Analytical Procedures Employing Karl Fischer Reagent.[1] II. The Determination of Alcoholic Hydroxyl

BY W. M. D. BRYANT, J. MITCHELL, JR., AND DONALD MILTON SMITH

Alcoholic hydroxyl is usually determined acidimetrically by means of acetyl chloride and pyridine[2] or by one of the several acetic anhydride procedures. These methods, however, are lacking in sensitivity where the sample contains considerable amounts of water or acids. Water, for example, reacts mole for mole with acetyl chloride, in competition with alcohols, and necessitates the use of smaller analytical samples in order to maintain the necessary excess of reagent.

In the present research a titrimetric procedure for hydroxyl independent of acidimetry has been developed. This new procedure is useful over a wide range of compositions and is remarkably precise in the presence of large amounts of water or acids. The analysis depends upon the general reaction

$$ROH + CH_3COOH = CH_3COOR + H_2O$$

according to which one mole of water is liberated for each equivalent of hydroxyl esterified. By employing a large excess of acetic acid and making use of boron fluoride as an esterification catalyst,[3] it is possible to shift the equilibrium almost completely in favor of water and ester. A measure of the water formed is obtained by direct titration with Karl Fischer reagent.

(1) This reagent, discussed in detail in the first paper of the series [Smith, Bryant and Mitchell, THIS JOURNAL, **61**, 2407 (1939)], consists of a solution of iodine, sulfur dioxide and pyridine in methanol. It is specific for water.

(2) Smith and Bryant, THIS JOURNAL, **57**, 61 (1935). References covering the acetic anhydride procedures are included.

(3) (a) Bowlus and Nieuwland, *ibid.*, **53**, 3837 (1931); (b) Hinton and Nieuwland, *ibid.*, **54**, 2017 (1932); (c) Hennion, Hinton and Nieuwland, *ibid.*, **55**, 2857 (1933).

The new hydroxyl procedure is applicable to aliphatic and alicyclic alcohols in general, including branched chain types and hydroxy acids, also such aromatic alcohols as have the hydroxyl group attached to an aliphatic side chain. Phenols, however, do not react completely. Some unsaturated terpene alcohols, on the other hand, give results greater than the theoretical.

Differences in the relative esterification rates of aliphatic and strictly aromatic alcohols (*i. e.*, phenols) have made possible a method for differentiating these two classes of compounds. Under the proper conditions aliphatic alcohols are esterified or dehydrated[4] almost completely, while phenols react only to a very small extent. The selective action observed here is probably due as much to differences in the equilibrium constants of the two series, as to purely kinetic differences.

Experimental

Analytical Procedure.—Five to 10 ml. of sample is weighed into a 100-ml. g. s. volumetric flask about one-third filled with dioxane. This mixture is made up to volume with more of the solvent, shaken until homogeneous and finally adjusted after standing at least thirty minutes in a water-bath at 25 ± 1°. Five ml. (using calibrated pipet) of the sample solution is transferred to a 250-ml. g. s. volumetric flask and 20 ml. of the catalyst solution added.[5]

(4) Dehydration of tertiary alcohols to olefins liberates the same amount of water per hydroxyl group as esterification would do, hence it is not necessary to isolate these two effects.

(5) This solution is prepared by dissolving about 100 g. of boron trifluoride gas and 1 or 2 ml. of water in sufficient Merck C. P. glacial acetic acid to make one liter of solution. Boron trifluoride of suitable quality can be obtained in cylinders from the Ohio Chemical Company, Cleveland, Ohio.

The flask is tightly stoppered[6] and together with a control containing 20 ml. of catalyst solution and 5 ml. of dioxane, is placed in an oven or water-bath at 67 ± 2° for two hours.[7] At the end of this time the flasks are removed and allowed to cool to room temperature spontaneously. Five ml. of Baker C. P. pyridine is added to each,[8] and the mixture titrated with Karl Fischer reagent.

After correction for water in the dioxane, catalyst and pyridine, the millimoles of water present after treatment, less the water originally present, are equal to the milliequivalents of free hydroxyl in the sample.

The water originally present may be obtained by titrating 5 ml. of the original dioxane solution with Fischer reagent. A correction must be made for the water initially present in the dioxane as this quantity is usually appreciable. The correction is made on the basis of the volume of dioxane in the aliquot figured with sufficient precision as the difference between the total volume of solution and the volume of concentrated sample employed, neglecting volume changes on mixing.

Analytical Results

The experimental results obtained with a number of alcohols and other hydroxy compounds are given in Table I. In all cases the trade products were used without further purification.

It is interesting to note that aliphatic tertiary alcohols react stoichiometrically.[9] This reaction is undoubtedly due to both esterification and dehydration. The analysis is specific, however, since only one mole of water is released per mole of hydroxyl added.

Phenols do not esterify completely under the conditions of the general procedure. Phenol, pyrogallol and α-naphthol reacted only about 65%. An increase in catalyst concentration from 100 to 300 g. per liter raised the results with phenol to 85%. The substitution of either trimethylacetic or *n*-caproic acid for acetic acid in the catalyst solution had no appreciable effect on the phenol esterification, a recovery of about 60% being obtained in both cases.[10]

Terpenes react differently according to structure. Geraniol and terpineol, the two unsaturated terpenes analyzed, gave results of 109 and 114%, respectively. Borneol, on the other hand, showed 98.4% reaction, checking the analysis by the acetyl chloride–pyridine method.[2]

The precision and accuracy average about ±0.3%, comparing very favorably with the involved acetic anhydride procedures. The stoichiometric accuracy appears to be somewhat better than that of the acetyl chloride–pyridine method,[2] for in all cases noted, with the exception of allyl alcohol and 2-methylbutanol-4, the results were more nearly quantitative.

TABLE I

ANALYTICAL DATA FOR ALCOHOLS AND OTHER HYDROXY COMPOUNDS

Substance	% Hydroxyl compound (various methods)		Complete analysis (using Karl Fischer reagent) % Hydroxyl compound	% Water	% Total

Ethyl tartrate[e]	94.7[c]	(2)	93.9 ± .2	.0	93.9
Methylcellosolve[k]	93.2[a]	(2)	94.5 ± .2	4.5	99.0

[a] Acetyl chloride–pyridine procedure. [b] Alkali titration. [c] Saponification. [d] Figures in parentheses represent number of determinations. [e] Eastman Chemical. [f] Sharples Solvent Corp. [g] J. T. Baker C. P. [h] American Cyanamide Co. [i] Eimer & Amend Technical. [j] Eastman Practical. [k] Carbide & Carbon.

In Table II are collected results obtained with alcohols containing various quantities of water. In each case the alcohol added was calculated as the difference between the per cent. water found by analysis and 100%. It is interesting to note that reasonably accurate results were obtained with aqueous ethanol samples containing as little as 0.8% ethanol.

The procedure was exactly the same as that described above.

(6) A simple spring clamp (#4799), serving to prevent expulsion of the stopper on heating is furnished by the Precision Scientific Company, 1730 N. Springfield Ave., Chicago, Illinois.

(7) Methanol reacts to completion in one hour at 60°; ethanol in two hours at 60°.

(8) The addition of pyridine just before titration with Karl Fischer reagent is essential. Its probable purpose is to destroy the activity of the catalyst and prevent esterification of the methanol of the Karl Fischer reagent. If the 5 ml. of pyridine is omitted and the activity of the catalyst is not otherwise destroyed, impossibly high titers are obtained.

(9) The tertiary hydroxyl of citric acid, however, is only 35% esterified.

(10) By using acetic anhydride in place of acetic acid, roughly quantitative results were obtained. The end-point was so obscure, because of unusual darkening of the solution, that accurate end-point adjustments were not possible. Checks of ±4% were an average measure of the precision to be expected.

Analytical Procedures Employing Karl Fischer Reagent.[1] III. The Determination of Organic Acids

BY J. MITCHELL, JR., DONALD MILTON SMITH AND W. M. D. BRYANT

The most obvious procedures for the quantitative determination of carboxylic acids are those based on neutralization by strong alkalies. These methods, however, are so general as to be subject to interference from many other types of compounds producing hydrogen ions. For example, where inorganic acids are present, these must be separated or determined separately by specific methods before a measure of the carboxyl group can be obtained by the usual titration with standard base.

In the present investigation a carboxyl procedure independent of ordinary acid–base titrimetry was devised. Its basis is the estimation of water liberated by the reaction $RCOOH + CH_3OH \longrightarrow RCOOCH_3 + H_2O$. This reaction is almost identical with the one used in the authors' hydroxyl procedure.[2] It proved possible to obtain practically stoichiometric conversions of a large number of organic acids to the corresponding esters and water by using a large excess of methanol containing boron fluoride. Nieuwland and his collaborators found the latter substance to be an efficient esterification catalyst.[3] Inasmuch as one mole of water is formed for each equivalent of carboxyl esterified, the water found by titration with Karl Fischer reagent, less that originally present, becomes a measure of the carboxyl content. Strong inorganic acids, with the exception of sulfuric, are not esterified by this procedure. The apparatus requirements are very simple, the entire analysis including the esterification and titration steps being carried out in glass-stoppered flasks.

The new carboxyl procedure is applicable to aliphatic acids generally, including branched chain and hydroxyl substituted types, and also aromatic acids having the carboxyl attached to an aliphatic side-chain. Typical aromatic acids having the carboxyl group attached directly to the ring do not react quantitatively. The heterocyclic furoic acid and the sterically hindered alicyclic camphoric acid also fail to react completely.

Changes in the concentration of the catalyst solution have a marked effect on the esterification of strictly aromatic acids.[3d] An increase, for example, gave results more nearly quantitative. By careful control of this variable it was possible to esterify aliphatic acids without appreciably affecting aromatic acids.

The average precision and accuracy based on comparisons with alkali titration are about $\pm 0.3\%$.

Experimental

Analytical Procedure.—Five to 10 ml. of sample is weighed into a 100-ml. g. s. volumetric flask half-filled with dioxane. The mixture is made up to volume with more dioxane, shaken until homogeneous and allowed to stand at least thirty minutes in a water-bath at 25 ± 1°. Five ml. (using calibrated pipet) of the dioxane solution is placed in a 250-ml. g. s. volumetric flask. To this is added exactly 20 ml. of the catalyst solution.[4] The flask is then placed in a water-bath[5] at 60 ± 1°, and after momentarily raising the stopper to allow for expansion of the included air, is firmly stoppered and maintained at that temperature for one hour.[6] At the end of this period the sample is removed, allowed to cool to room temperature spontaneously, and then titrated with Karl Fischer reagent.[7] A blank is run using 5 ml. of dioxane and 20 ml. of catalyst solution. After correction for water in the dioxane and catalyst, the millimoles of water present after treatment, less the water originally present, are equal to the milliequivalents of free carboxyl in the sample.

The water originally present may be obtained by titrating 5 ml. of the original dioxane solution with Fischer reagent. A correction must be made for the water initially present in the dioxane as this quantity is usually appreciable.

(1) This reagent, discussed in detail in the first paper of the series (Smith, Bryant and Mitchell, THIS JOURNAL, **61**, 2407 (1939)), consists of a solution of iodine, sulfur dioxide, and pyridine in methanol. It is specific for water.

(2) Bryant, Mitchell and Smith, THIS JOURNAL, **62**, 1 (1940).

