, C. O. Guss and H. H. Hoehn.

the product was washed several times with water and dried over sodium sulfate. This solution of the chloride X was added to sodium malonic ester (ethyl malonate 16.5 g., sodium 2.3 g.) in dry ether (100 cc.) and the mixture was refluxed for two and one-half hours. The mixture was poured into water and the organic layer was removed and washed first with water, then with dilute hydrochloric acid, and again with water. The solvent was removed and the residual oil (XI) was refluxed for five hours with potassium hydroxide in methanol (75 cc., 30%). Water was added and the solution was extracted thoroughly with ether. The aqueous layer was then acidified; a yellow oil (1.3 g.) formed, which was removed, taken up in ether, and then extracted from the ether solution with dilute carbonate. Acidification of the carbonate regenerated the oil, which was again taken up in ether and dried over Drierite. Removal of the solvent left an oil which slowly crystallized. Recrystallization from dilute alcohol gave a white crystalline product melting at 143.5–148.5° with decomposition. This was the malonic acid XII. It was not analyzed, but was decarboxylated by heating it in a test-tube to 160°. The escaping gas was identified as carbon dioxide; the melt solidified on cooling. After crystallization from dilute ethanol, the product, VI, melted at 79–81°. A mixture with the acid VII (m. p. 111–112°), melted at 67–69°.

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.36; H, 9.09. Found: C, 76.39; H, 9.02.

Rearrangement of VI to VII.—The acid VI (0.085 g.) was dissolved in carbon disulfide (3 cc.) and aluminum chloride (0.10 g.) was added. A vigorous reaction occurred and a red oil precipitated. The mixture was refluxed for fifteen minutes, after which the solvent was removed. The residual oil was decomposed with dilute hydrochloric acid and the resulting white solid was extracted with ether (5 cc.). The ethereal solution was washed with water and then extracted with carbonate. Acidification of the carbonate solution produced a solid melting at 78–95°. After two crystallizations from dilute alcohol, the substance (VII) melted at 101–107°. A mixture of this and pure VII (m. p. 111–112°) melted at 104–108°; a mixture of this specimen of VII and the starting material VI melted at 65–69°.

3,3,5,6,7-Pentamethylhydrindone, XIII.—The acid VII (4.4 g.) was dissolved in concd. sulfuric acid (30 cc.) and allowed to stand for four hours at room temperature. The mixture was poured over cracked ice and the hydrindone (4 g., 99%, m. p., 100–101°) was removed and crystallized from dilute ethanol. It formed long white needles which melted at 103.5–104°.

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.16; H, 8.91. Found: C, 83.21; H, 8.70.

Oxime XIV.—The hydrindone XIII (3.82 g.) was dissolved in ethanol (50 cc.) and a solution of hydroxylamine hydrochloride (4.0 g.) and sodium acetate (8.0 g.) in water (10 cc.) was added. The mixture was refluxed for thirty minutes and then cooled. The solid (3.12 g., m. p. 179–185°) was removed and crystallized from dilute ethanol. It was white, and melted at 196–196.5°.

Anal. Calcd. for $C_{14}H_{19}ON$: C, 77.42; H, 8.75. Found: C, 76.08, 76.65; H, 8.51, 8.62.

Isopropylidene - 2,3,4 - trimethylacetophenone, XVII.—Hemimellitene (6 g., 0.05 mole) and dimethylacrylic acid chloride (5.0 g., 0.042 mole) were dissolved in carbon disulfide (15 cc.). Aluminum chloride (5.64 g., 0.042 mole) was slowly added to the rapidly stirred, cooled (−10°) solution. After nearly all of the catalyst had been added, a vigorous evolution of hydrogen chloride began. The reaction mixture was allowed to warm to room temperature (twelve minutes) and was then immediately poured over iced hydrochloric acid. The organic layer was removed and the aqueous layer was extracted three times with ether (10 cc. each time). The extracts were combined with the main organic layer and the whole was washed several times with water, then with dilute carbonate, and again with water. Solvent and unchanged hydrocarbon were removed by steam distillation (total distillate 100 cc.). The residue was extracted with ether and the extract was dried over Drierite. After removal of the solvent, the residual oil was distilled under reduced pressure (6 mm.) through a six-inch (16-cm.) column packed with glass helices. After a small forerun (0.8 g.) boiling at 136–138°, the bulk of the product (3.4 g.) came over at 138–139°.

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.16; H, 8.91. Found: C, 82.63; H, 8.90.

Oxidation of the ketone (1.0 g.) by permanganate (14.6 g. in 300 cc. of water) and alkali (20% KOH, 30 cc.) was accomplished by refluxing the mixture for six hours. The product was isolated through the barium salt as described above in the preparation of VIIIa from VIII. **Benzene-1,2,3,4-tetracarboxylic acid** was obtained but the specimen melted indefinitely about 170°. It accordingly was converted into the tetramethyl ester by action of diazomethane; after crystallization from dilute methanol, the ester melted at 130–130.5° alone or when mixed with an authentic specimen.

Hydrindone, XIII.—The ketone XVII (1 g.) was dissolved in carbon disulfide (5 cc.) and aluminum chloride (0.7 g.) was added. The solution was saturated in the cold with dry hydrogen chloride and then refluxed for forty minutes. The solvent was evaporated and the residual red oil was decomposed with iced hydrochloric acid. A white solid (0.90 g.) formed at once; it melted at 90–95°. Crystallized once from dilute ethanol, it separated in long white needles which melted at 103.5–104°, alone or when mixed with a specimen of XIII prepared from the acid VIII.

Isopropylidene - 2,4,5 - trimethylacetophenone, XV.—Pseudocumene (15 g., 0.10 mole) was condensed with dimethylacrylic acid chloride (10.5 g.) in carbon disulfide (25 cc.), using aluminum chloride (13.3 g.) in exactly the same manner described above for the preparation of XVII. The product (8.5 g.) isolated and purified in the same way, boiled at 131–131.5° under 6 mm. pressure.

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.16; H, 8.91. Found: C, 82.27; H, 9.12.

Oxidation of this ketone (1.0 g.) using the procedure described above for oxidation of XVII gave **pyromellitic acid** (0.4 g.) melting with decomposition at about 225°. Esterification of this acid by diazomethane gave the tetramethyl ester, m. p. 138–139°, alone or when mixed with an authentic specimen.

3,3,4,5,7-Pentamethylhydrindone, XVI.—The ketone XV (2 cc.) was cyclized with aluminum chloride (1.3 g.) in carbon disulfide (10 cc.) by the procedure used in cyclizing XVII. The hydrindone XVI, obtained in quantitative yield, crystallized in flat plates from dilute ethanol. It melted at 54–55.5°.

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.16; H, 8.91. Found: C, 83.37; H, 9.05.

2,4,5-Trimethyl-α,β-dibromoisovalerophenone, XVIII.—A solution of the ketone XV (1.0 g.) in dry ether (10 cc.) was brominated by liquid bromine (0.79 g.). The color was discharged instantly and no hydrogen bromide was evolved. Evaporation of the solvent left an oil which solidified rapidly. After crystallization from ethanol, the substance melted at 74–76°.

Dimethylacrylic acid (15 g.) in carbon disulfide (25 cc.) was brominated with liquid bromine (7.7 cc.) at 0°. The solvent was pumped off and the solid residue was suspended in benzene (25 cc.). Phosphorus pentachloride (31.2 g.) was added slowly to the cooled (0°) solution. The acid gradually dissolved, and after solution was complete the volatile materials were pumped off and the residue was distilled. The acid chloride (27 g., 66%) boiled at 77–82° under 5 mm. pressure; there was some decomposition during the distillation. The acid chloride was dissolved in pseudocumene (16.5 g., 0.11 mole) and carbon disulfide (25 cc.). The solution was cooled to −10° and aluminum chloride (14.6 g., 0.11 mole) was added with stirring. As soon as all of the aluminum chloride was added, the reaction mixture was poured into iced hydrochloric acid.

The solvent was removed by steam distillation and the residue was extracted with ether. Removal of the ether left an oil which solidified. This solid (XVIII), crystallized from ethanol, melted at 74–76° and was identical with the product obtained by brominating the ketone XV. The yield was 12 g. (33%); a large amount of a greenish oily by-product was also formed.

Anal. Calcd. for $C_{14}H_{18}OBr_2$: C, 46.42; H, 4.97. Found: C, 46.41; H, 5.09.

2-Bromo-3,3,4,5,7-pentamethylhydrindone, XIX.—The dibromo ketone (0.5 g.) was mixed with aluminum chloride (1.0 g.) in a test-tube and the mixture was warmed to 50°. A vigorous reaction occurred, with evolution of hydrogen bromide. The melt was decomposed with ice and the solid product was removed and crystallized from ethanol. It melted at 102–104°.

Anal. Calcd. for $C_{14}H_{17}OBr$: C, 59.79; H, 6.05. Found: C, 59.75; H, 6.52.

β-[2,5-Dimethylphenyl]-isovaleric Acid.—Dimethylacrylic acid (5.0 g.) dissolved in *p*-xylene (8.0 g.) was added slowly with stirring to a cooled (0°) solution of aluminum chloride (16 g.) in *p*-xylene (12 g.). After stirring for one and one-half hours at 0°, the mixture was poured into iced hydrochloric acid. The product, isolated and purified as described for other similar condensations above, weighed 4.12 g. and melted, after crystallization from dilute acetic acid, at 93–100°. After two crystallizations from dilute ethanol, the product melted at 108–110°. Analysis showed that this substance was a dimethylphenylisovaleric acid, but the orientation of the methyl groups in the benzene ring is not certain.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.72; H, 8.71; n. e., 206. Found: C, 75.50; H, 8.60; n. e., 205.7.

3,3,4,7-Tetramethylhydrindone.—The above acid (1.0 g.) was allowed to stand in sulfuric acid (20 cc.) for one hour. The mixture was poured onto ice and the solid was removed and crystallized from dilute ethanol. It melted at 52–53°. The position of the methyl groups in the benzene ring is not certain.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.99; H, 8.52. Found: C, 82.73; H, 8.79.

Condensation of Mesitylene with Dimethylacrylic Acid.—The hydrocarbon (31.5 g.) was condensed with the acid at 0° by adding aluminum chloride and the product was isolated as described above in similar experiments. A small yield (3.0 g.) of solid resulted. This solid was crystallized successively from dilute methanol, petroleum ether (b. p. 28–35°), dilute ethanol (twice) and dilute acetic acid. It then melted at 110–111°. Although it was a dimethylphenylisovaleric acid, it was not identical with the product (m. p. 108–110°) obtained in a similar manner from *p*-xylene; a mixture of the two substances melted at 85–90°.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.72; H, 8.71. Found: C, 75.53; H, 8.90.

When this acid (0.10 g.) was cyclized with sulfuric acid in the usual way, the product was a **tetramethyl hydrindone** melting at 62–63° which likewise was different from the product similarly derived from *p*-xylene.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.99; H, 8.52. Found: C, 82.16; H, 8.65.

1,1,3,4,5,7-Hexamethylindene, V.—Pseudocumene (12 g., 0.1 mole) was cooled to 0° and aluminum chloride (15 g., 0.11 mole) was slowly added. To this mixture at 10°, mesityl oxide (8 g., 0.08 mole) was added slowly. The aluminum chloride gradually dissolved to give a cherry-red solution which was allowed to stand at room temperature for three hours. It was decomposed by iced hydrochloric acid, the organic layer was separated and the aqueous layer was extracted with ether. The organic layers were combined, washed first with water and then with carbonate, and dried over calcium chloride. The solvent was removed and the residue was distilled under 11 mm. pressure. Pseudocumene and mesityl oxide (12 g.) came over at 42–50°; the boiling point then rose to 145–146° and 4 g. of distillate which solidified at once was collected. When crystallized from ethanol, this material melted at 87.5–88.5°. No carbonyl derivatives could be obtained, nor could any acid be isolated when the substance was oxidized with hypobromite. The product instantly decolorized bromine in carbon tetrachloride, with evolution of hydrogen bromide.

Anal. Calcd. for $C_{15}H_{20}$: C, 90.00; H, 10.00. Found: C, 90.08; H, 10.40.

Phenol and Mesityl Oxide.—The ketone (9.9 g.) and phenol (9.4 g.) were mixed and concd. sulfuric acid (10 cc.) was added slowly at 0°. The light red solution stood at room temperature for six days and was then poured into ice. The viscous product was triturated with water and then taken up in 20% potassium hydroxide. The alkaline solution was extracted with ether, and then saturated with carbon dioxide. A yellow amorphous solid precipi-

tated. This solid could not be crystallized from any of a number of solvents tried; the usual result was a brown sirup. A portion of this sirup was subjected to high vacuum distillation. It started to evolve gas at about 78° and at 100° a sublimate slowly formed. This sublimate resembled shellac, and it could not be crystallized. Repetition of the experiment, using acetic acid as a diluent and a temperature of 85° for one hour, gave the same results.

Pseudocumenol-6 and Mesityl Oxide.—The same treatment converted the mixture of these substances into a brown oil, soluble in potassium hydroxide. Carbon dioxide precipitated from the alkaline solution a tan solid containing some unchanged phenol. This solid, after repeated precipitation from dilute alcohol and dilute acetic acid, melted at 63–70° but it was not crystalline and it could not be purified further.

***p*-Bromophenol and mesityl oxide** likewise gave only amorphous products.

Hydroquinone Dimethyl Ether and Mesityl Oxide.—The ether (6.9 g.) and the ketone (4.95 g.) were dissolved in carbon disulfide (50 cc.) and aluminum chloride (20 g.) was added. After refluxing for one hour, the mixture was decomposed with iced hydrochloric acid. No alkali-soluble product was obtained and 85% of the ether was recovered.

***p*-Chlorophenol** (3.4 g.) and **mesityl oxide** (2.97 g.) were similarly treated with aluminum chloride (4 g.) at 100° for three hours. The product was separated into alkali-soluble and -insoluble parts but nothing but starting materials could be isolated from these.

***p*-Chloroanisole** (4.26 g.) and **mesityl oxide** (2.97 g.) were mixed in nitrobenzene (15 cc.) and heated for two and one-half hours at 100° with aluminum chloride (4.0 g.). Distillation of the steam volatile part of the product showed nothing but the starting materials to be present.

***o*-Hydroxyphenyldimethylcarbinol.**—Methylmagnesium iodide (0.194 mole) was prepared in the usual manner. Methyl salicylate (9.8 g., 0.0645 mole) in ether (40 cc.) was added to the Grignard solution. The mixture was allowed to stand overnight and was then worked up in the usual manner, every precaution being taken to prevent dehydration of the product. The carbinol was obtained in 64% yield; after crystallization from petroleum ether, it melted at 43–44°.

The carbinol (8.85 g.) was dissolved in benzene and a little Drierite was added. The mixture was saturated with dry hydrogen chloride. A layer of water formed. The benzene layer was removed and washed repeatedly with water. Removal of the solvent under reduced pressure left an oil which solidified on standing. This solid (m. p. 95–96°) did not contain halogen, gave a very weak Folin phenol test, and rapidly decolorized bromine in carbon tetrachloride. An orange-yellow color was produced with sulfuric acid. The solid was insoluble in aqueous potassium hydroxide, hot or cold.

Summary

1. In the presence of aluminum chloride, the condensation of pseudocumene with dimethylacrylic acid is accompanied by a rearrangement of the alkyl groups. The product does not have the substituents in positions 1, 2, 4 and 5 (VI) but is β-[3,4,5-trimethylphenyl]-isovaleric acid, VII.

2. Pseudocumene condenses normally with dimethylacrylic acid chloride in the presence of aluminum chloride, the acyl group entering the 5-position.

3. Hemimellitene condenses with dimethylacrylic acid to give the isovaleric acid VII in 95% yield, condensing in the 5-position.

4. Hemimellitene condenses with dimethylacrylic acid chloride, however, in the 4-position.

5. These ketones and acids were converted to hydrindones, and the relationship existing between the different hydrindones thus obtained is discussed.

6. β-[2,4,5-Trimethylphenyl]-isovaleric acid (VI) was synthesized and found to rearrange to the 3,4,5-trimethylphenyl compound in the presence of aluminum chloride.

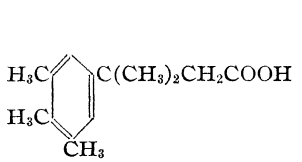
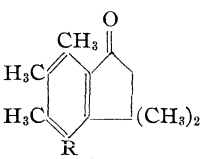
3,3,5,6,7-Pentamethylhydrindone and 4,4,5,6,8-Pentamethylhydrocarbostyril

BY LEE IRVIN SMITH AND WILLIAM W. PRICHARD[1]

In the preceding paper[2] there were outlined the general lines of attack by means of which 4,4-dialkyl-6-hydroxychromans might be prepared. The reactions chosen for this purpose failed to produce the proper intermediates, because when

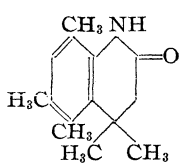


I

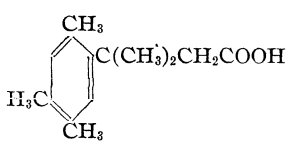


II, R = H
III, Oxime of II
V, R = NO_2
VI, R = NH_2
VII, R = OH
VIII, Oxime of VII

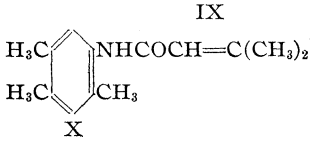
pseudocumene was condensed with dimethylacrylic acid, rearrangement occurred and a derivative of hemimellitene (I) resulted. In the early stages of this work it was discovered that the acid I could be converted readily into a hydrindone.



IV



IX



X

Although not convertible to a 6-hydroxychroman, this hydrindone II was studied in some detail, and for comparison, the hydrocarbostyril IV, although likewise not convertible to a 6-hydroxychroman, was synthesized.

The hydrindone II gave a good yield of the oxime III, but this oxime gave very unsatisfactory results when attempts were made to carry out a Beckmann rearrangement. Frequently a small amount of solid product was obtained, but this product was a mixture from which, in no case, could any pure substance be isolated. These results were surprising in view of the fact that the unsubstituted hydrindone oxime can be rearranged to a hydrocarbostyril (although in poor yield) by refluxing it in ether with phosphorus pentachloride,[3] while fluorenone oxime gives a 90% yield of product when rearranged with phosphorus pentachloride in phosphorus oxychloride.[4]

Since no pure product could be obtained by rearrangement of the oxime III, it was decided to introduce the hydroxyl group into the hydrindone II and then attempt the Beckmann rearrangement of the phenolic oxime VIII. The hydrindone was readily nitrated to a mono nitro compound V which was reduced to the amino hydrindone VI. Replacement of the amino group by hydroxyl was accomplished by diazotization in the usual way. The phenolic hydrindone VII formed an oxime VIII, but this oxime could not be rearranged to a crystallizable product, either by the method of Kipping[3] or by that of Huntress.[4]

In order to examine the properties of the hydrocarbostyrils which should result from the rearrangement of hydrindone oximes, the hydrocarbostyril IV was synthesized from pseudocumidine-5 via the trimethyl anilide of dimethylacrylic acid (X). It was hoped also that this hydrocarbostyril IV could be converted into the phenylisovaleric acid IX which would also have been the product had the condensation of dimethylacrylic acid with pseudocumene involved the 6-position of the hydrocarbon. The amide X was readily prepared, and in the presence of aluminum chloride this amide was converted into an excellent yield of the hydrocarbostyril IV. This reaction is of interest, since Mayer, van Zütphen and Phillips[5] found that the N-methylanilide of acrylic acid did not give the corresponding hydrocarbostyril with aluminum chloride while several substituted anilides of β-chloropropionic and β-chlorobutyric acids gave excellent yields of hydrocarbostyrils. These authors concluded therefore that the ring closure occurred by loss of hydrogen chloride from the β-chloroanilides and that the α,β-unsaturated anilide was not involved. The easy cyclization of the unsaturated amide X apparently refutes this argument, but it is of course possible that cycliza-

tion of X by aluminum chloride is preceded by the addition of hydrogen chloride to the double bond.

Mayer, Phillips, Ruppert and Schmitt[6] succeeded in opening the heterocyclic ring of their hydrocarbostyrils by action of aqueous barium hydroxide at 150°. In this Laboratory, Mayer's method had been used with success in an analogous situation[7] but all attempts to open the ring of the hydrocarbostyril IV failed and it appears that when the anilides of α,β-unsaturated acids have two substituents in the β-position, ring closure to the hydrocarbostyril is particularly easy and the heterocyclic compound, once formed, is particularly stable.

Experimental Part[8]

3,3,5,6,7-Pentamethylhydrindone, II, and its Oxime, III.—Preparation of these substances is described in the previous paper.[2]

Beckmann Rearrangement of Oxime III.—The oxime (0.34 g.) was dissolved in a mixture of phosphorus pentachloride (1.0 g.) and phosphorus oxychloride (5.0 g.). A vigorous reaction occurred, accompanied by evolution of hydrogen chloride. The mixture was refluxed for twenty minutes and then poured over ice. The product, a sticky brown material, was taken up in chloroform. Removal of the solvent left a brown gum, whose solution in dilute ethanol deposited a small amount of a somewhat gummy solid melting at about 85°. This substance could not be purified further. Repetitions of the experiment always gave products of the same gummy nature; on one occasion a small amount of crystalline product melting at 150–170° was obtained. This was a mixture which could not be separated.

3,3,5,6,7-Pentamethyl-4-nitrohydrindone, V.—The hydrindone II (3.0 g.) was dissolved in chloroform (20 cc.) and the solution was cooled (−5°) and stirred with sulfuric acid (50 cc.) while a solution of sodium nitrate (1.3 g.) in sulfuric acid (10 cc.) was slowly added. The solution was cooled and stirred for ten minutes longer and then poured on ice. The chloroform layer was removed and the acid layer was extracted thoroughly with chloroform. The combined chloroform solutions were washed with water, dilute carbonate and again with water. The solvent was removed at about 50° under reduced pressure, and the residual oil was crystallized from dilute methanol. The nitrohydrindone (1.14 g.) melted at 94–94.5°; the mother liquor, when concentrated, deposited a second crop (0.4 g.) melting at 92–93°. The remainder of the product was a red oil.

Anal. Calcd. for $C_{14}H_{17}O_3N$: C, 68.01; H, 6.88. Found: C, 68.74; H, 6.98.

3,3,5,6,7-Pentamethyl-4-aminohydrindone, VI.—The nitrohydrindone V (1.10 g.) was dissolved in acetic acid (10 cc., 60%) and the solution was warmed with zinc (20 mesh, 1.0 g.) for ten minutes after the initial vigorous reaction subsided. Dilution of the solution with ice precipitated the amine (0.90 g.) as a white solid which melted sharply at 81–82°. Two crystallizations from dilute methanol gave a product melting at 101–102°. Investigation showed that this compound had two melting points. A fairly large crystal of the substance was powdered and packed into two melting point capillary tubes. One of these was placed in a bath the temperature of which was raised at a moderate rate. This specimen was completely liquefied at 84°; it then re-solidified and melted again sharply at 101–102°. The other tube was placed in the bath at 70° and the temperature was raised very slowly. There was no evidence of softening until a temperature of 100° was reached; the sample then melted sharply at 101–102°. A similar dimorphism was shown by some of the other compounds in the series.

Anal. Calcd. for $C_{14}H_{19}ON$: C, 77.42; H, 8.76. Found: C, 75.74; H, 8.89.

3,3,5,6,7-Pentamethyl-4-hydroxyhydrindone, VII.—The amino compound VI (0.46 g.) was dissolved in sulfuric acid (10%, 10 cc.) by warming. The solution was cooled to 0°, and to the resulting suspension there was slowly added a solution of sodium nitrite (0.15 g.) in water (2 cc.). The mixture was allowed to stand for thirty minutes. Copper sulfate (saturated solution, 5 cc.) and sulfuric acid (1 cc.) were added and the mixture was refluxed for twenty minutes. Nitrogen was evolved and a white solid (0.40 g.) separated. This was removed and crystallized from dilute methanol. The substance melted at 183–185° and was completely soluble in cold Claisen alkali.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.07; H, 8.26. Found: C, 77.02; H, 8.60.

Oxime, VIII.—The oxime was prepared from the hydrindone in dilute methanol in the usual way with hydroxylamine hydrochloride and sodium acetate. After crystallization from dilute methanol, it melted at 183–185° to a dark liquid. When mixed with the hydrindone VII (m. p. 183–185°) the substance melted at 165–170°.

Anal. Calcd. for $C_{14}H_{19}O_2N$: C, 72.10; H, 8.15. Found: C, 71.70; H, 8.90.

The oxime (0.1 g.) in ether (5 cc.) was refluxed with phosphorus pentachloride (0.5 g.) for four hours. The ether solution was washed with water and dilute carbonate and dried over Drierite. Removal of the solvent left a yellow oil containing chlorine. The oxime (0.15 g.) in phosphorus oxychloride (3 cc.) was refluxed with phosphorus pentachloride (0.5 g.) for one hour. Addition of water slowly precipitated an amorphous solid which could not be crystallized from dilute alcohol, although the expected hydrocarbostyril (synthesized in another way; see next paper) crystallized readily from this solvent.

2,4,5-Trimethyl Anilide of Dimethylacrylic Acid, X.—Pseudocumidine-5 (11.1 g.) was dissolved in benzene (50 cc.) and a solution of dimethylacrylic acid chloride (4.85 g.) in benzene (15 cc.) was slowly added. The amine hydrochloride precipitated at once. The mixture was refluxed for thirty minutes and the suspended solid was filtered off. The benzene filtrate was extracted several

times with dilute hydrochloric acid, washed with water and then concentrated to about 40 cc. On cooling, a solid was deposited. Petroleum ether (100 cc., b. p. 28–35°) was added and the solid was filtered off. It weighed 7.1 g. (80%) and melted at 107.5–108°.

Anal. Calcd. for $C_{14}H_{19}ON$: C, 77.42; H, 8.76. Found: C, 76.90; H, 9.08.

4,4,5,6,8-Pentamethylhydrocarbostyril, IV.—The anilide X (3.0 g.) was mixed with aluminum chloride and the dry mixture was warmed on the water-bath for twenty-five minutes. Ice was added, and the nearly white solid (2.9 g.) which separated was removed. It melted at 207–209°. Crystallization from ethanol gave a slightly yellow product which melted at 209–210°.

Anal. Calcd. for $C_{14}H_{19}ON$: C, 77.42; H, 8.76. Found: C, 77.18; H, 9.09.

One gram portions of the hydrocarbostyril were heated to 150, 200 and 250° for fifteen, ten and eight hours, respectively, in a bomb with barium hydroxide (3.0 g.) and water (15 cc.). In each case the starting material was recovered unchanged, and the alkaline solution contained no organic matter.

Summary

1. This paper contains a description of the conversion of 3,3,5,6,7-pentamethylhydrindone II to 3,3,5,6,7-pentamethyl-4-hydroxyhydrindone VII via the nitro compound and the amine.

2. Neither the oxime of II, nor that of VII, could be made to undergo a Beckmann rearrangement.

3. The 5-pseudocumidide of dimethylacrylic acid, X, is converted smoothly to 4,4,5,6,8-pentamethylhydrocarbostyril IV by action of aluminum chloride. The heterocyclic ring in IV is extremely stable; it is not opened by treatment with barium hydroxide at 250°.

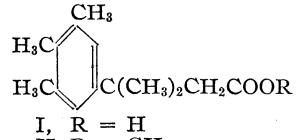
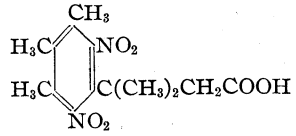
The Nitration of β-[3,4,5-Trimethylphenyl]-isovaleric Acid and its Methyl Ester I. Formation of 4,4,6,7,8-Pentamethyl-5-nitrohydrocoumarin

BY LEE IRVIN SMITH AND WILLIAM W. PRICHARD[1]

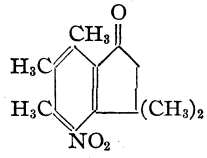
In the preceding papers[2] it was established that condensation of dimethylacrylic acid with pseudocumene was accompanied by rearrangement of the methyl groups and that the resulting β-[trimethylphenyl]-isovaleric acid had structure I, with the methyl groups in positions 3, 4 and 5.



I, R = H
II, R = CH_3



III



IV

The acid I, obtained in good yield, offered a suitable material for model researches on the conversion of such β-phenylisovaleric acids into 4,4-dimethylhydrocoumarins. Accordingly it was planned to carry out this transformation by the series of reactions already used for this purpose[3] which involved reduction of the nitro compound to the amine or hydrocarbostyril, and conversion of the latter to the hydrocoumarin by the method of Mayer, Phillips, Ruppert and Schmitt.[4]

Astonishingly, nitration of the acid I by the method of Smith and Denyes[3] produced neither the dinitro compound III nor the known nitrohydrindone IV[2b] but the nitrohydrocoumarin V, $C_{14}H_{17}O_4N$, melting at 152.5–153°. The yield of this substance was very poor, but when the methyl ester II was nitrated by a solution of sodium nitrate in sulfuric acid there resulted in almost quantitative yield a mixture of two substances, one of which was the compound $C_{14}H_{17}O_4N$, m. p. 152.5–153°. These two nitration products crystallized well, but their solubilities were so nearly identical that the separation was very difficult and was effected only after repeated crystallization supplemented by manual separation of the two types of crystals. The nitrohydrocoumarin V was neutral, but dissolved in strong alkali after continued boiling, giving a bright cherry-red solution, and it was precipitated unchanged when this alkaline solution was satu-

rated with carbon dioxide. Reduction of V produced an amine VI which dissolved readily in hot dilute mineral acids, and which crystallized as the hydrochloride or sulfate when the solutions were cooled. The amine VI also dissolved readily in strong alkalies, but it could not be recovered from these solutions. When the solution of VI in alkali was saturated with carbon dioxide, there resulted an isomer of VI, the hydroxyhydrocarbostyril VII. The hydroxyhydrocarbostyril VII was soluble in alkali and was precipitated unchanged when the solution was acidified; it was insoluble in dilute acids, however, and formed no salts with them, but it could be converted into a monoacetyl derivative, VIII. While the amine VI was readily diazotized and coupled with naphthols to give colored azo compounds, the hydrocarbostyril VII could not be diazotized. This hydroxyhydrocarbostyril is the one which should result from a Beckmann rearrangement of the oxime of 4-hydroxy-3,3,5,6,7-pentamethylhydrindone[2b] but unfortunately no crystalline material could be obtained from the rearrangement product of this oxime.

The diazonium salt from the amine VI reacted with potassium iodide to give the iodo compound IX which slowly dissolved in boiling alkali to give a red solution. This solution contained ionic iodine, but acidification gave no pure products. When the diazonium sulfate derived from VI was refluxed with a little copper sulfate, there resulted the hydroxyhydrocoumarin X. This substance dissolved readily in alkali and was recovered unchanged when the solution was acidified. Various attempts to convert X into a dimethoxy methyl ester by action of methyl sulfate and alkali invariably gave the monomethyl ether XI and no product resulting from opening of the hydrocoumarin ring could be obtained. However, this ether XI slowly dissolved in boiling alkali, indicating either that the ring had opened under these condition, or else enolization of the carbonyl group had occurred. No benzoyl derivative resulted when the alkaline solution of XI was shaken with benzoyl chloride, nor was it possible, by any means tried, to recover anything from the alkaline solutions except the ether XI.

Previous work on some similar hydrocoumarins without the two methyl groups in the 4-position[5] has indicated that it is extremely difficult to open the rings in these compounds; introduction of the two methyl groups in position 4 adjacent to the benzene ring apparently results in rings of even greater stability. Solubility of many of these compounds in alkali indicates that although salts of open chain derivatives may be formed in alkaline solutions, these revert at once to the cyclic compounds as soon as the strong alkali is removed, even when the alkaline solutions are shaken with methyl sulfate. The easy conversion of the amino hydrocoumarin VI into the hydroxyhydrocarbostyril VII must involve at least a momentary opening of the hydrocoumarin ring, although the reverse transformation, from VII to VI, cannot be brought about even partly. No compounds analogous to open chain derivatives of VI, VII or X are known with certainty. Niederl,[6] who condensed mesityl oxide with phenol, oxidized the product and described the resulting substance as β-[*o*-hydroxyphenyl]-isovaleric acid, but he gave no properties nor analysis of his compound, and consequently exact information is lacking. John, Günther and Schmeil,[7] who prepared 4,4,5,7,8-pentamethyl-6-hydroxyhydrocoumarin, did not give any discussion of the properties of this compound nor were any derivatives of it cited which resulted from reactions in which the ring was opened.

The surprising formation of the hydrocoumarin V by nitration of the acid I or its ester II and which involves the equivalent of hydroxylation at position 6, finds a parallel in a reaction discovered in connection with α-tocopherol, a 2,2-dialkyl-6-hydroxychroman (XII). When α-tocopherol is subjected to the action of any of a number of mild oxidizing agents, the first products formed are yellow *p*-quinones, such as XIII.[8] When, however, certain silver salts, notably silver nitrate, are used and the action is prolonged, oxidation proceeds beyond the yellow stage and

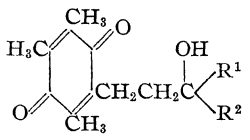
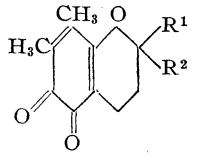
XII



XIII



XIV

brilliant red solutions result.[8,9] These red solutions also result when nitric acid in ethanol is used as the oxidizing agent.[8b,10] Crystalline red compounds have been isolated as nitric acid oxidation products of simple model substances having structure XII, and it has been shown that these red substances are *o*-quinone derivatives such as XIV.[11] The transformation of XII into XIV thus involves the equivalent of hydroxylation of the ring by nitric acid or a silver salt and it is comparable to the transformation of the acid I into the nitrohydrocoumarin V. There are considerable differences between the two cases, however. Formation of orthoquinones from coumaran and chroman compounds results only when the hydroxyl group para to the bridge oxygen is present; it takes place via the yellow *p*-quinone intermediate and is accompanied by elimination of the group adjacent to the carbon junction of the two rings. Moreover, 6-hydroxyhydrocoumarins do not give the reaction.[11] In the transformation of I into V, no group is eliminated, the reaction is accompanied by nitration, and the position para to the bridge oxygen is blocked by a methyl group. Whether or not the two series of reactions have a common mechanism remains to be decided.

As stated above, nitration of the ester II gave two products, one of which was V. The other product, melting at 125–125.5°, was a substance having the composition $C_{15}H_{20}O_6N_2$. This composition corresponds to that of the methyl ester of III; but the properties of the substance indicate quite clearly either that it does not have this structure, or, if it does, that the methyl ester of III is a most remarkable substance. Reduction of this substance results in the loss of two carbon atoms and most of the oxygen, giving a compound $C_{13}H_{20}ON_2$. The structure and properties of this second nitration product are still under investigation and the results will form the subject of a later paper.