(3) (a) Bowlus and Nieuwland, *ibid.*, **53**, 3837 (1931); (b) Hinton and Nieuwland, *ibid.*, **54**, 2017 (1932); (c) Hennion, Hinton and Nieuwland, *ibid.*, **55**, 2857 (1933); (d) Sowa and Nieuwland, *ibid.*, **58**, 271 (1936).

(4) This solution is prepared by dissolving 100 g. of boron trifluoride gas and 2 ml. of water in sufficient du Pont synthetic methanol (water content 0.15% or less) to make a final volume of one liter. Boron fluoride of suitable quality may be obtained in cylinders from the Ohio Chemical Co., Cleveland, Ohio.

(5) Smith and Bryant, THIS JOURNAL, **57**, 62 (1935), describe a convenient water-bath.

(6) Acetic and propionic acids react to completion at 25° in one hour, while formic acid requires two hours.

(7) In the presence of the catalyst solution, the iodine color of the reagent may persist during the addition of about the first 15 ml., producing a false end-point. The water included in the catalyst solution is sufficient to permit the addition of 15 ml. of reagent directly. Further addition of reagent produces a normal discharge of the brown color until the true end-point is reached. The false end-point may be avoided altogether if 5 ml. of pyridine of known water content is added just before titration. Unlike the hydroxyl method,[2] this procedure is reliable without the extra pyridine.

TABLE II

ANALYTICAL DATA FOR AQUEOUS ALCOHOL SOLUTIONS

Substance	Wt. % by difference Alcohol	Wt. % by analysis Alcohol	Water	Total
Ethanol	0.8	1.0 ± 0.2	99.2 ± 0.0	100.2
Ethanol	3.9	3.9 ± .2	96.1 ± .1	100.0
Ethanol	7.6	7.4 ± .3	92.4 ± .0	99.8
Ethanol	15.8	15.6 ± .2	84.2 ± .0	99.8
Ethanol	19.4	19.0 ± .2	80.6 ± .2	99.6
Ethanol	38.9	39.0 ± .3	61.1 ± .1	100.1
Isobutanol	8.3	8.3 ± .2	91.7 ± .0	100.0
t-Butanol	16.2	16.0 ± .2	83.8 ± .1	99.8
n-Propanol	17.8	17.9 ± .2	82.2 ± .1	100.1
2-Methylbutanol-4	2.2	2.5 ± .2	97.8 ± .0	100.3
Pentanol	3.5	3.8 ± .2	96.5 ± .1	100.3

The procedure for the approximation of aliphatic alcohols in the presence of aromatic alcohols is based on the use of less concentrated catalyst solutions. Experimental results under various conditions are given in Table III.

TABLE III

ANALYTICAL RESULTS WITH ALCOHOLS USING LESS CONCENTRATED CATALYST SOLUTION

Substance	Percentage of theoretical hydroxyl: 2 hrs. at R. T. (26 ± 1°) a	2 hrs. at R. T. (26 ± 1°) b	2 hrs. at 60° a	2 hrs. at 60° b
Ethanol	25	45	96.8 ± 0.3	99.0 ± 0.0

Glycol			90.6 ± .2	
Glycerol			78.1 ± .2	
Cyclohexanol			55.9 ± .0	
Benzyl alcohol			97.2 ± .4	
Phenol	0.0	2.5	3.9 ± .2	26.6 ± .2
Guaiacol	0.0	2.5	4.5 ± .2	28.2 ± .5

[a] Catalyst concentration 25 g./liter. [b] Catalyst concentration 50 g./liter.

The favorable results obtained with tertiary butanol at room temperature are of interest. These probably were due to dehydration since esterification to this extent seems unlikely.

Conditions which seemed best for the analysis of aliphatic in the presence of aromatic alcohols were those of the third column of figures. Ethanol–phenol mixtures were analyzed by this procedure and the results summarized in Table IV.

TABLE IV

ANALYTICAL RESULTS ON THE DETERMINATION OF ETHANOL IN THE PRESENCE OF PHENOL

% C_6H_5OH added	% C_2H_5OH added	% C_2H_5OH found
93.3	6.7	9.0 ± 0.2
57.0	43.0	43.8 ± .2
11.1	88.9	88.2 ± .1

It is believed that the results obtained with phenol and guaiacol are typical of what may be expected with other phenols and that the degree of differentiation would be much like that in Table IV. As previously noted, using the general catalyst solution, pyrogallol and α-naphthol react to about the same extent as phenol.

Interfering Substances.—The new hydroxyl procedure is unfavorably affected by the presence of a few classes of organic compounds. Aldehydes and ketones react to a considerable extent, *e. g.*, formaldehyde (37% aqueous) and cyclohexanone showed about 70 and 50% reaction, respectively. The reaction with carbonyl compounds in general is probably analogous with that proposed for formaldehyde

$$CH_2O + 2CH_3COOH \longrightarrow (CH_3COO)_2CH_2 + H_2O$$

Acetals and ketals react nearly to completion assuming two moles of water are formed for each mole of sample. For methylal the reaction can be written as

$$CH_2(OCH_3)_2 + 4CH_3OOH \longrightarrow 2CH_3COOCH_3 + (CH_3COO)_2CH_2 + 2H_2O$$

Analyses of methylal, acetal and di-*n*-butyl formal on this basis gave results of 92, 91 and 88%, respectively.

Most amines interfere with the method, by affecting catalyst activity.

Summary

1. A specific quantitative method for the determination of hydroxy compounds has been described. The method is based on quantitative esterification and subsequent titration of the water liberated, using the highly specific Karl Fischer reagent.

2. Analytical results for more than twenty-five hydroxy compounds, principally aliphatic, are tabulated.

3. The method is quantitative for samples containing large excesses of water.

4. Tertiary aliphatic alcohols may be analyzed by this procedure.

5. A quantitative method for the determination of aliphatic alcohols in the presence of phenols is described.

WILMINGTON, DELAWARE RECEIVED AUGUST 1, 1939

ble. The correction is made on the basis of the volume of dioxane in the aliquot, figured with sufficient precision as the difference between the total volume of solution and the volume of concentrated sample employed, neglecting volume changes on mixing.

Analytical Results

The experimental results obtained with a group of organic acids are given in Table I. In most cases the results are within 0.3% of those obtained by aqueous caustic titration.

Benzoic and salicylic acids reacted only to the extent of 58 and 19%, respectively; furoic and camphoric, 35 and 75%. Benzilic acid, which should esterify as an aliphatic, reacted only 45%, probably due to steric hindrance.[8]

The solid acids studied in the present research, with the exception of glycolic, phenylacetic and cinnamic acids are not very soluble in dioxane. The original sample should therefore be no larger than 2.5 g. per 100 ml. of dioxane solution.

TABLE I

ANALYTICAL DATA FOR ORGANIC ACIDS

Acid[b]	% Acid (alkali titration)		Complete analysis Using Karl Fischer reagent % Acid	% Water	Total
Formic		(6)[a]	97.2 ± 0.2	2.2	99.4
Acetic[c]		(2)	99.6 ± .2	0.1	99.7
Propionic		(2)	99.8 ± .1	.2	100.0
n-Butyric	99.5	(8)	99.5 ± .4	.5	100.0
i-Butyric	99.5	(6)	99.7 ± .2	.5	100.2
dl-Methylethyl acetic		(2)	95.1 ± .0	.7	95.8
Trimethylacetic		(2)	99.6 ± .0	.4	100.0
n-Caproic	99.1	(6)	99.3 ± .3	.4	99.7
Stearic[d]		(4)	100.3 ± .1	.0	100.3
Succinic[g]		(2)	99.1 ± .5	.7	99.8
Oleic[d]	99.5	(2)	99.2 ± .0	.5	99.7
Linoleic[d]	98.2	(2)	96.5 ± .5	1.2	97.7
Glycolic	99.9	(4)	99.6 ± .2	0.0	99.6
α-Hydroxy-*i*-butyric[f]	97.6	(4)	97.9 ± .5	.1	98.0
Tartaric[g]	94.5	(4)	94.3 ± .5	.1	94.4
Ricinoleic[e]	58.3	(4)	58.4 ± .5	1.7	60.1
Phenylacetic		(2)	100.0 ± .2	0.0	100.0
Cinnamic		(2)	99.7 ± .3	0.0	99.7

[a] Figures in parentheses represent number of determinations. [b] Except where noted, above acids are Eastman Kodak Co. chemicals. [c] Merck glacial c. p. [d] Eimer and Amend pure. [e] Eimer and Amend technical. [f] American Cyanamid Company. [g] J. T. Baker Analyzed c. p.

An increase in catalyst concentration had a marked effect on the esterification of aromatic and heterocyclic acids. Table II shows this change from the regular catalyst solution to a solution three times as strong (300 g. per liter).

(8) Citric acid is about 92% esterified.

TABLE II

ESTERIFICATION USING HIGHER CONCENTRATIONS OF CATALYST

Substance	% Acid esterified: Regular catalyst concn.	High catalyst concn.
Benzoic	58	98.5 ± 0.3
Salicylic	18	67
Anisic		88.5
Phthalic		88
Camphoric	40	46
Furoic	34	83

It is interesting to note that by substituting in the one case glycol and in the other di-isopropylcarbinol for methanol in the catalyst solution and following the conditions of the general procedure, the extent of reaction with benzoic acid was increased to 75% with the glycol solution and decreased to 16% with the di-isopropylcarbinol solution.

A decrease in the concentration of the catalyst solution (25 and 50 g. per liter), while having little effect on the esterification of aliphatic acids, reduced considerably the reaction of aromatic and heterocyclic acids and the sterically hindered camphoric acid. These results are noted in Table III.

TABLE III

ESTERIFICATION USING LOWER CONCENTRATIONS OF CATALYST

Substance	% Acid esterified: Catalyst, 25 g./liter a	b	Catalyst, 50 g./liter a	b
Formic	96.9 ± 0.1	97.7 ± 0.0	97.7 ± 0.0	
Acetic	98.8 ± .0	98.8 ± .0	99.1 ± .2	99.8 ± 0.1
Isobutyric	96.2 ± .0	99.0 ± .2	98.9 ± .2	
Trimethylacetic	31.7 ± .0	95.8 ± .3	52.9 ± .0	96.5 ± 0.3
n-Caproic	98.6 ± .0			
Oleic	95.6 ± .0			
Stearic	100.3 ± .1			
Succinic	87.6 ± .6	99.1 ± .3		
Camphoric	1.3 ± .5			
Benzoic	1.4 ± .8	34.9 ± .3	6.2 ± .0	52.5 ± 0.3
Salicylic	0.0 ± .6	8.4 ± .0	1.1 ± .5	18.4
Furoic	0.9 ± .3			

[a] Conditions: 1 hour at room temperature (26 ± 1°). [b] Conditions: 1 hour at 60°.

Examination of the results in Table III suggests that mixtures of aliphatic and aromatic acids should behave in the same manner as the pure substances. Mixtures of acetic–benzoic and acetic–salicylic acids were analyzed, following the conditions of column 1; *i. e.*, 25 g./l. of catalyst for one hour at room temperature. These results are given in Table IV.

On the basis of Table III, the above procedure may be modified for other mixtures, taking into account the behavior of the pure acids.

TABLE IV

ANALYSIS FOR ACETIC ACID IN THE PRESENCE OF BENZOIC AND SALICYLIC ACIDS

Nature of mixture	% Aromatic acid added	% CH_3COOH added	% CH_3COOH found
Acetic and	89.6	10.4	12.6 ± 0.0
benzoic	50.8	49.2	50.1 ± .1
acids	11.8	88.2	88.1 ± .1
Acetic and	91.3	8.7	9.0 ± .0
salicylic	47.1	52.9	52.9 ± .0
acids	11.7	88.3	87.7 ± .1

Interfering Substances.—Aldehydes and ketones react with the methanol of the catalyst solution presumably to form acetals and ketals:

$$RCHO + 2CH_3OH \longrightarrow RCH(OCH_3)_2 + H_2O$$
$$RCOR' + 2CH_3OH \longrightarrow RR'C(OCH_3)_2 + H_2O$$

In all observed cases, however, the reaction was stoichiometric, so that suitable corrections could readily be made. It is self-evident that substances easily dehydrated interfere with the analysis. Of several classes of substances tried, tertiary alcohols were the only chemicals that were dehydrated sufficiently to affect the method. Tertiary butanol was dehydrated 37% by the above catalyst solution.

Among the strong inorganic acids tried, sulfuric acid was the only one esterified by the catalyst solution. The reaction is quantitative, however, in that one mole of water is formed per mole of the acid: $H_2SO_4 + CH_3OH \longrightarrow CH_3HSO_4 + H_2O$. Other acids, such as benzenesulfonic, phosphoric and hydrochloric, do not interfere with the method.

In the titration of sulfuric acid for water a dioxane solution of the acid should be used. Apparently some charring occurs when concentrated sulfuric acid is titrated directly with Karl Fischer reagent.

Those compounds which fume or volatilize readily, such as hydrochloric acid, are best titrated for water in the presence of an inert solvent.

Boric acid reacts stoichiometrically with the methanol in Karl Fischer reagent, even in the absence of catalyst solution: $H_3BO_3 + 3CH_3OH \longrightarrow (CH_3)_3BO_3 + 3H_2O$.

Anhydrides also interfere with the procedure, probably as follows

$$(RCO)_2O + CH_3OH \longrightarrow RCOOCH_3 + RCOOH$$
$$RCOOH + CH_3OH \longrightarrow RCOOCH_3 + H_2O$$

On this basis the extent of reaction with acetic anhydride was 61% in dioxane solution, but essentially quantitative in methanol solution.

Unsaturated alcohols and hydrocarbons do not interfere with the procedure, as indicated particularly by experiments with allyl alcohol and amylene.

Summary

1. A specific quantitative method for the determination of organic carboxylic acids has been described. The method is based on complete esterification and subsequent titration of the water liberated, using the highly specific Karl Fischer reagent.

2. Analytical results for eighteen acids, principally aliphatic, are tabulated.

3. The effect of changes of catalyst concentration upon esterification has been noted.

4. A method for the estimation of aliphatic acids in the presence of aromatic acids, based on large differences in esterification rate, has been demonstrated for selected cases.

The Reaction between Hydrogen Selenide, Formaldehyde, and Secondary Amines

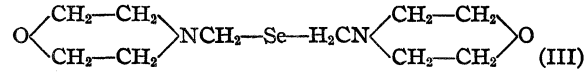
BY ARTHUR H. BINZ, FRANCIS E. REINHART AND HARRY C. WINTER

The formation of substituted *bis*-(aminomethyl) sulfides from secondary amines, formaldehyde, and hydrogen sulfide has been reported by Le Fèvre and Le Fèvre[1] and by Binz and Pence from this Laboratory.[2] The preparation of *bis*-(1-piperidylmethyl) sulfide (II) was described by the former authors; they assumed that the reaction proceeded in two stages, 1-piperidinemethanol (I) being formed in the first step

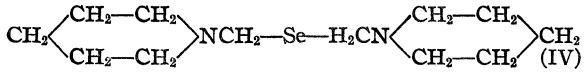
$$2C_5H_{10}NH + 2CH_2O \longrightarrow \underset{(I)}{2C_5H_{10}NCH_2OH} + H_2S \longrightarrow \underset{(II)}{C_5H_{10}NCH_2—S—H_2CNH_{10}C_5}$$

This assumption was confirmed by Binz and Pence, who prepared the same compound, as well as the morpholine analog, by treating the respective aminomethanols with hydrogen sulfide.[3]

By an extension of this reaction, analogous selenides from morpholine and piperidine have been prepared in this Laboratory. Thus 4-morpholinemethanol, or 1-piperidinemethanol, obtained by the action of formaldehyde on the corresponding amine, was found to react readily in ether solution with hydrogen selenide to yield *bis*-(4-morpholylmethyl) selenide (III), or *bis*-(1-piperidylmethyl) selenide (IV). Better yields of compound (III), however, were obtained by saturating an aqueous morpholine solution with hydrogen selenide at 0° and pouring this into cold dilute formaldehyde. Attempts to prepare similar selenides from dimethylamine and diethanolamine gave unstable oils which could not be purified.



(III)



(IV)

After recrystallization from ethyl acetate, compounds (III) and (IV) were found to be quite stable, but unlike the corresponding sulfur derivatives decomposed easily under the combined influence of solvents and air. Selenium was precipitated quantitatively when a warm dilute alcoholic solution of the morpholine selenide was aerated. Colloidal solutions of selenium, which were stable for several days, were obtained when an aqueous suspension of either selenide was treated with an equivalent amount of hydrogen peroxide.

The compounds proved to be highly toxic when injected intravenously into rats, the lethal dose being of the order of 0.012–0.017 g. per kg. of body weight.

(2) Binz and Pence, THIS JOURNAL, **61**, 3134 (1939).

(3) For uniformity these authors have named both sulfides as substituted 2-thiapropanes.

Experimental

Hydrogen Selenide.—The hydrogen selenide used in this investigation was prepared by the action of dilute hydrochloric acid on aluminum selenide according to the procedure described by L. Moser.[4] Prior to the generation of the gas, air was removed from the generator and reaction flasks by passing a current of nitrogen through the apparatus for thirty minutes. Because of the toxicity of hydrogen selenide, all unreacted gas was absorbed in a trap containing 20% potassium hydroxide. After completion of the reaction, nitrogen was again passed through the apparatus and traces of hydrogen selenide remaining in the generator were oxidized with hydrogen peroxide.

***bis*-(4-Morpholylmethyl) Selenide (III).**—A solution of morpholine (12 cc.) in water (75 cc.) was cooled in an ice-bath and saturated with hydrogen selenide prepared from aluminum selenide (9 g.). This was poured into a cold solution of 37% formaldehyde (75 cc.) in water (150 cc.). The dense white crystalline precipitate which formed immediately was separated by filtration and recrystallized from ethyl acetate. The yield was 9.1 g. of glossy white plates, melting to a clear liquid at 136–138°. The analytical sample was dried to constant weight at 80° *in vacuo*. The selenium determination was carried out by the microprocedure of Alber and Harand.[5]

Anal. Calcd. for $C_{10}H_{20}O_2N_2Se$: N, 10.0; Se, 28.3. Found: N, 9.9; Se, 28.0.

bis-(4-Morpholylmethyl) selenide was found to be soluble in alcohol and benzene but only slightly soluble in water, decomposing rapidly in the presence of the latter, particularly when hot. When a solution of 0.7842 g. of the compound dissolved in 115 cc. of 80% ethyl alcohol at 40° was shaken in an open flask for fifteen minutes, 98.1% (0.2176 g.) of the total combined selenium precipitated as elementary selenium.

***bis*-(1-Piperidylmethyl) Selenide (IV).**—Piperidine (11.6 cc.) was added slowly with stirring to 37% formaldehyde (20 cc.) cooled in an ice-bath. Anhydrous potassium carbonate (10 g.) was then added and the mixture shaken until the solid dissolved and the solution separated into

two layers. The upper layer of 1-piperidinemethanol was separated and dried over anhydrous sodium sulfate.

Crude 1-piperidinemethanol (3 g.) was dissolved in dry ether (30 cc.) and treated with hydrogen selenide obtained from aluminum selenide (1 g.). A slow stream of nitrogen gas was passed through the apparatus during the reaction and continued until the ether had evaporated. The selenide remained as a white crystalline precipitate and was recrystallized by dissolving in ethyl acetate at room temperature and cooling to 0°. After drying *in vacuo* over sulfuric acid, 1.8 g. of glossy white plates, melting at 67°, were obtained.

Anal. Calcd. for $C_{12}H_{24}N_2Se$: N, 10.2; Se, 28.7. Found: N, 10.3; Se, 28.6.

bis-(1-Piperidylmethyl) selenide dissolved readily in the common organic solvents. It was only slightly soluble in water, decomposition occurring in this solvent as in the case of the morpholine analog.

Summary

1. *bis*-(4-Morpholylmethyl) and *bis*-(1-piperidylmethyl) selenides were prepared from hydrogen selenide, formaldehyde, and the corresponding secondary amines. Attempts to prepare stable selenides using dimethylamine and diethanolamine were unsuccessful.

2. Both selenides were found to be very sensitive to oxidizing agents and highly toxic when injected into rats.

Dielectric Evidence of Molecular Rotation in the Crystals of Certain Non-aromatic Compounds*

BY ADDISON H. WHITE AND W. S. BISHOP

A molecular crystal may be considered, as a first approximation, to be a collection of rigid molecules held in a regular arrangement by rather weak intermolecular forces. In 1930 thermal evidence led Pauling to suggest that certain molecules of small moment of inertia are able to rotate in the high-temperature forms of such crystals,[1] the center of gravity of each molecule remaining at or near a point of the appropriate space lattice. He predicted that when the molecule in question is polar the dielectric constant of the high-temperature phase of the crystal should behave like that of a pure polar liquid.[2] This prediction was confirmed by measurement of hydrogen chloride, hydrogen bromide, hydrogen iodide and hydrogen sulfide, whose dielectric constants were found to drop from the high values characteristic of rotating polar molecules at transitions from one solid phase to another, instead of at the freezing points.[3,4,5] By far the greatest number of molecular crystals are organic. Dielectric, volumetric, and thermal measurements of such crystals have more recently revealed similar evidence of the rotation of organic molecules of large moment of inertia, including certain polar derivatives of camphane, cyclohexane and ethane.[6,7,8,9] Dielectric measurements have now been extended to other compounds belonging to these three classes, and show as reported below that the molecules of a surprisingly large number of organic crystals engage in rotational motion nearly or quite as freely as in the corresponding liquids.

In this communication the term "molecular rotation" will be used in the sense in which it has been generally adopted to explain the dielectric behavior of pure polar liquids. Although recent work indicates that the rotation of molecules in liquids is not free,[10] there can be no doubt that its amplitude is far greater than in most solids; *e. g.*, the dielectric constant of nitrobenzene drops from 35.8 to about 3.2 upon freezing.[11] Such a value or lower is characteristic of ordinary organic crystals, in which to a first approximation the rotational motion of the molecules is considered to be an harmonic oscillation.[12]

Preparation of Materials

The sources of compounds not prepared in these laboratories are indicated by the footnotes of the first column of Table I; the remainder of them were prepared as indicated by the references of the third and fifth columns. The thiocamphor prepared by Sen's method contained camphor as an impurity; 16.08% sulfur was found by analysis, as compared with a theoretical content of 19.05%. Among five samples sulfur content was found to decrease steadily with increasing melting point. The optical activity of *l*-camphor and *l*-borneol was checked with a polarimeter. Chlorocyclohexane, bromocyclohexane and camphoricimide were measured as received. Other materials obtained from outside sources were fractionally recrystallized or redistilled, several times when necessary. The purity of the samples measured is indicated in columns two to five of Table I by the comparison of their boiling and melting points with those of the literature. Where the melting point recorded in column four is below room temperature it designates the temperature at which the specimen was observed to solidify in the cell used for dielectric measurement, and is hence not very accurate. Sharp melting points and visible regularities of structure indicated that in the solid state these samples were crystalline rather than amorphous.