Experimental Part[12]

β-[3,4,5,-Trimethylphenyl]-isovaleric Acid, I, and its Methyl Ester, II.—The preparations of I, m. p. 111–112°, and of II, b. p., 130–130.5° under 6 mm., are described in a previous paper.[2a]

4,4,6,7,8-Pentamethyl-5-nitrohydrocoumarin, V. A. By Nitration of the Ester II.—The ester (10.41 g., 0.045 mole) was dissolved in chloroform (30 cc.) and stirred with sulfuric acid (60 cc.) at −15°. A solution of potassium nitrate (10 g., 0.098 mole) in sulfuric acid (20 cc.) was added slowly (one hour and fifteen minutes). After 18 cc. of the nitrating mixture had been added, the dark red color of the mixture faded to light yellow. The cooling bath was removed and the mixture was allowed to warm to 5°. Ice was added, the chloroform layer was separated and the aqueous layer was extracted three times with chloroform (20 cc. each time). The combined chloroform solutions were washed with water, 10% carbonate, and again with water. Evaporation of the solvent at 50–60° under diminished pressure left an oil which solidified when rubbed with a little methanol. The product was taken up in methanol (75 cc.) and allowed to crystallize slowly. The first crop of crystals weighed 10.3 g.; a second crop (0.83 g.) was obtained by concentrating the mother liquor. This material, a mixture of two nitration products, was best separated by allowing the solution in methanol to crystallize very slowly at room temperature. Crystals of one of the compounds separated first and, by watching carefully, the first crystals of the other compound could be seen. At this point the solution was decanted from the crystals; the solution then deposited the other substance. Working in this way alternate crops of the two substances could be obtained. The solubilities of these two compounds were nearly the same in all solvents tried; seeding the solutions with one or the other compound was not effective as this often caused both substances to crystallize together. When the whole mixture was allowed to crystallize very slowly, the two substances could be separated manually. The hydrocoumarin V crystallized in stubby rods which melted at 152.5–153°. The other product formed long needles of square cross section, which melted at 125–125.5°. Using the method of manual separation, the first crop of the nitration product (10.3 g.) was separated with 4.56 g. (53%) of the hydrocoumarin V and 4.66 g. (45%) of the other product.

Anal. V. Calcd. for $C_{14}H_{17}O_4N$: C, 63.87; H, 6.46; N, 5.14. Found: C, 63.97; H, 6.63; N, 5.25. *Anal.* of second nitration product. Calcd. for $C_{15}H_{20}O_6N_2$: C, 55.55; H, 6.17; N, 8.64. Found: C, 55.35; H, 6.31; N, 8.72.

B. By Nitration of the Acid I.—A solution of acid I (0.5 g.) in acetic acid (5 cc.) was dropped slowly into

(12) Microanalyses by J. W. Opie, C. O. Guss and H. H. Hoehn.

fuming nitric acid (5 cc., d. 1.6). Each drop produced a dark color, which immediately faded. The mixture was stirred for fifteen minutes and then diluted with ice. The gummy yellow material was taken up in ether, dried, and the ether was removed. The product (V) was crystallized from dilute ethanol, when it melted at 146–148° alone or when mixed with a specimen of V prepared from the ester. The yield was about 20%. Several attempts to nitrate the acid at lower temperatures without using sulfuric acid failed; only starting material was recovered.

4,4,6,7,8-Pentamethyl-5-aminohydrocoumarin, VI.—Granulated zinc (1.0 g., 20-mesh) was added to a boiling solution of the nitro compound V (1.0 g.) in acetic acid (8 cc.) and water (3 cc.). The mixture was refluxed for ten minutes; the solution was then carefully decanted from the zinc onto ice. The solid was removed and crystallized from dilute methanol. The amine (0.8 g., 90%) crystallized in long needles melting at 125–125.5°. It dissolved readily in hot dilute acids or bases; the hydrochloride and sulfate were both fairly insoluble in cold water. Several attempts were made to reduce the nitro compound V catalytically under low pressures, but the starting material was always recovered in these cases.

Anal. Calcd. for $C_{14}H_{19}O_2N$: C, 72.10; H, 8.15. Found: C, 71.88; H, 8.39.

4,4,6,7,8-Pentamethyl-5-hydroxyhydrocarbostyril, VII.—When a solution of the amine VI in dilute sodium hydroxide was acidified with hydrochloric acid or saturated with carbon dioxide, the hydrocarbostyril precipitated almost quantitatively. After crystallization from dilute ethanol it melted at 193–194°. The substance was soluble in 20% sodium hydroxide and was recovered unchanged when the solution was acidified. No color was produced when VII was subjected to the successive action of nitrous acid and β-naphthol.

Anal. Calcd. for $C_{14}H_{19}O_2N$: C, 72.10; H, 8.15. Found: C, 71.43; H, 8.19.

Acetate, VIII.—The hydrocarbostyril VII (0.1 g.) was refluxed for ten minutes in acetic anhydride (3 cc.) containing a drop of sulfuric acid. The mixture was poured into water and the solid was removed and crystallized from dilute methanol. It melted at 207–208°.

Anal. Calcd. for $C_{16}H_{21}O_3N$: C, 69.82; H, 7.64. Found: C, 69.75; H, 7.56.

4,4,6,7,8-Pentamethyl-5-iodohydrocoumarin, IX.—The amino compound VI (0.50 g.) was warmed with sulfuric acid (10%, 5 cc.). The amine dissolved and, as the solution was cooled, the sulfate separated. To the cooled (0°) suspension of the sulfate a solution of sodium nitrite (0.152 g.) in water (2 cc.) was slowly added. The amine sulfate gradually dissolved and a finely divided, foamy solid appeared at the surface of the solution. The diazonium solution was allowed to stand at 0° for thirty minutes, and then a solution of potassium iodide (1.0 g.) in water (5 cc.) was added. After standing at room temperature for an hour, the mixture was warmed on the steam-bath for thirty minutes. The solution became dark and a black solid separated. Saturated thiosulfate solution (2 cc.) was added and the heating was continued. The dark color gradually disappeared and a light yellow solid then remained suspended in the liquid. The solid was removed and crystallized from ethanol. It formed white plates (0.45 g.) which melted at 131.5–132.5°. The substance contained no nitrogen.

Anal. Calcd. for $C_{14}H_{17}O_2I$: C, 49.16; H, 5.12. Found: C, 48.83; H, 4.94.

The substance dissolved in boiling 20% potassium hydroxide, giving a crimson solution. Acidification of this solution by nitric acid produced a small amount of a solid melting at 150–180°; the aqueous solution gave a heavy precipitate of silver iodide when silver nitrate was added.

4,4,6,7,8-Pentamethyl-5-hydroxyhydrocoumarin, X.—When the diazonium solution prepared from the amine VI (0.50 g.) was refluxed with copper sulfate (saturated solution, 2 cc.) and sulfuric acid (3 cc.), a vigorous evolution of nitrogen occurred and a white solid separated. After crystallization from methanol, this substance (0.40 g.) formed square plates melting at 207–208°. The phenol dissolved readily in Claisen's alkali, giving a red solution, from which the phenol was recovered unchanged when the solution was acidified with hydrochloric acid or saturated with carbon dioxide.

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.79; H, 7.69. Found: C, 71.38; H, 8.04.

4,4,6,7,8-Pentamethyl-5-methoxyhydrocoumarin, XI.—The phenol X (0.343 g.) was dissolved in methyl sulfate (1.66 g.) and methanol (2 cc.). To the boiling solution potassium hydroxide (0.75 g.) in methanol (3 cc.) was added slowly. The mixture was refluxed for fifteen minutes and then diluted with water. The product separated readily and after crystallization from dilute methanol it formed long, flat needles (0.340 g.), melting at 132–132.5°. The substance was soluble in dilute alkali, giving a faintly pink solution. Acidification of this solution regenerated the ether XI. Several attempts were made to methylate this compound further in order to open the hydrocoumarin ring, but repeated action of methyl sulfate and 20% potassium hydroxide was without any effect. Likewise the action of benzoyl chloride and 20% potassium hydroxide was without effect; in all cases the ether XI was recovered practically quantitatively and in a pure state.

Anal. Calcd. for $C_{15}H_{20}O_3$: C, 72.57; H, 8.06. Found: C, 72.59; H, 8.25.

Summary

1. Nitration of β-[3,4,5-trimethylphenyl]-isovaleric acid (I) results in the formation of 4,4,-6,7,8-pentamethyl-5-nitrohydrocoumarin (V). Nitration of the methyl ester of this acid produces the nitrohydrocoumarin and a second product $C_{15}H_{20}O_6N_2$ in about equal amounts. The structure of this second product has not yet been established.

2. Several transformations of the nitrohydrocoumarin V are described. In particular, the aminohydrocoumarin VI rearranges readily into the isomeric hydroxyhydrocarbostyril VII when its solution in alkali is acidified.

3. It was not possible to open the heterocyclic

rings of any of the derivatives of the hydrocoumarin or of the hydrocarbostyril.

4. The formation of the hydrocoumarin V by nitration of the ester II is paralleled by a similar reaction in connection with the tocopherols and compounds related to them. Here also the action of nitric acid is equivalent to hydroxylation of a ring at one of the stages of the reaction.

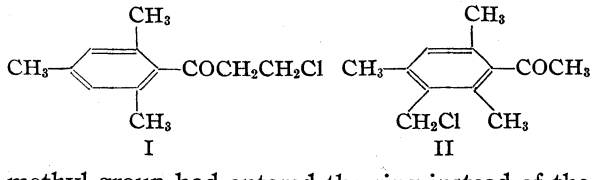
Chloromethylation of Aryl Ketones

BY REYNOLD C. FUSON AND C. H. MCKEEVER[1]

The chloromethylation of methyl aryl ketones was undertaken in the hope of obtaining a useful synthesis of β-chloropropiophenones. The success of Colonge[2] in chloromethylating aliphatic ketones by treatment with formalin in the presence of hydrogen chloride and zinc chloride suggested that a similar procedure might prove effective in the aromatic series. We therefore attempted to adapt his method to serve our purpose. In order to minimize the amount of water present, and thus enhance the solubility of the ketones, paraformaldehyde was used in place of formalin. Preliminary experiments on acetomesitylene showed that zinc chloride was not necessary to bring about the reaction. However, the product was not the expected β-chloropropiomesitylene (I) but a chloroacetoisodurene (II). The chloromethyl group had entered the ring instead of the side-chain. In other words, we appeared to have a method for nuclear chloromethylation similar to that developed by Blanc[3] for aromatic hydrocarbons and extended by others, notably Quelet,[4] to other types of aromatic compounds.



I II

Experiments with other aromatic ketones have substantiated this surmise. The method appears to be general for ketones in which the aryl radical carries two or more alkyl groups. Acetophenone and benzophenone failed to react under these conditions.

The reaction provides an indirect method of methylation; this is shown by the fact that acetoisodurene and pentamethylacetophenone were obtained in 80 and 90% yields, respectively, by reducing the corresponding chloromethyl derivatives according to the method of v. Braun and Nelles.[5]

TABLE OF RESULTS

Compound	Time, hr.	Yield, %	M. p., °C.	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found	Chlorine, % Calcd.	Chlorine, % Found
5-Chloromethyl-2,4-dimethylacetophenone[a]	41	50	68.5–69	67.17	67.03	6.66	6.75	18.02	17.94

rate from the reaction mixture. It was then necessary to pour the mixture into 500 cc. of water and extract with benzene or ether. After the extracts were washed several times with water and dried over calcium chloride, the solvent was removed and the residue distilled *in vacuo*. The chloromethyl derivative was separated easily from the parent ketone by this method.

All but one of the chloromethylated ketones prepared were low-melting solids which, although very soluble in organic solvents, could be recrystallized from low-boiling petroleum ether or methyl alcohol.

Summary

A method has been developed for nuclear chloromethylation of certain types of aromatic ketones.

Hexahydroacetomesitylene[1]

BY E. P. KOHLER, THOMAS L. JACOBS[2] AND H. M. SONNICHSEN[3]

In continuation of a series of investigations made in this Laboratory[4] as to the effect of hindrance on the stability of enols of aliphatic monoketones, it appeared of interest to study the behavior of hexahydroacetomesitylene and its derivatives from this same point of view. The results of such a study are presented herewith.

It was decided to undertake the preparation of hexahydroacetomesitylene by catalytic hydrogenation of the mesitylene nucleus because that method seemed likely to involve the fewest stereochemical complications, although it is probable that there are other easier routes to that substance.

Preliminary experiments showed that the carbonyl group of acetomesitylene is reduced catalytically before nuclear hydrogenation begins, and the alcohol produced is dehydrated under much less drastic conditions than are necessary for the hydrogenation of the ring; consequently it was necessary to find another derivative of mesitylene which could be hydrogenated in the nucleus and later transformed into an acetyl derivative, and for this purpose mesitylene carboxylic acid seemed the logical choice. The sodium salt of this acid was successfully hydrogenated in water solution using Raney nickel catalyst activated with ammonium chloroplatinate.

It was not possible to separate the isomeric hexahydromesitylene carboxylic acids by simple crystallization, due partly to their great solubility in common organic solvents, and sublimation also failed. The acids were therefore converted into a mixture of amides from which a pure amide melting at 230° and a mixture melting sharply at 167° were obtained. The mixture was shown to contain the 230° amide.

When the residues from the amide preparation were distilled under reduced pressure the principal product was the nitrile, 2,4,6-trimethylhexahydrobenzonitrile, and from the solid residue in the distillation flask was recovered more of the mixture of amides melting at 167°. The structure of the nitrile was proved by the fact that methyl alcoholic potassium hydroxide hydrolyzed it to the 230° amide. The failure of the nitrile to be hydrolyzed past the amide stage by heating with methyl alcoholic potassium hydroxide for several hours was our first indication of the hindered nature of these derivatives of trimethylcyclohexane.[5] The amide also resisted concentrated phosphoric acid and was remarkably inert toward nitrous acid, although by this means it was possible to obtain enough pure trimethylhexahydrobenzoic acid (m. p. 85–87°) for an analysis.

The mixture of amides melting at 167° gave an acid melting at 114–117° when partially hydrolyzed with nitrous acid, and the material remaining unattacked was a mixture of the 230° amide and the 167° mixture. A mixture of the acid

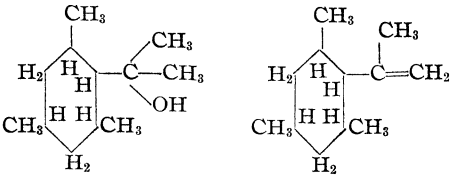
melting at 85–87° with the 114° acid melted below 80°. Carbon–hydrogen analyses showed that both had the composition of 2,4,6-trimethylhexahydrobenzoic acid. Although the troublesome separation of the amide mixture made it difficult to estimate the composition of the crude reduced acids, the fact that about 60% of the acid could be accounted for as the 230° amide in a reaction with an over-all yield not greater than 70% convinced us that the trimethylhexahydrobenzoic acid obtained by hydrogenation of mesitylene carboxylic acid was nearly all one substance, and this assumption was confirmed by the failure of any significant amount of separation of isomeric substances in subsequent reactions.

There are six possible geometric isomers of hexahydromesitylene carboxylic acid,[6] two of which are racemic mixtures separable into optical antipodes. Obviously no decisions can be made from the experimental evidence as to the configurations of the acids isolated. The rule of Skita[7] concerning the production of *cis* and *trans* isomers by hydrogenation in acid or alkaline media is of doubtful validity here because of the complicated structure of the molecule and the drastic conditions of the hydrogenation. Chavanne and Becker's observation[8] that reduction with Raney nickel favors the production of *trans*-isomers and reduction with platinum the formation of *cis*-isomers is of just as little use, not only because of the complexity of the molecule, but also because of the mixed catalyst used. Work on the configurations was not taken up because the primary object of this research was the comparison of the effect of the mesityl and the trimethylcyclohexyl radicals on the stability of enols of monoketones.

The material at hand best suited for the preparation of hexahydroacetomesitylene seemed to be the 230° amide, but when the carefully purified crystalline solid was added to a solution of methylmagnesium chloride, the main product was the nitrile obtained previously. Another possible path was the reaction of the methyl ester of hexahydrotrimethylbenzoic acid with Grignard reagent. The ester reacted slowly with methylmagnesium chloride, but the only product isolated was a small amount of 1-methyl-1-hexahydromesitylethylene (II), a hydrocarbon obtained later by the dehydration of hexahydromesityldimethylcarbinol (I).

Hexahydroacetomesitylene was finally obtained by Fuson's[9] method for preparing ketones from hindered acid chlorides. The addition of 2,4,6-trimethylhexahydrobenzoyl chloride to excess methylmagnesium chloride in benzene at the boiling point gave a mixture containing 70% hexahydroacetomesitylene, 10 or 15% hexahydromesityldimethylcarbinol (I) and 5% of the hydrocarbon obtained by dehydration of the carbinol (II). Separation by fractionation was difficult, and the chemical methods ordinarily available for the demonstration of the presence of ketone and alcohol groups failed because of hindrance. Even condensations of the ketone with aldehydes by the usual procedure failed to give more than traces of α,β-unsaturated ketone. Benzalacetohexahydromesitylene was finally prepared using sodamide as the condensing agent.

The structures of the tertiary alcohol and the hydrocarbon were more difficult to establish, for analyses do not distinguish very well between a secondary and a tertiary methyl carbinol. Of course the production of a secondary alcohol by the reaction of methylmagnesium chloride with an acid chloride seemed extremely unlikely since this reagent lacks the hydrogen in the beta-position usually associated with reductions by Grignard reagents. Reduction by metallic magnesium or magnesium–magnesium chloride mixture could be definitely ruled out, since the yield of alcohol was the same in preparations in which considerable unchanged magnesium was present and in those in which the addition of methyl chloride had been continued for several hours after the last trace of magnesium had disappeared. Nevertheless the possibility of the production of a secondary alcohol by some obscure mechanism had to be considered. The following evidence can be adduced to prove that the structures of the alcohol and the hydrocarbon are those shown below



I II

(6) A similar case involving a less symmetrical molecule is the hexahydropseudocumidines investigated by Skita (*Ber.*, **53**, 1792 (1920); Hennenbruch, Dissertation, Freiburg, 1920).

(9) Fuson, THIS JOURNAL, **59**, 1508 (1937); **60**, 2063 (1938).

The alcohol reacted rapidly with Grignard reagent in the Zerewitinoff apparatus, giving off a mole of gas in the cold. When treated with phenylisocyanate it was dehydrated and no urethan was isolated. Both acetyl chloride and acetic anhydride dehydrated the alcohol smoothly to the hydrocarbon, and when it was shaken with sodium hypobromite for a long period at room temperature the hydrocarbon was again produced in good yield. The alcohol absorbed hydrogen chloride at 0° in aqueous hydrochloric acid solution and formed an unstable chloride which boiled several degrees lower than the original alcohol. Perhaps the best evidence in favor of the tertiary alcohol structure is that when the ketone was reduced with sodium and alcohol the resulting secondary alcohol exhibited quite different properties. This might be a case of geometrical isomerism, but it is not likely.

Investigation of the hydrocarbon gave further support to the hypothesis that methylmagnesium chloride had added to the carbonyl group of hexahydroacetomesitylene. Ozonization of the hydrocarbon furnished little information, since the only product which could be detected with any certainty was formaldehyde. A trace of hexahydroacetomesitylene was detected in the ozonization products but the amount was so small that it might as reasonably be assumed to be a trace of impurity as a product of ozonolysis. No acetone could be found in the mixture, nor could any other products be isolated. Apparently ozone produced a good deal of general oxidation.

Final proof was furnished by the bromination of the unsaturated hydrocarbon, although the course of the reaction was unexpected. The hydrocarbon absorbed bromine rapidly, but almost immediately began to give off hydrogen bromide. When the product was distilled decomposition was evident, and a second distillation of the product produced further decomposition. The distillate crystallized giving a solid monobromide whose analysis, due to the introduction of the bromine, made it possible to distinguish between the various possibilities and show that the hydrocarbon resulted from dehydration of hexahydromesityldimethylcarbinol.

The above evidence shows that under the conditions of the reaction used in its synthesis hexahydroacetomesitylene adds methylmagnesium chloride to produce hexahydromesityldimethylcarbinol to the extent of about 15% of the ketone formed. Here again was an excellent opportunity to compare the hindrance of the mesityl and the trimethylcyclohexyl radicals. A large amount of 2,4,6-trimethylbenzoyl chloride was treated with methylmagnesium chloride under exactly the same conditions as had been used in the preparation of hexahydroacetomesitylene. Absolutely no evidence of any addition of Grignard reagent to the carbonyl was obtained and the yield of acetomesitylene was good enough to establish that under these conditions not more than 1 or 2% could have occurred.

The addition of Grignard reagents to hexahydroacetomesitylene was investigated further on the pure ketone. In the Zerewitinoff apparatus the hydroaromatic substance acted almost exactly the same as acetomesitylene, giving off gas slowly in the cold and requiring some heating before the reaction was complete. The hydroaromatic ketone could be recovered practically unchanged when treated with ethylmagnesium bromide in the cold, but if the ether solution was boiled for two hours 15 to 20% of by-products resulted. The treatment of the bromomagnesium enolate with acylating and alkylating agents also was undertaken but will not be reported, since the work is not complete.

Hexahydroacetomesitylene was reduced easily with sodium and alcohol to hexahydromesitylmethylcarbinol, a liquid, which was characterized by means of its phenylurethan.

Three weeks of shaking with alkaline hypobromite produced a small amount of cleavage of hexahydroacetomesitylene to hexahydromesitylene carboxylic acid. The cleavage product was found to be the geometrical isomer melting at 86–87°. The bromine-containing oil which formed the remainder of the product decomposed on distillation, and there was isolated not a tribromo but a dibromo ketone, $(CH_3)_3C_6H_8COCHBr_2$.

Benzalacetohexahydromesitylene formed a dibromide which was converted to a β-diketone by the usual treatment with alcoholic base. The liquid diketone was characterized as its copper derivative.

The preparation of the enol peroxide of β,β-diphenylpropiohexahydromesitylene was carried out according to the general method used for the preparation of peroxides of this type,[10] furnishing further evidence that di-ortho-substitution pro-

(10) R. B. Thompson, Harvard Ph.D. Thesis, 1938, p. 65, and ref. (4).

duces considerable hindrance in this derivative of cyclohexane. The isolation of this peroxide adds another to the list of hindered ketones whose enols are sufficiently stable in solution to permit their reaction with molecular oxygen. The list now includes β,β-diphenylpropiomesitylene,[11] β,β-diphenylpropiohexahydromesitylene, α,β,β-triphenylpropiophenone,[12] α,β-diphenylvalerophenone,[13] β,β-diphenylpropiotriphenylmethane,[14] 2-diphenylmethyl - 6 - benzalcyclohexanone,[15] and β,β-diphenylpropiotriphenylfuran.[16]

The first peroxide preparation gave two isomers, both of which behaved as peroxides with potassium iodide and on heating. In a second preparation only the lower melting isomer was obtained. It should be mentioned that there are a number of possibilities for isomers of this peroxide, and no decision can be made concerning either structure or configuration in this case. In addition to the usual problem of whether the peroxide is cyclic or in the hydroperoxide form, the existence of two carbon atoms bearing hydrogens in the alpha-position to the carbonyl introduces extra complications. The possibility of *cis* and *trans* isomers of a cyclic peroxide structure and of dimorphic crystalline forms should not be forgotten, and finally there is the stereoisomerism of the cyclohexane ring already mentioned, a list of possibilities so large that exploration seems futile. Thermal decomposition of the peroxide was attempted, but none of the products obtained could be identified.

Experimental

Mesitylene Carboxylic Acid.—Mesitylene carboxylic acid was prepared by carbonation of mesitylmagnesium bromide and purified by recrystallization from methanol. Acid which had been recrystallized only once was found to serve as well for the hydrogenation reaction as very carefully purified material.

Reduction of Mesitylene Carboxylic Acid.—A solution of the sodium salt of mesitylene carboxylic acid was prepared from 100 g. of the acid, 24.3 g. of sodium hydroxide, and 150 cc. of water, and shaken with 5 to 10 g. of Raney nickel catalyst and 0.2 g. of ammonium chloroplatinate at 250° under 3600 lb. (240 atm.) pressure of hydrogen for twenty-four hours. The catalyst was then filtered off and a fresh portion of Raney nickel and ammonium chloroplatinate added. During the first treatment the aromatic acid sometimes absorbed as much as half the theoretical amount of hydrogen, but in the majority of runs no hydrogen was taken up. The material was again shaken at the same temperature and pressure for forty-eight hours before the catalyst was again filtered off and a fresh batch added. The process ordinarily required three treatments, but in some cases without the use of ammonium chloroplatinate as many as six were required to obtain the complete conversion of the aromatic acid to the corresponding derivative of cyclohexane. The primary factor affecting the rate of absorption seemed to be the condition of the copper can used as a reaction vessel. After continued use the inside of the can became covered with a dark-colored deposit of metal and the hydrogenations were completed in much less time.

After the solution of the sodium salt had absorbed the theoretical amount of hydrogen it was filtered and acidified with concent ratedhydrochloric acid. Hexahydromesitylene carboxylic acid was precipitated in 95–99% yield as a thin oil which slowly solidified to a waxy mass from which the water could be decanted. The crude solid was taken up in petroleum ether and separated from the remaining water. If the hydrogenation had not been carried to completion most of the aromatic acid remaining was precipitated at this point.

Preparation of Trimethylhexahydrobenzamides.—A mixture of 7.5 cc. of thionyl chloride and 10 g. of trimethylhexahydrobenzoic acid was allowed to stand overnight, heated on the steam-bath to drive off excess thionyl chloride, and poured into 50 cc. of concentrated ammonium hydroxide cooled in an ice-bath. The precipitate after drying weighed 8.0 g. and consisted of 5.0 g. of an amide melting at 230°, some ammonium chloride, and some oily material containing a good deal of sulfur. From the ammonia solution was recovered 2.1 g. of unchanged acid. The amide was recrystallized from methyl alcohol.

Anal. Calcd. for $C_{10}H_{19}ON$: C, 70.94; H, 11.31. Found: C, 70.75; H, 11.04.

The above analysis is of a sample burned in air. Samples burned in oxygen exploded with an audible detonation. The results of analyses in oxygen agreed with the theoretical percentage of carbon but were four to six-tenths per cent. low in hydrogen.

The oily residues from several preparations of the 230° amide were distilled *in vacuo*. The main fraction boiled at 61–62° at 3 mm., but there was water in the distillate and considerable smell of methyl mercaptan. When the liquid boiling at 62° was heated for twelve hours with saturated methyl alcoholic potassium hydroxide, there was obtained in about 50% yield the same 230° amide which had been isolated earlier.

The flask residue crystallized, giving a solid which melted at 167° after recrystallization from benzene or ether. This substance when mixed with the 230° amide melted between 180 and 220°, different samples of apparently equal purity giving a different mixed melting point. In subsequent preparations the residues from a number of runs were combined and the 167° amide obtained by very tedious fractional crystallization from benzene. Hydrolysis with sodium nitrite in acetic acid showed that this substance was a mixture of the amide melting at 230° and an isomeric amide which it was not possible to isolate in pure form.

Anal. Calcd. for $C_{10}H_{19}ON$: C, 70.94; H, 11.31. Found: (burned in air) C, 70.75; H, 10.93.

Hydrolysis of 230° Amide.—Two grams of amide, m. p. 230°, was added to 50 cc. of glacial acetic acid. The mixture was heated until the amide dissolved, then 2 g. of solid sodium nitrite was added in small portions. The solution was heated for fifteen minutes, then neutralized with 20% sodium hydroxide and filtered. Half of the original amide was recovered. The water solution was acidified and extracted with ether. The ether solution was dried over calcium chloride, filtered and evaporated. The solid material remaining was sublimed and 0.13 g. of crystals obtained which after two more sublimations melted at 85–87°.

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.57; H, 10.65. Found: C, 70.90; H, 10.43.

Hydrolysis of the 167° Amide.—The substance melting at 167° was submitted to the same procedure as above, but its solubility in water (approximately 0.1 g. per 100 cc.) made it necessary to extract the crude hydrolysis mixture with ether, and then extract the ether solution with bicarbonate. When the bicarbonate solution was acidified there was deposited in about 15% yield a solid melting at 95–105°. The ether solution deposited a mixture of the 230° amide and the 167° substance, showing that the original 167° substance was a mixture of two amides. The acid was recrystallized twice from petroleum ether (in which it was extremely soluble) and resublimed. The analytical sample sintered slightly at 100° and melted at 114–117°.

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.57; H, 10.65. Found[17]: C, 70.63; H, 10.42.

Reaction of 230° Amide with CH_3MgCl; Preparation of Hexahydrotrimethylbenzonitrile.—A solution of methylmagnesium chloride was prepared from 7.2 g. (0.30 mole) of magnesium and to this was added in small portions 20 g. (0.12 mole) of the pure amide melting at 230°. The ether boiled vigorously during the addition and the amide went into solution. After all of the solid had been added the ether was almost all gone and a pasty mass was left. The product was allowed to stand overnight, boiled for one hour and poured into iced dilute hydrochloric acid. When the mixture was extracted with a large amount of ether, the ether solution extracted with sodium bicarbonate, dried with calcium chloride and evaporated it deposited 1.7 g. of unchanged amide. The residue, distilled through a short column, boiled 66–71° (3 mm.). The product gave a qualitative test for nitrogen.

Anal. Calcd. for $C_{10}H_{17}N$: C, 79.41; H, 11.33. Found: C, 80.32; H, 11.28.

When burned in oxygen the sample (14 mg.) exploded with such violence that it shattered the combustion tube. The above analysis is of a sample burned in air. The composition of the compound was made certain by treatment with strong alcoholic potassium hydroxide which produced in good yield the original 230° amide, leaving no doubt that the liquid was the corresponding nitrile.

Preparation of Trimethylhexahydrobenzoyl Chloride.—A mixture of 90 cc. of purified thionyl chloride and 180 g. of hexahydromesitylene carboxylic acid was allowed to stand for four hours, during which time hydrogen chloride was evolved rapidly. The acid chloride was then distilled *in vacuo* (20 mm.), and there was obtained:

Fraction	B. p., °C.	Weight, g.
Forerun		6.0
Fraction I	102–104	27.0
Fraction II	104	111.0
Flask residue	.....	42.0

The flask residue when hydrolyzed yielded 14.0 g. of a neutral fraction from which nothing could be obtained, 21.0 g. of mesitylene carboxylic acid and 7.0 g. of hexahydromesitylene carboxylic acid. This represents a yield of 79% and a recovery of 91%. In most preparations the amount of mesitylene carboxylic acid recovered was much smaller, representing more complete reduction of the original material. The acid chloride was a clear colorless liquid with a pungent odor, $n^{20}D$ 1.472, d^{20}_4 1.01.

Preparation of Methyl Ester of Trimethylhexahydrobenzoic Acid.—Methyl alcohol (75 cc.) was added to 51 g. of trimethylhexahydrobenzoyl chloride and heated in an all-glass apparatus on the steam-bath overnight. The ester was taken up in ether, washed with water and bicarbonate solution, dried over sodium sulfate and distilled. All of the material came over between 90 and 96° at 14 mm.; recovery 96%; $n^{20}D$ 1.452; b. p. 93° (14 mm.); d^{20}_4 0.934.

Anal. Calcd. for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94. Found: C, 72.14; H, 11.22.

Reaction of Ester with Methylmagnesium Chloride.—In the Zerewitinoff machine the ester gave off gas very slowly at 100° and a white solid separated. The total amount of gas given off after heating for one and one-quarter hours at 100° was 0.25 mole. When 29.5 g. of the ester was added dropwise to a solution in boiling benzene of methylmagnesium chloride prepared from 24 g. of magnesium, heat was evolved and solid separated. The suspension was boiled for thirty-six hours, and decomposed with ice and hydrochloric acid. Fractionation through a 50-cm. column at 15 mm. pressure gave:

Fraction	B. p., °C.	Weight, g.
Fraction I	83–92.2	5.3
Fraction II (unchanged ester)	93.4–94.2	11.0
Flask residue	.....	4.4

Anal. of Fraction II. Calcd. for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94. Found: C, 73.60; H, 11.25.

The low-boiling fraction was redistilled and the material boiling 84.5 to 86° was analyzed.

Anal. Calcd. for $C_{12}H_{22}$: C, 86.65; H, 13.33. Found: C, 86.26; H, 13.63.

Comparison of physical properties ($n^{20}D$ 1.444, d^{20}_4 0.831) with the hydrocarbon obtained by dehydration of the tertiary alcohol $(CH_3)_3C_6H_8C(OH)(CH_3)_2$ showed that the material was still impure.

Addition of $(CH_3)_3C_6H_8COCl$ to Methylmagnesium Chloride.—Methylmagnesium chloride was prepared from 60 g. of magnesium in one liter of ether solution in a two-liter three-necked flask. Dry benzene was added and the

(17) This analysis was performed by Mr. H. S. Wight.

solution boiled until the temperature of the vapor was 75° and the volume of the solution approximately 800 cc. Hexahydrotrimethylbenzoyl chloride (100 g.) dissolved in 200 cc. of benzene was added slowly with vigorous stirring. The resulting paste was boiled for one-half hour, then poured into iced hydrochloric acid. The mixture was extracted with ether, and the ether layer was washed with water and sodium bicarbonate. Most of the benzene was evaporated and the residue was distilled at 9 mm.

Fraction	B. p., °C.	Weight, g.
Forerun	60–86	5.0
Fraction II	86–87	46.0
Fraction III	87–95	17.0
Flask residue	...	16.8

Fraction III was redistilled along with the flask residue and there was obtained 17.0 g. more of hexahydroacetomesitylene, b. p. 86–87°, and 14.5 g. of a solid boiling at 105° at 11 mm. This represents a 5.5% yield of the low-boiling material, which was shown to be the same hydrocarbon as that obtained from the action of methylmagnesium chloride on the ester and of dehydrating agents on the alcohol, a 70% yield of hexahydroacetomesitylene and a 16% yield of the solid $(CH_3)_3C_6H_8C(OH)(CH_3)_2$; total recovery, 91% of the theoretical. The same ketone was produced when methylzinc chloride prepared by the addition of anhydrous zinc chloride to a solution of methylmagnesium chloride was treated with trimethylhexahydrobenzoyl chloride, but the yield was only 55% of the theoretical.

Hexahydroacetomesitylene, $(CH_3)_3C_6H_8COCH_3$.—The ketone was a colorless liquid, b. p. 86–87° (9 mm.), 93–94° (15 mm.), 97–98° (25 mm.), $n^{20}D$ 1.452; d^{20}_4 0.892. *MR* obsd., 50.85; calcd., 50.83; surface tension at 25°, 30.9; parachor, calcd. 445.7; found 445.

Anal. Calcd. for $C_{11}H_{20}O$: C, 78.50; H, 11.98. Found: C, 78.76; H, 12.21. Found[18]: C, 78.93; H, 12.41.