Experimental Methods

The equipment used in this work for measurement of the capacity, conductance and temperature of the condenser containing the test specimen, and for control of the temperature, was essentially that described by Morgan and Lowry.[13] The type of cell in which the dielectric properties of each of these compounds were measured is indicated in the last two columns of Table I. "A" specifies that grounded capacity measurements were made with a condenser consisting of three parallel plates of gold-plated brass, which was immersed in the liquid and, where the melting point was below room temperature, in the solid that was formed after sufficient cooling. This condenser is described and illustrated in more detail elsewhere.[9] "B" indicates that the cell illustrated in Fig. 1 was used; it was designed for use with small amounts of material and requires only 6 cc. The cell consists of two concentric gold-plated brass cylinders which are held in place with respect to each other by the shape of the glass container. There is a clearance of only about 0.08 mm. between brass and glass both inside and outside, allowing for differential thermal expansion. Leads consist of small gold-plated brass rods which are silver-soldered to the electrodes and which are rigid enough to permit their use for adjusting the electrodes into identical positions for successive measurements. Since only grounded capacity measurements can be made in this condenser and since the high potential electrode is in direct contact with the inner glass tube, the condenser was calibrated in place in the bath used for temperature control in subsequent measurements. The alterable capacity of this cell is 36.6 $\mu\mu$f, and was found to be reproducible to within about 3%. Although less accurate than a more rigid condenser, it was used for measurement of liquids or of solids freezing below room temperature when only small quantities were available.

(13) Morgan and Lowry, *J. Phys. Chem.*, **34**, 2385 (1930).

C indicates that rectangular sheets of the solid were pressed, using pressures as high as 14,000 lb./sq. in. (1000 atm.). These sheets measured 5.08 × 1.75 cm. and were about 1.2 mm. thick. Comparison of accurately measured densities with those calculated from the weight and dimensions of the pressed sheets indicated that not more than 4% of the volume of such sheets was occupied by voids; where the waxy high-temperature form of a compound existed at room temperature, the volume of voids was negligible. When the sheet was not waxy enough for the gold-plated brass facing plates used in the die to adhere strongly to it, tin-foil electrodes were affixed, using a very thin film of petrolatum as adhesive. These sheets were measured as previously described and illustrated.[9] Sheets of the tetramethylethylene halides sublimed so rapidly at higher temperatures that circular electrodes with a guard ring were provided in an arrangement otherwise similar in principle to the above. When direct capacitance measurements on a pressed disk were thus made, evaporation of that part of the sample covered by the guard ring had no effect on the observed dielectric constant. The use of this method is indicated by D in Table I.

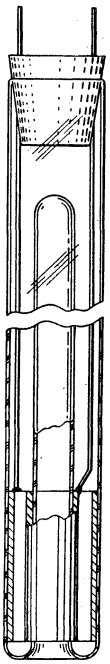

Fig. 1.—Condenser for measurement of small quantities of liquid.

Experimental Results

A summary of the experimental results is included in Table I, in which the compounds are listed more or less in the order of the complexity of their molecular structures. Under t_T° is given the temperature range in which the greater part of the increase of dielectric constant from its low-temperature to its high-temperature value occurs; such an abrupt change of dielectric constant will be designated in this paper as a transition, although the heating curves required to establish isothermal absorption of heat have not been run.[14] The word "none" indicates that no such transition was observed in the solid state. Columns seven and eight, under $\Delta\epsilon_T$, list the dielectric constants observed at the lower and upper limits, respectively, of the transition temperature range t_T°. These values were observed at a frequency of 30 or 100 kc. except in cyclopentanol, where because of anomalous dispersion the 1 kc. value is more representative of the static polarizability due to the rotational motion of the dipoles. Under $\Delta\epsilon_{MP}$ columns nine and ten of Table I record the 100-kc. dielectric constant at the melting point for

(14) Isothermal absorption of heat and abrupt change of density have been observed at the temperature of the discontinuity of dielectric constant in a number of similar crystals (see references 3–9).

the solid and liquid states, respectively, as measured in the immediate neighborhood of this temperature, or as determined by extrapolation in cases such as those illustrated in Fig. 11.

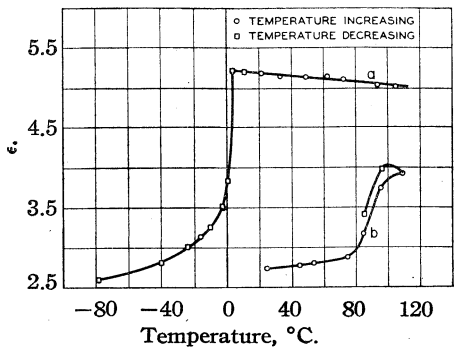

Fig. 2.—Dielectric constant of (a) tetramethylethylene chloride and (b) tetramethylethylene bromide at 100 kc.

Figures 2–13 provide a more complete record of those measurements which constitute evidence that molecular rotation occurs in the crystal. A considerable frequency range, usually 1–100 kc., was covered in this work. Only one measurement is recorded for each temperature except where anomalous dispersion appears, or the spurious effects of electrode polarization capacity are found at low frequency. Total a. c. conductivity also was measured but is reported only where anomalous dispersion and the accompanying dielectric loss are found. The observed conductivities are then used to calculate loss in terms of imaginary dielectric constant ϵ'', which is equal to the product of the ordinary dielectric constant ϵ' by the tangent of the loss angle.

Experimental points in the figures represent

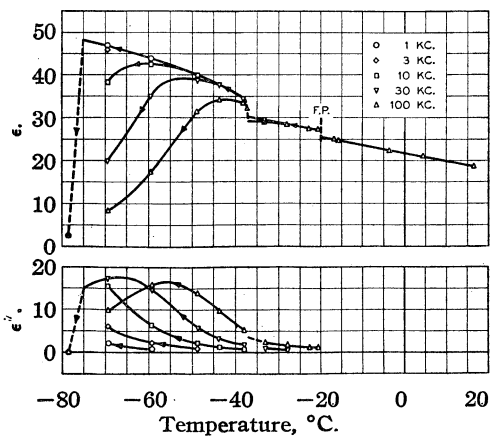

Fig. 3.—Dielectric properties of cyclopentanol as functions of declining temperature.

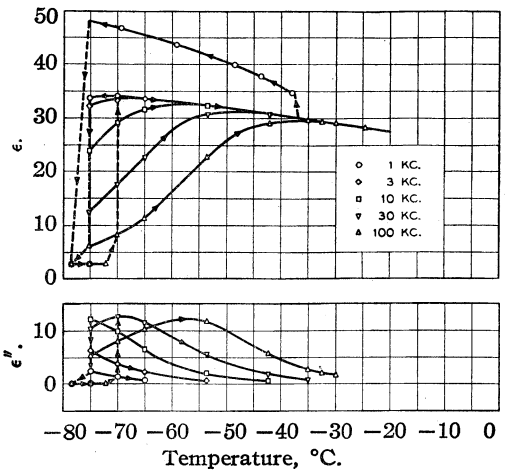

Fig. 4.—Dielectric properties of cyclopentanol as functions of rising temperature.

temperature equilibrium in the sense that each temperature was held constant within 0.1° until the dielectric properties of the sample ceased to change with time. Apparently discontinuous changes of dielectric constant are indicated in the figures by broken lines whose horizontal components measure the interval between successive constant temperatures of measurement. More exact determination of such temperatures of transition is best made with cooling and heating curves.

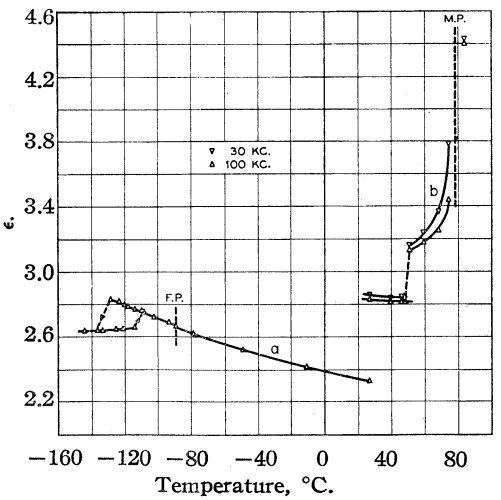

Fig. 5.—Dielectric constant of (a) 1,3-cyclohexadiene and (b) 1,4-cyclohexadione.

Lack of space forbids detailed discussion of the individual experiments except where the figures are not adequately self-explanatory. Inspection of these figures shows, however, that in most cases where measurements of the liquid were obtained, any discontinuity of the dielectric constant curve

at the freezing point is so small as to indicate that the polar molecules are able to rotate about as freely in the crystalline as in the liquid state. Only in 1,4-cyclohexadione (Fig. 5b) and cyclohexyl fluoroform (Fig. 7b) is there an extensive drop of dielectric constant upon freezing; any molecular rotation in these crystals must be considerably restricted as compared with the corresponding liquids.

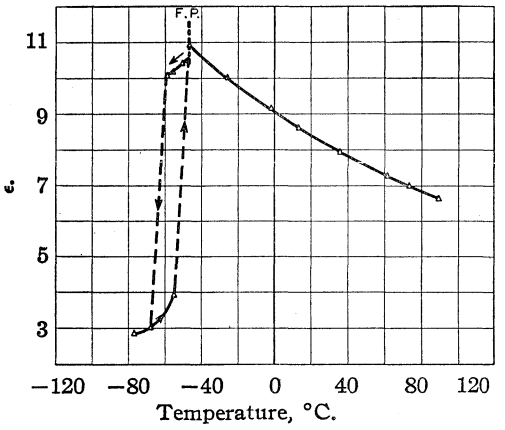

Fig. 6.—Dielectric constant of chlorocyclohexane.

When solid cyclopentanol is cooled through a sequence of constant temperatures, a transition occurs between −36.7 and −37.4°. After cooling to −40.4°, the same transition is observed with rising temperature. The results of only one run are represented in Figs. 3 and 4 by experimental points because the absolute values observed after successive solidifications differed by 5%, due probably to variability in the formation of voids. The data obtained in other runs were used to define the temperature range of each of the transitions more accurately than indicated by the points of Figs. 3 and 4. Immediately below the transition at −37° the dielectric constant at frequencies lower than 30 kc. was found to have risen from about 30 to about 34, and $-d\epsilon/\epsilon dt°$ to have increased from 0.006 to 0.015. No change in the translucent, camphor-like appearance of the solid was visible. To assume that density increases at this transition does not explain the large increase in the negative temperature coefficient of dielectric constant nor the increase of its absolute value, as measured under circumstances where the total number of molecules between the plates of the condenser does not change.

Below −37° an anomalous dispersion involving all or nearly all of the rotational polarization affects dielectric measurements made at frequencies between 1 and 100 kc., as in the supercooled high-temperature form of cyclohexanol.[8] This is evidence that at these temperatures the frequency of rotational motion of the cyclopentanol molecules in the crystal ranges in the neighborhood of 10^6 c. p. s. At −75.2° the frequency of maximum loss is 11.5 kc. and the relaxation time τ calculated according to Debye[2] is 1.30×10^{-6} second.

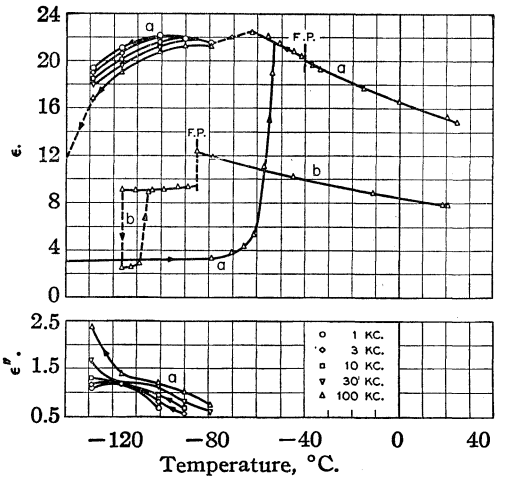

Fig. 7.—Dielectric properties of (a) cyclohexanone and (b) cyclohexyl fluoroform.

Between −75.2 and −78.5° the dielectric constant of cyclopentanol drops abruptly at all frequencies alike to about 2.7. Figure 4 shows that with increasing temperature the solid goes back to a form in which there is again rotational motion of the molecules, the transition occurring between −72 and −70°. At all frequencies, however, the values of ϵ' and ϵ'' are much lower than when −70° was approached from higher temperatures. Upon cooling immediately to −75.2° the transition was not reversed; a complete frequency run at this temperature showed the frequency of maximum loss to be 16 kc., yielding a relaxation time of 1.31×10^{-6} second, about the same as when ϵ' as observed at 1 kc. and −75.2° was 48 instead of 34. Further cooling again produced the transition to the non-rotational form of the solid between −75.2 and −78.5°. From this point temperature was increased regularly, until it became evident as in Fig. 4 that the dielectric constant curve is continuous with that originally observed above −37°, and that with temperature rising from below −75° there is no dielectric evidence of the transition at −37°.

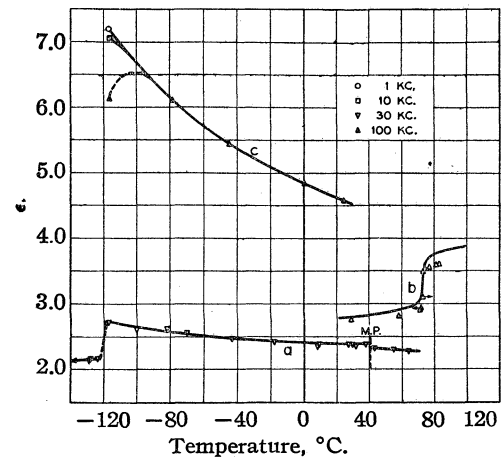

Fig. 8.—Dielectric constant of (a) *d*-camphene, (b) *l*-borneol and (c) *dl*-thioborneol.

l-Borneol and *l*-camphor were measured in order to compare their dielectric behavior with that of the corresponding dextrorotatory compounds. To this end the curves drawn in Figs. 8b and 9b are reproductions of those reported for the *d* compounds by Yager and Morgan,[7] while the points represent experimental values obtained from the *l* isomers. An arrow attached to an experimental point represents the direction of temperature change before and after its observation. The similarity of dielectric constant and transition temperature exhibited by the *d* and *l* forms of each of these two compounds shows as expected that the forces acting between molecules are of identical symmetry and magnitude in crystals of optically active isomers.

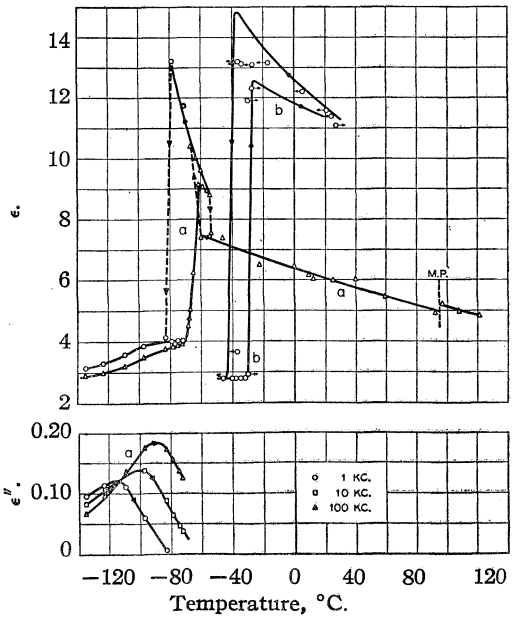

Fig. 9.—Dielectric properties of (a) *dl*-bornyl bromide and (b) *l*-camphor.

Since the behavior of *dl*-bornyl bromide is very complicated, the temperature range in which the transitions occur is illustrated in Fig. 10 on a larger scale than in Fig. 9a. With falling temperature the first transition, from what will be called Phase I to Phase II, occurred between −60.1 and −66.5°. Dielectric constant and its negative temperature coefficient increased greatly, much as in cyclopentanol. When the temperature was increased before converting to the non-rotating form, hysteresis appeared and the transition from

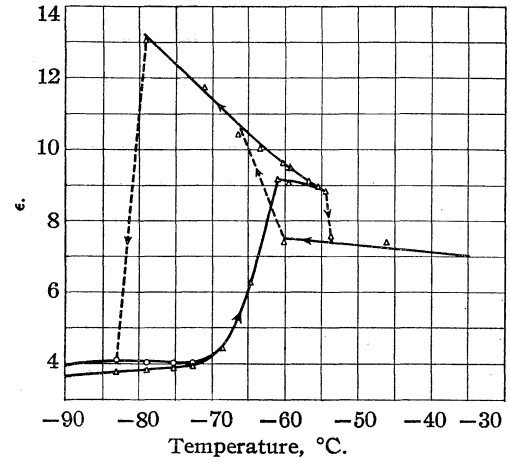

Fig. 10.—Dielectric constant of *dl*-bornyl bromide in region of transitions.

Phase II to Phase I was found between −54.5 and −53.7°. Upon cooling again, dielectric constant fell on the curve of Phase II as indicated by points at −71.1 and −79.1°. The transformation to Phase III was characterized by an abrupt fall of dielectric constant from 13 to about 4 between −79.1 and −83.0°. Evidence of a residual molecular rotation in Phase III was found in the high value of its dielectric constant and the anomalous dispersion which caused the high-frequency dielectric constant to drop to 2.9 at −135°. After reversing the direction of temperature change, dielectric constant rose rapidly but with a measurable temperature coefficient between −70 and −61°. The value to which it rose was 9.16, showing that this transition was from Phase III to Phase II rather than to Phase I

The failure of the dielectric constant of *dl*-thiocamphor to return to its original value with rising temperature, as shown in Fig. 11a, is not a

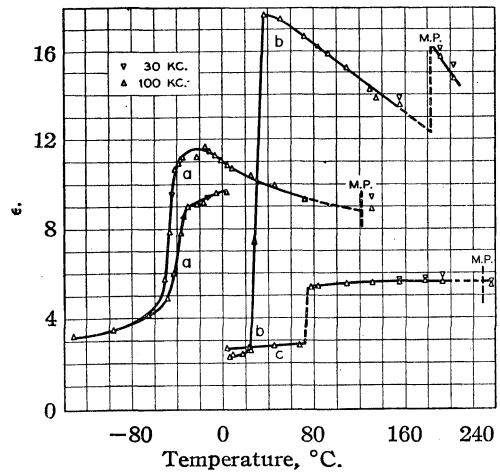

Fig. 11.—Dielectric constant of (a) *dl*-thiocamphor, (b) *dl*-2,3-camphanedione and (c) camphoric imide.

real effect. It was found that the waxy sheets originally pressed had been shattered by the embrittlement and the presumably large density change which occurred when the sample went over to the low-temperature form, leaving voids which were not eliminated when the transition was reversed, because of the lack of constraint along the edge of the sheets. When the specimens which had been through this temperature cycle were pressed again, dielectric constant returned to its original value of 11.0.

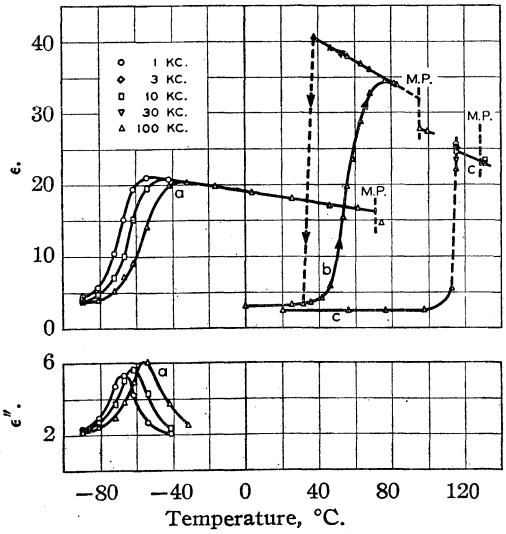

Fig. 12.—Dielectric properties of (a) 3,x-dichloro-*dl*-camphor, (b) α-chloro-α'-nitro-*dl*-camphor and (c) 3-cyanocamphor.

The dielectric constant of 3-nitro-*dl*-camphor at room temperature is not very different from that of the 3-nitro-*d*-camphor in the high-temperature form, as may be seen in Fig. 13. Upon cooling

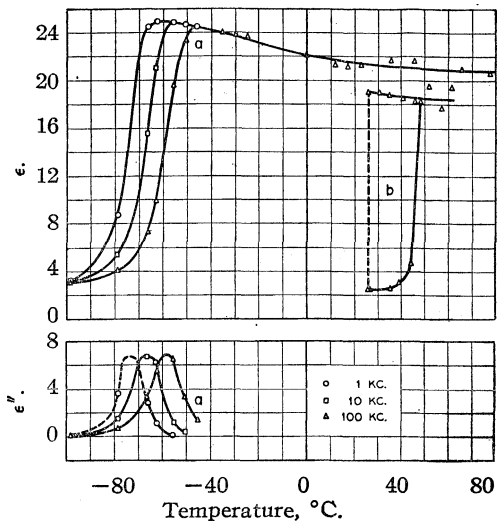

Fig. 13.—Dielectric properties of (a) 3-nitro-*dl*-camphor and (b) 3-nitro-*d*-camphor.

to low temperature there was no transition at which dielectric constant fell at all frequencies alike to a low value indicative of no molecular rotation. Anomalous dispersion appeared instead, eliminating at −98.7° practically all effect of molecular rotation on the dielectric constant at frequencies as low as 1 kc. This presumably means only that the relaxation time of the rotational motion of the molecules is much longer than 10^{-3} second at this temperature. Two other crystalline compounds in which dielectric constant similarly falls off with anomalous dispersion rather than at a transition are 3,x-dichloro-*dl*-camphor (Fig. 12a) and *dl*-thioborneol (Fig. 8c).

Discussion of Results

Taken all together these measurements and those previously reported[6,7,8,9] constitute convincing evidence that extensive rotational motion of large organic molecules is much more commonly found in crystals than has been suspected. It is also evident that this ability of the molecule to rotate in the crystal lattice is much more frequently found among the derivatives of cyclic polymethylenes than among the generality of organic compounds, whose polarizations have normally been found to be so low in the solid state as to be ascribed to distortional effects only. Inspection of Table I indicates that among the

cyclic polymethylene derivatives the attachment of a large substituent to the ring inhibits molecular rotation, as in cyclohexyl adipate, the cyclohexylphenols, and cyclohexane carboxylic acid. Even the substitution of one methyl group for a hydrogen atom has the same effect in such cases as the methylcyclohexanones and 1-methylcyclopentanol-1. There is no satisfactory correlation of ability to rotate or of transition temperature with either the dipole moment or the moment of inertia of the molecule.