The ketone had a faint pleasant odor and was quite volatile with steam. It gave no iodoform test by Fuson's method.[19] When hexahydroacetomesitylene was treated with Grignard reagent in the Zerewitinoff apparatus it gave off gas slowly in the cold. The total amount of gas evolved was 0.84 equivalent and the total amount of reagent which added was only 0.05 equivalent.[20] When 20.0 g. of hexahydroacetomesitylene was treated with two equivalents of ethylmagnesium bromide at 0° for thirty minutes, gas was given off slowly during the addition (acetomesitylene reacts more vigorously). When distilled at 10 mm. the product of decomposition of the clear colorless Grignard solution boiled over a range of seven degrees but refractive index measurements indicated that not more than a negligible amount of addition had occurred. Boiling the ketone with ethylmagnesium bromide in ether solution for two hours produced between 12 and 25% of by-products.

Hexahydromesityldimethylcarbinol, $(CH_3)_3C_6H_8C(OH)(CH_3)_2$, was a white solid which boiled at 106° under 10 mm. pressure. It was extremely soluble in all the ordinary organic solvents, but could be recrystallized from methanol–water mixtures, forming stout needles, m. p. 67–69°.

Anal. Calcd. for $C_{12}H_{24}O$: C, 78.19; H, 13.12. Found[21]: C, 78.43, 78.66; H, 12.53, 12.58. Found[22]: C, 78.56; H, 12.91.

When treated with Grignard reagent in the Zerewitinoff apparatus,[20] the alcohol gave off 1.12 equivalents of gas rapidly in the cold. When treated with phenyl isocyanate it reacted vigorously at 120°, but the only product isolated was diphenyl urea. When treated with acetyl chloride or acetic anhydride the hydrocarbon $C_{12}H_{22}$ was produced in good yield. The sample of this hydrocarbon redistilled for analysis boiled 70.8–71.2° (10 mm.), $n^{20}D$ 1.4605, d^{20}_4 0.831, *MR* calcd. 54.97, found 54.83.

Anal. Calcd. for $C_{12}H_{22}$: C, 86.65; H, 13.33. Found[17]: C, 86.60; H, 13.43.

The same hydrocarbon was produced when 5.0 g. of the alcohol was shaken for two weeks with a mixture of 75 cc. of water, 7.5 g. of sodium hydroxide, and 7.5 g. of bromine.

When 4.0 g. of the alcohol was added to 15 cc. of concentrated hydrochloric acid at −5° and dry hydrogen chloride bubbled through the mixture, the solid disappeared and was replaced by a layer of clear liquid. This was separated from the aqueous layer, washed with water, dried over sodium carbonate and distilled through a small column. The main fraction boiled 94.6–97.1° (9 mm.) and was a clear, almost odorless liquid, $n^{20}D$ 1.472. It was allowed to stand overnight before redistillation, and this time it gave off hydrogen chloride and the sole product was the same hydrocarbon obtained in the dehydration of the alcohol. Lack of material prevented repetition of the reaction.

Determination of Structure of the Hydrocarbon $C_{12}H_{22}$.—A solution of 4.1 g. of the hydrocarbon in 30 cc. of glacial acetic acid was treated with 4% ozone at room temperature. The ozone was absorbed quantitatively at first, but after about two-thirds of the theoretical amount had been taken up absorption ceased. The ozonide was rinsed into a hydrogenation bottle with glacial acetic acid and hydrogenated with palladium catalyst. There was an induction period of nearly an hour before the catalyst began to be reduced. The solution then took up one-third of the theoretical quantity of hydrogen in about twenty minutes, after which absorption stopped. The solution, after filtering off the catalyst, gave a faint test with hypoiodite and a strong test with ammoniacal silver nitrate. When 2,4-dinitrophenylhydrazine was added to a portion of the product the dinitrophenylhydrazone of formalde-

(18) By H. S. Wight.

(19) R. C. Fuson, THIS JOURNAL, **56**, 1638 (1934).

(20) This determination performed by Mr. Richard Cramer.

(21) These analyses by the Arlington Laboratories, Arlington, Va. The sample had been distilled three times through a 3-ft. (90-cm.) column. The boiling point was constant at 105.9° (10 mm.). Unfortunately it was necessary to distil rather rapidly to prevent the product solidifying in the condenser. The freezing point of the product was 50.4°. The material was a white waxy-looking solid.

(22) This analysis was performed by H. S. Wight. The sample had been recrystallized four times from methanol–water solution and melted at 67–69°. The analyses do not distinguish very well between the tertiary alcohol and the corresponding secondary alcohol, $(CH_3)_3C_6H_8CH(OH)CH_3$ (calcd.: C, 77.58; H, 13.03). The composition of the ketone is also very close to the same figure (calcd.: C, 78.49; H, 11.98). The chemical evidence leaves no doubt about the structure.

hyde was obtained, identified by a mixed melting point with an authentic sample. No other crystalline substance was isolated. The original solution, after oxidation with ammoniacal silver nitrate, no longer gave a detectable amount of iodoform when hypoiodite was added, proving that acetone was absent.

An attempt to isolate hexahydroacetomesitylene from the product of ozonization by condensation with benzaldehyde and formation of the dibromide of the benzal compound gave such a small amount of product (identified by a mixed melting point) that it might conceivably have come from a trace of ketone present as an impurity in the hydrocarbon before ozonization, so this cannot be considered a proof of structure.

Better evidence was furnished by bromination of the unsaturated hydrocarbon: 9.5 g. of crude material in 50 cc. of carbon tetrachloride was cooled in an ice-bath and a solution of 9.0 g. of bromine in 30 cc. of carbon tetrachloride was added slowly. Hydrogen bromide was evolved almost immediately. The solution was decolorized with sodium bisulfite, filtered, and washed with sodium bicarbonate. When the carbon tetrachloride was pumped off and the remaining oil distilled under reduced pressure, it boiled 60–135° (10 mm.) with no evidence of any pure substance being present. The distillate was mixed with methyl alcohol and cooled in dry-ice until it deposited about 1.5 g. of gummy crystals which were filtered off and recrystallized from methanol to give a product melting at 41–42°. The analysis indicated that it was the unsaturated monobromohydrocarbon $(CH_3)_3C_6H_8C(CH_3)=CHBr$. It was not investigated further.

Anal. Calcd. for $C_{12}H_{21}Br$: C, 58.77; H, 8.63. Found[17]: C, 58.78; H, 8.38.

Reaction of Trimethylbenzoyl Chloride with CH_3MgCl.—Trimethylbenzoyl chloride was treated with methylmagnesium chloride under exactly the same conditions as had been used in the preparation of hexahydroacetomesitylene. From 103.0 g. of the acid chloride there was obtained 79.9 g. of acetomesitylene, $n^{20}D$ 1.517–1.519 ($n^{20}D$ of purest sample on hand 1.5190). There was also obtained 4.8 g. of forerun, refractive index 1.515, and 4.0 g. of high-boiling material. This high-boiling material was shaken with copper acetate and there was obtained 3.2 g. of the copper enolate of dimesitoylmethane. This represents a 90% yield of acetomesitylene and leaves only 1.25% of the liquid obtained unidentified. Therefore it is estimated that there could not have been more than 1 or 2% of addition to the carbonyl group under conditions where hexahydroacetomesitylene adds to the extent of 16%.

Reduction of Hexahydroacetomesitylene. Preparation of $(CH_3)_3C_6H_8CHOHCH_3$.—A solution of 10 g. of hexahydroacetomesitylene in 100 cc. *t*-amyl alcohol was heated on the steam-bath and metallic sodium (8 g.) was added in small pieces over a period of six hours. The mixture was heated six hours more, let stand overnight, then treated with methyl alcohol and water to destroy traces of sodium remaining. The resulting emulsion was poured into water, extracted with ether and the ether solution steam distilled. The steam distillate was extracted with ether, dried over sodium sulfate, and distilled at 8 mm. After 1.5 g. of forerun boiling at 76–97°, there was obtained 6.3 g. of secondary alcohol, b. p. 97.5–98.2°, $n^{20}D$ 1.470. A second distillation divided the material into three fractions boiling at 94–99.5° (8 mm.), $n^{20}D$ of all three fractions 1.4700, $n^{20}D$ of flask residue 1.4701. The fraction taken as an analytical sample boiled at 99.5°, d^{20}_4 0.905, *MR* obsd., 52.5; calcd., 52.35.

Anal. Calcd. for $C_{11}H_{22}O$: C, 77.58; H, 13.03. Found[17]: C, 77.36; H, 12.83.

Phenylurethan of Methylhexahydromesityl Carbinol.—Two cc. of the secondary alcohol was mixed with 2 cc. of phenyl isocyanate and heated in an oil-bath. Reaction began when the temperature reached 130°. The mixture was heated for one-half hour at 150° then cooled in ice, when 1.0 g. of solid material was precipitated melting around 100°. Three recrystallizations from ether–petroleum ether raised the melting point to 130–132°. Three more recrystallizations from ligroin raised the melting point slightly to 132–134°.

Anal. Calcd. for $C_{18}H_{26}O_2N$: C, 74.72; H, 9.41; N, 4.84. Found[17]: C, 74.94; H, 9.28; N, 5.24.

Alkaline Bromination of Hexahydroacetomesitylene. Preparation of $(CH_3)_3C_6H_8COCHBr_2$.—When 5 g. of hexahydroacetomesitylene was shaken for seventy-four hours with 100 cc. of a 10% solution of bromine in 10% sodium hydroxide, the organic material increased in density sufficiently to cause it to settle to the bottom of the flask. When it was distilled some decomposition was evident and on redistillation more decomposition occurred. The distillate crystallized on standing and was recrystallized three times from petroleum ether to give a substance melting at 63–65°.

Anal. Calcd. for $C_{11}H_{18}OBr_2$: Br, 49.01. Found:[21] Br, 48.90.

From the aqueous hypobromite layer was recovered a very small amount of acid which gave an amide melting at 215–225° after three recrystallizations. A mixture with the 230° amide melted at 220–228°.

Condensation of Hexahydroacetomesitylene with Benzaldehyde.—Finely ground sodamide (12 g.) was suspended in 100 cc. of benzene and 42.0 g. of hexahydroacetomesitylene was added. Benzaldehyde (30.0 g.) was added slowly to the suspension of ketone and sodamide and a vigorous reaction ensued. A gelatinous solid was produced which was allowed to stand for six hours, then extracted with ether and water. The ether layer was treated with a saturated solution of sodium bisulfite to remove excess benzaldehyde and then washed thoroughly with sodium bicarbonate solution and water. When the ether was evaporated and the residue distilled in a Claisen flask at 15 mm., 12.8 g. of unchanged ketone was recovered (30% of the starting material). The pressure was then reduced to 2.5 mm. and 43.7 g. of the unsaturated ketone distilled over as a yellow viscous oil at 160–165° (68% yield). The flask residue weighed 8.4 g. but only a trace of the dibromide of benzalacetohexahydromesitylene could be recovered from it when it was treated with bromine. Redistillation of the main fraction gave a pale yellow liquid, b. p. 148–150° (0.5 mm.). This was again distilled and an analytical sample, b. p. 148.0° (0.5 mm.), was removed, $n^{20}D$ 1.562, d^{20}_4 0.994; *MR* obsd., 83.62; calcd., 79.09. The yellow liquid crystallized in dry-ice but melted again below 0°.

Anal. Calcd. for $C_{18}H_{24}O$: C, 84.34; H, 9.44. Found: C, 84.59; H, 9.74.

Dibromide of Benzalacetohexahydromesitylene, $C_6H_5CHBrCHBrCOC_6H_8(CH_3)_3$.—When the unsaturated ketone was treated with a solution of bromine in carbon tetrachloride and the carbon tetrachloride evaporated, there remained a white solid melting near 180°. Three recrystallizations from benzene brought the melting point to 211–212° (with slight decomposition).

Anal. Calcd. for $C_{18}H_{24}OBr_2$: C, 51.95; H, 5.81. Found[17]: C, 52.50; H, 6.04.

Preparation of $C_6H_5COCH_2COC_6H_8(CH_3)_3$.—A solution of 1.8 g. of the dibromide, $C_6H_5CHBrCHBrCOC_6H_8(CH_3)_3$ in 10 cc. of methyl alcohol was heated for thirty minutes on the steam-bath with 0.75 g. of potassium hydroxide. The solution was acidified with hydrochloric acid and again heated for thirty minutes. Fifty cc. of water was added, the solution extracted with ether, and the ether layer shaken with saturated cupric acetate solution. The copper derivative of the beta-diketone was soluble in ether. When the ether layer was evaporated to dryness and the resulting solid recrystallized from ether–petroleum ether, there was obtained 1.2 g. of crystals, m. p. 195–200° (90% yield). Two more recrystallizations gave an analytical sample with m. p. 197–199°.

Anal. Calcd. for $C_{36}H_{46}O_4Cu$: C, 71.20; H, 7.65. Found[17]: C, 71.19; H, 7.81.

Hydrogenation of Unsaturated Ketone. Preparation of $C_6H_5CH_2CH_2COC_6H_8(CH_3)_3$.—When benzalacetohexahydromesitylene was hydrogenated with Adams catalyst it took up exactly one equivalent of hydrogen. The product boiled between 179 and 187°, and when redistilled for analysis boiled 180–182° (8 mm.), $n^{20}D$ 1.514, d^{20}_4 0.967; *MR* obsd., 80.4; calcd., 79.56. The analytical sample was a pale yellow liquid, indicating that the material still contained some unchanged unsaturated ketone.

Anal. Calcd. for $C_{18}H_{26}O$: C, 83.68; H, 10.15. Found[18]: C, 83.35; H, 10.34.

Reaction of Benzalacetohexahydromesitylene with Phenylmagnesium Bromide.—Five grams (0.0195 mole) of unsaturated ketone was added rapidly to a solution of phenylmagnesium bromide prepared from 1.05 g. (0.045 mole) of magnesium. The solution boiled during the addition but remained colorless and clear. It was allowed to stand for eight hours under nitrogen, then cooled in ice and decomposed by the addition of iced dilute hydrochloric acid. The mixture was allowed to stand overnight under nitrogen, then extracted with water and steam distilled to remove diphenyl and bromobenzene. The residue from the steam distillation was extracted with ether, dried over calcium chloride, evaporated, and diluted with petroleum ether. Cooling in dry-ice caused the mixture to solidify, and after allowing it to warm to room temperature 3.5 g. of an oily solid was filtered off. The remaining 2.5 g. of oil would deposit no more solid material. The solid, after three recrystallizations from petroleum ether, melted at 78–80° and a mixture with β,β-diphenylpropiomesitylene melted below 60°.

Anal. Calcd. for $C_{24}H_{30}O$: C, 86.18; H, 9.05. Found[17]: C, 86.38; H, 8.88.

Enol Peroxides of β,β-Diphenylpropiohexahydromesitylene.—A solution of phenylmagnesium bromide was prepared from 1.9 g. of magnesium, and to this was added 10 g. of $C_6H_5CH{=}CHCOC_6H_8(CH_3)_3$ dissolved in dry ether. The solution was boiled for fifteen minutes, then poured into a mixture of 500 cc. of ice, 50 cc. of concentrated hydrochloric acid, and 250 cc. of water. The mixture formed an emulsion with a clear ether layer on top. The ether layer was removed, washed three times with ice-water and diluted to 200 cc. Oxygen was passed into this solution for several hours until it had evaporated to 50 cc., then 100 cc. of petroleum ether was added and oxygen passed in until the solution had evaporated to a yellow viscous oil. The oil was allowed to stand overnight in ice, then cooled in dry-ice, when it deposited 2.0 g. of crystals melting over a wide range around 75°. Recrystallization from ether and petroleum ether gave 0.1 g. or less of material melting at 119–121° and 1.3 g. melting 83–87°. Both substances depressed the melting point of β,β-diphenylpropiohexahydromesitylene, of β,β-diphenylpropiomesitylene and its enol peroxide. Both substances liberated a small amount of iodine from acidified potassium iodide solution and both decomposed vigorously when heated slightly above the melting point. When the higher-melting substance was mixed with the lower-melting peroxide the mixture melted at the same point as the lower-melting substance alone. Both substances were soluble in ether, the higher-melting one much less than the other, and both were precipitated by petroleum ether in micro-crystalline form.

Anal. Calcd. for $C_{24}H_{30}O_3$: C, 78.65; H, 8.25. Found[17]: (87° peroxide) C, 79.51, 79.56; H, 8.83, 8.57: Found[21]: (87° peroxide) C, 79.34; H, 8.56. Found[17]. (133° peroxide) C, 78.51; H, 8.43.

There was not enough of the higher-melting peroxide to investigate further. When the preparation of the peroxide was repeated 10.8 g. of crude solid peroxide (50% yield) was obtained from 20.0 g. of benzalacetohexahydromesitylene, but this was found to be entirely the 86–87° material, and none of the higher-melting peroxide could be isolated.

Preparation of Hydroxyketone.—Both peroxides took up hydrogen very rapidly, but the amount of the higher melting substance available was so small that the quantitative results were not significant. When 0.666 g. of the 87° peroxide was dissolved in 50 cc. of absolute alcohol and hydrogenated with Adams catalyst, it took up 34.0 cc. of hydrogen (90% of the theoretical amount). When the alcohol solution was filtered and evaporated, a yellow oil was obtained which deposited 0.25 g. of white crystals melting at 81–84°. After two more recrystallizations from petroleum ether the melting point was 86–87°; mixed melting point with 87° peroxide 75–80°.

Anal. Calcd. for $C_{24}H_{30}O_2$: C, 82.23; H, 8.62. Found[17]: C, 82.00; H, 8.76.

The product is therefore a hydroxyketone, analogous to the substance $(CH_3)_3C_6H_2COCHOHCH(C_6H_5)_2$ obtained in the mesitylene series.[11]

Thermal Decomposition of the Peroxide.—When 1.5 g. of crude peroxide (m. p. 85°) was dropped into a hot test-tube it decomposed with a rush, giving off quantities of gas. When the residue was cooled and extracted with sodium bicarbonate only a trace of acidic material was ob-

tained. This was taken up in ether, dried, evaporated to dryness and treated with thionyl chloride. When the thionyl chloride solution was poured into an excess of iced ammonium hydroxide, the precipitate was barely visible and embedded in a yellow oil. When washed with ether it melted at 165–170° and lowered the melting point of the 167° amide thirty degrees. The melting point of a mixture with the 232° amide was 180–190°. Apparently the substance was not the amide of hexahydromesitylene carboxylic acid. No conclusions can be drawn from this evidence as to the structure of the peroxide, since apparently most of the material gave up its oxygen without cleavage. The remaining neutral material when treated with hydroxylamine deposited a trace of crystalline material which analysis showed to be a hydrocarbon, m. p. 200–205°.

Anal. Found[17]: C, 92.64; H, 6.83. No other crystalline material could be isolated.

Summary

The preparation and properties of one of the six possible geometric isomers of hexahydroacetomesitylene are described.

Investigation of this isomer of hexahydroacetomesitylene and some of its derivatives indicates that this particular configuration of the trimethylcyclohexane ring offers slightly less hindrance to the reactions of a ketone group adjacent to the ring than does the mesitylene nucleus.

The Separation of the Isomeric Hexenes by Batch Fractionation

BY ARTHUR ROSE

The maximum sharpness of separation between any two components in a batch fractionation may be estimated by an extension of the reasoning of Sydney Young[1] and of Rayleigh[2] as will soon be described in detail elsewhere.[3] The present paper applies this line of reasoning to the separation of the isomeric hexenes so as to obtain a definite idea of the fractionating efficiency required and the results to be expected in attempts at such separations.

The Vapor Pressure Ratios of the Hexenes.—In order to estimate the maximum possible sharpness of separation for any pair of substances it is necessary to know the vapor pressure ratio (α) for the pair. These may be obtained for the hexenes by using the boiling points of Schmitt and Boord[4] and the boiling point correction method cited by Eaton.[5] Thus 2-ethyl-1-butene boils at 66.45° at 760 mm. while 3-hexene boils at 66.8°. At this temperature the b. p. correction would be about 0.042° per mm., so that at 66.8° the vapor pressure of 2-ethyl-1-butene must be about 768 mm. and *alpha* for this pair must be about 768/760 = 1.011.

(5) E. S. Beale, "Science of Petroleum," Vol. II, Oxford University Press, Oxford, 1937, p. 1280, etc.

The values in Table I were obtained in a similar manner. In every case only three significant figures are retained but in dropping excess figures the value of *alpha* was increased, except for pair A, so the other pairs are actually more difficult to separate than the values of *alpha* indicate.

TABLE I

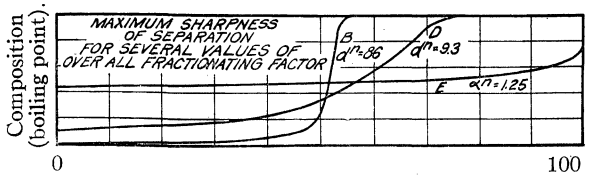
	Hexene pair	Alpha
(A)	2-Ethyl-1-butene and 3-hexene	1.01
(B_1)	2-Methyl-2-pentene and 3-methyl-2-pentene-*trans*	1.02
(B_2)	3-Hexene and 2-methyl-2-pentene	1.02
(B_3)	3-Methyl-2-pentene-*cis* and 3-ethyl-1-butene	1.02
(C)	2-Ethyl-butene-1 and 2-methyl-2-pentene	1.03
(D)	3-Methyl-2-pentene-*cis* and -*trans*	1.07

The estimates of maximum sharpness of separation to be given below assume that α is constant over the temperature range and concentrations involved in the distillations. The temperature ranges involved are so narrow that the variation in α from this source may certainly be disregarded. The conclusions of Beatty and Calingaert[6] make it reasonable to assume that none of the hexene mixtures would depart sufficiently from ideality to alter the general nature of the conclusions to be drawn in this paper.

Distillation Curves to be Expected.—It can be shown[3] that a distillation curve with a maximum sharpness of separation approximately like that

(6) H. A. Beatty and G. Calingaert, *Ind. Eng. Chem.*, **26**, 504 (1934).

of curve E in Fig. 1 would be obtained if the column employed had only a sufficient number of plates (n) so that the over-all fractionating factor (α^n) would be 1.25. Thus α^n would need to be



Per cent. distilled over.

Fig. 1.

1.25 where α is the vapor pressure ratio of the pair being separated and n is the equivalent number of plates used in the separation. The zero of the horizontal coördinates on the figure coincides approximately with the beginning of the plateau of the *lower boiling* component, and the 100 of the horizontal coördinates coincides approximately with the end of the plateau of the higher boiling component of the pair being separated. On this basis the number of plates required to obtain a separation like that indicated by curve E would be as listed in Table II.

TABLE II

Pair	Plates required for curve E
A	22
B	11
C	8
D	4

In other words the number of plates indicated would lead to no noticeable separation.[7] In Table III, from similar[3] calculations, are given the number of plates necessary to obtain the reasonable separation indicated by curve D or the sharp separation of curve B of Fig. 1.

TABLE III

Pair	α	Plates required Curve D $\alpha^n = 9.3$	Curve B $\alpha^n = 86$
A	1.01	224	450
B	1.02	112	224
C	1.03	75	150
D	1.07	33	66

Interpretation of Curves.—In studying curves B, D and E of the figure it should be recalled that the vertical coördinates have been greatly stretched and the horizontal coördinates compressed. Actually for the case of the hexenes under discussion the entire vertical scale of the figure represents only about 0.3, 0.6, 0.9, 2.0°, for pairs A, B, C and D, respectively. As stated above, the entire length of the horizontal scale of the figure corresponds approximately with the distance from the beginning of the plateau of the low boiler to the end of the plateau of the high boiler of the particular pair under discussion. Thus curve E indicates no separation at all. Curve D represents a separation in which the intermediate fraction is about 40% of the combined amount of the two components being separated, and curve B a good separation in which the intermediate fraction is only about 5% of the combined amount of the two components being separated.

Comparison with Results of Goldwasser and Taylor.—These authors[8] have recently described the separation of isomeric hexenes with a modified Podbielniak–Simons type column, and it is of interest to compare their results with those to be expected from the above calculations. The comparison must be approximate because the small scale of the distillation curves in their paper makes it difficult to interpret them accurately. One case has been worked out in some detail. In Fig. 2 of the paper by Goldwasser and Taylor there is shown the separation of a hexene boiling at 67.5° from another boiling at 67.8°. The value of α for such a pair would be approximately 1.01. The combined amount of these two components corresponds to a length of 16.8 mm. on their figure, the length of the intermediate cut is about 3 mm., so the intermediate cut is about 18% of the total amount of the two components. Assuming a 95% purity along the plateaus as stated by Goldwasser and Taylor, this would require[3] α^n to be about 70, and with α = 1.01 it would require about 425 plates to achieve this separation, if it was carried out in the absence of other components and under total reflux in a column with zero holdup. The assignment of 3 mm. to the length of the intermediate cut is rather arbitrary but even if 6 mm. were assigned the minimum plates required would be 350. The separations of hexene pairs boiling at 67.8 and 68.0°, and 67.2 and 67.5° would require a similar efficiency; in fact, all except the first four pairs shown on this figure would require in excess of 200 theoretical plates for the separations indicated. Deviations from ideality and the presence of additional components would not be expected to change the order

(7) Data obtained in this Laboratory since these calculations were made confirm these predictions; see Whitmore, *et al.*, **62**, 795 (1940).

(8) S. Goldwasser and H. S. Taylor, THIS JOURNAL, **61**, 1751 (1939).

of magnitude of the number of plates required, but consideration of the holdup and the 30 to 1 reflux ratio actually used in these distillations would certainly increase the estimates considerably.[9]

Consideration of Holdup and Reflux Ratio.—All the above computations are on the assumption that reflux was nearly total and that holdup was zero so that the conclusions are for maximum sharpness of separation and minimum plates required. No statement of the holdup in the Podbielniak–Simons–Taylor[8] column is given but it must be appreciable compared with the amount of any one component and quite large compared with the amounts of the components present in small amount so that the separations involving these would be expected to be much less sharp than the above discussion indicates.

Summary

Calculations have been made to show that a minimum of 400 or more theoretical plates are required for sharp separation of certain close boiling hexenes, and that the use of a fractionating column with a small number of theoretical plates can produce no appreciable separation in such cases even with low holdup and high reflux ratio.

STATE COLLEGE, PA. RECEIVED NOVEMBER 20, 1939

Attempted Separation of Isomeric Hexenes by Fractional Distillation

BY FRANK C. WHITMORE, M. R. FENSKE, D. QUIGGLE, H. BERNSTEIN, T. P. CARNEY, S. LAWROSKI, A. H. POPKIN, R. B. WAGNER,[1a] W. R. WHEELER AND J. S. WHITAKER

These laboratories have long been interested in the separation of difficult mixtures, especially of olefins, by fractional distillation. Consequently, it was hoped that the recent work by Goldwasser and Taylor[1] would point the way to separations hitherto not possible. We are indeed sorry to have to report that this hope has not been realized.

The Podbielniak–Simons–Taylor column[1] seems to be an excellent one of its type but has an efficiency of only about fifteen theoretical plates. Whereas the published results[1] seem to indicate a successful separation of six hexenes with a total boiling point spread of 2.5°, we have found it impossible to obtain separations even with two binary mixtures of pure hexenes having boiling point spreads of 1.5 and 2.7°, or with a ternary mixture having an over-all spread of 2.7°.

It is interesting to note that a calculation of the column efficiency needed to effect the indicated separation of the six hexenes[1] gives a value of at least 450 theoretical plates.[2]

Goldwasser and Taylor[1] use the boiling point and density to identify an olefin. This is at least difficult because of the conflicting values recorded for these constants.

Inconsistencies appear in the paper.[1] Thus, on pp. 1753–1754 there is a confusion of the *cis* and *trans* forms of 3-methyl-2-pentene. Agreement with the work of van Risseghem[3] is cited "to emphasize the confidence that may be placed in the fractionations obtained." As a matter of fact such agreement is lacking. The authority cited[3] obtained three fractions in the careful distillation of the hexenes from 3-methyl-3-pentanol, *viz.*: I, b. p. 65.1–65.7°; II, 67.2–67.8°; III, 69.9–70.2°. She states that I and III are stereoisomers of 3-methyl-2-pentene and that II is a mixture containing some of the methylene isomer. The boiling points given by Goldwasser and Taylor (Table 1a[1]) for the two 3-methyl-2-pentenes are 65.7–66.2° and 67.6–68.2°. These differ from those actually reported by van Risseghem,[3] which are 65.1–65.7° and 69.9–70.2°.

In certain cases where geometrical isomerism is possible, one constant used for identification[1] belongs to the *trans* form, while the other belongs to the *cis*. The literature values given for the isomers of 3-hexene are: *cis*, b. p. 70–71.2°, d^{20}_4 0.7190; *trans*, 67.3–67.5°, 0.7170. However, in the dehydration of 1-hexanol, 3-hexene was identified by the observed values, 67.5° and 0.720.

For 4-methyl-2-hexene the accepted values[4] are:

1 isomer, b. p. 87.1–87.6°, d^{20}_4 0.7007; 2 isomer, 85.1–85.6°, 0.6981. In reporting the presence of 4-methyl-2-hexene the literature values given by Goldwasser and Taylor[1] are 85.1–85.6° and 0.7007 and the observed values[1] are 85.1–85.2° and 0.701.

The significance of the cyclopropane mechanism suggested[1] for the formation of the suspected isomeric olefins need not be discussed.[5]

Experimental

Distillation Equipment.—Column I was of the total condensation partial take-off type.[6] It was packed with 1/8-inch inside diameter single turn glass helices.[7] The packed section was 65 × 1.5 cm., and its efficiency was about 13 theoretical plates. A calibrated thermometer gave the head temperature.

Column II was also of the total condensation partial take-off type. It was packed with 3/32-inch single turn stainless steel helices made from no. 30 wire.[8] The packed section was 100 × 1.0 cm., and its efficiency equal to at least 35–40 theoretical plates. The still was heated by an air-bath that was controlled automatically by utilizing the pressure drop through the column. A calibrated thermometer gave the head temperature.

Column III was identical with Column I, but with a packed section 45 × 0.9 cm. It had an efficiency of about 12 theoretical plates.

Column IV was built exactly as described by Goldwasser and Taylor[1] in their reported separation of the isomeric hexenes. It was a Podbielniak type column, the section within the jacket being 150 × 0.45 cm. The jacket was evacuated to below 10^{-6} mm. The head was of the total condensation partial take-off type designed by Simons.[9] Column V was made exactly like Column IV, except that the jacket was air-filled instead of being evacuated. The efficiencies of columns IV and V are given in the next section.

Determination of Theoretical Plate Values.—The theoretical plate values were determined for columns IV and V using carbon tetrachloride–benzene mixtures.[10] This method was also used to determine the efficiencies of Columns I, II, and III.

The operating conditions varied with respect to rate of refluxing at the condenser and the control of the jacket temperature. Three rates of refluxing were used, namely, a very slow rate of one drop per minute, an intermediate rate of 150 drops per minute, and a very fast rate of approximately 360 drops per minute. The last was just below flooding. The jacket temperature for the two columns was varied 1° above and 1° below the head temperature, and in the case of Column V also 5° above and 5° below the head temperature. A typical run will be described in detail.

About 100 cc. of a carbon tetrachloride–benzene mixture in a 200-cc. flask was used in making the tests. The refractive indices, $n^{20}D$, of the carbon tetrachloride and benzene were 1.4595 and 1.4999, respectively. The column was brought to equilibrium with total refluxing at a rate just below flood stage. The jacket thermometers read 1° below the head thermometer. Samples of 1 cc. were taken from the flask and from the head at the end of each specified time. The following data will illustrate the operating conditions: reflux time fifteen minutes, bath 118°, jacket 74°, head 75°, flask $n^{20}D$ 1.4960, head $n^{20}D$ 1.4820, theoretical plates 12.6. Identical theoretical plate values were obtained at 60, 90, 120, and 180 minutes. Other runs duplicated this procedure and the results are summarized in Table I.

TABLE I

Condition	Theoretical plates with air jacket (Column V)	Theoretical plates with vacuum jacket (Column IV)
Rapid rate		
Jackets 1° below head	14.0	13.4
1° above	14.0	12.6
5° above	14.6	..
5° below	14.6	..
Intermediate rate		
Jackets 1° below head	11.7	12.1
1° above	..	12.7
5° above	10.8	..
5° below	13.7	..
Very slow rate		
Jackets 1° below head	11.4	11.5
1° above	11.4	12.7
5° above	..	..
5° below	12.5	..

Thus columns IV and V are equivalent under these test conditions to approximately 13 theoretical plates regardless of the rate of operation or the use of a vacuum jacket. This is to be compared with the value of 450 theoretical plates calculated by Rose and Welshans[2] as necessary for the separations reported by Goldwasser and Taylor.[1]

The above studies on distillation Columns IV and V were made according to the analytical technique used by Goldwasser and Taylor.[1] However, they did not report any test data. In addition, a separate investigation on the efficiency of Column IV, as well as on analytical distillation columns in general, gave the results summarized in Table II. These results show that the single-turn wire helices combine at one time the four important qualities so necessary in packing for analytical fractionating columns; namely, they are efficient as shown by the low H. E. T. P. values given in Column 4, they allow a high operating throughput as shown by Column 2, they have a low holdup as shown by Column 5, and they make possible operation at low pressure drops as shown by Column 6. The data presented are representative of hundreds of tests and it is believed that the manner of presentation of the data will facilitate the work of the designer of packed fractionating columns.

Preparation of 2-Ethyl-1-butene.—2-Ethyl-1-chlorobutane, b. p. 83° at 202 mm. and $n^{20}D$ 1.4222, was prepared

[a] Packings A, B, C, and D were tested in this Laboratory. [b] Packings E, F, G, and H were tested by Bragg, *Ind Eng. Chem., Anal. Ed.*, **11**, 283 (1939). [c] Column (1) is the inside diameter of the test fractionating column in mm. [d] Column (2) is the liquid boilup or throughput under total reflux as liters of liquid per hour per square cm. of column cross section. [e] Column (3) is the number of theoretical plates in the packed section of the fractionating column. With packings A, B, C, and D a series of careful tests were made under total reflux using pure binary hydrocarbon mixtures such as heptane–toluene, heptane–methylcyclohexane, and methylcyclohexane–toluene. Packings E, F, G, and H were tested with benzene–ethylene dichloride mixtures. [f] Column (4) is the height of packing in cm. equivalent to one theoretical plate. [g] Column (5) is the dynamic holdup in cc. per theoretical plate (cc. of liquid per theoretical plate retained in the packed section while operating). With packings A, B, C, and D the principle described in *Ind. Eng. Chem.*, **26**, 1215 (1934), was used to obtain such dynamic holdup data. With packings E, F, G, and H the holdup was obtained by diverting the vapors and measuring the liquid draining from the packing, allowing for the static holdup. However, such holdup values are believed to be definitely low, for static holdup values for this type of packing appear to be 0.05–0.1 cc. of liquid per cc. of packing, while the values reported for packings F, G, and H are about one-fifth to one-tenth of this value. [h] Column (6) is the pressure drop as mm. of mercury per theoretical plate for the corresponding throughputs tabulated in Column (2).

from 2-ethyl-1-butanol (Carbide and Carbon), 439 g. thionyl chloride, and pyridine in 74% yield.