Among the compounds of Table I molecular rotation in the crystal is much more noticeably correlated with the gross physical properties of the crystal than with the chemical structure of the molecule. Crystals in which there is no molecular rotation at room temperature are relatively hard and brittle; those in which the molecules rotate at room temperature are soft and waxy. When one of these compounds is solidified from the melt in a test-tube, the formation of a semi-transparent mass having an appearance similar to that of camphor is characteristic of molecular rotation; the transition to the form in which there is no such rotation is marked by the rise of opacity, possibly because of shattering due to change of density. Perhaps the most significant physical characteristic of the crystals in which we have found molecular rotation is their low heat of fusion, as roughly observed by the rapidity with which a large sample is able to freeze at a temperature only a few degrees below its melting point. Since the crystal does not "freeze" with respect to rotational motion until the transition temperature is reached, a low heat of fusion is to be expected, as has been pointed out by Clusius.[15]

Pirsch[16] reports that molecules of approximately spherical shape are found to produce crystals of much lower heats of fusion than molecules of roughly circular or linear shape. He suggests that this may result from the small ratio of surface to volume in a sphere, which means that the effectiveness of interatomic forces in producing intermolecular forces is low, relative to the number of atoms, in molecules of roughly spherical shape. Among such compounds cited by Pirsch for their large cryoscopic constants and correspondingly low heats of fusion are camphorquinone (2,3-camphanedione), camphor, borneol, bornyl chloride, bornyl bromide, and camphene, all of which we have found to exhibit molecular rotation immediately below the melting point. In these cases at least Pirsch's explanation of low heat of fusion may be modified by saying that at the melting point the crystal freezes with respect to translational motion of the molecules only; the intermolecular forces are so small, or, at least, so symmetrical, that the crystal does not "freeze" with respect to rotational motion until the transition temperature is reached. Hence the change of entropy which ordinarily would occur at the freezing point alone is divided between the freezing point and the transition temperature.

The other camphane derivatives and the tetramethylethylene halides in which we have observed molecular rotation are spherical in the sense in which Pirsch uses the term. However, cyclopentanol, ethylene cyanide and the many cyclohexane derivatives which exhibit a similar freedom of molecular rotation in the crystal, are not even approximately spherical. Pirsch[17] has noted that certain cyclohexane and cyclopentane derivatives exhibit much lower heats of fusion than do other circular compounds. The heat of fusion of 406 calories per mole observed in cyclohexanol[18] and that of 940 calories per mole reported for ethylene cyanide[19] fall on the curve of heat of fusion against temperature which Pirsch characterizes as that of spherical molecules.[19] On the other hand, such a spherical molecule as *t*-butyl alcohol shows no dielectric evidence of molecular rotation in the crystal,[20] while its heat of fusion of about 1600 cal./mole[19] is fully twice as high as that indicated by Pirsch's curve for spherical molecules without rings. Pirsch cites other spherical molecules of anomalously large heat of fusion.[17] It appears likely that among these non-aromatic compounds very low heat of fusion is more immediately associated with the ability of a molecule to rotate in the crystal lattice than with its spherical shape. For rotation in the crystal to be possible, however, a certain degree of either spherical or circular geometrical symmetry obviously is required of the molecule, and its center of figure should not be displaced too far from its center of gravity. The approximately spherical symmetry of the molecules of the cam-

phane derivatives and the tetramethylethylene halides indicates that they rotate about all three axes in the solid state. It has been suggested that internal motion of atoms unrestrained by valence forces may produce in ethylene cyanide[9] and the cyclohexane derivatives[8] sufficient time-average molecular symmetry to account for their rotation about three Cartesian axes in the crystal. Since this suggestion was made, there has been an accumulation of evidence that internal motion about the single carbon-to-carbon bond is not as free as was then supposed,[21] although no other explanation of the dipole moments of ethylene chloride[22] and ethylene cyanide[23] has yet appeared. Finbak and Hassel interpret their X-ray measurements of solid cyclohexane derivatives in terms of molecular rotation about only one axis, although the nearest distance of approach of methylene groups of neighboring molecules thus calculated is anomalously large.[24]

Summary

Dielectric evidence of the rotation of polar molecules has been observed in the crystals of two derivatives of ethane, one derivative of cyclopentane, five derivatives of cyclohexane, and thirteen derivatives of camphane. In most of these solids dielectric constant rises abruptly at a transition, as temperature is increased, to a value characteristic of polar liquids. A relatively symmetrical gravimetric and volumetric distribution of atoms around the center of gravity of the molecule evidently facilitates its rotation in the crystal.

Dielectric Evidence of Molecular Rotation in the Crystals of Certain Benzene Derivatives*

BY ADDISON H. WHITE, B. S. BIGGS AND S. O. MORGAN

This paper presents dielectric measurements which show that molecular rotation may occur in the crystalline form of benzene derivatives as well as in aliphatic compounds, provided certain requirements of symmetry are met. The use of dielectric constant data as evidence of the existence of molecular rotation[1] is based on the fact, now well established, that a dielectric constant higher than the refraction value (that equal to the square of the optical refractive index) in a homogeneous, non-conducting organic material arises from the orientation or rotational motion of polar molecules or groups. Since the refractive index for organic compounds rarely exceeds 1.7, the excess of dielectric constant over about 3 is a good measure of the extent to which orientation of dipoles is contributing thereto. There is little tendency to question such a statement as it applies to the dielectric constant of organic liquids whose molecules have been shown by dipole moment measurements to be polar. It has become evident from the work of Smyth and his associates and from papers from this Laboratory that the same view can be carried over to organic solids having large molecules.

Baker and Smyth have presented evidence of rotation in rod-like molecules,[2] in comparatively spherical molecules,[3] and in intermediate "pear-shaped" molecules.[3] The earlier work from this Laboratory on camphor compounds[4,5] and ethane derivatives[6] has been extended to include other members of these series. The work reported in the present paper represents an extension of the ideas of the importance of symmetry gained from our earlier work to a new class of compounds, substi-

tuted benzenes, which are geometrically symmetrical about one axis, but electrically assymmetrical.

Experimental Methods

The apparatus and methods employed were similar to those described elsewhere.[7,8] Tin-foil electrodes were affixed to pressed sheets of each compound, using a very thin film of petrolatum as adhesive. Measurements of such solid sheets and of the corresponding liquids were made in the cells of Fig. 2 and Fig. 1, respectively, of a previous paper.[6] The density of the sheets at room temperature was determined roughly from their weights and dimensions. As an example of the accuracy of this procedure, the densities of hexamethylbenzene and hexachlorobenzene thus measured are 1.05 and 1.96, respectively; the corresponding densities calculated from X-ray data are 1.035 and 2.044.[9] Although such density measurements as the former are often in error because of voids in the sample, they determine the actual number of molecules per cc. of the specimen upon which dielectric measurements are made and are thus more appropriate than the true density for the calculation of molar polarization.

Preparation of Materials.—The substances marked E. K. in Table I were obtained from the Eastman Kodak Company. The liquids were fractionally distilled and a middle fraction taken for measurement. The solids were recrystallized from a non-polar solvent (usually petroleum ether, 30–60° range) before use. The other compounds were all prepared in this Laboratory. All are pure materials with the exception of the trichloro-*m*-xylene and trichloro-*o*-xylene, which were distillation fractions from chlorination products obtained by direct chlorination of the respective hydrocarbons.

3,4,5-Trichloro-*o*-xylene was obtained by chlorination of *o*-xylene and fractionation of the product. Of the two possible trichloro-*o*-xylenes the 3,4,6- melts at 48° and the 3,4,5- at 96°. The fraction boiling at 269–270° goes completely solid on being cooled and melts at 94–96°. It is therefore rather pure 3,4,5-trichloro-*o*-xylene.

The trichloro-*m*-xylene studied was that obtained by fractionally distilling the product of chlorination of *m*-xylene. The fraction boiling between 250 and 260° was recrystallized from alcohol and then from cold petroleum ether. The compound separates in long, glistening waxy needles melting at 95°.

3-Nitro-4,5-dichloro-*o*-xylene and 5-nitro-3,4-dichloro-*o*-xylene were prepared from the corresponding dichloro-*o*-xylenes by the method of Hinkel.[10] The 4,5-dichloro compound could not be obtained completely free of isomers and the resulting nitro compound melted at 82° rather than at 78°, its recorded melting point. This 5-nitro compound probably contained a small amount of the higher melting 3-nitro-4,5-dichloro-*o*-xylene in solid solution.

Pentachloroethylbenzene was prepared by chlorination of ethylbenzene in carbon tetrachloride solution with antimony pentachloride as catalyst. It was fractionally distilled, the 300° fraction being recrystallized from alcohol several times and finally crystallized from heptane. The melting point recorded in Beilstein is in error. The value consistently obtained here was 56° and this is in agreement with that reported by E. I. du Pont de Nemours & Company.[11] Because of the wide discrepancy between the recorded melting points the material was analyzed.

Anal. Calcd. for $C_8H_5Cl_5$: C, 34.53; H, 1.78. Found: C, 34.28; H, 1.87.

Pentaethylacetophenone is apparently a new compound. It was prepared from pentaethylbenzene and acetyl chloride by the Friedel–Crafts reaction, heptane being used as the reaction medium. The aluminum chloride addition compound was decomposed in the usual manner and sufficient benzene was added to keep the crystalline product in solution. The benzene solution was washed with dilute hydrochloric acid, with sodium carbonate solution, and finally with water. The solvent was then allowed to evaporate from an open dish. The crystalline residue was recrystallized twice from alcohol and finally from heptane. It crystallizes in thick, colorless needles which melt at 141°.

Anal. Calcd. for $C_{18}H_{28}O$: C, 83.00; H, 10.84. Found: C, 83.15; H, 10.74.

Pentamethylnitrobenzene and *o*-dinitrotetramethylbenzene were prepared by the methods of Smith and Taylor, and Smith and Harris, respectively.[12,13]

Experimental Results

A summary of the dielectric properties of some of the benzene derivatives which were measured is provided in Table I. A (+) in the third column indicates that rotation of the molecule is observed in the crystalline solid and a (−) that it is not. The last column gives data on the circumstances attending the cessation of molecular rotation, *i. e.*, whether it ceases at the melting point (m. p.), at a transition point (t. p.) or with anomalous dispersion (a. d.).[14] The measurements on compounds which show evidence of molecular rotation in the solid are represented in Figs. 1 to 13. When anomalous dispersion appeared measurements were made at the frequencies of 1, 3, 10, 30, 100 kc. The dielectric loss in regions of anomalous dispersion is represented in terms of the imaginary part ϵ'' of the complex dielectric constant,[15] which is equal to the product of real dielectric constant ϵ by the tangent of the loss angle. The generally negligible d. c. conductivity was not subtracted from the total a. c. conductivity in calculating ϵ''.

Discussion of Results

The data supply two kinds of evidence of molecular rotation in the crystal: (1) the dielectric constant of the solid behaves like that of the corresponding liquid, and (2) among these solids, ϵ may be correlated with dipole moment of the molecule.