A 2-liter three-neck flask was attached by one neck to Column I, set for total reflux, and a mercury-seal stirrer

and dropping funnel were placed in the other two necks. In the flask were placed 647 g. (14.5 moles) of absolute ethyl alcohol and 336 g. (6 moles) of potassium hydroxide. This mixture was heated to refluxing and stirred. When solution of the potassium hydroxide was complete, 439 g. (3.6 mole) of 2-ethyl-1-chlorobutane was added at the rate of one drop per second. After the addition of the halide had begun, the reflux temperature dropped from 76 to 54°. Product was then taken off at a reflux ratio of 20:1. The distillation was continued until the distillate did not form two layers upon the addition of water. The combined upper layers were washed several times with water, dried, filtered, and distilled through Column I. There resulted 64 g., or a 21% yield, of 2-ethyl-1-butene, b. p. 63° at 728 mm. and $n^{20}D$ 1.3967.

This olefin, combined with that obtained from a later run, was redistilled through Column II at 734 mm. to give fractions: 1, 2.0 g., b. p. 59–63.3°, $n^{20}D$ 1.3948; 2, 2.2 g., 63.6°, 1.3967; 3–11, 52.9 g., 63.6°, 1.3968; residue 5.5 g.

Fractions 4–10 were distilled at 733 mm. through Column IV following exactly the technique of Goldwasser and Taylor[1] to give fractions: 12, 3.0 g., b. p. 63.7°, $n^{20}D$ 1.3967; 13–16, 26.8 g., 63.8°, 1.3968; 17, 5.0 g., 63.8°, 1.3969; residue 2.0 g.

Only fractions 13–16 were used to make the isomeric hexene mixtures for the attempted separations using Column IV. Physical constants for the 2-ethyl-1-butene used were Cottrell b. p. (50%) 63.75 ± 0.05° at 731 mm., $n^{20}D$ 1.3968 ± 0.0001, d^{20}_4 0.6992 ± 0.0002.

It should be noted that this material is the best from successive distillations through Columns I, II, and IV.

Preparation of 2-Methyl-1-pentene.—Into a one-liter flask with a one-liter dropping funnel, a mercury-seal stirrer, a thermometer, and a reflux condenser was placed 77.4 g. (0.86 mole) of redistilled 2-methyl-3-chloro-1-propene (Shell Technical), b. p. 70.2–73.0° at 732 mm. and $n^{20}D$ 1.4270. Ethylmagnesium bromide prepared from 105 g. (0.96 mole) of redistilled ethyl bromide, b. p. 37.8° at 727 mm., and 23 g. (0.96 mole) of magnesium turnings was filtered through glass wool under nitrogen pressure into the dropping funnel. The Grignard reagent was added dropwise to the halide with vigorous stirring, keeping the reaction mixture below 0° with a salt–ice-bath. The addition was completed in twelve hours, and stirring was continued for an additional ten hours. To the reaction mixture surrounded by a salt–ice-bath was added with vigorous stirring 300 cc. of ice water, which was sufficient to dissolve the magnesium chloride. The layers were then separated and the ether layer washed once with water. The combined water layers were then extracted several times with ether, and the combined ether extracts dried over anhydrous potassium carbonate. The ethereal solution was then filtered and distilled through Column III, the ether being removed with a reflux ratio of 10:1. The distillation, carried out at 731 mm., yielded fractions: 1–5, 22.8 g., b. p. 34.5–60.0°, $n^{20}D$ 1.3616–1.3903; 6–11, 28.2 g., 61.0°, 1.3923–1.3925; 12–13, 6.7 g., 61.0°, 1.3933–1.3935.

Fractions 6–11, combined with 2-methyl-1-pentene from a similar run making a total of 54.4 g., were distilled through Column II at 737 mm. to give fractions: 14–16, 6.3 g., b. p. 41–61.3°, $n^{20}D$ 1.3794–1.3919; 17–18, 8.3 g., 61.3°, 1.3925; 19, 3.9 g., 60.5–61.3°, 1.3924; 20–21, 9.6 g., 61.3°, 1.3925; 22–23, 7.1 g., 61.3°, 1.3927.

Fractions 17, 18, 20, and 21 were distilled through Column IV at 737 mm. using the technique of Goldwasser and Taylor[1] with the resulting fractions: 24, 2.0 g., b. p. 61.3°, $n^{20}D$ 1.3923; 25–26, 7.2 g., 61.3°, 1.3925; 27–28, 5.3 g., 61.3°, 1.3926–1.3927.

Only fractions 25 and 26 were used with isomeric hexenes for attempted separation through Column IV. The physical constants for the 2-methyl-1-pentene used were Cottrell b. p. (50%) 61.35 ± 0.05° at 738 mm., $n^{20}D$ 1.3925 ± 0.0001, d^{20}_4 0.6817 ± 0.0002.

Preparation of 1-Hexene.—The method of preparation was similar to that used for 2-methyl-1-pentene. *n*-Propylmagnesium bromide was prepared from 615 g. (5 moles) of *n*-propyl bromide, b. p. 70–71° at 738 mm. and $n^{20}D$ 1.4340, and 121 g. (5 moles) of magnesium. This was added to 500 g. (4.1 mole) of allyl bromide, b. p. 70–71° at 735 mm. and $n^{20}D$ 1.4653. Ether was first removed through Column I at 739 mm. using a 10:1 reflux ratio. Continued distillation yielded fractions: 1–6, 62.8 g., b. p. 53–61.2°, $n^{20}D$ 1.3720–1.3886; 7–15, 82.7 g., 61.2–63.0°, 1.3886–1.3889; 16–21, 53.5 g., 63.0°, 1.3889–1.3885; 22–30, 74.6 g., 63.0°, 1.3883–1.3880.

Fractions 7–21 were distilled through Column II at 737 mm., and there resulted fractions: 31–36, 30.4 g., b. p. 60.3–60.7°, $n^{20}D$ 1.3901–1.3889; 37–39, 15.3 g., 60.7–62.5°, 1.3890–1.3897; 40, 4.6 g., 62.5°, 1.3893; 41–48, 32.8 g., 62.5°, 1.3890; 49–52, 9.3 g., 62.5°, 1.3889–1.3883.

Fractions 41–48 were distilled through Column IV at 733 mm. using the technique of Goldwasser and Taylor[1] to give fractions: 53–54, 7.0 g., b. p. 62.5°, $n^{20}D$ 1.3892; 55–57, 16.3 g., 62.5°, 1.3891; 58, 5.6 g., 62.5°, 1.3890; 59–60, 5.8 g., 62.5°, 1.3889.

Only fractions 55–58 were used with isomeric hexenes for attempted separation with Column IV. The physical constants for the 1-hexene used were Cottrell b. p. (50%) 62.52 ± 0.05° at 737 mm., $n^{20}D$ 1.3891 ± 0.0001, d^{20}_4 0.6873 ± 0.0002.

Table III shows a comparison of our physical constants with those of Boord and his co-workers.[11,12,13]

Attempted Separation of Isomeric Hexenes.—Three mixtures for distillation were made up as follows: 1, 15 cc. of 1-hexene (fractions 55–58) and 15 cc. of 2-ethyl-1-butene (fractions 13–16); 2, 11.6 cc. of 2-ethyl-1-butene (fractions 13–16) and 9.0 cc. of 2-methyl-1-pentene (fractions 25–26); 3, the distillates from the above two distillations were combined to give a mixture containing 50% 2-ethyl-1-butene, 26% 2-methyl-1-pentene, and 24% 1-hexene. The latter figures are weight %, and were calculated from refractive index–composition curves.

The procedure followed was exactly that used by Goldwasser and Taylor,[1] even to the extent of requiring one-half hour after the heat was applied for the material to boil. The rate of reflux was just below the flood stage, or approximately 360 drops per minute. The rate of

TABLE III

Hexene	B. p., °C. Expt.	B. p., °C. Lit.	$n^{20}D$ Expt.	$n^{20}D$ Lit.	d^{20}_4 Expt.	d^{20}_4 Lit.
1-Hexene	63.4	63.4–63.7	1.3891[a]	1.3870	0.6873[a]	0.6732
2-Ethyl-1-butene	64.9	64.9–65.1	1.3968	1.3970	.6892	.6899
2-Methyl-1-pentene	62.2	61.5–62.0	1.3925	1.3921	.6827	.6817 .6831

[a] The higher values obtained were probably due to impurities of hexadiene not removable by distillation. Since our 1-hexene was a constant boiling constant index material during three distillations through efficient columns, it was suitable for checking Column IV.

take-off was 1 drop every five seconds. Jackets were kept within 0.1° of the reflux temperature. The reflux temperature was noted for every 0.2 cc. of product obtained and a curve plotted while the distillation was in progress. At the end of each horizontal part of the resulting curve the column was put at total reflux for five minutes. In case the reflux temperature dropped to the preceding value and the horizontal continued for another 1 cc., total reflux was again used for five minutes. The care with which this technique was followed is illustrated by the exaggerated distillation curve in Fig. 1. One-cc. fractions were collected in a 1-cc. receiver calibrated to 0.01 cc.

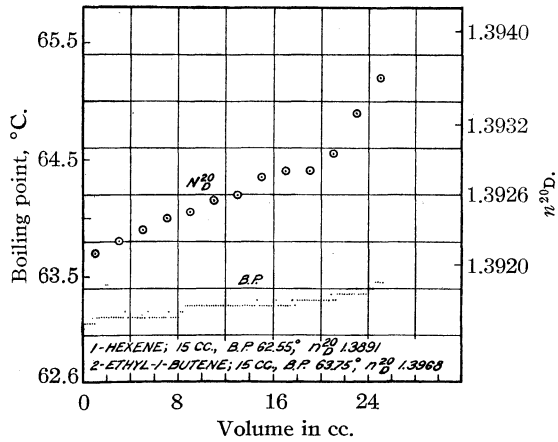

Fig. 1.—Fractionation of 2-ethyl-1-butene and 1-hexene through column IV.

Figures 2, 3, and 4 illustrate three attempts to separate isomeric hexene mixtures. Each distillation was followed by both the boiling point and index of refraction. The continuous lines in the accompanying figures are the theoretical distillation curves assuming perfect separation, while the experimental points are shown by dots.

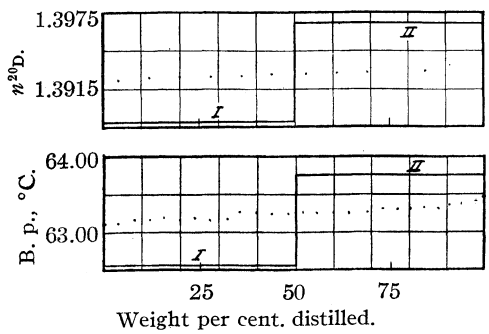

Fig. 2.—I, 50%, 1-hexene; II, 50%, 2-ethyl-1-butene.

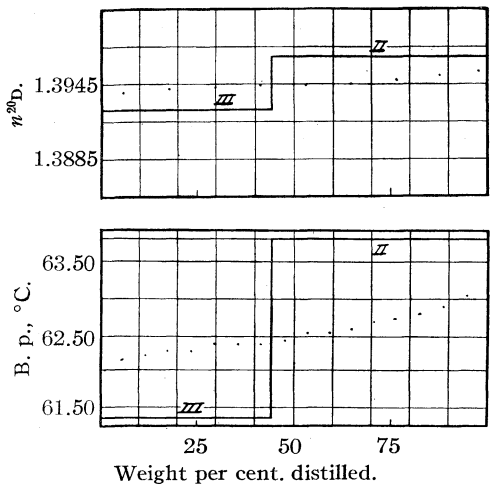

Fig. 3.—II, 56%, 2-ethyl-1-butene; III, 44%, 2-methyl-1-pentene.

It will be seen that the over-all temperature spreads produced in the course of these fractionations are much less than the temperature differences stated to exist between the boiling points of the pairs of substances in question. This obviously means that little separation occurred in the course of the fractionations. The same is true for indices of refraction. Density values further substantiate the data on temperature and refractive index, namely, that little if any separation resulted.

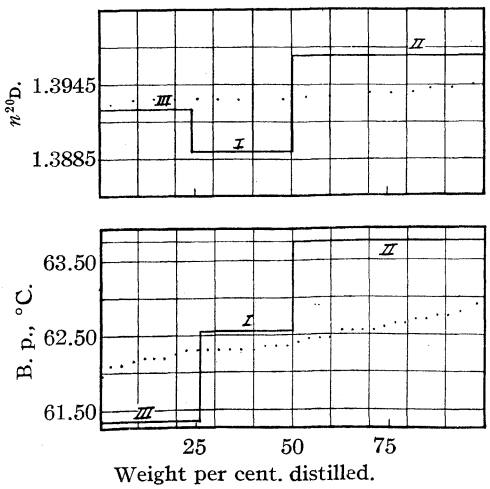

Fig. 4.—I, 24%, 1-hexene; II, 50%, 2-ethyl-1-butene; III, 26%, 2-methyl-1-pentene.

Acknowledgment is made to the following members of the Petroleum Refining Laboratory for help in connection with the data compiled in Table IV: J. P. Haimovicz, G. Herbolsheimer, J. H. Jones, R. H. McCormick, A. E. Schubert, and K. A. Steel.

Summary

1. The identification of olefins as reported by Goldwasser and Taylor in their dehydration of certain alcohols is questioned.

2. The Podbielniak–Simons–Taylor column has an efficiency of about fifteen theoretical plates.

3. Fruitless efforts were made to separate by distillation through the Podbielniak–Simons–Taylor column two binary mixtures having boiling point spreads of 2.7 and 1.5°, and a ternary mixture having an over-all boiling point spread of 2.7°. Our failure is in sharp contrast to the reported separation and identification of six hexenes with an over-all boiling point spread of 2.5°.

4. The Podbielniak–Simons–Taylor column is compared in Table IV with other types of fractional distillation columns.

Ionic Character and Dipole Moments

BY FREDERICK T. WALL

In discussing the nature of the chemical bond in hydrogen halides, Pauling[1] has found it convenient to regard the normal states of those molecules as superpositions of ionic and covalent states. As a measure of the fraction of ionic character in the molecules he took the values of μ/er where μ is the dipole moment and r the internuclear separation. In this paper the notion is extended somewhat, and a theory of dipole moments for the normal and first excited states is developed.

In a previous paper[2] the author considered the problem by supposing that the wave function (unnormalized) for the molecule can be taken as

$$\psi = \psi_c + a\psi_i$$

where ψ_c is a purely covalent function and ψ_i a purely ionic function, and a is a parameter. To get the best energy value from that function, the energy expression was minimized with respect to a. If W represents that minimized value and W_c and W_i the covalent and ionic energies, then it was shown that

$$a^2 = \frac{W - W_c}{W - W_i} \qquad (1)$$

By use of equation (1) estimates of values for a^2 were obtained for the different hydrogen halides at their equilibrium internuclear separations and the results roughly correlated with dipole moment values.

A more precise relationship between dipole moment and ionic character will now be developed and some conclusions drawn from it. Using the function $\psi = \psi_c + a\psi_i$ in which ψ_c and ψ_i are each normalized to unity, then the general expression for the dipole moment becomes

$$\mu = \frac{\mu_{cc} + 2a\mu_{ci} + a^2\mu_{ii}}{1 + 2a\Delta + a^2} \qquad (2)$$

where μ_{cc} is the moment of the covalent structure, μ_{ii} that of the ionic structure and μ_{ci} the corresponding integral of the moment expression over the states ψ_i and ψ_c. That is

$$\mu_{ci} = \int \psi_c^* \mu \psi_i d\tau = \int \psi_i^* \mu \psi_c d\tau$$

Also

$$\Delta = \int \psi_c^* \psi_i d\tau = \int \psi_i^* \psi_c d\tau$$

Now the moment of the covalent structure can be taken as zero and that of the ionic structure as er. It remains then to find the value of μ_{ci}.

In order to get an idea as to the nature of μ_{ic}, consider the hypothetical case of resonance between HH and H^+H^-. (For the actual hydrogen molecule, the structure H^-H^+ is equally as important as H^+H^-,[3] but it will not be considered here in order that the results can be used for the hydrogen halides for which only the structures HX and H^+X^- are important.) Setting up a purely covalent function of the Heitler–London[4] type for HH and a simple ionic function such as was used by Weinbaum[3] for H^+H^-, the integral μ_{ic} readily can be evaluated. In this case it turns out that

(3) S. Weinbaum, *J. Chem. Phys.*, **1**, 593 (1933).

(4) W. Heitler and F. London, *Z. Physik*, **44**, 455 (1927).

$$\mu_{ic} = \frac{\mu_{cc} + \mu_{ii}}{2}\Delta \qquad (3)$$

where $\mu_{cc} = 0$ and $\mu_{ii} = er$.

The result expressed by equation (3) is a simple one which seems quite plausible. It will be assumed that (3) also holds for the hydrogen halides. Combining (3) with (2) there is obtained

$$\mu = \frac{\mu_{cc}(1 + a\Delta) + \mu_{ii}(a\Delta + a^2)}{1 + 2a\Delta + a^2} \qquad (4)$$

Letting $\mu_{cc} = 0$ and $\mu_{ii} = er$, equation (4) becomes

$$\mu = \frac{a\Delta + a^2}{1 + 2a\Delta + a^2} er \qquad (5)$$

Equations (4) and (5) can be demonstrated to be satisfactory in several ways. Obviously they have the correct characteristics for the two limiting cases when $a \longrightarrow 0$ (covalent) and when $a \longrightarrow \pm\infty$ (ionic). They are also highly satisfactory for the intermediate cases when $a = \pm 1$. If $a = \pm 1$, then

$$\mu = \frac{\mu_{cc} + \mu_{ii}}{2} \text{ from (4)}$$

or

$$\mu = {}^1/_2 er \text{ from (5)}$$

In other words, when the ionic and covalent states contribute equally, the moment is just the mean of the moments (or half the ionic moment).

It is also seen from (5) that whenever $-1 < a < 1$, then $0 < \mu < 1/2(er)$. This situation can be realized for the normal state of a molecule whenever the covalent state is more stable than the ionic state. The fact that hydrogen chloride, hydrogen bromide and hydrogen iodide all have dipole moments less than $1/2(er)$ is in agreement with this result and their assumed energy curves.

On the other hand, when $1 < a < \infty$ or $-1 > a > \infty$ then $\mu > 1/2(er)$. This state of affairs should exist for normal hydrogen fluoride according to Pauling's energy curves, because the ionic curve cuts below the covalent one. We should expect then that the dipole moment of hydrogen fluoride would be greater than $1/2(er)$.

Another interesting result can be derived as follows. The energy W for a system with a wave function $\psi_c + a\psi_i$ is given by

$$W = \frac{H_{cc} + 2aH_{ic} + a^2H_{ii}}{1 + 2a\Delta + a^2} \qquad (6)$$

Letting $\partial W/\partial a$ equal zero and combining that result with equation (6), there is obtained a quadratic equation in a, the two roots of which are subject to the relations

$$a_1a_2 = \frac{\Delta H_{cc} - H_{ic}}{H_{ic} - \Delta H_{ii}}$$
$$a_1 + a_2 = \frac{H_{ii} - H_{cc}}{H_{ic} - \Delta H_{ii}} \qquad (7)$$

One of the roots (say a_1) corresponds to dissociation into neutral atoms and the other (a_2) to dissociation into ions. Each of the two resultant states has a dipole moment given by (4) or (5) by putting into those equations a_1 and a_2. But from (7) it can be shown that

$$1 + (a_1 + a_2)\Delta + a_1a_2 = 0 \qquad (8)$$

which is precisely the condition for orthogonality of $\psi_c + a_1\psi_i$ and $\psi_c + a_2\psi_i$. But

$$\mu_1 + \mu_2 = \frac{\mu_{cc}(1 + a_1\Delta) + \mu_{ii}(a_1\Delta + a_1^2)}{1 + 2a_1\Delta + a_1^2} + \frac{\mu_{cc}(1 + a_2\Delta) + \mu_{ii}(a_2\Delta + a_2^2)}{1 + 2a_2\Delta + a_2^2} \qquad (9)$$

Simplifying this expression and making use of (8), we find that

$$\mu_1 + \mu_2 = \mu_{cc} + \mu_{ii} \qquad (10)$$

or if $\mu_{cc} = 0$ and $\mu_{ii} = er$

$$\mu_1 + \mu_2 = er \qquad (11)$$

Equations (10) and (11) express the simple result that the total dipole moment of the two resultant states is equal to the sum of the moments of the interacting states. For that reason, the quantity μ/er is an excellent measure of ionic character even though it is not simply related to the quantity a.

The qualitative features of the relationship between dipole moments and energy curves are shown in Figs. 1 and 2. In these figures the dotted energy curves apply to the purely covalent and ionic states, whereas the solid curves represent the energies of the states resulting from the resonance. Immediately below are given dipole moment curves. In each case, for large internuclear separations the ionic moments approach the line $\mu = er$ asymptotically and the covalent moments approach zero.

In Fig. 1, the purely covalent energy is everywhere less than the ionic energy so that the moment associated with the normal state is everywhere less than $1/2(er)$ and the other moment greater than $1/2(er)$. In Fig. 2, the purely ionic curve cuts below the covalent curve, so that the moment of the normal molecule is greater than $1/2(er)$ for a certain range of r. The two moment curves cross with the value $1/2(er)$ at the same internuclear separation where the idealized energy curves cross. The case exhibited by Fig. 2 is to be expected for hydrogen fluoride.

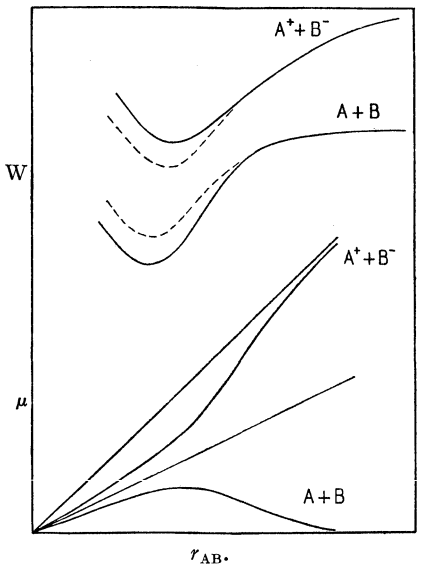

Fig. 1.—Energy and dipole moment curves with covalent state everywhere more stable than ionic state.

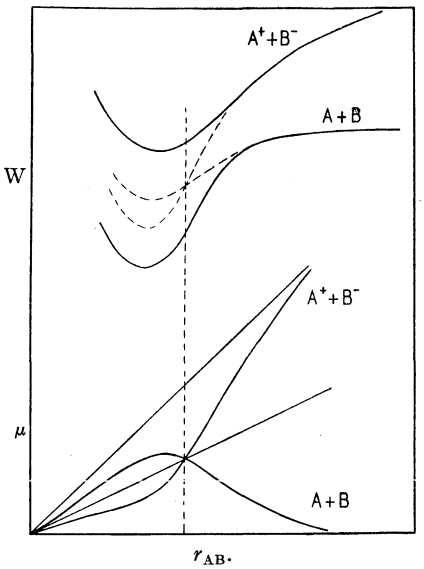

Fig. 2.—Energy and dipole moment curves with ionic state more stable than covalent state for certain range of internuclear separations.

The behavior of the moment curves for small internuclear separations is not certain, though it seems reasonable to suppose that the slopes are both different from zero for $r = 0$. At any place, of course, the sum of the slopes equals e by reason of equation (11). The two curves for the moments of the normal molecules were drawn to resemble those proposed by Mulliken.[5]

Since $0 \leqslant |\Delta| \leqslant 1$, it follows from equation (5) that a must lie in the range

$$\sqrt{\frac{\mu}{er - \mu}} \text{ to } \frac{\mu}{er - \mu}$$

From a knowledge of μ/er, one can then calculate upper and lower limits for $|a|$ for the normal molecules. The results of such calculations are given in Table I. Values of $|a|$ could of course be obtained for any value of Δ by use of equation (5). Such values have been calculated taking $\Delta = 0.3$, since it is likely that Δ is nearer 0 than it is to 1.

TABLE I

Molecule	μ/er	a values $\Delta = 0$	$\Delta = 0.3$	$\Delta = 1$	From energy data[2]
HF	0.60[a]	1.22	1.30	1.50	
HCl	.170	0.45	0.35	0.20	0.39
HBr	.114	.36	.25	.13	.35
HI	.049	.23	.13	.052	.26

[a] Value estimated by Pauling.[1]

In a previous paper,[2] values for a^2 were computed by means of energy data using equation (1). The corresponding values of $|a|$ except for hydrogen fluoride are shown in the last column of Table I. The energy curves used in those calculations were not very reliable, especially in the case of hydrogen fluoride, in which case they were way off. However, it is seen that the values for hydrogen chloride and hydrogen bromide calculated by the use of those energy curves lie between the upper and lower limits specified by dipole moment data. The value from energy curves for hydrogen iodide is a little higher than the upper limit from dipole moment data.

Since $a^2/(1 + a^2)$ might well be adopted as a measure of ionic character, values for that quantity are given in Table II for $\Delta = 0$, $\Delta = 0.3$ and $\Delta = 1$, as well as those values obtained from energy data. It should be noted that if $\Delta = 0$, then $a^2/(1 + a^2)$ is just μ/er. It is clear from the results in the tables that with increasing atomic number, a and $a^2/(1 + a^2)$ become increasingly sensitive to variations in Δ. It might well be that for hydrogen bromide and hydrogen iodide, Δ is nearer zero than 0.3.

TABLE II

Molecule	$a^2/(1 + a^2)$ $\Delta = 0$	$\Delta = 0.3$	$\Delta = 1$	From energy data[2]

Summary

A theory of dipole moments of diatomic mole-

(5) R. S. Mulliken, *J. Chem. Phys.*, **2**, 400 (1934).

cules is developed and it is shown that the sum of the dipole moments of two states resulting from resonance is the same as the sum of the dipole moments of the original states. Assuming a wave function $\psi = \psi_c + a\psi_i$ for a system resonating between covalent and ionic states, upper and lower limits to $|a|$ are calculated using dipole moment data, and the results compared to calculations of $|a|$ based on energy values.

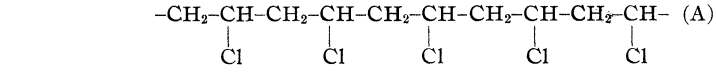
Removal of Substituents from Vinyl Polymers

BY FREDERICK T. WALL

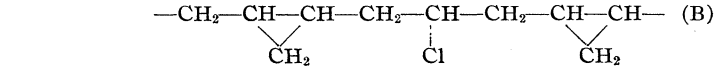
Experimental studies by Marvel and coworkers[1] have shown that chlorine can be partly removed from vinyl chloride polymers by means of zinc. The removal of chlorine is not quantitative, however, owing to the fact that some of the chlorides become isolated. A given chlorine atom is considered isolated when its nearest neighbor is so far away that it and that neighbor can no longer be removed as a pair by means of zinc.

This notion can be illustrated as follows. Suppose the polymer has all its substituents in 1–3 relationship with respect to their nearest neighbors. Then a portion of the polymer would look as follows



(A)

If this portion of the polymer were attacked by zinc, some of the chlorides might be removed in any of several ways. If, say, zinc removed the first and last pairs, there would result



(B)

in which the middle chloride is now isolated and hence incapable of removal.

Assuming that zinc removes chlorides in a perfectly random way, the problem of what fraction of the chlorides becomes isolated is simply a question of probability. This problem has been solved by Flory[2] for the cases where all of the substituents are the same. His results show that if the polymer has all of its chlorides in 1–3 relationship, then the portion $1/e^2$ (or 13.53%) of the original chlorides will become isolated, a result for which there is experimental support.[1] This was derived after making the reasonable assumption that no two chlorides separated by more than three carbons can be removed as a pair.

Flory also considered the case where the polymer is not necessarily 1–3 throughout, but is made up of vinyl units oriented at random. Since a given vinyl unit can be oriented in either of two ways along the line of the polymer chain, 1–2, 1–3 and 1–4 relationships will exist between substituents. Assuming that 1–2 and 1–3 substituents can be removed with equal ease but that 1–4 or more widely separated substituents cannot be removed, he showed that the portion $1/2e$ (or 18.40%) of the original substituents could be expected to remain after reaction.

More recently, Marvel and Mastin[3] have studied the removal of chlorine from mixed vinyl chloride vinyl acetate polymers. In such a case, the acetates will divide up the long polymer into isolated groups of chlorides. Assuming that the acetates are interspersed at random in the polymer, one is confronted with a more general statistical problem in attempting to calculate the fraction of the original chlorides which can be expected to remain after treatment with zinc. In this paper, the solution to that problem is given for the two cases when the linkages are all 1–3 and when the orientations are random.

Statistical Treatment.—In attacking both cases of this problem, it is first to be noted that any two chlorides which have one or more acetates between them as substituents along the chain cannot be removed as pairs by means of zinc. The problem then resolves itself first into finding the number of groups of chlorides of given lengths formed by interspersing acetates, and, second, into summing up those numbers multiplied by the chloride expectancy per group. The chloride expectancy per group depends upon whether or

(1) C. S. Marvel, J. H. Sample and Max F. Roy, THIS JOURNAL, **61**, 3241 (1939).

(2) P. J. Flory, *ibid.*, **61**, 1518 (1939).

(3) Private communication.

not the linkages are all 1–3 or are random. The number of groups of specified lengths, however, does not depend upon the presence or absence of link orientation restrictions, as far as probability alone is concerned.

We shall accordingly first turn to the problem of group distribution. Let N_X equal the total number of X's (chlorides) and N_Y the total number of Y's (acetates) in the long polymer. In the following treatment it will be assumed that these N's are very large numbers. Then if p_i equals the number of groups of X's containing i members, it follows that

$$N_X = \sum_i i p_i \tag{1}$$

and

$$N_Y = \sum_i p_i \tag{2}$$

In order for (2) to be valid, it is necessary that we include values for $i = 0$. Regarding the Y's as spacers, two adjacent Y's surround a group of X's zero members long. Each group of X's has one Y as a spacer; hence the equality (2).

Now the number of complexions in the statistical state represented by $p_0, p_1, p_2, \ldots$ is given by

$$W = \frac{N_Y!}{p_0!p_1!p_2!\ldots} \tag{3}$$

The most probable distribution corresponds to the maximum value for W. Using Stirling's approximation for ln W and setting the variation of it equal to zero, we have[4]

$$\delta \ln W = -\sum_i \ln p_i \, \delta p_i = 0 \tag{4}$$

This equation is subject to two additional equations obtained by taking variations of (1) and (2).

$$\delta N_X = \sum_i i \, \delta p_i = 0 \tag{5}$$

$$\delta N_Y = \sum_i \delta p_i = 0 \tag{6}$$

Introducing Lagrangian multipliers and combining in the usual way, we find that

$$p_i = e^{-\lambda - \mu i} \tag{7}$$

To determine μ and λ, equation (7) is combined with equation (1) and with equation (2), giving

$$N_X = \sum_i i e^{-\lambda-\mu i} = e^{-\lambda-\mu}\{1 + 2e^{-\mu} + 3e^{-2\mu} + \ldots\} = \frac{e^{-\lambda}e^{-\mu}}{(1 - e^{-\mu})^2} \tag{8}$$

(4) This treatment is similar to that employed in deriving the Maxwell–Boltzmann distribution law; see for example, Tolman, "Statistical Mechanics," Oxford University Press, 1938.

and

$$N_Y = \sum_i e^{-\lambda-\mu i} = e^{-\lambda}\{1 + e^{-\mu} + e^{-2\mu} + \ldots\} = \frac{e^{-\lambda}}{1 - e^{-\mu}} \tag{9}$$

From (8) and (9) it is found that

$$e^{-\mu} = \frac{N_X}{N_X + N_Y} \tag{10}$$

and

$$e^{-\lambda} = \frac{N_Y^2}{N_X + N_Y} \tag{11}$$

Substituting (10) and (11) into (7), we find

$$p_i = \frac{N_Y^2}{N_X + N_Y}\left(\frac{N_X}{N_X + N_Y}\right)^i \tag{12}$$

Define

$$x = \frac{N_X}{N_X + N_Y} \tag{13}$$

Then

$$p_i = N_X(1 - x)^2 x^{i-1} \tag{14}$$

Equation (14) tells us the number of groups of X's containing i members in terms of the mole fraction of substituents which are of the X variety and the total number N_X.

If the average number of X's (chlorides) remaining after treatment with zinc is S_i for a group originally containing i members, then the total number N_r of X's remaining in the infinite polymer is

$$N_r = \sum_i S_i p_i \tag{15}$$

and the fraction, f, of the original number is

$$f = \frac{N_r}{N_X} = \sum_i S_i(1 - x)^2 x^{i-1} \tag{16}$$

Expanding and rearranging

$$f = \sum_i S_i(x^{i-1} - 2x^i + x^{i+1}) = \sum_i (S_{i+1} - 2S_i + S_{i-1})x^i \tag{17}$$

Defining $\Delta_n = S_n - S_{n-1}$ we see that

$$f = \sum_i (\Delta_{i+1} - \Delta_i)x^i \tag{18}$$

Case 1: 1–3 Coupling Throughout.—If all of the substituents are 1–3 with respect to each other, then $\Delta_{i+1} - \Delta_i$ is subject to a relationship derived by Flory,[2] namely

$$\Delta_{i+1} - \Delta_i = (-2)^i/i! \tag{19}$$

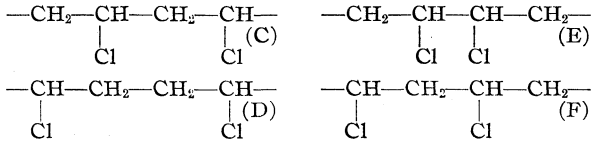
Substituting into (18)

$$f = \sum_i \frac{(-2)^i}{i!}x^i = e^{-2x} \tag{20}$$

Equation (20) gives a very simple expression for the fraction of chlorine remaining after

treatment with zinc. If $x = 1$, which would be the case when all of the substituents are chlorides, $f = 1/e^2$ in agreement with Flory's result for that special case. On the other hand, it is seen that the smaller the value of x, the greater will be the fraction of original chlorides remaining at the end. This follows because of the tendency of acetates to isolate many chlorides. Preliminary experimental evidence obtained by Marvel and Mastin[5] supports the validity of the result $f = e^{-2x}$.

Case 2: Random Coupling Throughout.— In the event that the vinyl links join together in a random way, the chloride expectancy per group will not be the same as for the case where all the linkages are 1–3, assuming that 1–4 or more widely separated pairs cannot be removed by zinc. Consider, for example, the situation possible for a group containing two vinyl units. Four possibilities will exist, namely



Of the four possibilities, C, E and F will have no chlorides remaining after treatment with zinc, whereas D will have two remaining. If each possibility is equally probable, then the average number of chlorides remaining from randomly built up groups of two vinyl units will be 2/4 or 1/2 per group. This value, which we will denote by S_2', is different from the S_2 value for 1–3 orientation, which equals zero.