The figures show that with one exception the dielectric constant of the solid at the highest temperature measured is higher than that of the liquid in those cases where the latter has been observed. As among non-aromatic compounds,[4,5,6] this is taken to be evidence that the molecules rotate with much the same freedom in the solid as in the liquid.

Since no determination of the corresponding dipole moments has been found in literature, the fifth column of Table I lists values estimated by vectorial addition for some of these compounds, assuming the moment of the methyl radical to be $+0.4\ D$ and of the chlorine atom $-1.5\ D$.[16] In 3,4,5-trichloro-*o*-xylene the presence of an unsubstituted hydrogen atom probably leads to a considerably lower dipole moment than that estimated as above. The dielectric constant of 1,2,3-trimethyl-4,5,6-trichlorobenzene will be shown below to suffer an unusually large reduction due probably to intermolecular action. Otherwise the correlation between dielectric constant and calculated dipole moment is good in spite of the tendency of density and intermolecular action to mask it. Since a permanent dipole cannot affect the dielectric constant except through rotational motion, this correlation is convincing evidence that the molecules of all of these solids engage in such motion.

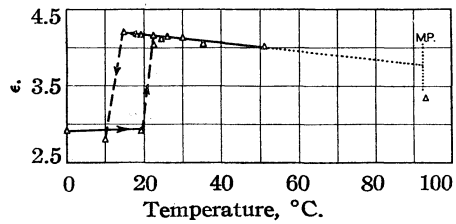

Fig. 1.—Dielectric constant of trichloro-*m*-xylene at 100 kc.

The abrupt rise of ϵ with temperature between 19 and 22° exhibited in Fig. 1 by trichloro-*m*-xylene is typical of a transition marking the onset of molecular rotation. As among the non-aromatic transition compounds, the solid is brittle below the transition temperature and quite waxy above it. Above 50° the specimen sheets became so waxy as to deform in the condenser, and hence could not be measured accurately. Extrapolation of the observed curve to the melting point indicates that ϵ is at least as high after solidification as before and hence that molecular rotation is about as extensive in the solid as in the liquid.

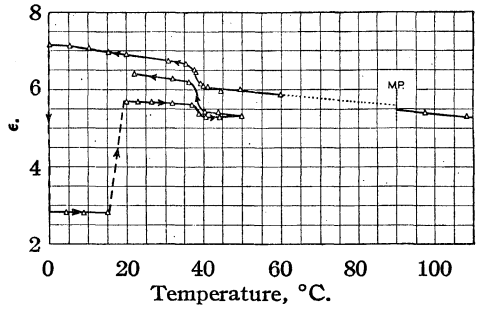

Fig. 2.—Dielectric constant of 3,4,5-trichloro-*o*-xylene at 100 kc.

Figure 2 portrays the complicated behavior of 3,4,5-trichloro-*o*-xylene. Waxiness again prevented measurement of sheets above 60°, but extrapolation indicates that ϵ does not change much at the freezing point and hence that the molecules of the crystal are rotating. Upon cooling through a declining sequence of constant temperatures, a transition appears between 40 and 36°, at which ϵ rises by about 0.5. With further cooling the transition to the brittle non-rotating form of the crystal had occurred after the sample had been left at −0.2° for one hour. The corresponding rise of ϵ with heating occurs between 15 and 20°; the value of ϵ at which the rise ceases is, however, much lower than expected. Figure 2 shows that after heating to 50°, ϵ returned at 25° much more nearly to its original value. This behavior may be explained by the formation of voids upon transformation to the low temperature form; such voids would be at least partially eliminated at temperatures where the material is very waxy.

The dielectric constant of 3.4 found in 5-nitro-3,4-dichloro-*o*-xylene at 0° as shown in Fig. 3 is enough higher than the refraction value to indicate some molecular rotation even at this low temperature. The dielectric constant rises progressively as temperature increases, particularly between 50 and 64°. Above the latter temperature the specimen became so waxy that no further measurement of sheets could be made. After measuring the liquid the material was therefore allowed to solidify with the condenser for liquids immersed in

(16) Smyth, "Dielectric Constant and Molecular Structure," Chem. Catalog Co., New York, N. Y., 1930, pp. 106–114.

it. Although such measurements are accurate only for temperatures near the melting point of the solid, the essential continuity of the ϵ curves for liquid and solid indicates that the freedom of molecular rotation is approximately the same in the solid and liquid phases. In this condenser the reverse transition to the low temperature form had not occurred after the temperature of the sample had remained in the neighborhood of 30° for several days.

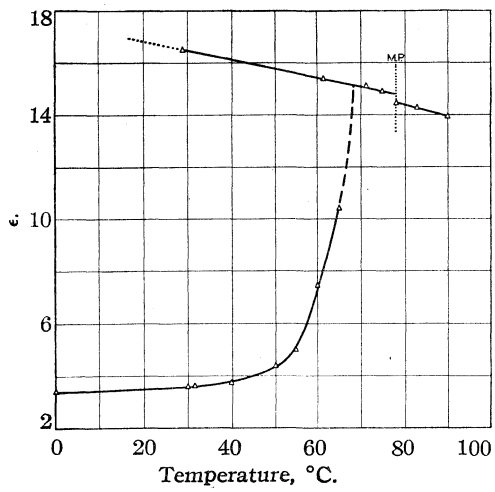

Fig. 3.—Dielectric constant of 5-nitro-3,4-dichloro-*o*-xylene at 100 kc.

The behavior of the isomer of this compound, 3-nitro-4,5-dichloro-*o*-xylene, is striking by contrast; at 111°, only six degrees below its melting point, ϵ is 3.02, which is evidence of no molecular rotation in the crystal. Its nitro group lies between chlorine and methyl radicals, while in the isomer the adjacent methyl is replaced with a hydrogen atom.

Figure 4 shows the gradual rise of the dielectric constant of *o*-dinitrotetramethylbenzene. The abrupt completion of this rise at 154° leaves the dielectric constant of the solid as extrapolated to the melting point much lower than that of the liquid. The behavior of this compound is consistent with the onset of a considerable degree of rotational motion between 100 and 154°, but it is evident that there is a further increase of such motion at the melting point. There was no great degree of waxiness to be observed above 154°; electrode polarization capacity prevented measurement at temperatures higher than 165°.

The behavior illustrated in Figs. 1 to 3 and to some extent in Fig. 4 is very similar to that usually observed in the many non-aromatic compounds

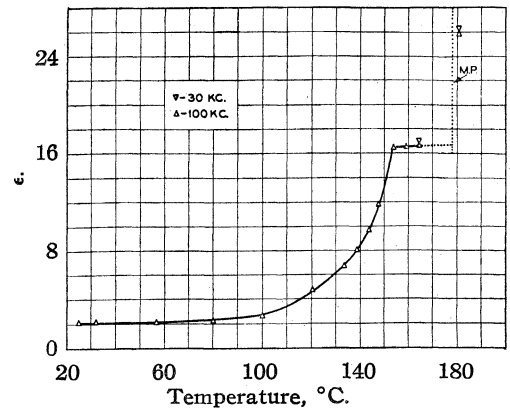

Fig. 4.—Dielectric constant of *o*-dinitrotetramethylbenzene at 30 and 100 kc.

in which there is molecular rotation below the freezing point. Dielectric constant rises more or less sharply at what appears to be a transition of the solid from one crystalline form to another. With cooling, the corresponding fall of ϵ often occurs at a lower temperature, producing a temperature hysteresis loop. The dielectric constant is independent of frequency through the range measured except for electrode polarization effects such as in Fig. 4 at 164°. There are no dielectric loss maxima. Above the transition temperature these materials are waxy; pressed sheets or solidified melts are very translucent. Below the transition temperature the same materials are brittle; the progress of the transformation to the low temperature form often may be observed as a growth of opaque regions in the translucent matrix of the high temperature form. There is evidence of a considerable change of density at such transitions. The molar volume estimated from the weight and dimensions of sheets of 3,4,5-trichloro-*o*-xylene pressed below the transition temperature was 136 cc.; when the sheets were pressed above the transition temperature, the molar volume was 143 cc. The actual difference in molar volume of the rotating and non-rotating forms is undoubtedly even greater since the apparent molar volume of the low temperature form is the more likely to be enhanced by voids in the sheet.

Although the evidence of molecular rotation below the freezing point as exhibited in Figs. 5 to 13 is equally good, the behavior of these solids is otherwise strikingly different from that of the compounds discussed above. Dielectric constant rises gradually from its low temperature value, and through a different temperature range for each frequency of measurement. There is no tem-

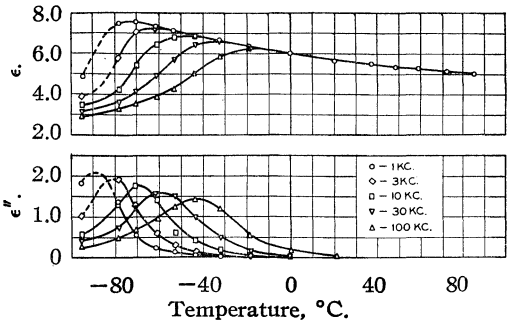

Fig. 5.—Dielectric properties of pentamethylchlorobenzene.

perature hysteresis. For any given frequency the rise of dielectric constant is accompanied by a maximum of dielectric loss as a function of temperature. This temperature behavior of ϵ and ϵ'' is, of course, typical of anomalous dispersion. Although the dielectric constants of these materials are high at room temperature, the solids are so brittle that they can be powdered easily, and the pressed sheets are opaque.

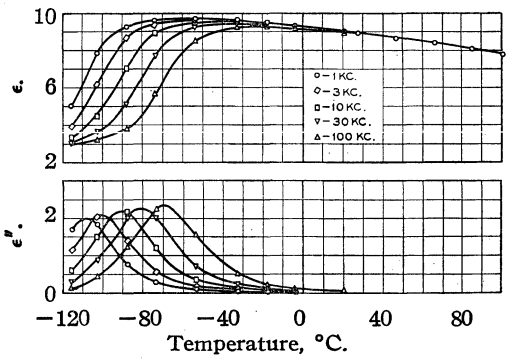

Fig. 6.—Dielectric properties of 1,2,3,4-tetramethyl-5,6-dichlorobenzene.

In Fig. 8 the static dielectric constant of 1,2,3-trimethyl-4,5,6-trichlorobenzene falls gradually over a temperature range of fully 120°, but the behavior of this compound does not otherwise resemble that of the solids which show sharp transitions; its pressed sheets are brittle, opaque, and their density is 1.48, agreeing with the value 1.49 in the isomer, 1,2,4-trimethyl-3,5,6-trichlorobenzene. Furthermore, these two isomers exhibit in Figs. 7 and 8 the same general temperature range of anomalous dispersion.

Several derivatives of camphane, 3-nitro-*dl*-camphor for example, have also exhibited no transition of the static dielectric constant,[17] the rotational polarization disappearing with anoma-

(17) White and Bishop. THIS JOURNAL, 62, 8 (1940).