The problem in case 2 is precisely the same as that of case 1 up through equation (18). That is

$$f' = \sum_i (\Delta'_{i+1} - \Delta'_i)x^i \qquad (18')$$

the primes serving to distinguish case 2 from case 1.

Consider once more the situation for $n = 2$. By the use of + and − signs, where a plus sign denotes a vinyl unit with its substituent on the right-hand side and a minus sign denotes a vinyl unit with its substituent on the left-hand side, the array CDEF can be abbreviated as follows.

$$\begin{array}{ll} + + & \text{(C)} \\ -|+ & \text{(D)} \\ + - & \text{(E)} \\ - - & \text{(F)} \end{array}$$

(5) Private communication. Their results will be published soon.

For n greater than 2, similar arrays of 2^n members could be set up. Whenever a minus sign is followed by a plus sign, the member is divided into two smaller groups (indicated by the vertical line in D above). For $n = 3$ we would have the array

$$\begin{array}{ll} + + + & + + - \\ -|+ + & -|+ - \\ + -|+ & + - - \\ - -|+ & - - - \end{array} \qquad \text{(G)}$$

where four of the members are broken up by minus signs followed by plus signs. Direct counting would then tell us that $S_3' = 1$.

Let us now consider the case of a general array each of whose 2^n members will be considered equally probable. For a particular value of n, let r_i equal the number of groups i members long ending with + signs on the right and let s_i equal the number of groups i members long ending with − signs in the extreme right-hand column. Also let l_i equal the number of groups (ending with − signs) without their terminal symbol in the extreme right-hand column. It follows then, that

$$2^n S_n' = (r_1 + s_1 + l_1)S_1 + (r_2 + s_2 + l_2)S_2 + \ldots + (r_n + s_n + l_n)S_n \qquad (21)$$

assuming 1–2 and 1–3 removals are equally probable.

Now in going from the array of 2^n members to the next higher array, one need only add + signs to all members of the n array and then − signs to all members of the n array to arrive at the 2^{n+1} members of the $n + 1$ array. The effect of adding + or − signs upon the classes of groups defined in the previous paragraph is apparent. We see that

$$2^{n+1}S'_{n+1} = (2^{n-1} + s_1 + 2l_1)S_1 + (2r_1 + s_1 + s_2 + 2l_2)S_2 + (2r_2 + s_2 + s_3 + 2l_3)S_3 + \ldots + (2r_n + s_n)S_{n+1} \qquad (22)$$

where the r_i's, s_i's and l_i's refer back to the case of n members. Combining (21) and (22)

$$2^{n+1}(S'_{n+1} - S'_n) = (2^{n-1} - 2r_1 - s_1)S_1 + (2r_1 + s_1 - 2r_2 - s_2)S_2 + (2r_2 + s_2 - 2r_3 - s_3)S_3 + \ldots + (2r_n + s_n)S_{n+1} \qquad (23)$$

Rearranging (23)

$$2^{n+1}\Delta'_{n+1} = 2^{n-1}S_1 + (2r_1 + s_1)\Delta_2 + (2r_2 + s_2)\Delta_3 + \ldots + (2r_{n-1} + s_{n-1})\Delta_n + (2r_n + s_n)\Delta_{n+1} \qquad (24)$$

But by an inductive method for the various arrays, it can be shown that

$$r_j = 2^{n-j-1} \text{ and } s_j = 2^{n-j-1}(j-1) \text{ for } j < n \quad \text{and } r_j = 1 \quad \text{and } s_j = n \quad \text{for } j = n \qquad (25)$$

Combining the results expressed by (25) with equation (24) there is obtained

$$\Delta'_{n+1} = \frac{S_1}{2^2} + \frac{2\Delta_2}{2^3} + \frac{3\Delta_3}{2^4} + \cdots + \frac{n\Delta_n}{2^{n+1}} + \frac{(n+2)\Delta_{n+1}}{2^{n+1}} \quad (26)$$

Also

$$\Delta'_n = \frac{S_1}{2^2} + \frac{2\Delta_2}{2^3} + \frac{3\Delta_3}{2^4} + \cdots + \frac{(n+1)\Delta_n}{2^n} \quad (27)$$

Subtracting (27) from (26) we see that

$$\Delta'_{n+1} - \Delta'_n = \frac{n+2}{2^{n+1}}(\Delta_{n+1} - \Delta_n) \quad (28)$$

But

$$\Delta_{n+1} - \Delta_n = \frac{(-2)^n}{n!} \quad (19)$$

Hence

$$\Delta'_{n+1} - \Delta'_n = \frac{(2+n)(-1)^n}{2n!} \quad (29)$$

Substituting (29) into (18′) there results

$$f' = \sum_i \frac{(2+i)(-1)^i}{2i!}x^i$$
$$= \sum_i \frac{(-x)^i}{i!} - \frac{x}{2}\sum_i \frac{(-x)^{i-1}}{(i-1)!}$$
$$= e^{-x} - \frac{x}{2}e^{-x} = e^{-x}\left(1 - \frac{x}{2}\right) \quad (30)$$

The result expressed by equation (30) is also a simple result, yet substantially different from that applying to case 1, namely, $f = e^{-2x}$. It should be noted that if $x = 1$, equation (30) gives $f' = 1/2e$ in agreement with Flory's result for that special case.

Discussion

A certain amount of evidence as to the nature of the vinyl polymers can be obtained by seeing which of the two formulas e^{-2x} or $e^{-x}(1 - x/2)$ best predicts the fraction of chlorine isolated in the mixed polymers. Preliminary evidence obtained by Marvel and Mastin[5] indicates that the former expression is the better of the two. This alone would not prove the 1–3 hypothesis, since the same result could be obtained with the random distribution, if 1–2, 1–3 and 1–4 pairs could be drawn off with equal ease and 1–5 or higher pairs not removed at all. However, agreement with the formula e^{-2x} would substantiate other evidence[1] for the 1–3 hypothesis.

The author is indebted to Professor Marvel and Mr. Mastin for bringing this problem to his attention.

Summary

By statistical methods, formulas are developed to predict the fraction of chlorine remaining in mixed vinyl chloride–vinyl acetate polymers upon treatment with zinc, assuming the acetates to be distributed in a random manner. Two cases are considered: first, 1–3 coupling throughout with the assumption that only 1–3 pairs of chlorides can be removed; second, random coupling with only 1–2 and 1–3 pairs of chlorides capable of removal by zinc, it being assumed that 1–2 and 1–3 removals are equally probable. These two cases yield the results $f = e^{-2x}$ and $f' = e^{-x}\cdot(1 - x/2)$ for the two respective cases where x is the chlorine mole fraction of the substituents.

The Vapor Pressures of Certain Unsaturated Hydrocarbons

BY ARTHUR B. LAMB AND EDWIN E. ROPER

In connection with a study of the adsorption of the vapors of certain unsaturated hydrocarbons upon charcoal and other adsorbents, more accurate and extensive information as to the vapor pressures of these hydrocarbons was required than was available in the literature. The measurements of vapor pressure here presented were therefore made over a considerable range of temperature and, since our samples of hydrocarbons were of exceptional purity, with particular care.

Materials.—The hydrocarbons studied by us (Tables II–IV) were those used by Professor Kistiakowsky and his collaborators in their studies of the heats of hydrogenation, etc., and were prepared in part by them and in part by them and ourselves jointly. We wish to express our appreciation of this generous arrangement. A description of the methods of preparation has already been published.[1]

The high purity of these hydrocarbons has been demonstrated by the close concordance of the heats of hydrogenation, boiling points, freezing points and other physical properties of different distillation fractions of the same samples

and of samples of the same hydrocarbons prepared by different methods. Further evidence of their high purity also has been obtained in our own work by the close concordance of the vapor pressures of successive fractions obtained in a further isothermal distillation of our samples at 0°, as will be explained later. No deterioration of these samples over the period of our measurements has been detected except in the case of 2-methylpropene which in the liquid phase was found to undergo a slow change, its vapor pressure at 0° decreasing at the rate of about 1 mm. per day. Definitive measurements of this substance were therefore made only upon freshly distilled samples.

Apparatus and Procedure

A static method of measurement was adopted as affording the greatest promise of accuracy. A cryostat to maintain a constant, known temperature over a considerable period of time and over the temperature range of −130 to 25° was therefore required; also, a carefully standardized platinum resistance thermometer and an accurately legible manometer.

Cryostat.—This (see Fig. 1) was of the type developed by Scott and Brickwedde[2] in which the bath liquid contained in an inner cylindrical Dewar flask (E) is circulated through and around a submerged vertical tube of bakelite (J) about which the heating element (H) is wound. Refrigerant (liquid air) in an outer Dewar flask surrounds the inner Dewar flask and by adjusting the pressure in its jacket the rate of cooling of the cryostat bath can be controlled. The intermittent, regulated current in the heating element is superposed upon a continuous one. The thermoregulator is of a type of which many designs have been published[2,3] which comprises a Mueller thermometer bridge, a galvanometer, a photocell, a 3-stage amplifier and a relay. The sensitivity of the regulator is such that the total, cyclical fluctuation of temperature in the center of the cryostat is 0.003°. The stirrer and gear shafts are of Monel metal and the bearings of a lead–tin alloy, high in lead; two bearings and one set of gears are immersed in the bath liquid. About one gram of finely divided graphite added to the bath liquid aids materially in lubrication at the lower temperatures. The non-inflammable bath liquid is a five-component mixture (No. 39) as recommended by Kanolt.[4] To compensate for the slow sinking of the liquid air level in the outer container during an experiment, an automatic modulator was installed which slowly increases the continuous energy input during the time that the intermittent heater is on and slowly decreases it during the time that the intermittent heat input is off.[5] For the measurements on the vapor pressure of the crystals and on the triple point of propadiene, an aneroid cryostat was utilized, which has been described in another connection.[6]

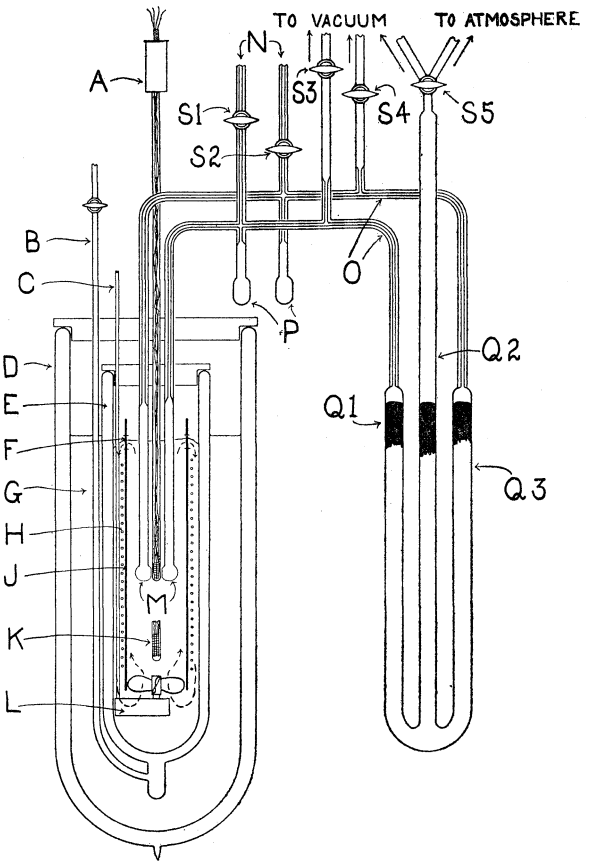

Fig. 1.—Double vapor pressure apparatus: A, measuring thermometer; B, connection for exhausting jacket of E; C, stirrer shaft; D, outer Dewar tube; E, inner Dewar tube; F, ports in J for circulating liquid; G, refrigerant; H, heating coil on J; J, bakelite tube; K, control thermometer; L, stirrer gearing; M, vapor pressure bulbs; N, gas admitted or withdrawn here; O, to manometers; P, condensing bulbs; Q, double manometer; S, stopcocks.

The Platinum Resistance Thermometer.—This had a resistance of 25 ohms and was of the coiled filament type.[7] It has shown a high stability over a long period. Its resistance was measured on a calibrated Mueller type Wheatstone bridge in an oil thermostat at 25.0 ± 0.1° to 0.0001 ohm, which corresponds to about 0.001° and produces a galvanometer deflection of 1.8 mm. with a measuring current in the thermometer of 1.3 ma. This thermometer assembly already has been described elsewhere.[6,8]

To obtain the constants in the quadratic calibration equation[9] of this thermometer for

temperatures above 0°, observations were made at three primary points: the sulfur b. p.,[9,10] the steam point[9,11] and the ice-point.[8] The thermodynamic temperature of the last was taken as 273.16°K.[12] To obtain the two additional constants of the biquadratic equation[13] for temperatures below 0°, one additional primary point, the vapor pressure of oxygen,[14a] and one secondary point, the vapor pressure of crystalline carbon dioxide,[14a] were also observed. As a check upon the accuracy of our temperature scale, three other secondary points were observed, namely, the b. p. of naphthalene,[9,15] the transition point of sodium sulfate decahydrate[9,16] and the f. p. of mercury,[9,14b] these observations indicating that the absolute accuracy was of the order of 0.01°, while the relative precision was of the order of 0.002°. In all cases more than one standardizing run was performed, bracketed in each instance with a determination of the ice-point, using material for standardization from different sources, purified by different methods. For the fixed point temperatures above 0° we took the values as defined by the International Temperature Scale[9]; for those below 0°C., the values determined by Heuse and Otto.[14b,c]

Vapor Pressure Apparatus.—This was a double apparatus permitting the simultaneous measurement of the vapor pressure of two samples at a given temperature-setting of the cryostat. This proved convenient, since eight of the nine hydrocarbons studied-formed well-defined pairs with boiling points close together. The bulbs (M) to contain the liquid samples were small (volume about 0.5 cc.) with thin walls and were placed close to the sensitive part of the thermometer (A). The thermometer and twin bulb assembly was wound with thin aluminum foil to facilitate thermal equilibration. The manometer was of 18, and the connecting tube (0) of 3 mm., bore (to minimize the effect of changes in room temperature). The height of the mercury was read to ±0.04 mm. with an accurate cathetometer, a correction for the meniscus being applied always and the pressures converted to millimeters of mercury at 0° and g = 980.665 cm./sec.[2,9] In most cases the final value for the pressure was rounded off to the nearest 0.1 mm. All stopcocks were of the type having a bulb sealed onto the base of the barrel for evacuation, giving a seating force of one atmosphere on the plug at all times. For pressures greater than 900 mm. (the length of the cathetometer scale), manometer Q2 with stopcock S5 turned to the atmosphere was utilized in conjunction with a barometric manometer read with the same cathetometer. High vacuum technique was followed in all operations.

Procedure.—The compounds, after being freed from all water[17] and air, were stored in 5-liter Pyrex glass reservoirs connected to cocks S1, S2 (Fig. 1). The vapor was condensed into the bulbs (P) from the storage reservoirs by the use of refrigerants. The vapor pressure bulbs (M) were not visible during a measurement, but it was easy to ascertain from the pressure changes during distillation from P to M whether liquid phase was present in them. The cryostat was then adjusted to the desired temperature and after equilibrium had been established as shown by no change for ten minutes, the pressure and the temperature were read, the latter observations bracketing the former.

The measurements on propadiene were made with the aneroid cryostat and McLeod gage (except the one at 188.17°). This gage was carefully standardized and comparison of it with the U-type manometer at 2 mm. showed satisfactory correspondence. The hydrocarbon was purified by pumping for a half-hour on the liquid phase at −136° and this purging was continued until no further change in vapor pressure could by detected at this temperature. Nine separate determinations of the triple point in three different cryostats gave 136.94 ± 0.02°K. (pressure 0.1448 mm.).

For the six highest-boiling hydrocarbons studied, a test was made for the presence of impurities. For this purpose the bulbs (P) were surrounded with cracked ice in an unsilvered Dewar tube. The ice-bath was brought to 0.000 ± 0.001° by a modified White washing technique,[8] the vapor pressure of the condensed sample determined, slow isothermal vaporization

at 0° carried out until only about one-twentieth of the original sample remained in the bulbs, and the vapor pressure then re-determined. The decrease in the vapor pressure under such treatment is a partial measure of the purity of the sample.[18] Table I gives the results, and also the temperature changes corresponding to the observed decrease in vapor pressure computed from the temperature coefficient at 0°.

These slight changes between the beginning and end of the fractionation indicate that the liquids were quite pure.

However, since in the actual vapor pressure measurements during the transfer of hydrocarbon from the reservoirs to the vapor pressure bulbs and when the temperature of the cryostat was raised much of the liquid vaporized from the vapor pressure bulb, similar though perhaps not so drastic fractionation may have taken place. If this occurred, deviations similar to those in Table I, namely, of about 0.08°, would be expected. Actually the average of the apparently random deviations of our observed boiling points from those computed from our empirical vapor pressure formulas derived by least squares was about ±0.06°. This shows that our fractionation and vapor pressure data are in accord and indicates that the random deviations of our vapor pressure measurements are probably due to the presence of these slight impurities, rather than to thermometric errors.

The Observed Vapor Pressures and Empirical Formulas.—Tables II, III and IV contain the results of our measurements.[19]

(18) Shepherd, *Bur. Standards J. Research*, **12**, 185 (1934).

(19) One earlier set of measurements on the liquid phase of propadiene using the Scott–Brickwedde type of cryostat where the purging was done on the solid phase gave slightly higher vapor pressures than those obtained later and listed in Table IV. We suspected inadequate purging and perhaps adsorption on the crystalline material and have not included them in our table although they agreed with certain earlier measurements recorded in the literature.[20] All measured values will, however, be found in "An Experimental Study of Various Manifestations of Van der Waals Forces in Certain Hydrocarbons," by Edwin E. Roper, a thesis submitted to the Faculty of Harvard University, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

[a] Utilized in conjunction with the triple point coördinates, 136.94°K. and 0.1448 mm., to evaluate the constants in the vapor pressure equation for the crystalline phase.

A preliminary examination showed that the vapor pressures could be represented within the accuracy of our measurements by a three-constant equation of the form $\log p = A/T + BT + C$, equations with four and more constants affording very little improvement. Equations of this form were therefore derived for all of our data on each hydrocarbon by the method of least squares. In the case of certain of the more complex hydrocarbons (with the exception of propadiene) this disclosed a very few erratic values[19]; these were discarded and a new set of constants evaluated. The resulting constants and the temperature range covered are given in Table V.

Crystalline Phase Equilibrium				
Propadiene	1464.40	0.000	9.8545	118 to 137

The deviations of our experimental results from these empirical equations are given in columns three, four, seven and eight of Table II and columns three, four, six and seven of Table III, expressed both in mm. and in °C., the latter being obtained from the differential of the equations together with the pressure deviations. In general the over-all accuracy of the measurements is governed at the lower temperatures by the accuracy of the pressure measurements, and at the higher temperatures by the accuracy of the temperature measurements.

The constants of the empirical equation for the crystalline phase of propadiene were derived by drawing the best line through the data. Those for the liquid were derived by least squares, as usual.

Boiling Points, Temperature Coefficients of Vapor Pressure and Heats of Vaporization.—The boiling points and the temperature coefficients of the vapor pressures were computed from the empirical equations for the vapor pressure and from these in turn the molecular heats of vaporization were computed using the Clausius–Clapeyron equation in the form

$$\Delta H^{p}_{vap} = \frac{RT_b^2}{p}\frac{dp}{dT} = 0.0026147T_b^2\left[\frac{dp}{dT}\right]_{T_b}$$

which neglects the volume of the liquid phase and assumes the saturated vapor to behave as a perfect gas. These values are listed in Table VI.

It can be seen from this table that, as would be expected, isomers exhibit very similar properties. However, it is surprising that 1-butene and 2-methylpropene are more nearly identical than are *cis*- and *trans*-2-butene.

In order to appraise the reliability of our values for the vapor pressures and boiling points of these hydrocarbons more rigorously, we have tested them by the rules of Ramsay–Young and of Dühring and by an equation giving the slopes of the vapor pressure curves at the boiling point as a function of the absolute boiling point.

The Ramsay–Young Rule.—This may be expressed[28] as $T_A/T_B = T'_A/T'_B$ where T_A and T_B are the temperatures of the saturated vapors of substances A and B at one, and T'_A and T'_B those at another pressure. Values for the ratio T_{100}/T_{760} for the hydrocarbons studied, corresponding to a 7.6-fold change in pressure, are given in the second column of Table VII.

It can be seen that the ratios for these alkenes are indeed very constant, the average deviation from the mean being only ±0.27%. There is a a slight tendency for the ratios to increase with increasing boiling point. If allowance is made for this by expressing the ratio as a linear function of the absolute boiling point, *i. e.*, $T_{100}/T_{760} = 0.8225 + 5.66 \times 10^{-5} T_{760}$, the agreement becomes even better, the average deviation, Δ, of the calculated from the observed ratio being only 0.15%. Omitting the values for propadiene, a still better correspondence (0.07) is noted (see third column, Table VII).

A similar tabulation has been made for the corresponding saturated hydrocarbons using values calculated from the vapor pressure equations in

Discarding the *cis*-2-butene value:			Average	.039	.12°K.

the literature. The results are given in the fifth column of the above table. The mean value of the ratios of comparable hydrocarbons is 0.8384 and the average deviation from the mean is ±0.37%, close to the value for the unsaturated hydrocarbons. A similar variation with the absolute boiling point is also evident here. Using the linear equation $T_{100}/T_{760} = 0.8176 + 8 \times 10^{-5}T_{760}$, values of the ratios are obtained whose percentage deviations, Δ, from the observed values average only 0.17 (omitting methane).

Summarizing, it appears that these hydrocarbons in general obey the Ramsay–Young rule closely, particularly if the rule is slightly modified. Among the hydrocarbons studied by us only propadiene shows more than the usual minimum discrepancy, suggesting that our vapor pressure data for this substance are relatively less accurate.

Dühring Rule.—This may be expressed[28] as $T_B = b_1 + b_2T_A$ where T_A and T_B have the same significance as above and b_1 and b_2 are constants characteristic of substances B. To test our results by this rule we have computed from our empirical vapor pressure equations the temperatures of the saturated vapor corresponding to nine round pressures over the range 1 mm. to 1000 mm. Taking the values for propene as standard (T_A) we find for the nine hydrocarbons we have studied and for four additional hydrocarbons for which sufficiently reliable data are available in the literature, that the temperatures of the saturated vapor can be represented by these linear equations (Dühring lines) over the whole range with an average deviation of only ±5% corresponding to about ±1.5° (omitting the discordant values for *cis*-2-butene).

While these lines appear almost linear, examination shows some curvature. Addition of a quadratic term giving the equation $T_B = B_1 + B_2T_A + B_3T_A^2$ suffices to reproduce them with great fidelity, as can be seen from the values in the last columns of Table VIII, where the average deviations and the average maximum deviations are only ±0.04 and 0.12°, respectively, again omitting the discordant values for *cis*-2-butene.

This agreement with the Dühring rule also encourages us to think that our vapor pressure data are reliable except perhaps in the case of *cis*-2-butene where the presence of some slight impurity is to be inferred. It should be remarked, however, that the values for propadiene which appeared to be in some doubt from the point of view of the Ramsay–Young rule show no irregularity here.

The Temperature Differential of the Vapor Pressure.—It follows from the Clausius–Clapeyron equation, assuming the gas to be perfect and the heat of vaporization ΔH_{vap} to be independent of the temperature, that $dp/dT = p\Delta H_{vap}/RT^2$. Combining this with Trouton's rule gives

$$\left[\frac{dp}{dT}\right]_{T_b} = \frac{760 \times 20.85}{RT_b} = \frac{7975}{T_b}$$

(34) Data of this research.

where 20.85 is the Trouton constant (the mean value for the 35 hydrocarbons listed in Table IX) and T_b the absolute boiling point at 760 mm. pressure. Values of $[dp/dT]_{T_b}$ computed from our measurements and for some 26 additional hydrocarbons for which accurate vapor pressure data are available are in good agreement with this equation, the average deviation being 2.5%. Trouton's rule often can be replaced advantageously by the equation of Nernst[35] $\Delta H_{vap} = 9.5 \log T_b - 0.007 T_b$. Our equation then becomes

$$\left[\frac{dp}{dT}\right]_{T_b} = \frac{3634 \log_{10} T_b}{T_b} - 2.68$$

The differences between the values of $[dp/dT]_{T_b}$ computed from this equation and from the empirical equations (observed values) are listed in the fifth column of Table IX. The average percentage deviation is, however, still 2.5%.

Since the deviations were in general positive, we have altered the constants in the above equation slightly to obtain the general equation

$$\left[\frac{dp}{dT}\right]_{T_b} = 3461 \frac{\log T_b}{T_b} - 1.77$$

Using this equation we find the deviations listed in the sixth column of the above table, averaging 1.7%.

Finally, since a constitutive influence is evident we have framed special equations of the general type

$$\left[\frac{dp}{dT}\right]_{T_b} = a_s \frac{\log_{10} T_b}{T_b} + b_s$$

for each group of hydrocarbons and the resulting deviations are listed in the seventh column of the table. It can be seen that an even better agreement is attained, particularly with the alkanes and alkenes, the deviations averaging on the whole 0.9%.

Here again we find that the values of *cis*-2-butene show a considerably greater discrepancy than any of the other alkenes or alkanes, which confirms our previous inference that our data for this substance are less reliable than our other data.

Summary

1. Measurements have been made of the vapor pressures of very pure samples of liquid ethene, propene, 2-methylpropene, 1-butene, *cis*-2-butene, *trans*-2-butene, 1,4-pentadiene and 2-methyl-2-butene over the approximate range 10 to 1000 mm. by the static method. Equations with three constants have been derived by the method of least squares from the results of these measurements expressing the vapor pressure as a function of the temperature. The vapor pressure of liquid and of crystalline propadiene its triple point temperature and pressure also have been ascertained.

2. From the least square equations the normal boiling points and the slopes of the vapor pressure curves at these points as well as the heats of vaporization of these substances as perfect gases have been computed.

3. Our vapor pressures, with one or two exceptions, have been found to agree excellently with the Ramsay–Young and the Dühring rules, particularly when in each rule an additional constant is introduced. A general equation has been derived expressing the temperature differential of the vapor pressure at the absolute boiling point as a function of the absolute boiling point. With this equation, too, our data are found to be in excellent agreement.

The Solubility of Carbon Dioxide in Water at Various Temperatures from 12 to 40° and at Pressures to 500 Atmospheres. Critical Phenomena*

BY R. WIEBE AND V. L. GADDY

The present paper extends previous work on the solubility of carbon dioxide in water. The apparatus and procedure are essentially the same as described.[1]

Aside from the particular interest in the solubility data themselves, we were also interested in investigating a phenomenon we had noticed in our previous work but had not reported. It was found that during saturation at pressures exceeding 700 atm. there was some pressure above which the solubility of water in the gas phase increased tremendously. This was shown by the appearance of large amounts of water in the expanded gas. We had apparently reached the critical solution pressure for the carbon dioxide–water system.

Discussion of Results

The results on the solubility are given in Table I and are expressed as the number of cc. of carbon dioxide (S. T. P.) contained in 1 g. of water.

TABLE I

SOLUBILITY OF CARBON DIOXIDE IN WATER

(cc. S. T. P. PER G. OF H_2O)

Total pressure in atm.	Temperatures, °C. 12	18	25	31.04	35	40

400			38.62	36.78	35.73	34.87
500				38.67	37.99	36.73

In Fig. 1 the solubility is plotted *versus* temperature, our previous data having been included. For the most part the curves resemble those obtained for hydrogen, nitrogen, and helium[2] except that the minimum solubility occurs at higher temperatures, but there are decided differences in the low temperature range. The principal reason for this is undoubtedly the fact that we are dealing here with two liquid systems but other factors are also influential and will be discussed presently.

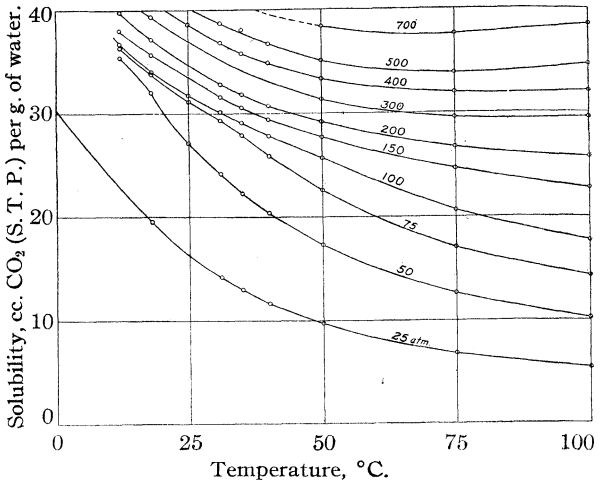

Fig. 1.

Although several attempts were made to get data at 10° above 50 atm. total pressure, only one series of measurements, at 150 atm., was obtained. When proceeding to check these values, a solid, presumably carbon dioxide hexahydrate, formed and the freezing of the liquid in the connecting lines made further measurements impossible. The fact that one series was obtained is very typical of the mode of formation of these gas hydrates.[3] A special technique, *e. g.*, sudden expansion, must often be used to initiate the formation of the hydrate, although once started it will form readily. At 12° we were able to get measurements up to 300 atm. but above this pressure, aside from solid formation, another difficulty was encountered, the disappearance of one phase, indicating complete miscibility. The compositions of the gas and liquid phases at 12° and 600 atm. were identical. We believe this to be true also for 500 atm. at the same temperature. At 18° similar conditions prevail.

In Fig. 2 we have attempted to portray qualitatively the probable course of the critical curve. With our present set-up it was not possible to determine accurately the change of the critical

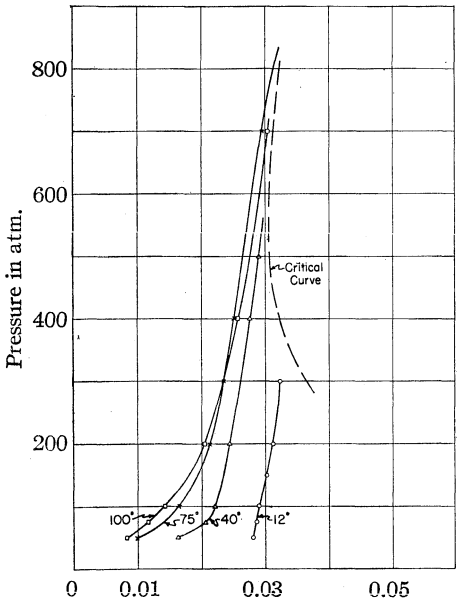
solution pressure with either temperature or composition. It will be seen that apparently there is a pressure maximum at about 75° and that both the 100 and 40° solubility curves will end at lower pressures than the 75° isotherm. It must be emphasized that we are basing our discussion on qualitative evidence only.



Mole fraction of CO_2 in water at various temperatures.

Fig. 2.

The dissociation pressure curve of the system hydrate–vapor–water saturated with carbon dioxide is shown in the lower left-hand corner of Fig. 3.[4] This curve ends in the critical decomposition point at 10° and 44.3 atm., the latter being practically the vapor pressure of pure carbon dioxide at that temperature. The critical decomposition point represents the invariant system consisting of hydrate, vapor, carbon dioxide saturated with water, and water saturated with carbon dioxide. When increasing the pressure the vapor phase disappears and the univariant system, hydrate, carbon dioxide saturated with water, and water saturated with carbon dioxide will continue to exist under certain temperature and pressure conditions.

We found evidence of this univariant system at 10 and 12°, *i. e.*, increase of pressure raises the temperature of coexistence of the three phases. At the point of complete miscibility (possibly 500 atm.), even at 12° no solid was detected, though the possibility of its existence is not ex-

ever we try to obtain values higher than about 40 cc. of carbon dioxide (S. T. P.) per gram of water. We have mentioned the likelihood of a possible pressure maximum at 75° in connection with the discussion of Fig. 2.

Figure 4 shows solubility isotherms that illustrate particularly the change of state of carbon dioxide from gas to liquid. At the lower temperatures this amounts to almost a discontinuity. In Table III we have made a few additional calculations by means of the approximate formula derived previously[1]

$$\mathrm{d} \ln N_1 = \frac{\overline{V}_1^1 - \overline{V}_1}{RT} \mathrm{d}P$$

where $\overline{V}_1^1$ and $\overline{V}_1$ are the partial molal volumes of carbon dioxide in the vapor and liquid phases, respectively; and N_1 the mole fraction of carbon dioxide in the liquid phase. The agreement between calculated and observed values is good and only breaks down at about 400 and 700 atm. at 40° and 50°, respectively.

Summary

The solubility of carbon dioxide in water has been determined at 12, 18, 25, 31.04, and 40° and at pressures to 500 atmospheres.

Evidence of complete miscibility was found particularly in the low temperature range and an attempt was made to portray qualitatively the course of the critical curve.

Solid carbon dioxide hexahydrate was discovered at 10° at all pressures above 50 atm. and at 12° between 300 and 500 atm.

The Specific Heats at Low Temperatures of Tantalum Oxide and Tantalum Carbide[1]

BY K. K. KELLEY[2]

The measurement of specific heats, at low temperatures, of metallurgically important substances has been one of the programs of study of the Metallurgical Division of the Bureau of Mines for the past several years. This paper presents results for tantalum oxide and tantalum carbide for which no low-temperature specific heat or entropy data have been available heretofore. The results for tantalum carbide may be of special interest in that they are the first adequate set of low-temperature true specific-heat measurements to be obtained for a metal carbide, the only other pertinent data being those of Nernst and Schwers[3] and Günther[4] for silicon carbide in the temperature range 22 to 97°K.

Materials

The tantalum oxide was a product of the Fansteel Products Co., purchased several years ago. It was stated to be of virtually atomic weight purity. Because of its low apparent density, it was compressed into pellets and the pellets broken into sizes below 2 mm. for filling the calorimeter. A 210.5-g. sample was used.

The tantalum carbide was loaned for this work by the Fansteel Metallurgical Co. through the courtesy of Mr. J. H. Harper and Mr. F. L. Hunter. This material was in powder form and according to the manufacturers contained 4.26% carbon compared with 4.23%, the theoretical figure for TaC. Impurities other than the excess carbon were stated to be of the order of 0.02%. It required 803.5 g. to fill the calorimeter.

Results

Specific Heats.—The method and apparatus have been described previously.[5]

The results, expressed in defined calories (1 calorie = 4.1833 int. joules), are given in Table I and shown graphically in Fig. 1. The values for tantalum carbide have been corrected for the 0.03% excess carbon on the assumption that it is present as graphite. The correction increases with the temperature and ranges from 0.02 to 0.09%.

The tantalum oxide results appear normal and require no discussion. There are, however, two items of interest to be mentioned concerning the measurements for tantalum carbide. Comparison of the results for this substance with those for pure tantalum[6] shows that at temperatures below 125°K. the former has the lower specific heat per gram formula mass, the difference at 54°K. being 0.59 calorie. Also, if C_p for tantalum carbide is plotted against log T, an inflection point in the neighborhood of 100–110°K. is readily apparent. This is caused by the carbon skeleton, the vibrations of which contribute only a very minor portion of the specific heat at the lowest temperatures studied, beginning to take up vibrational energy. Such an inflection is not usual in low temperature specific-heat curves but has been observed in other instances in which the constituent atoms differ widely in atomic mass, as, for example, hydrogen chloride.[7]

The results for tantalum oxide may be adequately represented throughout the entire temperature range studied by the function combination

$$D\left(\frac{170}{T}\right) + 2E\left(\frac{265}{T}\right) + 2E\left(\frac{528}{T}\right) + 2E\left(\frac{880}{T}\right)$$

In the case of tantalum carbide

$$D\left(\frac{268}{T}\right) + E\left(\frac{861}{T}\right)$$

represents the data adequately except in the region near the inflection point, where the function sum is somewhat low (at worst 0.1 calorie). Below 72°K., however, the Debye function alone is adequate.

Entropy Calculations.—The entropies at 298.1°K. were calculated in the usual manner. The extrapolated portions below 53.1°K. were obtained from the functions given above. Only the Debye function and first pair of Einstein functions for tantalum oxide need be considered at 53.1°K. while for tantalum carbide only the Debye function is significant at this temperature. The results are given in Table II.

There are no other values for these substances with which to compare the present results. It may be of interest to note, however, that the figure for tantalum carbide is only 0.2 unit higher than the entropy at 298.1°K. of pure tantalum.[6]

Related Thermal Data.—The heat of formation of tantalum carbide never has been determined. Several values exist for tantalum oxide: −498,400, Moose and Parr[8]; −480,500, Sieverts, Gotta and Halberstadt[9]; −486,000 ± 500, Becker and Roth[10]; and −499,900 ± 1000, Neumann, Kröger and Kunz.[11]

TABLE II

ENTROPIES AT 298.1°K.

	Ta_2O_5	TaC
0–53.1°K. (extrapolation)	2.83	0.95
53.1–298.1°K. (graphical)	31.36	9.16
$S_{298.1}$	34.2±0.4	10.1±0.1

The spread in these values probably may be attributed to the presence of different amounts of hydrogen in the samples of metal burned to oxide. For the present purpose the result of Becker and Roth is adopted. From this value and the entropies of the oxide, metal (9.9 ± 0.1)[6] and oxygen (49.03)[12] there is computed $\Delta F^0_{298.1} = -453{,}700$ as the free energy of formation of tantalum oxide from the elements.

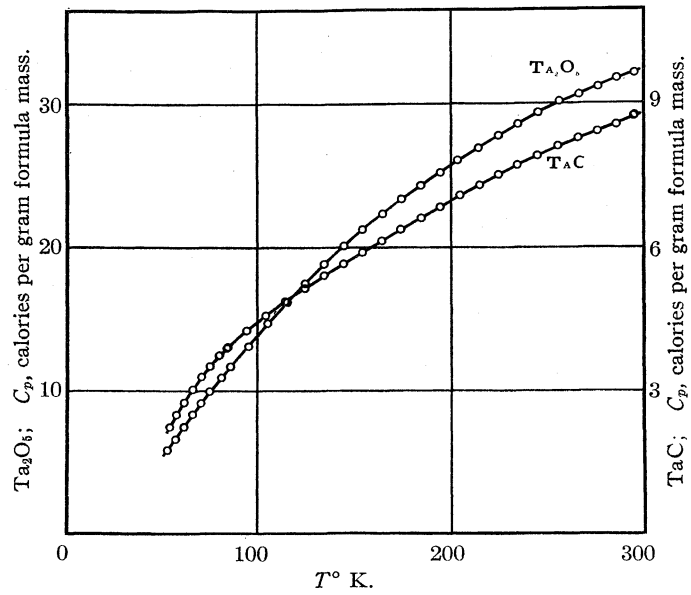

Fig. 1.—Specific heats of Ta_2O_5 and TaC.

Summary

Specific heat measurements of tantalum oxide and tantalum carbide were made in the temperature range 53 to 298.1°K.

The entropies are $S_{298.1} = 34.2 \pm 0.4$ for tantalum oxide and $S_{298.1} = 10.1 \pm 0.1$ for tantalum carbide.

The free energy of formation of tantalum oxide from the elements has been computed as $\Delta F^0_{298.1}$ −453,700.

The Stereochemistry of Complex Inorganic Compounds. VII.[1] The Mechanism of the Walden Inversion in Some Reactions Leading to the Formation of the Carbonato-diethylenediamine Cobaltic Ion

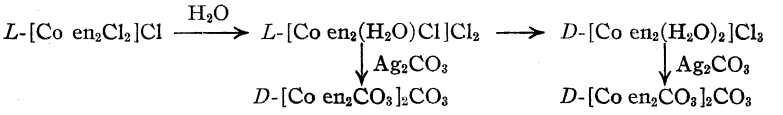
BY JOHN C. BAILAR, JR., AND DONALD F. PEPPARD[2]

It has been shown recently[1e] that the carbonato-di-levopropylenediamine cobaltic ion exists in two diastereoisomeric forms. One of these is less stable than the other, and is readily converted into it by warming. Both of them can be prepared from the one known form of the corresponding dichloro salt. The more stable (and, hence, the non-inverted) isomer, evidently is formed through an intermediate aquo complex, for it is obtained only under conditions in which such an intermediate is known to form. The less stable form, on the other hand, is obtained under conditions which would minimize the formation of aquo complexes. This gives a clue to the mechanism of the Walden inversion which takes place in the formation of the carbonato-diethylenediamine cobaltic ion from the corresponding dichloro ion,[1a,b] and has led us to study the mechanism of this and some related reactions.

It is indicated that the change of *L*-dichloro-diethylenediamine cobaltic ion to the *D*-carbonato ion probably proceeds through the formation of the *L*-chloro-aquo ion. Since this takes place under the same conditions which produce the non-inverted carbonato complex in the propylenediamine series,[1e] it is probable that the *L*-dichloro-diethylenediamine salt and the *D*-carbonato salt have the same configuration. Mathieu has come to the same conclusion, but from very different evidence.[3]

That aquation plays an important part in the reaction of dichloro-diethylenediamine cobaltic ion and silver carbonate is shown by the fact that the rotation of the carbonato complex obtained depends upon how long the solution of the dichloro salt is allowed to stand before the silver carbonate is added (Table I).

Mathieu[4] has shown that *L*-dichloro-diethylenediamine cobaltic chloride aquates to give both the *L*-chloro-aquo complex and the *D*-diaquo complex. The latter is formed only in small amounts, however, and the equilibrium between the two, when disturbed, is restored very slowly. It thus appears that the chloro-aquo complex is the important intermediate in the reaction under investigation. The diaquo complex may take part to some extent; upon treatment with silver carbonate it also gives the *dextro* carbonato complex. It seems probable that none of the reactions shown in the following scheme involves change of configuration



Mathieu[3] has come to the same conclusion from studies of circular dichroism. From this and the data of Table I it follows that the conversion of *L*-[Co en$_2$Cl$_2$]Cl to *L*-[Co en$_2$CO$_3$]$_2$CO$_3$ does not go through an intermediate and involves a change of configuration. These hypotheses completely explain the results of the experiments previously reported.[1a,b,c] The addition of potassium carbonate, or the slow addition of silver carbonate, to solutions of the dichloro salt allows aquation to take place before the carbonate group is introduced into the complex; direct entrance of the

carbonate group is effected only when an *excess* of silver carbonate is ground with the dichloro salt as soon as it is put in solution, or when a large excess of dry potassium carbonate is ground with the dry complex before solution takes place.[1e]

The dichloro complex reacts rapidly with potassium carbonate; it also aquates rapidly in the presence of potassium carbonate, due to the basicity of the solution. When a fresh solution of the dichloro salt is mixed with a solution of potassium carbonate, a mixture of *D* and *L* carbonato salts is formed, with the *D* in preponderance.[5] If the solution is allowed to age until aquation is essentially complete (about sixty-five minutes for a 4% solution) before the carbonate is added, a nearly pure *D* carbonato salt may be obtained.

The reactions of the chloro-bromo and dibromo-diethylenediamine cobaltic complexes with carbonates also have been studied. These behave just as the dichloro complex does, and their reactions give inversions under the same conditions. They evidently aquate in the same way, and the chloro-bromo, at least, at about the same rate. The data of Table II are strictly comparable to those of Table I.

TABLE II

EFFECT OF AGING A 4% SOLUTION OF *L*-[Co en$_2$ClBr]Cl

t	[α]D
1	−190
10	+ 90
20	+220
65	+510

Experiments with [Co en$_2$ClBr]Cl showed conclusively that the relative amounts of complex and silver carbonate used are of little significance compared to the time the solution is allowed to stand before the reagent is added. In one series of experiments, the reactants were ground together before the water was added. The amount of silver carbonate used varied from the calculated amount to a ten-fold excess, but the rotation of the resultant carbonato salt varied only slightly, [α]D −160 to −200°. In another series, the cobalt complex stood in a 4% solution for sixty-five minutes before the reagent was added. The same amounts of silver carbonate were used as before; [α]D +470 to +500°.

If the hypothesis here suggested is correct, conversion of the chloro-aquo complex to the carbonato complex should proceed under all conditions without inversion. This has been found to be the case: *L*-chloro-aquo-diethylenediamine cobaltic bromide was treated with potassium carbonate and silver carbonate under a wide variety of conditions, and always gave a dextro-rotatory product. The positive rotation was somewhat lower when potassium carbonate was used, but this is evidently due to racemization, rather than to any tendency to form the levo-rotatory product.

These experiments naturally suggest a reinvestigation of the reactions of potassium and silver oxalates with *L*-dichloro-diethylenediamine cobaltic chloride, which have previously been shown[1a] to give a dextro-oxalato complex under all conditions. The formation of the oxalato complex takes place somewhat more slowly than that of the carbonato complex, which suggests that aquation may always take place before the oxalate group enters the complex. A comparison of Table III with Table I shows how differently the silver oxalate and silver carbonate react.

TABLE III

EFFECT OF AGING A 4% SOLUTION OF *L*-[Co en$_2$Cl$_2$]Cl BEFORE TREATING WITH A TEN-FOLD EXCESS OF SILVER OXALATE

"*t*" represents the time of aging, in minutes, and "[α]D" represents the specific rotation of the resultant oxalato salt, in degrees.

t	[α]D
0	+357
1	+357
25	+293
60	+266
100	+238
150	+202
270	+147

It is possible that silver oxalate cannot react directly with the *L*-dichloro complex, but only with the *L*-chloro-aquo complex which is formed by aquation. This ion has been shown to react with silver oxalate to give the dextro-oxalato ion. On the other hand, it is possible that the oxalate and carbonate reactions are entirely different in character.

One entirely new reaction was studied in the course of this investigation, the change of the chloro-aquo complex to the dichloro complex. This is effected by allowing the complex to stand in a large excess of thionyl chloride for about one hundred hours. The reaction evidently proceeds without inversion.

(5) Werner and McCutcheon, *Ber.*, **45**, 3284 (1912).

Experimental

L-[Co en$_2$Cl$_2$]Cl was prepared and resolved as previously described.[1a]

L-[Co en$_2$(H$_2$O)Cl]Br$_2$ was prepared according to the directions of Werner and Tschernoff[6] and was resolved following Werner and Schwyzer's[7] description of Fischlin's method.[8] The hydrobromic acid used in the last step of the procedure may be replaced by hydrochloric, thus giving the levo-chloro-aquo chloride.

A more convenient method of preparing the active chloro-aquo salts was devised using racemic *cis* dichloro diethylenediamine cobaltic chloride as the starting material.

Ten grams of *cis* [Co en$_2$Cl$_2$]Cl and 40 cc. of water are shaken with glass beads for twelve hours. The beads and any small amount of residue are removed by filtration and the solution allowed to stand in a stoppered flask for sixty hours. It is then cooled to 20°, 6 g. of ammonium dextro-α-bromocamphor-π-sulfonate added, and the mixture stirred by a mechanical stirrer at 18–20° for ten minutes. The solution is filtered from the green crystalline precipitate, 6 g. more of the resolving agent is added, and the stirring continued. Precipitation of the pink levo-chloro-aquo diethylenediamine cobaltic dextro-α-bromocamphor-π-sulfonate begins after some time. The filtrate from this precipitate (about 35 cc.) is treated with 20 cc. of cold aqueous hydrobromic acid (density, 1.4) and cooled in ice–salt mixture with occasional stirring. In from fifteen to twenty-five minutes precipitation of *D*-[Co en$_2$Cl(H$_2$O)]Br$_2$ begins. After fifteen minutes, this is filtered and washed with absolute alcohol and ether. For purification it is dissolved in water at 33° (5 cc. of water per g. of salt), filtered quickly, treated with one-third its volume of hydrobromic acid (density, 1.4), and cooled in an ice–salt mixture. The salt precipitates almost at once on scraping the sides of the beaker. The yield is 0.7–1.0 g. of purified salt. For a 0.1% solution $[\alpha]_D$ −220°.

The precipitated levo-chloro-aquo diethylenediamine cobaltic dextro-α-bromocamphor-π-sulfonate is washed on the filter with 5 cc. of ice water, followed by alcohol and ether. The dry salt is ground in a cold mortar with 6 cc. of cold hydrobromic acid for one minute. The *L*-[Co en$_2$Cl(H$_2$O)]Br$_2$ is filtered and washed with alcohol and ether. It is purified in the same manner as the dextro isomer. The yield is 0.9 to 1.3 g. of purified salt. For a 0.1% solution, $[\alpha]_D$ is +220°.

Usually one purification is sufficient to give a maximum optical activity for either isomer.

In order to obtain the levo-chloro-aquo chloride the precipitate of levo-chloro-aquo dextro-α-bromocamphor-π-sulfonate obtained from 10 g. of racemic dichloro diethylenediamine cobaltic chloride is ground in a cold mortar with 5 cc. of cold concentrated hydrochloric acid for thirty seconds. Fifteen cubic centimeters of cold alcohol–ether mixture (1:1) is added with grinding. At the end of about two minutes the red crystals are filtered and washed with alcohol and ether. For a 0.1% solution, $[\alpha]_D$ is +200°.

(6) Werner and Tschernoff, *Ber.*, **45**, 3296 (1912).
(7) Werner and Schwyzer, *Helv. Chim. Acta*, **4**, 117 (1921).
(8) Fischlin, Dissertation, Zürich, 1919.

[Co en$_2$ClBr]Br was prepared and resolved according to the directions of Werner and Tschernoff.[6]

trans-[Co en$_2$Br$_2$]Br was prepared by the method of Werner, Gerb, Lorie and Rapiport.[9] A modification of their method was used, however, in converting this to the *cis* form. Fifteen grams of *trans*-[Co en$_2$Br$_2$]Br (heated at 110° for eight hours to remove traces of acid) is heated on the steam-bath in 80 cc. of water for twenty minutes. It is then allowed to stand at room temperature in an acid-free atmosphere for twenty-four hours. Thirty cubic centimeters of water is added, and the mixture is well ground. After standing for a day the gray-violet powder, which is essentially *cis*-[Co en$_2$Br$_2$]Br, is filtered. A further quantity of the salt is obtained by allowing the filtrate to evaporate. It is purified by extracting the admixed *trans*-dibromo- and *cis*-bromo-aquo complexes with water.[9]

The resolution of the salt, which has not been previously described, was carried out as follows. Six grams of finely ground racemic [Co en$_2$Br$_2$]Br is added to 500 cc. of water at 20° and stirred rapidly for three minutes. The small amount of residue is removed by filtration and 14 g. of ammonium dextro-α-bromocamphor-π-sulfonate added to the filtrate. The mixture is cooled to about 5° and stirred for fifty minutes. (Precipitation begins in about four minutes.) The precipitate is washed with alcohol and ether. Approximately 1.5 g. of a gray-violet crystal powder is obtained. This is ground in a cold mortar with 8 cc. of ice cold hydrobromic acid (density 1.4). Thirty cubic centimeters of cold alcohol–ether mixture (1:1) is added and the grinding continued. The gray-violet powder is filtered and washed with absolute alcohol and ether. Sometimes it has a pronounced greenish color, probably due to the presence of a small amount of the *trans* dibromo salt. The product always has a slight greenish cast.

For a 0.025% solution at 29°, $[\alpha]_D$ is +520°. The rotation was observed exactly two minutes after adding water to the solid salt.

Werner and McCutcheon's method[5] of preparing the *D*-[Co en$_2$CO$_3$]$^+$ ion gives a product of low activity, so the following modification was developed. Twenty-five grams of *L*-[Co en$_2$Cl$_2$]Cl is dissolved in 500 cc. of water at about 25° and kept at approximately this temperature for eighty-five minutes. Forty-five grams of silver carbonate is then added and the mixture stirred mechanically for two hours. The silver salts are removed and the filtrate is evaporated by blowing a current of air across the surface. For a 0.1% solution at 29°, $[\alpha]_D$ is +740°.

Active [Co en$_2$BrH$_2$O]Br$_2$·$^1/_2$H$_2$O.—Five grams of *D*-[Co en$_2$CO$_3$]$_2$CO$_3$·3H$_2$O is ground with 20 cc. of hydrobromic acid for forty minutes. After cooling to 0°, the red-purple salt is removed by filtration and washed with alcohol and ether. Approximately 4.5 g. of salt is obtained. For purification it is dissolved in water at 30° (5 cc. of water per gram of salt), filtered, and treated with one-third its volume of hydrobromic acid. The solution is cooled rapidly in a salt–ice mixture and the walls of the beaker scraped with a glass rod; yield: about 1 g. For a 0.05% solution at 29°, $[\alpha]_D$ is +260°. For analysis the salt was dried over potassium hydroxide.

(9) Werner, Gerb, Lorie and Rapiport, *Ann.*, **386**, 111–112 (1912).

Anal. Calcd. for $[Co\,en_2(H_2O)Br]Br_2 \cdot {}^1/_2H_2O$: Br, 53.81. Found Br, 53.93. Werner[10] reports the air dried racemic product to be the monohydrate.

The reactions of *L*-$[Co\,en_2Cl_2]Cl$, *L*-$[Co\,en_2ClBr]Cl$, and *L*-$[Co\,en_2Br_2]Br$ with silver carbonate were all carried out in essentially the same way. If the complex (say, 0.1 g.) is ground with a large excess of silver carbonate (say 1 g.) in a small amount (5–10 cc.) of water, the *L*-carbonato carbonate is formed. This may be isolated by pouring the solution into a large volume of a 1:1:1 mixture of alcohol, ether and acetone or may be precipitated as the bromide by the addition of solid potassium bromide (about 0.1 g.). In a typical experiment, the bromide showed $[\alpha]_D$ −650° for a 0.1% solution.

Anal. of the carbonate. Calcd. for $[Co\,en_2CO_3]_2CO_3 \cdot 2H_2O$: C, 22.98; H, 6.27. Found: C, 23.20; H, 6.27. *Anal.* of the bromide. Calcd. for $[Co\,en_2CO_3]Br$: Br, 25.05. Found: Br, 25.22, 24.96.

In experiments with aged solutions, 0.2–0.4 g. of the complex was dissolved in 10 cc. of water and, after a definite length of time, was ground with an excess of silver carbonate. Complete reaction can be obtained only by grinding for half an hour. The solution was evaporated at room temperature, and the salt isolated as before. In one typical experiment, a 4% solution was aged for sixty-five minutes. The product was isolated as the bromide, $[\alpha]_D$ +1040, for a 0.1% solution.

Anal. Calcd. for $[Co\,en_2CO_3]Br$: Br, 25.05. Found: Br, 25.11.

The reactions with potassium carbonate were carried out as follows. About 0.1 g. of the complex, 0.04 g. of potassium carbonate, and 0.4 cc. of water were warmed to 80° for a minute. The solution was diluted to 100 cc., and the rotation taken at the sodium D line. The rotations were always positive.

L-$[Co\,en_2(H_2O)Cl]Br_2$ and *L*-$[Co\,en_2(H_2O)Br]Br_2 \cdot {}^1/_2H_2O$ were treated with silver carbonate in the same ways as the di-halo complexes, and the products were isolated as before. The rotatory power of the product was always positive, and varied between +700 and +850°. The carbonate from a typical run gave the following analysis. Calcd. for $[Co\,en_2CO_3]_2CO_3 \cdot 2H_2O$: C, 22.98; H, 6.27. Found: C, 23.41; H, 6.10.

Potassium carbonate was allowed to react with the aquo complexes in the same manner as with the di-halo complexes. The solutions obtained all showed strong positive rotations.

The reactions of *L*-$[Co\,en_2Cl_2]Cl$, *L*-$[Co\,en_2Br_2]Br$, *L*-$[Co\,en_2(H_2O)Cl]Br_2$ and *L*-$[Co\,en_2(H_2O)Br]Br_2$ with silver oxalate were carried out under the same conditions as those with silver carbonate, except that the grinding was continued for an hour and a half. The oxalato complexes were not isolated; the solutions were simply diluted to give a 0.1% concentration of the complex. In every case, a positive rotation was obtained.

The conversion of *L*-$[Co\,en_2(H_2O)Cl]Cl_2$ to *L*-$[Co\,en_2Cl_2]Cl$ was carried out by suspending 0.2 g. of the thoroughly dried aquo complex in 8 cc. of thionyl chloride. After one hundred hours, with occasional shaking, the violet salt was removed by filtration and washed with alcohol and ether. That the conversion to dichloro salt was essentially complete was shown by the change in color (purple to violet) and by the fact that the product reacted with silver carbonate to give the levo-rotatory carbonato salt. The chloro-aquo compound, under similar conditions, gives a dextro-rotatory product. In one experiment, a sample of the chloro-aquo salt having $[\alpha]_D$ +160° gave a dichloro salt having $[\alpha]_D$ +260°, both readings being made on a 0.05% solution.

(10) Werner, *Ann.*, **386**, 128 (1912).

Summary

It has previously been suggested that the conversion of levo-dichloro-diethylenediamine cobaltic chloride to the dextro-carbonato salt proceeds through the formation of an aquated intermediate, while conversion to the levo-carbonato salt proceeds directly. Evidence is now advanced to support this hypothesis.

The conversions of dibromo- and chloro-bromo-diethylenediamine cobaltic complexes to the carbonato complex are strictly analogous to the corresponding reaction of the dichloro salt.

Application of these views to the reaction of oxalates with levo-dichloro-diethylenediamine cobaltic chloride has failed to give a product of inverted configuration. Whether this is due to the lower rate of reaction, or to a more fundamental difference, is not known.

Chloro-aquo-diethylenediamine cobaltic carbonate has been changed to the *cis*-dichloro salt by suspending it in thionyl chloride. This reagent, which evidently has not been used before in such reactions, presents several advantages over alcoholic hydrogen chloride.

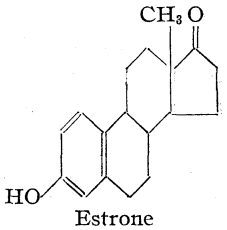
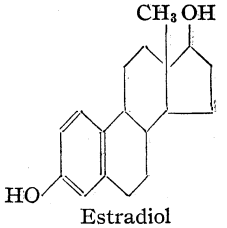
The Total Synthesis of the Sex Hormone Equilenin and Its Stereoisomers

BY W. E. BACHMANN, WAYNE COLE[1] AND A. L. WILDS[1]

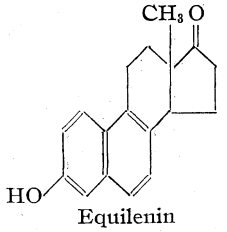
The estrogenic hormone estrone was the first sex hormone to be isolated.[2] Its isolation from pregnancy urine was reported in 1929 by Doisy, Veler and Thayer and by Butenandt. In 1932 Butenandt was able to propose a formula for estrone, which was proved to be correct in all respects by Cook and his associates. The true ovarian hormone appears to be a dihydro derivative of estrone, estradiol, which can be prepared in the laboratory by reduction of estrone. Another estrogenic hormone, equilenin, was isolated by Girard and co-workers[3] in 1932 from the urine of pregnant mares, and the structure which was proposed for it was definitely established by Cook.



Estrone



Estradiol



Equilenin

The synthesis of sex hormones and closely related compounds has engaged the attention of chemists ever since the structures of the natural products were established. One of the features of these compounds, which has been an obstacle in the synthetic path, is the presence of an angular methyl group between the C and D rings. Robinson has devised many ingenious methods for obtaining compounds which may prove useful intermediates for further synthesis. Recently he[4] succeeded in synthesizing a compound possessing the structure of equilenin except for the angular methyl group. Dane[5] has obtained an isomer of estrone by means of the Diels–Alder reaction, although the structure of the compound has not yet been established. Other important advances in the direction of the total synthesis of the sex hormones and related compounds have been made by Bardhan, Chuang, Cook, Hewett, Haberland, Kon, Linstead, Weidlich and others.[6] We have reported the synthesis of 3′-keto-1,2-cyclopentenophenanthrene and of compounds possessing a partially reduced cyclopentenophenanthrene structure.[7]

For some time we have centered our attention on a possible synthesis of equilenin. From the practical standpoint, the synthesis of this hormone possessed the advantage that equilenin contains a naphthalene nucleus and only two asymmetric carbon atoms (four stereoisomers) in contrast to the four asymmetric carbon atoms (sixteen stereoisomers) of estrone. Moreover, since Marker[8] has reported that equilenin can be reduced to estrone and to estradiol, a synthesis of equilenin would represent the synthesis of the other two hormones as well. We have succeeded in accomplishing the total synthesis of the hormone, *d*-equilenin, and also of its three stereoisomers, the antipode, *l*-equilenin, and the diastereoisomers, *d*-isoequilenin and *l*-isoequilenin. A preliminary account of the synthesis of the hormone was reported in a Communication in THIS JOURNAL.[9]

For the synthesis of these compounds we turned to the cyclic ketone, 7-methoxy-1-keto-1,2,3,4-tetrahydrophenanthrene (I), which was first prepared by Butenandt and Schramm[10] from the readily available 1-naphthylamine-6-sulfonic acid (Cleve's acid). We likewise started with the latter compound, but employed some of the procedures of Cohen, Cook, Hewett and Girard[11]

and introduced some modifications of our own in order to obtain the cyclic ketone. We found that the best yields in the final step were obtained by cyclizing the acid chloride of the intermediate γ-(6-methoxy-1-naphthyl)-butyric acid by short treatment with stannic chloride; by this procedure the cyclic ketone was obtained in an average yield of 91%.

From the cyclic ketone it was planned to prepare the 2-methyl-2-carbomethoxy derivative (IV) by the method used to prepare 2-methyl-2-carbethoxycyclohexanone from cyclohexanone,[12] which consisted in forming the glyoxalate of the ketone, converting it to the carbethoxy derivative by pyrolysis and introducing a methyl group between the carbonyl group and ester group by sodium alkoxide and methyl iodide. The prospect of eliminating carbon monoxide successfully from the glyoxalate (II) of 7-methoxy-1-keto-1,2,3,4-tetrahydrophenanthrene did not appear promising in view of Haworth's experience with the corresponding derivative of 1-keto-1,2,3,4-tetrahydrophenanthrene. Eight years ago, Haworth[13] prepared the glyoxalate IIa, but he was unable to eliminate carbon monoxide from the compound to give the 2-carbethoxy derivative; continued heating resulted in extensive decomposition of the glyoxalate.[14] In spite of this result, we ventured to try the reaction on the glyoxalate of the methoxy ketone.

Condensation of 7-methoxy-1-keto-1,2,3,4-tetrahydrophenanthrene with methyl oxalate by means of sodium methoxide in an atmosphere of nitrogen gave the glyoxalate II in 96% yield. When the reaction was carried out in air, the yield was decreased slightly, presumably through oxidation of the sodio derivative of the glyoxalate Like Haworth, we encountered difficulty in eliminating carbon monoxide from the glyoxalate. We were not entirely unsuccessful, for some samples of the compound underwent the reaction and the keto ester was obtained, but the results were erratic. We found, however, that by the simple expedient of adding powdered soft glass to the glyoxalate the latter smoothly lost carbon monoxide at 180°, and the keto ester III was isolated in yields of 90 to 94%.

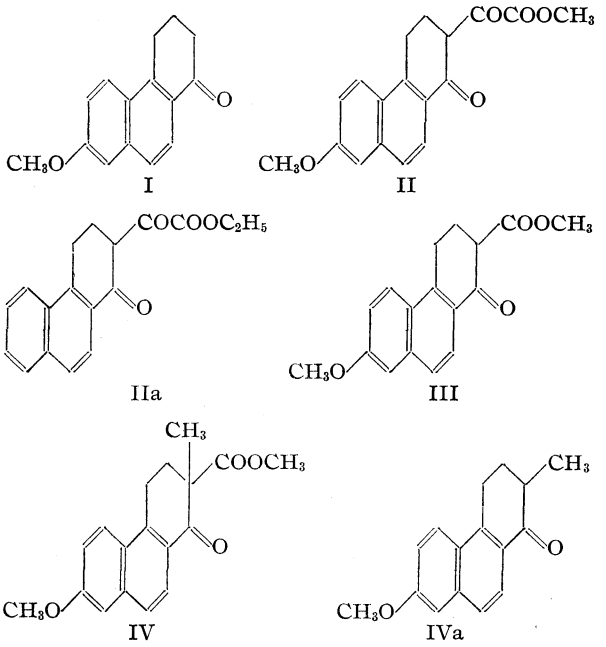
(12) Kötz and Michels, *Ann.*, **350**, 212 (1906).

(13) Haworth, *J. Chem. Soc.*, 1130 (1932).

(14) Robinson and Walker [*ibid.*, 61 (1937)] had a similar experience with a related compound, the 2-glyoxalate of 1-keto-7-methoxy-1,2,3,4,9,10-hexahydrophenanthrene. They state that the carbethoxy group cannot be introduced into this unsaturated ketone by way of the glyoxalate.

This procedure will undoubtedly prove useful with other glyoxalates. We have employed it successfully on the two glyoxalates (of 1-keto- and of 4-keto-1,2,3,4-tetrahydrophenanthrene) from which Haworth was unable to obtain the carboxy derivatives. The procedure can be used to advantage even in those cases where the glyoxalate reacts normally, for in the presence of powdered glass the reaction generally proceeds at a lower temperature and in a shorter time with less resultant decomposition. For example, this has proved to be the case with the glyoxalate of α-tetralone, the yield of carbomethoxy compound (94%) being considerably greater than has been reported previously.[15]

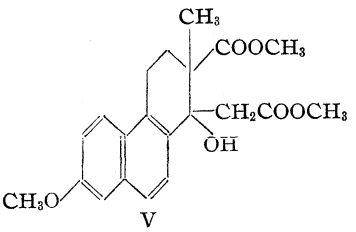
By treatment of the sodio derivative of the 7-methoxy-keto ester III with methyl iodide, 7-methoxy-2-methyl-2-carbomethoxy-1-keto-1,2,-3,4-tetrahydrophenanthrene (IV) was obtained in excellent yield.



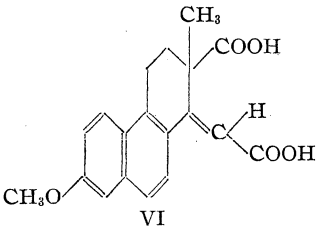
In order to build up the five-membered ring containing the carbonyl group, we proposed to introduce a propionic acid group in the 1-position, and then cyclize the dimethyl ester of the dicarboxylic acid by the Dieckmann method. First of all, conditions were determined so that a Reformatsky reaction on the keto ester IV using methyl bromoacetate gave the dimethyl ester of 7-methoxy-2-methyl-2-carboxy-1-hydroxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid (V) in 85

(15) These results will be published in future communications.

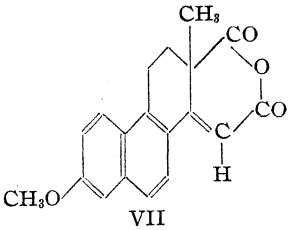
to 90% yields. This compound is susceptible to cleavage by alkali; thus, treatment with hot, concentrated aqueous potassium hydroxide stripped the molecule of its carbomethoxy and acetic ester groups and gave a good yield of 7-methoxy-2-methyl-1-keto-1,2,3,4-tetrahydrophenanthrene (IVa).[16] The same compound resulted by cleavage of IV by alkali. Accordingly dehydration was carried out on the Reformatsky ester (V), itself. This was accomplished by the indirect method, consisting in the replacement of the hydroxyl group by chlorine by means of thionyl chloride, followed by removal of the elements of hydrogen chloride by treatment with alcoholic potassium hydroxide; in this process the two ester groups also were hydrolyzed. Acidification of the alkaline solution yielded a mixture of two compounds: an unsaturated acid and an unsaturated acid anhydride. We consider the free acid and the acid corresponding to the anhydride to be geometrical isomers; to the free acid is assigned the configuration VI (in which the carboxyl group attached to the double bond extends away from the tertiary carboxyl group) and to the anhydride the structure VII.



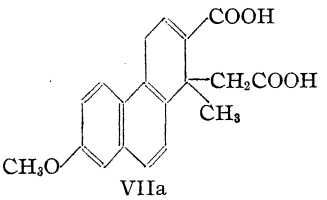
V



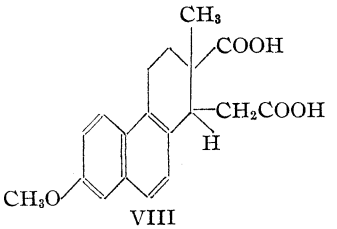
VI



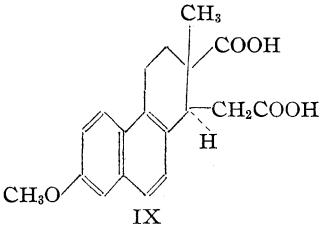
VII



VIIa



VIII



IX

In harmony with the behavior of β-aryl-α,β-unsaturated acids (cinnamic acid type), the potassium salts of the unsaturated acids from VI and VII were rapidly reduced by dilute sodium amalgam and water, and both yielded a mixture of the same two reduced acids, *cis-* (VIII) and *trans*-7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid (IX). These facts are proof that in the process of dehydration of the Reformatsky ester (V) no rearrangement took place, involving the migration of the methyl group to the 1-position, to form a compound having the formula VIIa, for such a compound could not give rise to an acid and anhydride of an isomeric acid which would yield a mixture of the identical reduced acids. Chuang, Tien and Huang[17] applied the Reformatsky reaction to 2-methyl-2-carbethoxycyclohexanone and converted the product by dehydration and catalytic reduction of the unsaturated compound to 2-methyl-2-carboxycyclohexane-1-acetic acid; it is of interest that they obtained only a single reduced acid.

The two isomeric reduced acids, which are actually racemic mixtures, were readily separated and were found to be present in nearly equal amounts. The formation of both acids on reduction was a fortunate circumstance, for it enabled us to synthesize all four stereoisomers possessing the structure of equilenin. Each of the acids was carried through the remaining series of reactions separately, the one eventually yielding racemic equilenin, the other racemic isoequilenin. Since the configuration of the C/D ring fusion of equilenin and the other steroids is still a moot point,[18] although the *trans* arrangement appears to be favored, no definite configuration is assigned to the two acids at this time, and we withdraw the prefixes *cis-* and *trans-* which were given to the two acids in our preliminary communication.[9] Until the configurations are definitely established, the acid from which isoequilenin was finally obtained is designated as the α-acid (m. p. 231–232°), and the one yielding equilenin is called the β-acid (m. p. 213–214°).

(16) Robinson and Walker [*J. Chem. Soc.*, 183 (1938)] submitted the product of the Reformatsky reaction on 7-methoxy-2-methyl-2-carbethoxy-1-keto-octahydrophenanthrene to hydrolysis with hot, concentrated potassium hydroxide. The acidic portion consisted of an intractable oily mixture which showed evidence of containing the desired acid. The principal product (67%) was the 2-methyl-1-keto compound. It occurs to us that this may have been formed by alkaline cleavage of the Reformatsky ester rather than from unreacted starting material.

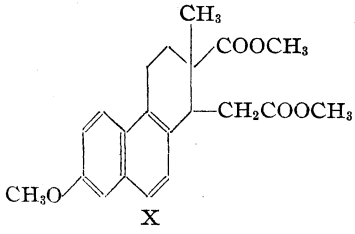
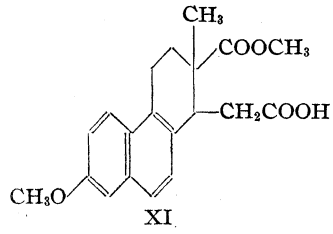
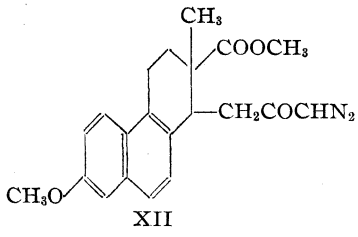
d- **and** *l*-**Equilenin.**—In order to lengthen the acetic acid side chain to a propionic acid group, we employed the reaction of Arndt and Eistert.[19] The β-acid was converted to its dimethyl ester (X), which was hydrolyzed readily to the acid ester XI. Under the conditions employed, which consisted in the use of one equivalent of sodium hydroxide in the form of a 1% solution in methanol, only the methyl group attached to the acetic acid portion was removed, the ester group of the hindered tertiary carboxyl group being unaffected. Similar instances of partial hydrolysis of esters have been observed by others. The acid chloride, formed by interaction of the acid ester and thionyl chloride, reacted with diazomethane to yield the crystalline diazo ketone XII. When the latter compound was warmed with methanol in the presence of silver oxide, the crystalline dimethyl ester of 7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-propionic acid (XIII) was obtained in 80–84% yields.[20]



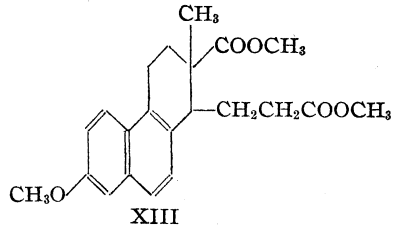
X



XI

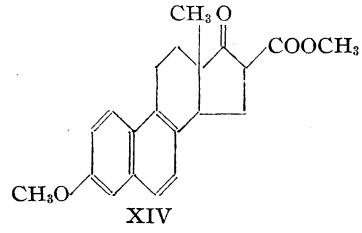


XII

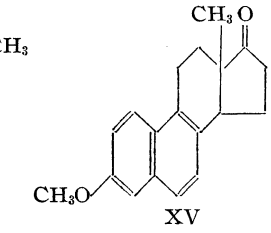


XIII

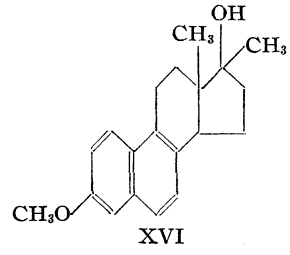
In order to effect the cyclization of the dimethyl ester XIII to XIV, we tried the action of sodium on a benzene solution of the ester containing a trace of methanol. The results by this method proved to be erratic. The powdered sodium became coated with a thin crust which effectively prevented complete reaction. Addition of methanol served to remove the coating, and all of the ester reacted, but the yield of cyclic product was only 40–50%. A thorough investigation of the reaction revealed that sodium methoxide could be used for the cyclization, and, furthermore, that the low yields of product were caused by oxidation of the substance by oxygen of the air. By running the reaction in an atmosphere of nitrogen, it was possible to prepare the methyl ether of 16-carbomethoxy-*dl*-equilenin (XIV) in 95–98% yields. By heating this compound with hydrochloric acid, the ester group was hydrolyzed and the resulting acid was decarboxylated to give the methyl ether of *dl*-equilenin (XV). When a mixture of acetic acid and hydrochloric acid was employed, it was found that even under these mild conditions the ether linkage also was cleaved and the product was *dl*-equilenin. The racemic equilenin melted at 276–278° (natural *d*-equilenin, 250–251°) and like the hormone it gave a deep red liquid when melted in air.



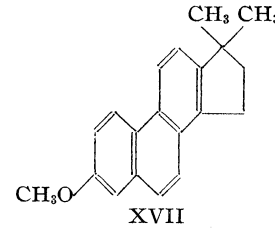
XIV



XV



XVI



XVII

The results of the brilliant investigations of Cook and co-workers[11] on the structures of estrone and equilenin were invaluable to us at this point, for we were enabled to confirm the structure of our racemic equilenin prior to resolution. By treatment with methylmagnesium iodide, the methyl ether of the racemic equilenin was converted to the carbinol XVI, which was dehydrated with migration of the angular methyl group and the dehydration product was dehydrogenated to 3′,3′-dimethyl-7-methoxy-1,2-cyclopentenophenanthrene (XVII), identical with the com-

(19) Arndt and Eistert, *Ber.*, **68**, 200 (1935); Eistert, *ibid.*, **69**, 1074 (1936).

(20) While this work was in progress, Litvan and Robinson [*J. Chem. Soc.*, 1997 (1938)] applied the Arndt-Eistert reaction to a closely related compound, which they obtained by degradation of estrone. They were able to isolate the pure, crystalline propionic acid derivative in about 1% yield.

pound obtained in the same manner from natural equilenin.

The *dl*-equilenin was resolved by converting it to the *l*-menthoxyacetic esters by reaction with *l*-menthoxyacetyl chloride. From the mixture of diastereoisomeric esters was isolated the ester (m. p. 174–174.5°) which on hydrolysis yielded *d*-equilenin.

l-Equilenin, the optical antipode of the natural hormone, was isolated by employing the action of *d*-menthoxyacetyl chloride on the racemic equilenin, or on the mixture obtained after some of the *d*-equilenin had been removed. It possesses the same melting point and specific rotation (opposite in sign) as the natural hormone. Its estrogenic activity is presented in Table III.

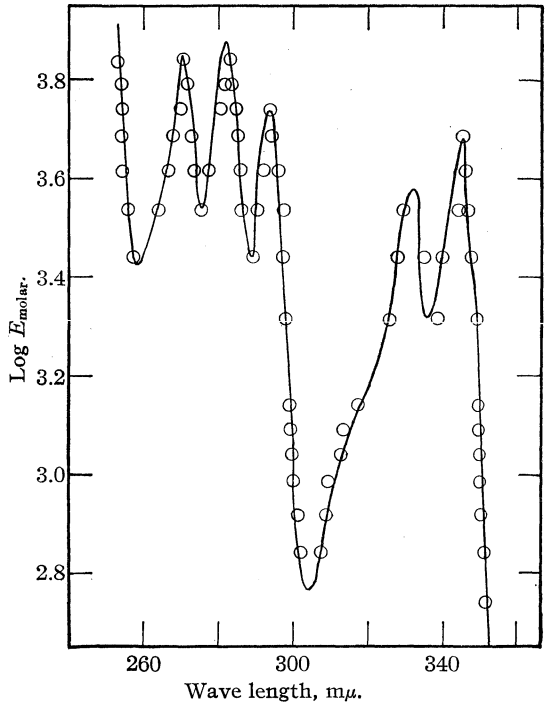


Fig. 1.—Ultraviolet absorption curve of equilenin, showing the logarithm of the extinction coefficient at various wave lengths. The solid line represents the curve for natural equilenin, the circles the values for synthetic *d*-equilenin.

Comparison of Synthetic *d*-Equilenin with the Hormone Equilenin.—The synthetic *d*-equilenin proved to be identical with the natural hormone in all respects. The identity of the two compounds was established by a determination of the melting points and mixed melting points of the hormone and a number of derivatives, by a comparison of the optical rotation, estrogenic activity, absorption spectrum and crystallographic properties. A comparison of the melting points and mixed melting points of the synthetic and natural equilenin and six derivatives is given in Table I.

TABLE I

COMPARISON OF MELTING POINTS[a]

Compound	Melting points, °C. Synthetic	Natural	Mixed
d-Equilenin	250–251	250–251	250–251
Benzoate	222.5–223	222.5–223.5	222.5–223.5
Acetate	156–157	156–156.5	156–157
l-Menthoxyacetic ester	174–174.5	173–173.5	173.5–174.5
Methyl ether	193.5–194	194–194.5	194–194.5
Trinitrobenzene complex	205.5–207	206.5–207.5	206–207
Methyl carbinol of methyl ether (XVI)	132.5–133.5	132–134.5	132.5–134.5

[a] M. p. (uncor.) determined in vacuum. The melting points of equilenin and its derivatives are in general unsatisfactory when determined in open capillary tubes because of the oxidation of the compounds to red products. By determining the melting points in sealed, evacuated (0.2 mm.) tubes, the melts remained colorless; on being cooled, the melts quickly solidified and when heated the solids showed the same melting points as before.

The specific rotation of the synthetic equilenin, $[\alpha]^{30}D$ + 84° (dioxane) agreed with the value reported for natural equilenin, $[\alpha]^{16}D$ + 87° (dioxane).[3] In estrogenic activity the synthetic hormone was indistinguishable from the natural product. In each case a dose of 30 γ produced estrus in 50% of the rats tested (Dr. Bradbury).

A comparison of the ultraviolet absorption spectrum of the synthetic and natural hormones was kindly made by Mr. Nelson V. Seeger. From Fig. 1 and the values for the maxima given in Table II, it can be seen that agreement is satisfactory throughout. This curve for the absorption spectrum in ether agrees with that of natural equilenin in alcohol given by Dirscherl and Hanusch[21] and supplemented by Wintersteiner, *et al.*,[22] in the location of the bands. However, the value of log *E* for the maximum at 282 mμ. was somewhat smaller and that for the maximum at 294 mμ. was somewhat larger than those pre-

TABLE II

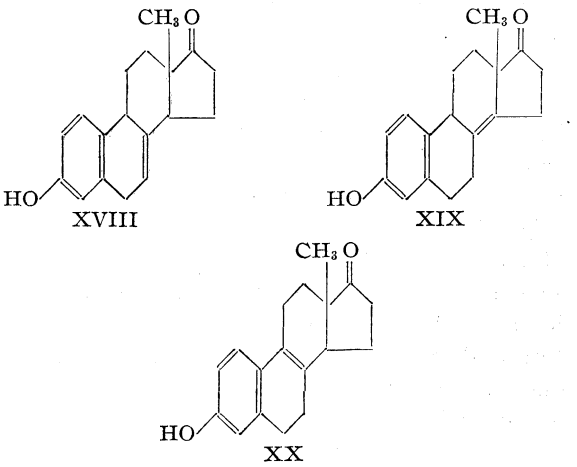
viously reported, while the minima were uniformly lower.

We are indebted to Dr. Chester B. Slawson of the Mineralogy Department for making a comparison of the crystals of the two compounds. He reports that the natural and synthetic equilenin have identical crystallographic properties. When crystallized from dilute alcohol, both formed elongated needles (probably orthorhombic) which are flattened in one direction. In both cases the crystals possessed the following optical properties: biaxial negative; $r > v$; α_D, 1.509 ($\pm$0.001); β_D, 1.718 ($\pm$0.001); γ_D, 1.800 ($\pm$0.010).[23] β may be measured parallel to the elongation and α across the flattened needles. β and γ show very strong dispersion nearly exactly equivalent to that of methylene iodide.

From all of these comparisons it is apparent that there is an exact agreement between the synthetic and natural hormone in all respects. The synthesis completely establishes the correctness of the structural formula which has been proposed for equilenin.

d- and *l*-**Isoequilenin.**—The α-acid (VIII or IX), when carried through the same series of reactions used on the isomeric acid, yielded *dl*-isoequilenin, which has the same structural formula as equilenin but a different spatial configuration. The *dl*-isoequilenin exists in two forms, one melting at 206–206.5°, the other 223–224°. Like the corresponding equilenin derivative, the methyl ether of isoequilenin could be converted to 3′,3′-dimethyl-7-methoxy-1,2-cyclopentenophenanthrene (XVII), although the yield of the product was poor. Attempts to resolve *dl*-isoequilenin by means of *l*-menthoxyacetyl chloride and certain other active compounds were unsuccessful, but resolution of the α-acid was accomplished readily. By reaction of the acid chloride of the α-acid ester (XI) with *l*-menthol, two diastereoisomeric methyl-*l*-menthyl esters were obtained, from which a pure ester was isolated. The pure active *l*-methyl-*l*-menthyl ester was hydrolyzed to the active α-acid, which was then carried through the series of reactions previously described, to yield *d*-isoequilenin. The mixture of methyl-*l*-menthyl esters remaining after removal of the pure individual was hydrolyzed to the dicarboxylic acids and the latter converted to the dimethyl esters (X). It was found possible at this stage to separate nearly completely the *d*-dimethyl ester from the *dl*-dimethyl ester which was present by taking advantage of the great difference in solubility and crystalline forms of the compounds. From the *d*-dimethyl ester was prepared *l*-isoequilenin. Both active forms of isoequilenin melted at the same temperature (257–258°) and possessed equal but opposite specific rotations (Table III).

Recently, Hirschmann and Wintersteiner[24] have converted the hormone equilin (XVIII) to an isomer of equilenin which they called 14-*epi*-equilenin. The transformation was accomplished by isomerizing equilin to isoequilin A (XX) by hydrogen chloride in boiling acetic acid. While dehydrogenation of equilin gives equilenin, dehydrogenation of isoequilin A gives the isomer of equilenin, 14-*epi*-equilenin. In the process of isomerization, epimerization at C_{14} takes place, presumably through an intermediate such as XIX. Inasmuch as equilenin can have only one dextrorotatory diastereoisomer, it follows that their 14-*epi*-equilenin (which is dextrorotatory) must be identical with our *d*-isoequilenin. A comparison of the two compounds and their acetates, which was kindly carried out by Dr. Wintersteiner, left little doubt about the identity of the samples of isoequilenin and 14-*epi*-equilenin.



As Hirschmann and Wintersteiner have pointed out, the configuration of the *d*-isoequilenin at C_{13} is the same as that of natural *d*-equilenin. It follows that the configurations of all of the stereoisomers of the natural hormone, which we have prepared, are established with reference to it.

In Table III are summarized some of the chief

(23) Gaudefroy, *Compt. rend.* **195**, 983 (1932), reports the following values for the refractive indices of natural equilenin: α, 1.51; β, 1.718.

(24) Hirschmann and Wintersteiner, *J. Biol. Chem.*, **126**, 747 (1938).

properties of the four stereoisomers and the two racemic compounds which we have prepared; included is a comparison of the estrogenic activities of the optically active compounds. These values are taken from the results of Dr. James T. Bradbury of the Department of Obstetrics and Gynecology.

TABLE III

PROPERTIES OF THE SYNTHETIC COMPOUNDS

Compound	M. p. (vac.), °C.	$[\alpha]_D$ dioxane	Estrogenic activity,[a] γ
d-Equilenin	250–251	+ 84	30
l-Equilenin	250–251	− 85	400
dl-Equilenin	276–278[b]	0	..
d-Isoequilenin	257–258[c]	+147	>500[e]
l-Isoequilenin	257–258[c]	−147	>500[e]
dl-Isoequilenin	223–224[d]	0	..

[a] Amount required to produce estrus in more than 50% of the rats tested. [b] Another form, m. p. 287–288°. [c] Another form, m. p. 272–273°. [d] Another form, m. p. 206–206.5°. [e] A dose of 500 γ produced only pro-estrus in about 25% of the rats, the rest being negative. Larger doses are being tested.

From the table it is apparent that the natural *d*-equilenin is more than thirteen times as active as its antipode, *l*-equilenin, and that both forms of isoequilenin are less potent than the forms of equilenin. It is of interest that here, as in the case of the four known forms of androsterone, the isomer with the greatest physiological activity is the one which occurs naturally.

In this investigation we usually endeavored to determine the conditions for obtaining maximum yields of the intermediates. Frequently this necessitated running a reaction twenty to thirty times under varying conditions before the optimum conditions were discovered. In this way it was sometimes possible to double the yield originally obtained and in nearly all cases we were able to raise the yields to about 90%. As a consequence of this, although numerous steps were involved, ten grams of 7-methoxy-1-keto-1,2,3,4-tetrahydrophenanthrene(I) yielded about two and one-half grams of *dl*-equilenin and the same amount of *dl*-isoequilenin.

Having successfully worked out the experimental conditions for the reactions in this investigation, it appeared of interest to determine whether they could be applied to similar reactions leading to the synthesis of other steroids, such as estrone, vitamin D and related compounds. As a matter of fact, the procedures have already proved successful in the synthesis of desoxyequilenin and desoxyisoequilenin. Moreover, the structural isomer of equilenin with the hydroxyl group in the 6-position has been prepared in both *cis* and *trans* forms by Mr. David W. Holmes in this Laboratory. It has proved a simple matter to introduce other alkyl groups in the position occupied by the angular methyl group, as well as to build up a six-membered D ring. In addition simple analogs of the sex hormones have been synthesized. These compounds should furnish interesting information in regard to the relation between structure and estrogenic activity.

We are extremely grateful to Dr. Oliver Kamm of Parke, Davis and Company for his generosity in supplying us with natural equilenin for purposes of comparison.

Experimental

The melting points of a number of compounds that were found to oxidize in air were determined in sealed, evacuated (0.2 mm.), capillary tubes; these values are indicated by (vac.).

β-(6-Methoxy-1-naphthyl)-ethyl Bromide.—1-Naphthylamine-6-sulfonic acid (Cleve's acid) was fused with alkali and the resulting aminonaphthol was acetylated and methylated according to the procedure of Butenandt and Schramm.[10] Hydrolysis of the 6-methoxy-1-acetylaminonaphthalene was accomplished by refluxing a mixture of 200 g. of the compound, 200 cc. of water and 250 cc. of concentrated hydrochloric acid for fifteen to twenty minutes. All of the compound went into solution and then the hydrochloride of 6-methoxy-1-naphthylamine began to precipitate. The hydrochloride which was filtered from the cooled solution was sufficiently pure for diazotization and conversion to 6-methoxy-1-iodonaphthalene, which was carried out according to the directions of Cohen, Cook, Hewett and Girard.[11]

A solution of 57 g. of 1-iodo-6-methoxynaphthalene and 21 g. of ethyl bromide in 150 cc. of benzene was added in six portions to 9.8 g. of powdered magnesium and 100 cc. of ether in a 1-liter flask. Refluxing was continued for five hours after all of the reagent had been added. The Grignard reagent was diluted with 200 cc. of dry benzene, the solution cooled to 5° and ethylene oxide gas after passing through a tube containing potassium hydroxide was led to within an inch of the surface of the solution. During the addition of 24 g. of ethylene oxide the solution was swirled every few minutes. After standing at room temperature for eight hours, the mixture was warmed to 50–80° for one hour. The mixture was hydrolyzed with ammonium chloride solution and cold 5% hydrochloric acid (about 30 cc.) was added until the emulsion broke. After being washed and dried, the organic layer was distilled; the product boiling at 140–185° at 1 mm. was found to be suitable for conversion to the bromide, although it contained some nerolin; yield, 31–34 g. (76–84%). This method is patterned after that of Cohen, Cook and Hewett.[11]

An ice-cold solution of 40.4 g. of β-(6-methoxy-1-naphthyl)-ethyl alcohol in 125 cc. of dry benzene was treated with a solution of 40 g. of phosphorus tribromide in 50 cc.

of benzene with swirling; the mixture was then kept at 60–75° for three hours. The cooled mixture was poured onto ice and water and worked up according to the procedure of Cohen, Cook and Hewett.[11] The total yield of bromide boiling at 160–175° at 0.6 mm. was 40–42 g. (75–79%).

γ-(6-Methoxy-1-naphthyl)-butyric Acid.—Ten grams of sodium (thin slices) in 25 cc. of benzene was treated with absolute alcohol (about 30 cc.) in portions until all of the sodium had reacted. One hundred grams of malonic ester was introduced and the mixture was warmed with swirling until a clear solution resulted. To the cooled solution was added 79.5 g. of β-(6-methoxy-1-naphthyl)-ethyl bromide in 100 cc. of benzene. After being warmed at 70–80° in a water-bath for eight hours, the mixture was refluxed on a steam-bath for four hours.

The warm solution was poured cautiously into a hot solution of 112 g. of potassium hydroxide in 150 cc. of water and 50 cc. of alcohol (2-l. flask); hydrolysis proceeds rapidly as the solutions mix. The benzene and much of the alcohol were removed in a current of air, more water was added and the turbid solution was heated for two hours on a steam-bath, then cooled and extracted with benzene. The clear aqueous solution was poured with stirring into 275 cc. of concentrated hydrochloric acid. The colorless plates of the substituted malonic acid were filtered from the chilled solution and dried. The product obtained by decarboxylation at 200° was poured while still hot into acetic acid, and the solution diluted with water. The yield of γ-(6-methoxy-1-naphthyl)-butyric acid melting at 149–150° was 55–65 g. (75–89%) depending on the purity of the bromide. Cohen, Cook and Hewett[25] prepared this acid (m. p. 150–151°) by means of potassiomalonic ester in boiling toluene.

7 - Methoxy - 1 - keto - 1,2,3,4 - tetrahydrophenanthrene (I).—Five grams of powdered γ-(6-methoxy-1-naphthyl)-butyric acid was added to a cold solution of 25 cc. of anhydrous ether, 2.4 cc. of thionyl chloride and 2 drops of pyridine. The mixture was allowed to stand at room temperature with occasional swirling until all of the solid had disappeared (about three hours). The mixture was warmed to 35° for ten minutes and the solvent removed under reduced pressure (water pump). Two cc. of benzene was added and then removed by means of a water pump and finally by means of an oil pump in order to remove completely the unreacted thionyl chloride, the acid chloride being warmed finally to 35°. A solution of the acid chloride in 100 cc. of benzene was cooled in a freezing mixture until the benzene began to crystallize, then removed from the cooling bath and treated rapidly with a solution of 5.5 g. of stannic chloride in 20 cc. of benzene, the mixture being swirled until a homogeneous, yellow slurry was obtained. After being kept cold for one minute, the mixture was poured onto ice and 30 cc. of concentrated hydrochloric acid and 30 cc. of ether. When all of the yellow solid had disappeared, more ether was added and the two layers were separated. The ether–benzene solution was washed three times with cold 10% hydrochloric acid, once with water, twice with 10% sodium hydroxide and several times with water. Evaporation of the solvents and the addition of methanol to the residue gave 3.8–4.0 g. of colorless prisms of the cyclic ketone (m. p. 98–100°).[10] From the mother liquors an additional quantity of only slightly less pure ketone was isolated and a further small amount was obtained by sublimation of the remainder at 200° at 0.5 mm. The total yield of ketone was 4.2–4.4 g. (90–95%). The yield was somewhat smaller when larger amounts were cyclized.

Methyl 7 - Methoxy - 1 - keto - 1,2,3,4 - tetrahydrophenanthrene - 2 - glyoxalate (II).—A solution of sodium methoxide prepared from 0.46 g. of sodium and 5 cc. of anhydrous methanol was evaporated to dryness at 100° under reduced pressure. The solid cake was broken up somewhat, 2.36 g. of dimethyl oxalate was added and the flask and condenser were evacuated and then filled with dry nitrogen. Ten cc. of dry, thiophene-free benzene was added and the mixture was refluxed for ten minutes in order to dissolve most of the solid. To the cooled solution was added a solution of 2.26 g. of the aforementioned cyclic ketone in 15 cc. of benzene and the mixture was swirled at room temperature. Within two minutes a clear, light-yellow solution resulted, which soon deposited a light-yellow precipitate of the sodio derivative of the glyoxalate. After four hours at room temperature, the mixture was hydrolyzed with cooling, and a small amount of sodium hydroxide solution was added in order to give two clear layers. After drawing off the aqueous layer, the benzene solution was extracted twice with 2% sodium hydroxide solution and the combined aqueous solution was acidified with cold, dilute hydrochloric acid. The light-yellow crystalline glyoxalate was filtered off and the dried product was digested with a warm mixture of acetone–methanol and cooled. By filtration, 2.95 g. of the glyoxalate (m. p. 133–135°) was obtained; this with an additional 0.06 g. isolated from the filtrate corresponded to a yield of 96%. When the condensation reaction was carried out in an atmosphere of air, using sodium methoxide prepared in benzene with the theoretical amount of methanol, the product was accompanied by varying amounts of a green oxidation product, and the yield of glyoxalate dropped to 88–92%.

The glyoxalate crystallized from methanol–acetone in clusters of long, thin, light-yellow prisms; these melted at 134–135° but the solid formed on cooling the melt showed a melting point of 139–140° with gas. In a Pyrex tube the crystals melted at 138–140°; the solid formed on cooling remelted at 130°; addition of powdered glass to the melt raised the melting point to 138–140° with gas. The glyoxalate gives an intense red-brown color instantly with an alcoholic solution of ferric chloride; it gives a red-brown color with concentrated sulfuric acid.

Anal. Calcd. for $C_{18}H_{16}O_5$: C, 69.2; H, 5.2. Found: C, 69.5; H, 5.0.

Methyl Ester of 7-Methoxy-1-keto-1,2,3,4-tetrahydro-2-phenanthroic Acid (III).—The first attempts to prepare this ester by heating the glyoxalate at 180–200° gave low and variable yields of an impure product. Frequently the reaction required more than two hours of heating before the evolution of carbon monoxide ceased. Excellent yields of the product were obtained when powdered glass was added to the glyoxalate, and on small runs the reaction was complete within ten minutes.

Ten grams of the glyoxalate was melted in an 8″ (22-cm.) test-tube in an oil-bath (140–150°); 5 g. of finely powdered soft glass was stirred into the melt with a glass rod and the

(25) Cohen, Cook and Hewett, *J. Chem. Soc.*, 52 (1936).

mixture heated to 180°. A vigorous evolution of carbon monoxide took place, all of the gas being evolved in one-half hour. After being cooled, the light-brown semi-solid product was dissolved in benzene and the solution was decanted from the glass. After decolorization with Norite, the solution was evaporated and the residue stirred with methanol, whereupon crystallization took place. The first crop of cream-colored crystals of the keto ester weighed 8.0 g. (m. p. 108–110° with solidification and remelting at 118–120°); the second crop (0.2–0.6 g.) of only slightly less pure product brought the yield to 90–94%. The product so obtained is sufficiently pure to be used in the next step.

A sample of the methyl ester of 7-methoxy-1-keto-1,2,3,4-tetrahydro-2-phenanthroic acid, after sublimation at 220° (0.5 mm.) and recrystallization from acetone–methanol and then from benzene–methanol, was obtained as clusters of colorless prisms. The crystals melted nearly completely at 110–111°; the melt solidified and the solid remelted at 125–126.5°. The keto ester is soluble in benzene and in hot acetone, but is only slightly soluble in methanol. It gives a light orange-yellow color with concentrated sulfuric acid, and slowly develops a deep blue-green color with alcoholic ferric chloride solution (two to ten minutes).

Anal. Calcd. for $C_{17}H_{16}O_4$: C, 71.8; H, 5.7. Found: C, 71.6; H, 5.7.

7 - Methoxy - 2 - methyl - 2 - carbomethoxy - 1 - keto-1,2,3,4-tetrahydrophenanthrene (IV).—To 2.3 g. of sodium dissolved in 45 cc. of anhydrous methanol was added 5.68 g. of the aforementioned keto ester (crude) as a finely divided solid, followed by 25 cc. of dry benzene. As the mixture was refluxed, the solid partially dissolved and then reappeared as the fine, powdery sodio-derivative, which ultimately nearly filled the solution; any lumps which formed were broken up. After thirty minutes of refluxing, the mixture was cooled and treated with 7 cc. of methyl iodide. After forty-five minutes at room temperature, during which time the mixture was swirled occasionally, much of the solid had dissolved. An additional 7 cc. of methyl iodide was added and within thirty minutes all of the solid had reacted. The clear yellow solution was refluxed for forty-five minutes, cooled and neutralized with acetic acid. After being evaporated nearly to dryness, the mixture was treated with benzene and water, and the benzene solution after separating was washed with 5% sodium hydroxide, again with water and dried over sodium sulfate. The solution was decolorized with Norite and evaporated. The residue crystallized from methanol in colorless crystals; yield 5.3–5.5 g. (89–92%); m. p. 84–86°.

After sublimation at 230° (0.2 mm.) and two recrystallizations from methanol, a sample of the 7-methoxy-2-methyl - 2 - carbomethoxy - 1 - keto - 1,2,3,4 - tetrahydrophenanthrene was obtained as colorless, hexagonal plates; m. p. 84.5–85°. The compound gives a light-yellow color with concentrated sulfuric acid, but neither the pure nor the unrecrystallized product gives a color with ferric chloride solution.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.5; H, 6.1. Found: C, 72.3; H, 5.8.

Cleavage of the Keto Methyl Ester (IV) by Alkali.—A mixture of 0.3 g. of the above ester, 3 cc. of 45% aqueous potassium hydroxide and 10 cc. of methanol was refluxed on a steam-bath for two hours, diluted with water and cooled. The resulting crystals were filtered off and recrystallized from methanol; from the solution 0.23 g. (96%) of 7-methoxy-2-methyl-1-keto-1,2,3,4-tetrahydrophenanthrene (IVa) crystallized in thin, colorless plates; m. p. 109–110° (Haberland and Blanke,[26] 108°).

7 - Hydroxy - 2 - methyl - 1 - keto - 1,2,3,4 - tetrahydrophenanthrene was obtained by refluxing 0.2 g. of the methyl ether (IVa) in 12 cc. of 42% aqueous hydrobromic acid for three hours. The residue obtained after removal of the liquids by distillation under reduced pressure was dissolved in aqueous potassium hydroxide, the solution filtered and acidified. The precipitated phenolic ketone (0.17 g.) after sublimation at 180° at 0.01 mm. crystallized from methanol in colorless plates; m. p. 195.5–197.5° (vac.); after cooling the product remelted sharply at 197–197.5° (vac.). In an open tube the compound melted at 193–196° to a brown melt. Haberland and Blanke[26] failed to report the melting point of the compound.

Dimethyl Ester of 7-Methoxy-2-methyl-2-carboxy-1-hydroxy - 1,2,3,4 - tetrahydrophenanthrene - 1 - acetic Acid (V).—To 2.5 g. of granulated zinc (20-mesh, previously washed with dilute hydrochloric acid, water, acetone and dried) and 0.07 g. of iodine in 25 cc. of dry benzene (thiophene-free) and 25 cc. of anhydrous ether was added 1.5 g. of the keto ester IV and 0.75 cc. of methyl bromoacetate. As the mixture was refluxed on a water-bath, the iodine color faded and the solution became cloudy. After five to ten minutes a colorless addition product was deposited. Five additions of 2.5 g. of zinc and a trace of iodine were made at forty-five minute intervals and an additional 0.75 cc. of methyl bromoacetate was introduced after one and one-half hours. The mixture was refluxed for a total of four hours. Frequently the mixture was shaken vigorously in order to free the zinc from the adhering mass of crystals.

The addition product was dissolved by adding a little acetic acid and methanol and the solution was decanted from the zinc into water and the mixture acidified with acetic acid. The ether–benzene layer was separated, the aqueous solution was extracted with benzene and the combined extracts were washed with water and then dilute ammonium hydroxide until no more color was removed. The residue obtained by evaporation of the ether–benzene solution crystallized readily from methanol; yield 1.5–1.6 g. of colorless crystals (m. p. 123–126°). Additional product from the filtrate brought the total yield up to 85–90%. Should the yield fall below this, retreatment of the material in the filtrates with zinc and methyl bromoacetate will give additional product.

The hydroxy ester crystallizes from methanol containing a few drops of acetone in colorless leaflets; m. p. 125–125.5°. With concentrated sulfuric acid the compound gives a blue color which soon changes to a red-brown color and then fades to yellow.

Anal. Calcd. for $C_{21}H_{24}O_6$: C, 67.8; H, 6.5. Found: C, 67.8; H, 6.6.

The zinc which is recovered from the reaction may be used over again after being cleaned with acid, washed with water, acetone and dried.

(26) Haberland and Blanke, *Ber.*, **70**, 169 (1937).

Cleavage of the Reformatsky Ester (V) by Alkali.—A mixture of 100 mg. of the ester and 3 cc. of 45% aqueous potassium hydroxide was heated on a steam-bath for forty-five minutes. The solid melted to an oil which later solidified in the hot mixture. The colorless crystals (55 mg. or 85%) of 7-methoxy-1-keto-2-methyl-1,2,3,4-tetrahydrophenanthrene (IVa) which were filtered off melted at 105–107°; when mixed with authentic ketone (m. p. 109–110°), the melting point was 107–109°. Only a trace of acidic material precipitated when the alkaline filtrate was acidified.

Conversion of the Reformatsky Ester (V) to the Unsaturated Acids.—To a cold mixture of 2 cc. of benzene and 0.6 cc. of pyridine was added 1.2 cc. of pure thionyl chloride. The solution was chilled and 1.65 g. of powdered Reformatsky ester was added. An immediate reaction ensued, and after a few minutes a clear yellow solution resulted. After standing at 25° for one-half hour, the mixture was evaporated under reduced pressure at room temperature and finally at 40°. The crystalline chloride was dissolved in 5 cc. of benzene and decanted from the insoluble pyridine hydrochloride; the latter was digested several times with small portions of benzene and the extracts were added to the main portion. (Alternately, the mixture of ester, thionyl chloride and pyridine in 10 cc. of benzene was allowed to stand at 25° for one-half hour, then chilled and shaken with ice and water; the benzene solution was then separated from the aqueous layer.) To the chilled benzene solution was added a solution of 1.6 g. of potassium hydroxide in 22 cc. of methanol and the mixture was refluxed for fifteen minutes. Four and one-half cc. of 45% aqueous potassium hydroxide was added to the cooled solution and refluxing was continued. After three-quarters of an hour, a large amount of precipitate was present. Sufficient water (20 cc.) was added to dissolve the solid, some of the methanol and benzene were removed in a current of air, and refluxing was continued for four hours.

The excess of alkali was carefully neutralized with 5% hydrochloric acid, and the solution was boiled with Norite and filtered. Acidification of the filtrate precipitated a mixture of unsaturated acid and acid anhydride. The dried product was boiled with 100 cc. of acetone and the insoluble acid anhydride (VII) was filtered from the solution, which contained all of the unsaturated acid (VI) and a small amount of anhydride. The **anhydride of *syn*-7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrylidene-1-acetic acid** (VII) crystallized from acetic acid–xylene in the form of colorless plates; yield, 0.71 g.; m. p. 233–234°. It dissolves only slowly in hot aqueous sodium hydroxide solution.

Anal. Calcd. for $C_{19}H_{16}O_4$: C, 74.0; H, 5.2. Found: C, 73.9; H, 5.2.

The acetone solution was evaporated to dryness and the residue was warmed with a 5% solution of sodium bicarbonate. The solution was filtered from 0.06 g. of the anhydride. Acidification of the aqueous filtrate gave 0.26 g. of the unsaturated acid. From benzene the ***anti*-7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrylidene-1-acetic acid (VI)** crystallized in broad, colorless needles; m. p. 216–217° with evolution of gas. When the acid is dissolved in sodium bicarbonate and the solution is acidified, the same acid and no anhydride is precipitated.

Anal. Calcd. for $C_{19}H_{18}O_5$: C, 69.9; H, 5.6. Found: C, 70.2; H, 5.8.

The unsaturated acid reacted immediately with an ether solution of diazomethane while the acid anhydride remained unaffected under the same conditions. The **methyl ester** of the unsaturated acid crystallized from methanol in thin, colorless, nacreous leaflets which melted at 86–87°. The second crop of crystals consisted of stout plates which melted about twenty-five degrees higher. This represented a second form of the ester; when the low-melting product was recrystallized from methanol–petroleum ether and the solution seeded with the high-melting form, stout, colorless plates of the methyl ester were formed; m. p. 113.5–114°.

Anal. Calcd. for $C_{21}H_{22}O_5$: C, 71.2; H, 6.3. Found: C, 70.9; H, 6.2.

Reduction of the Unsaturated Acid (VI).—A warm solution of 120 mg. of the unsaturated acid in 0.12 cc. of 45% potassium hydroxide and 2.4 cc. of water was shaken vigorously with 5 g. of 2% sodium amalgam for fifteen minutes. Acidification of the clarified solution precipitated a mixture of the reduced acids. The dried product was dissolved in a hot mixture of 0.48 cc. of acetic acid and 0.72 cc. of xylene and the solution without filtering was allowed to cool; 55 mg. (45%) of colorless crystals melting at 227–229° precipitated. From xylene–acetic acid the **α-7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid (VIII or IX)** crystallized in colorless rhombic prisms; m. p. 231–232°.

Anal. Calcd. for $C_{19}H_{20}O_5$: C, 69.5; H, 6.1. Found: C, 69.7; H, 5.8.

The filtrate was evaporated to dryness and the residue was dissolved in a small volume of hot benzene. On cooling, the solution deposited colorless plates (65 mg.). The compound melted slightly at 145°, the melt solidified and the solid melted at 208–210°. It melted completely with bubbling when put into a bath at 150°. It appears that the acid crystallizes with benzene of crystallization. A sample of the pure acid was prepared by hydrolysis of the pure acid ester (XI). From acetone–petroleum ether the **β-7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid (VIII or IX)** crystallized in colorless prisms; m. p. 213–214°.

Anal. Calcd. for $C_{19}H_{20}O_5$: C, 69.5; H, 6.1. Found: C, 69.6; H, 6.2.

Reduction of the Acid from the Unsaturated Anhydride (VII).—A mixture of 300 mg. of the acid anhydride, 100 mg. of potassium hydroxide and 10 cc. of methanol was refluxed for one-half hour. The methanol was removed in a current of air and the potassium salt of the unsaturated acid was dissolved in a small amount of water. After being shaken with 12 g. of 2% sodium amalgam for fifteen minutes the solution was acidified and the mixture of reduced acids was separated in the manner already described into 100 mg. (33%) of the α-acid and 130 mg. (43%) of the β-acid. The acids and their methyl esters were identical with the corresponding compounds obtained by reduction of the unsaturated acid.

Direct Preparation of the Reduced Acids, α and β.—Inasmuch as the unsaturated acid and the acid anhydride yielded the same two reduced acids on reduction, it was un-

necessary to isolate the unsaturated compounds. Usually 7.44 g. (0.02 mole) of the Reformatsky ester was converted to the potassium salts of the unsaturated acids as described. The aqueous solution of the salts was then transferred to a strong 500-cc. bottle and shaken vigorously for one-half hour with 150 g. of 2% sodium amalgam; in this process the yellow solution became practically colorless. The dried mixture of reduced acids (6.3–6.4 g.) was dissolved in a hot mixture of 20 cc. of acetic acid and 30 cc. of xylene. Without filtering, the solution is allowed to cool; 3.0–3.1 g. of the α acid crystallized (m. p. 222–225°). By evaporation of the solution and recrystallization of the residue from benzene, the β-acid was obtained; the weight of the latter varied from 2.8–3.5 g., depending on whether benzene of crystallization was present. The yields of the acids formed in the reaction were best obtained from the amount of dimethyl ester produced on treatment with diazomethane. Numerous runs showed that the yield of the α-acid was 44–47%, that of the β-acid 40–43% (total, about 87%) of the theoretical amount based on the Reformatsky ester.

Synthesis of *d*- and *l*-Equilenin

Dimethyl Ester of β-7-Methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-acetic Acid (X).—The ester was prepared from the β-acid by means of diazomethane and recrystallized from acetone–methanol. The yield of the ester varied with the purity of the acid. In a typical run, 0.69 g. of the acid as it was obtained in the reduction process yielded 0.62 g. of the ester melting at 107–109°; this product was found to be sufficiently pure for conversion to the acid ester (XI). Since the acid ester can be obtained more readily in a high state of purity, a pure sample of the dimethyl ester was prepared by reaction of the acid ester with diazomethane. The pure dimethyl ester crystallized from ether in thin, colorless plates; m. p. 114–115.5°.

Anal. Calcd. for $C_{21}H_{24}O_5$: C, 70.8; H, 6.8. Found: C, 70.6; H, 6.7.

β-7-Methoxy-2-methyl-2-carbomethoxy-1,2,3,4-tetrahydrophenanthrene-1-acetic Acid (XI).—A mixture of the aforementioned dimethyl ester (0.62 g., m. p. 107–109°), 10 cc. of methanol and 1.8 cc. of *N* sodium hydroxide was refluxed for two hours; the solution was clear after a few minutes. After evaporation of the methanol in a current of air, the residue was dissolved in a few cc. of water. About 2 cc. of ethyl acetate was added and the solution was acidified with hydrochloric acid; the precipitated acid went into solution in the ethyl acetate and then reprecipitated in the form of crystals. In the absence of the solvent, the acid usually precipitated in extremely fine crystals which were difficult to filter. The ethyl acetate was removed in a current of air, and the crystals were filtered off; yield, 0.58 g. (97%); m. p. 208–210°. Runs up to 10 g. were carried out in the same manner; two hours was found to be sufficient time for hydrolysis of the one ester group. Ethyl acetate can be used for recrystallization. For 7.2 g. of the acid ester about 400 cc. of boiling ethyl acetate was required to effect solution; the ethyl acetate was then concentrated by distillation until crystals of the acid ester appeared in the hot solution. The pure acid ester crystallizes from ethyl acetate in colorless plates; m. p. 211–212°.

Anal. Calcd. for $C_{20}H_{22}O_5$: C, 70.2; H, 6.5; neut. equiv., 342. Found: C, 70.1; H, 6.4; neut. equiv. 339.

A sample of the acid ester (0.15 g.) was hydrolyzed completely to the dicarboxylic acid by heating it with 1.5 cc. of 45% aqueous potassium hydroxide and 3 cc. of methanol for one hour.

Arndt–Eistert Reaction on the β-Acid Ester.—To 4 cc. of ice-cold dry benzene in a 125-cc. suction flask fitted with a drying tube was added 2 drops of pyridine and then 1.5 cc. of pure thionyl chloride. To the cold solution was added 1.71 g. of the aforementioned acid ester (unrecrystallized, m. p. 208–210°) in powdered form. After standing at room temperature for one-half hour, the mixture was warmed to about 40° for ten minutes. The orange-yellow solution containing some pyridine hydrochloride in suspension was evaporated under reduced pressure (water pump); 2 cc. of benzene was added and the solution again evaporated in order to remove traces of thionyl chloride from the crystalline acid chloride. The acid chloride was dissolved in 16 cc. of warm benzene, the solution was cooled somewhat and decanted carefully (through a small plug of cotton in the side-arm of the flask) drop by drop into a cold (5°) solution of diazomethane in ether; during the addition the diazomethane solution was swirled constantly.

Since the acid chloride being used was aliphatic in nature, it was felt desirable to employ a solution of diazomethane which was as free from alcohol as possible; hence, the diazomethane was prepared in *n*-propyl alcohol and ether free from alcohol was used. A solution of 2.8 g. of powdered potassium hydroxide (85%) in 10 cc. of warm *n*-propyl alcohol was prepared in a 125-cc. Claisen flask; 60 cc. of anhydrous ether was added to the solution and the flask was attached to a dry condenser which was attached to a receiver (a suction flask fitted with a drying tube) containing about 10 cc. of pure ether. Through a dropping funnel a solution of 4.5 cc. of nitrosomethylurethan in 10 cc. of anhydrous ether was dropped into the alkaline mixture; the diazomethane was distilled from the mixture as it was formed. The diazomethane solution was poured into a 200-cc. round-bottomed flask which had a ground-glass connection for a reflux condenser. The addition of the acid chloride resulted in the evolution of gas. After fifteen to thirty minutes, the ether and excess of diazomethane were removed under reduced pressure (water pump) at room temperature. The diazo ketone (XII) usually crystallized in the form of cream-colored, elongated, hexagonal plates.

To the diazo ketone was added 35 cc. of dry methanol and to the warm (50°) mixture was added one-half of the finely divided silver oxide obtained from 3.6 cc. of 10% silver nitrate solution (precipitating with alkali, washing well with water, filtering, washing with water and finally methanol, breaking up the silver oxide into a slurry with 1 cc. of methanol). The mixture was warmed on a water-bath at about 60° with frequent swirling of the contents. Nitrogen was evolved and after fifteen to twenty minutes the rather insoluble diazo ketone had gone into solution. At this time a small amount of silver oxide was added and heating was continued; further additions of silver oxide were made every five minutes; after six additions all of the silver oxide had been added. Then the mixture was refluxed for fifteen minutes.

The solution was boiled with Norite, filtered and concentrated to a small volume; on cooling, the product crystallized. Two crops of crystals (1.4–1.48 g.) were isolated; by sublimation of the material in the mother liquor at 240° (0.5 mm.), an additional 0.08 g. of the compound was obtained, making a total yield of 80–84%. The product (m. p. 97–101°) was sufficiently pure for cyclization. Should the crystals darken on exposure to light, the presence of traces of silver compounds is indicated; this impurity can be removed readily by passage of a benzene solution of the ester through a short column of anhydrous alumina. The pure **dimethyl ester of β-7-methoxy-2-methyl-2-carbomethoxy-1,2,3,4-tetrahydrophenanthrene-1-propionic acid (XIII)** crystallizes from methanol in glistening, colorless plates; m. p. 101–102°. It is readily soluble in acetone and in benzene, but is little soluble in methanol.

Anal. Calcd. for $C_{22}H_{26}O_6$: C, 71.3; H, 7.1. Found: C, 71.1; H, 6.9.

Cyclization to the Methyl Ether of 16-Carbomethoxy-*dl*-equilenin (XIV).—In the theoretical part mention was made of the difficulty encountered in trying to cyclize the aforementioned ester by the action of sodium on the ester in benzene containing a trace of methanol. Addition of methanol caused the ester to react completely but during the process the mixture became red and a considerable amount of acidic material (extractable by sodium bicarbonate solution) accompanied the cyclic keto ester; as a result the latter was obtained in only 40–50% yields. The observation that the acidic material on esterification did not give back the original ester suggested that oxidation was taking place during the cyclization, and this was found to be the case. By running the reaction in nitrogen and using two moles of sodium methoxide as the condensing agent, the cyclic keto ester was obtained in yields as high as 98%.

A solution of sodium methoxide was prepared from 0.3 g. of clean sodium and 5 cc. of anhydrous methanol; as soon as the reaction was complete, the excess methanol was removed on a steam-bath under reduced pressure. To the solid sodium methoxide, after breaking up the cake, was added 2.0 g. of the ester (XIII) (m. p. 97–101°), and the flask, which was fitted with a condenser, was evacuated and then filled with pure, dry nitrogen. Through the top of the condenser was added 20 cc. of dry benzene and the mixture was refluxed on a water-bath for two hours. The solution was cooled in nitrogen and acidified with acetic acid, and then water containing a little hydrochloric acid. The organic layer was washed with sodium bicarbonate solution to remove a trace of acidic product, the benzene solution was clarified with anhydrous calcium chloride, filtered and evaporated in a current of air. On addition of methanol the product crystallized in colorless plates; yield, 1.77 g. (97%); m. p. 175–180°. By recrystallization from acetone–methanol the methyl ether of 16-carbomethoxy-*dl*-equilenin was obtained in thin, elongated rectangular plates; m. p. 181–182° (vac.) with slight previous softening. It is desirable to recrystallize the compound before converting it to racemic equilenin. The compound gave no color with alcoholic ferric chloride solution.

Anal. Calcd. for $C_{21}H_{22}O_4$: C, 74.5; H, 6.6. Found: C, 75.1; H, 6.5.

***dl*-Equilenin.**—In view of our experiences with oxidation of the cyclic keto ester, subsequent operations were generally carried out in an inert atmosphere. A mixture of 1.56 g. of the methyl ether of 16-carbomethoxy-*dl*-equilenin, 75 cc. of acetic acid, 37 cc. of concentrated hydrochloric acid and 7 cc. of water was refluxed in a nitrogen or carbon dioxide atmosphere. A lively evolution of carbon dioxide took place during the first twenty minutes, corresponding to the formation of the methyl ether of *dl*-equilenin. When the evolution of gas had ceased, a slow stream of nitrogen (or carbon dioxide) was passed through a stopcock attached to the tube leading from the top of the condenser to a mercury trap; in this manner bumping of the boiling solution was prevented. After ten hours of refluxing all of the methyl ether was hydrolyzed, but if heating was discontinued before this time some of the methyl ether of *dl*-equilenin was present. Thus, after eight hours of refluxing, the solution was cooled in order to allow most of the product to precipitate (1.06 g.; m. p. 268–270°); by removal of the solvents under reduced pressure and treatment of the solid residue with sodium bicarbonate solution, an additional 0.11 g. was obtained. In order to separate the racemic equilenin from its methyl ether, the product was heated with 160 cc. of a 2.5% aqueous solution of potassium hydroxide and filtered; there remained 0.06 g. of the methyl ether. After sublimation at 180° (0.01 mm.), the **methyl ether of *dl*-equilenin (XV)** crystallized from acetone–methanol in colorless plates; m. p. 185–186.5° (vac.). The same methyl ether was obtained when the *dl*-equilenin was treated with methyl sulfate in alkaline solution.

Anal. Calcd. for $C_{19}H_{20}O_2$: C, 81.4; H, 7.2. Found: C, 81.7; H, 7.0.

The *dl*-equilenin obtained by acidification of the alkaline solution was dried and recrystallized from acetone–ethanol. The compound was obtained in at least two forms. In one run the product obtained by one crystallization formed colorless leaflets which melted at 287–288° (vac.). Usually, the racemic equilenin melted at 276–278° (vac.), although sometimes a melting point of 265° was observed; in the latter case the solid formed on cooling remelted at 276–278° (vac.). The yield of purified *dl*-equilenin varied between 90–95%. The *dl*-equilenin crystallized well from benzene, but the crystals were found to contain solvent of crystallization; they melted at about 180° with loss of solvent.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.2; H, 6.8. Found: C, 81.2; H, 6.8.

The **benzoate** of *dl*-equilenin, prepared by means of benzoyl chloride and pyridine, crystallizes from methanol–ethyl acetate in thin, colorless plates; m. p. 248.5–249.5° (vac.).

Anal. Calcd. for $C_{25}H_{22}O_3$: C, 81.1; H, 6.0. Found: C, 80.7; H, 5.8.

The **acetate** of *dl*-equilenin, prepared by the method described for the active product, crystallizes from methanol in broad, colorless needles, which melted at 153–154° (vac.), solidified and remelted at 159.5–160° (vac.).

Anal. Calcd. for $C_{20}H_{20}O_3$: C, 77.9; H, 6.5. Found: C, 77.8; H, 6.5.

Conversion of the Methyl Ether of Equilenin to 3',3'-Dimethyl - 7 - methoxy - 1,2 - cyclopentenophenanthrene (XVII).—Following the procedure of Cohen, Cook and Hewett,[11] 26 mg. of the methyl ether of *dl*-equilenin was converted to the methylcarbinol by means of methylmagnesium iodide. The product (23 mg., m. p. 119–135°) was heated with 100 mg. of powdered potassium acid sulfate (freshly fused) at 160–170° for one hour. The product was extracted with acetone, the solution decolorized with Norite and evaporated, and the residue crystallized from methanol. The thin, colorless plates (5 mg.) proved to be 3',3'-dimethyl-7-methoxy-1,2-cyclopentenophenanthrene rather than the dihydro compound, indicating that dehydrogenation occurred during the process of dehydration. No other products were found in the filtrate. The same action was observed when the carbinol from the natural equilenin was treated in the same manner. The product melted at 162–163.5° (Cohen, Cook and Hewett,[11] 165–165.5°) alone and when mixed with the compound (m. p. 160.5–161.5°) prepared from natural equilenin. Likewise, the trinitrobenzene complexes of the compounds obtained from the two sources melted at 170–171.5° (Cohen, Cook and Hewett, 174–175°) alone and when mixed with each other.

Resolution of *dl*-Equilenin

***d*-Equilenin-*l*-menthoxyacetate.**—Two hundred mg. of *dl*-equilenin was dissolved in 1.5 cc. of dry dioxane and 1 cc. of pyridine by warming. The solution was cooled, the air displaced by nitrogen, and 0.5 cc. of *l*-menthoxyacetyl chloride was added.[27] The flask was stoppered and the mixture was allowed to stand for five hours at room temperature with occasional swirling. The colorless, mobile solution, which may contain crystals of pyridine hydrochloride, was hydrolyzed, the product taken up in benzene and the benzene extract was washed with dilute hydrochloric acid, water, sodium bicarbonate solution and dried with sodium sulfate. The product obtained by evaporation of the benzene crystallized readily from petroleum ether containing a few drops of acetone. Sometimes the crystals consisted nearly entirely of one ester [100 mg., m. p. 160–171° (vac.)]; at other times both esters crystallized out [200 mg., m. p. 135–138° (vac.)]. After two to five recrystallizations from petroleum ether–acetone and finally from acetone alone, pure *d*-equilenin-*l*-menthoxyacetate was obtained as thin, colorless plates; m. p. 174–174.5° (vac.); yield, 85–96 mg. (49–55%). The melting point was 173.5–174.5° when the compound was mixed with the same ester (m. p. 173–173.5°) prepared from natural (*d*-) equilenin.

Anal. Calcd. for $C_{30}H_{38}O_4$: C, 77.9; H, 8.3. Found: C, 77.6; H, 8.4. *Rotation.* 30.4 mg. made up to 2 cc. in benzene gave a rotation of +0.27° at 30°; *l*, 1; $[\alpha]^{30}D$ +18°.

The remaining crystalline material (about 180 mg.; m. p. 135–140°), which could not be separated further by recrystallization, was hydrolyzed, and the product was used for the isolation of the ester of *l*-equilenin; this is described under the preparation of that compound.

***d*-Equilenin.**—A mixture of 115 mg. of *d*-equilenin-*l*-menthoxyacetate, 2.5 cc. of acetic acid, 1.5 cc. of concentrated hydrochloric acid and 0.3 cc. of water was refluxed in an atmosphere of carbon dioxide (mercury trap) for one hour. The light yellow solution was diluted with water and cooled; from the solution nearly colorless *d*-equilenin precipitated; yield, 57–62 mg. (86–94%); m. p. 246.5–249° (vac.). By recrystallization from dilute alcohol, using Norite, the synthetic hormone was obtained as colorless needles; m. p. 250–251° (vac.); 258–259° (vac., cor.). Mixed with natural equilenin (m. p. 250–251°), the melting point was unchanged. Effective purification also can be obtained by sublimation at 170–180° at 0.01 mm.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.2; H, 6.8. Found: C, 81.3; H, 6.7. *Rotation.* 12.8 mg. made up to 1.8 cc. in dioxane gave a rotation of +0.60° at 30°; *l*, 1; $[\alpha]^{30}D$ +84°. Girard, *et al.*[3] report 258–259° (cor.) for the melting point and $[\alpha]^{16}D$ +87° (dioxane) for the specific rotation of natural equilenin.

The acetate was prepared by mixing 5 mg. of *d*-equilenin, 2 drops of acetic acid, 1 drop of pyridine and 1 drop of acetyl chloride and allowing the mixture to stand at room temperature for fourteen hours. The product (4 mg.) which was isolated crystallized from methanol in broad, colorless needles; m. p. 156–157° alone, and when mixed with the acetate (m. p. 156–156.5°) of natural equilenin.[3]

The benzoate of *d*-equilenin crystallized from acetone–alcohol in colorless plates; m. p. 222.5–223° (vac.); the mixed melting point with the benzoate (222.5–223.5°) of natural equilenin[3] was 222.5–223.5° (vac.).

The methyl ether was prepared by treating a solution of 10 mg. of *d*-equilenin in 2 cc. of *N* sodium hydroxide and 3 cc. of water with 2 drops of methyl sulfate; the mixture was swirled while being heated on a steam-bath. More methyl sulfate (6 drops) was added until no further precipitate formed, the solution being kept alkaline throughout. By recrystallization from methanol, the methyl ether (6 mg.) was obtained in the form of long, narrow, colorless plates; m. p. 193.5–194° (vac.). Mixed with the methyl ether (m. p. 194–194.5°) of natural equilenin,[28] the melting point was 194–194.5° (vac.).

The **trinitrobenzene complex** of equilenin, which was made because it is more stable than the picrate, was prepared by dissolving 5 mg. of each component in hot absolute ethanol; the first crop of broad, yellow needles melted at 205–207.5° (vac.) and after recrystallization from absolute ethanol melted at 205.5–207° (vac.). When mixed with the same complex (m. p. 206.5–207.5°) of natural equilenin, the melting point was 206–207° (vac.).

Anal. Calcd. for $C_{24}H_{21}O_8N_3$: N, 8.8. Found: N, 9.1.

The methyl carbinol (XVI), prepared from the methyl ether of *d*-equilenin and methylmagnesium iodide according to the procedure of Cohen, Cook and Hewett,[11] crystallized from cyclohexane in colorless needles; m. p. 132.5–133.5° (vac.). The mixed melting point with the same derivative (m. p. 132.0–134.5°) of natural equilenin was 132.5–134.5° (vac.).

***l*-Equilenin.**—*dl*-Menthol[29] was resolved and the *d*-menthol was converted to *d*-menthoxyacetic acid according

(27) Frankland and O'Sullivan, *J. Chem. Soc.*, **99**, 2329 (1911); Read and Grubb, *J. Soc. Chem. Ind.*, **51**, 330T (1932).

Synthesis of *d*- and *l*-Isoequilenin

Dimethyl Ester of α-7-Methoxy-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-acetic Acid (X).—The α-acid as obtained by separation from its isomer was converted to its dimethyl ester by means of ethereal diazomethane; during the process benzene or acetone was added to dissolve the ester. After decolorization and filtration the solution was concentrated to a small volume and methanol added. From the solution the ester crystallized in large, colorless plates or prisms; yield, practically quantitative. The first time this compound was prepared it was obtained as broad, colorless needles melting at 86–89°; these gradually changed over to the plates which melted at 126–126.5°. In all subsequent runs the higher melting form was always obtained.

Anal. Calcd. for $C_{21}H_{24}O_5$: C, 70.8; H, 6.8. Found: C, 70.7; H, 6.7.

α-7-Methoxy-2-methyl-2-carbomethoxy-1,2,3,4-tetrahydrophenanthrene-1-acetic Acid (XI).—A mixture of 10.3 g. of the aforementioned dimethyl ester (powdered), 29.0 cc. of *N* sodium hydroxide and 150 cc. of methanol was refluxed for three hours. After removal of the methanol in a current of air, the residue was digested with 50 cc. of hot water; all but 0.21 g. of unchanged dimethyl ester dissolved. From the filtered solution 9.65 g. (99%, based on the ester used) of the acid ester was obtained on cautious acidification with hydrochloric acid; this product was sufficiently pure for the next step. When recrystallized from acetone–ligroin, it was obtained in fine, colorless needles; these melted at about 110–112° with bubbling; after long standing the melt solidified and the solid then melted at 137–138°. For analysis a sample was fused under reduced pressure.

Anal. Calcd. for $C_{20}H_{22}O_5$: C, 70.2; H, 6.5. Found: C, 69.7; H, 6.5.

Arndt–Eistert Reaction on the α-Acid Ester.—The reaction was carried out in essentially the same manner as for the β-acid ester except that anhydrous ether was used in place of benzene in the preparation of the acid chloride. The acid chloride from 1.71 g. of the acid ester was dissolved in 10 cc. of ether and the solution decanted into the ethereal solution of diazomethane. Evaporation of the resulting solution yielded broad, cream-colored needles of the diazo ketone. The latter was warmed with methanol and silver oxide in the manner described for the diazo ketone from the β-acid, and after the reaction was complete, the hot methanol solution was passed through a small column of alumina to remove colloidal silver from the solution. After treatment with Norite and concentration to a small volume, the chilled solution deposited 1.27 g. of the dimethyl ester of **α-7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-propionic acid** (XIII). In the filtrate an additional 0.10 g. (determined by cyclization to the cyclic keto ester) of the ester was present, making a total yield of 74%. The compound crystallizes from acetone–methanol in colorless plates; m. p. 89–89.5°.

Anal. Calcd. for $C_{22}H_{26}O_5$: C, 71.3; H, 7.1. Found: C, 70.9; H, 7.0.

***dl*-Isoequilenin.**—Cyclization of the aforementioned ester was carried out in nitrogen in the manner described for the isomer. A solution of 1.4 g. of the ester in 14 cc. of benzene refluxed with the dry sodium methoxide from 0.16 g. of sodium for one hour gave 1.115 g. (87%) of the **methyl ether of 16-carbomethoxy-*dl*-isoequilenin.** The compound crystallized from acetone–methanol in colorless plates; m. p. 149–149.5° in an open tube and 152.5–153.5° in a sealed, evacuated tube. The keto ester develops a deep blue-green color with alcoholic ferric chloride solution.

Anal. Calcd. for $C_{21}H_{22}O_4$: C, 74.5; H, 6.6. Found: C, 75.1; H, 6.6.

A mixture of 1.92 g. of the aforementioned cyclic keto ester, 40 cc. of acetic acid, 25 cc. of concentrated hydrochloric acid and 5 cc. of water was refluxed in an atmosphere of nitrogen for ten hours. The product obtained by evaporation of the solution under reduced pressure was digested with 200 cc. of a 2.5% aqueous solution of potassium hydroxide and the solution was filtered from 60 mg. (4%) of the **methyl ether of *dl*-isoequilenin.** After sublimation at 160–180° at 0.01 mm., the methyl ether crystallized from acetone–methanol in colorless prisms; m. p. 127–127.5° (vac.) with solidification and remelting at 130–130.5° (vac.).

Anal. Calcd. for $C_{19}H_{20}O_2$: C, 81.4; H, 7.2. Found: C, 81.4; H, 7.2.

Acidification of the alkaline solution precipitated the *dl*-isoequilenin (1.42 g., 93%). Recrystallization from acetone–ethanol gave nearly colorless plates (1.27 g.) of ***dl*-isoequilenin;** these melted at 206–206.5°, the melt solidified and the solid remelted at 221–222°. Further recrystallization from benzene–acetone and then from acetic acid containing some water raised the melting point to 223–224° (vac.). Frequently the high-melting form crystallized directly from the solution. By sublimation in a high vacuum (0.01 mm.) the product can be obtained perfectly colorless.

The **trinitrobenzene complex** crystallized from absolute ethanol in clumps of long, fine, yellow needles; m. p. 186–187° (vac.).

Anal. Calcd. for $C_{24}H_{21}O_8N_3$: N, 8.8. Found: N, 8.8.

Conversion of *dl*-Isoequilenin to 3′,3′-Dimethyl-7-methoxy-1,2-cyclopentenophenanthrene.—The methyl ether of the racemic isoequilenin (80 mg.) was treated with methylmagnesium iodide to give the corresponding methyl carbinol (63 mg., m. p. 88–92°), which was heated with potassium acid sulfate and worked up in the manner described for the *dl*-equilenin derivative. The product was treated with palladium-charcoal at 360° for one hour, then sublimed and crystallized from methanol. Unlike that from *dl*-equilenin methyl ether, the product was a mixture from which only a small amount (3%) of 3′,3′-dimethyl-7-methoxy-1,2-cyclopentenophenanthrene could be isolated as the trinitrobenzene complex; m. p. 170–171° alone and when mixed with an authentic sample prepared from natural equilenin.

Resolution of α-7-Methoxy-2-methyl-2-carbomethoxy-1,2,3,4-tetrahydrophenanthrene-1-acetic Acid.—To an ice-cold mixture of 4 cc. of anhydrous ether, 2 drops of pyridine and 2.2 cc. of thionyl chloride was added 3.38 g. of the acid ester of the α-acid. After forty-five minutes at room temperature, the solution was evaporated under reduced pressure; the acid chloride was dissolved in 2 cc. of benzene and the mixture was again evaporated. To the solution of the acid chloride in 4 cc. of ether 2 g. of *l*-menthol was added. After twenty-four hours at room temperature, the mixture of esters which had precipitated in solid form was filtered off and recrystallized from petroleum ether (60–75°), yielding 1.43 g. of methyl-*l*-menthyl ester melting at 135–138°; from the original filtrate an additional 0.09 g. of the same ester was isolated. The product (1.52 g.) crystallized from acetone–methanol in colorless needles (1.4 g.) which melted at 139–139.5°; this product is sufficiently pure for the next step. In the experiment just described practically only one of the esters came out; if both crystallize, the mixture of esters must be recrystallized several times in order to effect a separation. Further recrystallization of a sample of the ***l*-methyl-*l*-menthyl ester of α-7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid** raised the melting point to 139.3–139.8°.

Anal. Calcd. for $C_{30}H_{40}O_5$: C, 75.0; H, 8.4. Found: C, 75.2; H, 8.4. *Rotation.* 30.6 mg. made up to 2 cc. in benzene gave a rotation of −2.31° at 30°; *l*, 1; $[\alpha]^{30}D$ −152°.

***d*-Isoequilenin.**—The aforementioned ester was rather resistant to hydrolysis. A suspension of 1.2 g. of the active ester in a solution of 16 g. of potassium hydroxide (85%) in 40 cc. of methanol was heated on a steam-bath for seven hours. The methanol was removed in a current of air, and the residue was dissolved in water. After the menthol had been extracted by means of benzene, the solution was acidified with hydrochloric acid. The dicarboxylic acid (m. p. 220–224° unrecrystallized) was filtered off, dried and converted to the dimethyl ester by reaction with diazomethane. By recrystallization from methanol 0.82 g. (92%) of the ***l*-dimethyl ester** of the α-acid was obtained in the form of thin, colorless plates; m. p. 110–110.3°.

Anal. Calcd. for $C_{21}H_{24}O_5$: C, 70.8; H, 6.8. Found: C, 70.7; H, 6.7. *Rotation.* 30.2 mg. made up to 2 cc. in benzene gave a rotation of −2.28°; *l*, 1; temp. 30°; $[\alpha]^{30}D$ −151°.

The dimethyl ester was hydrolyzed to the acid ester in the same manner employed for the racemic ester. From acetone–petroleum ether the active acid ester crystallized in colorless needles; the crystals melt when put into a bath at 130°, the melt solidifies and the solid remelts at 159–160°. The high melting point is observed when the tube is placed into the bath at 90°. The acid ester (0.7 g.) was converted to the propionic acid derivative through the Arndt–Eistert reaction, yielding 0.56 g. in the first crop, which melted at 102–103.5°. From acetone–methanol the ***l*-dimethyl ester of α-7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-propionic acid** crystallized in broad, colorless needles; m. p. 103–103.5°.

Anal. Calcd. for $C_{22}H_{26}O_5$: C, 71.3; H, 7.1. Found: C, 71.1; H, 6.9. *Rotation.* 12.7 mg. made up to 1.8 cc. in benzene gave a rotation of −0.87° at 28°; *l*, 1; $[\alpha]^{28}D$ −123°.

Cyclization in the manner described for the *dl*-ester gave the active **methyl ether of 16-carbomethoxy-isoequilenin** (0.44 g. from 0.56 g.; after recrystallization, 0.39 g.; m. p. 147–150°); hydrolysis of the latter by refluxing with a mixture of 12 cc. of acetic acid, 8 cc. of concentrated hydrochloric acid and 1.5 cc. of water for ten hours yielded the *d*-isoequilenin, which was isolated in the same manner as the racemic compound. The product dissolved completely in 80 cc. of boiling 1% sodium hydroxide; acidification of the filtered solution precipitated the ***d*-isoequilenin** (0.29 g.). It was recrystallized by dissolving it in acetone, boiling the solution with Norite, filtering, adding alcohol and then concentrating the solution on a steam-bath until crystallization set in. The colorless plates (0.26 g.) melted at 272–273° (vac.). When the compound was recrystallized again, this time by dissolving it in 8 cc. of boiling acetic acid and adding a small amount of water to the solution, colorless leaflets or plates of a second form were obtained; m. p. 257–258° (vac.); 265–266° (vac., cor.).

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.2; H, 6.8. Found: C, 80.9; H, 6.7. *Rotation.* 30 mg. made up to 2 cc. in dioxane gave a rotation of +2.20° at 29°; *l*, 1; $[\alpha]^{29}D$ +147°. In absolute alcohol a specific rotation of +173° was observed with a solution of 8.1 mg. in 2 cc. of solution. In view of the higher concentration possible in dioxane, we consider the dioxane value to be the more accurate. Hirschmann and Wintersteiner reported $[\alpha]^{30}D$ +160° (0.4% in ethanol) for the specific rotation of their 14-*epi*-equilenin.[24]

The **methyl ether** of the *d*-isoequilenin, prepared by the action of methyl sulfate on an aqueous solution of the sodium salt, was obtained as thin colorless plates after two recrystallizations from methanol; m. p. 118.5–119.5°.

The **acetate** of *d*-isoequilenin, prepared by means of a mixture of acetic acid, acetyl chloride and pyridine, crystallized from methanol in long, colorless prisms; m. p. 146–147° (vac.).

Anal. Calcd. for $C_{20}H_{20}O_3$: C, 77.9; H, 6.5. Found: C, 77.9; H, 6.6.