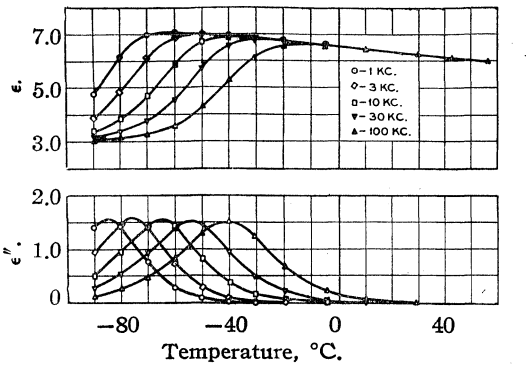

Fig. 7.—Dielectric properties of 1,2,4-trimethyl-3,5,6-trichlorobenzene as measured by W. A. Yager.

lous dispersion as temperature is reduced. In each such case, however, the waxiness and translucence of the material clearly indicate that it belongs to the same class as the high temperature forms of the transition dielectrics; there was some evidence that the failure of the transition to appear was due to the presence of solid solutions of optical isomers or to the existence of the high temperature form in a metastable state at temperatures below that of its presumed transition. If the compounds of Figs. 5 to 13 are existing in a metastable state at any temperature, not the slightest evidence of such behavior has been found.

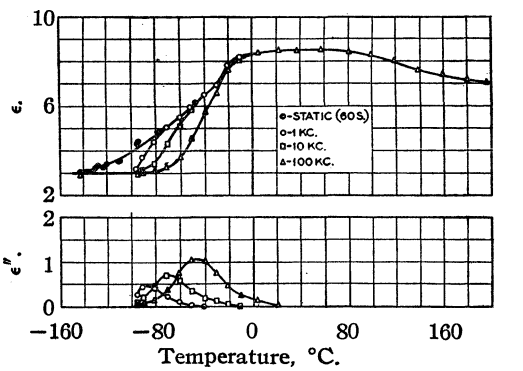

Fig. 8.—Dielectric properties of 1,2,3-trimethyl-4,5,6-trichlorobenzene.

In the following discussion the dielectric constant observed at frequencies so low that the rotational polarization is unaffected by anomalous dispersion will be designated the static dielectric constant ϵ_s. Figure 5 shows the curve of ϵ_s *vs.* $t°$ for pentamethylchlorobenzene to be concave upward, as in most polar liquids and in many solids in which dipole rotation is contributing to the dielectric constant. In 1,2,3,4-tetramethyl-5,6-

dichlorobenzene and 1,2,4-trimethyl-3,5,6-trichlorobenzene the corresponding curves are shown in Figs. 6 and 7 to be concave downward through the measured temperature range. In Fig. 8 this trend reaches its logical conclusion with the most unsymmetrical of the hexasubstituted methylchlorobenzenes when ϵ_s, after becoming almost independent of temperature from +70 to +20°, starts to decline with falling temperature. At −70° anomalous dispersion begins to affect the measurements at frequencies as low as 1 kc.; below this temperature ϵ was measured ballistically, using a charging time of sixty seconds.[18] The results are recorded in Fig. 8 with filled circles and probably represent ϵ_s down to about −100°, below which even the sixty-second ballistic measurements may be affected by anomalous dispersion.

The behavior of the maxima of curves of ϵ'' is consistent with the course of ϵ_s in the several isomers. This maximum should be proportional to the difference between the static and refraction values of the dielectric constant ($\epsilon_s - \epsilon_\infty$). Since ϵ_∞ changes only very slightly with temperature, the height of the maxima of ϵ'' should increase or decrease with ϵ_s. Figure 5 shows a pronounced increase of ϵ'' maxima with declining temperature, while Fig. 8 shows an even more striking decrease.

A reasonable explanation of the reduction of the rotational polarizability of a condensed phase below that of the corresponding gas is found in Debye's theory of hindered rotation, in which this reduction is ascribed to the restraining force of intermolecular action.[19] The sinusoidal potential function which he chooses to represent the effect of this interaction on a given molecule is inadequate for the explanation of the behavior of 1,2,3-trimethyl-4,5,6-trichlorobenzene, however, since it leads to a static polarizability which continually increases with declining temperature, and since without added assumptions it does not account for anomalous dispersion. These difficulties are eliminated by a model recently proposed,[20] in which the rotational motion is from one to another of two equilibrium orientations of different potential energy, with the frequency and temperature range of anomalous dispersion determined by the height of the intervening potential

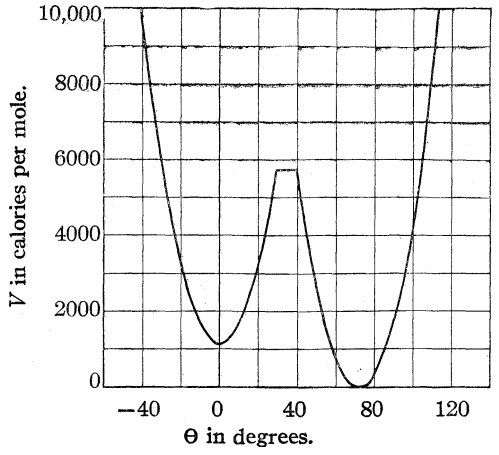

Fig. 9.—Potential function assumed for rotational motion of 1,2,3-trimethyl-4,5,6-trichlorobenzene molecule.

hill.[21,22] The potential function of Fig. 9 is an example showing how such an hypothesis can account for the observed dielectric properties of 1,2,3-trimethyl-4,5,6-trichlorobenzene. After inferring from the shape of this molecule that the rotation is about only one axis, the curve of Fig. 9 represents an assumed angular variation of the potential energy of interaction of a given molecule with all of its neighbors. This interaction is taken to be independent of both temperature and time. As actually drawn the equilibrium orientations are represented as minima in parabolic potential valleys. The polarization due to harmonic torsional vibration of the dipole in either of these valleys is independent of temperature and, at frequencies below about 10^{11} cps., of frequency. In a mass of randomly oriented microcrystals and with an estimated dipole of 3.8 *D*, the molar polarization due to this motion would amount to about 4.5 cc. At −195° (78°K.) practically all of a statistical assemblage of such molecules lie in the valley centered at $\theta = 72°$ and there is no additional contribution to the polarization due to rotational motion from one to the other of the valleys. As the temperature rises, statistical equilibrium permits increasing numbers of molecules to occupy the potential valley centered at 0°; application of an external field modifies this distribution and thus produces a static rotational polarization P_r in accordance with[20]

$$P_r = \frac{2\pi N_\mu^2 (1 - \cos \beta)}{9kT \cosh^2 (E/2kT)} \qquad (1)$$

N is Avogadro's number; μ is the dipole moment of 3.8 D; β is the angle of 72° between equilibrium orientations; and E is the difference between the energies of the two equilibrium orientations, in this case 7.8×10^{-14} erg per molecule or 1130 cal. per mole.

At temperatures above −100° the total molar polarization was derived from the observed values of static dielectric constant, employing at all temperatures the molar volume of 151 cc. observed in the sheets at 25°; in this method of measurement the number of molecules between the electrodes of the condenser is independent of temperature. After subtracting the entire polarization of 58.5 cc. observed at −195° and 100 kc., the remainder is represented as rotational polarization P_r by the circles in Fig. 10. P_r as calcu-

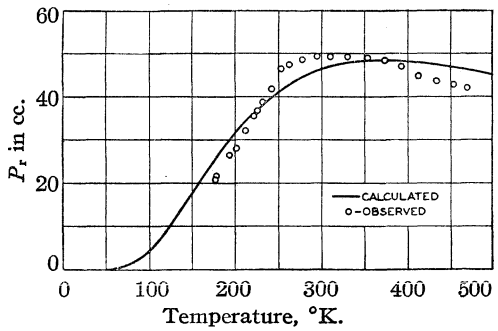

Fig. 10.—Rotational polarization of 1,2,3-trimethyl-4,5,6-trichlorobenzene.

lated by equation (1) is shown by the smooth curve. Despite the use of two adjustable parameters in the calculation, the similarity of the temperature variation of the observed and theoretical curves over a 300° range is significant in exhibiting the ability of the model to account qualitatively for the behavior of ϵ_s in 1,2,3-trimethyl-4,5,6-trichlorobenzene. In passing it may be noted that 72° is not altogether an arbitrary choice for β, since the interval between potential valleys for a truly hexagonal molecule should be 60°.

The height of the potential hill in Fig. 9 determines the time required to establish an equilibrium distribution of molecular orientations between the two potential valleys, and hence may be estimated from the observed principal relaxation time τ where

$$\tau = \frac{\epsilon_\infty + 2}{\epsilon_s + 2} \frac{1}{2\pi f_m} \qquad (2)$$

ϵ_∞ being the dielectric constant at frequencies too high (or temperatures too low) for any rotational

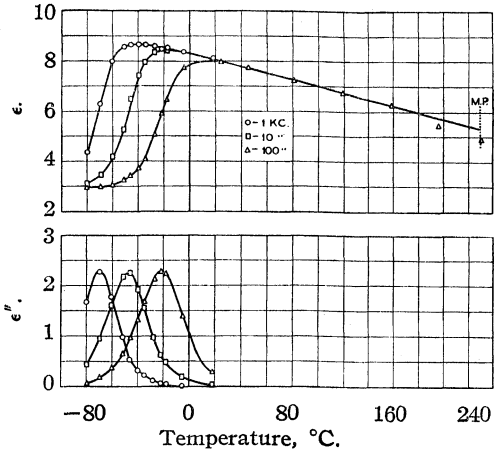

Fig. 11.—Dielectric properties of tetrachloro-*o*-xylene.

contribution, and f_m being at any given temperature the frequency at which $\epsilon = (1/2)(\epsilon_s + \epsilon_\infty)$. According to the Eyring–Frank theory of anomalous dispersion[21]

$$\frac{1}{\tau} = 5 \times 10^{11} e^{-V_0/kT} \qquad (3)$$

where V_0 is the height of the potential hill (above $V = 0$) and the factor 5×10^{11} is the frequency of torsional vibration in either potential valley, estimating the molecular moment of inertia to be 2.5×10^{-37} g.-cm.^{2}. Hence a potential hill V_0 of 3.97×10^{-13} erg per molecule or 5740 cal. per mole accounts for the observed relaxation time of 10^{-6} second at −52.5°. The value thus calculated for V_0 is undoubtedly artificial, for the model of Fig. 9 is analogous to chemical activation in one degree of freedom, while as Frank points out[21] there should be activation in many degrees of freedom in a crystal or liquid. Using $V_0 = 3.97 \times 10^{-13}$ erg, the relaxation time calculated from equation (3) is therefore not as sensitive to temperature as that observed in Fig. 8.

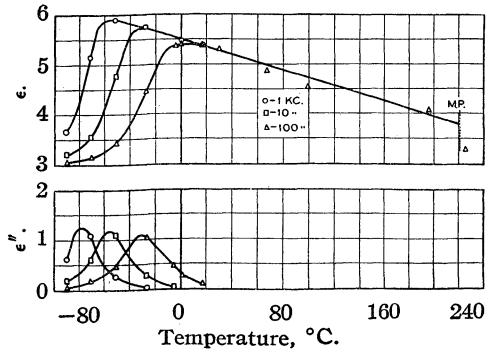

Fig. 12.—Dielectric properties of tetrachloro-*m*-xylene.

Potential functions similar to that of Fig. 9, but with the ratio V_0/E so large that the region of positive $d\epsilon_s/dt$ could not be observed at frequencies as high as 1 kc., are capable of accounting for both the reduction factors and the anomalous dispersion of the other compounds illustrated in Figs. 5 to 13. Once the idea of two or more potential minima is admitted to account for anomalous dispersion, it is difficult to avoid the conclusion that the energies of these minima should in general differ in crystals composed of polar molecules.

With the exception of 1,2,3,5-tetramethyl-4,6-dichlorobenzene, Figs. 5 to 13 include dielectric measurements on all possible polar hexasubstituted methylchlorobenzenes. Since the rotational polarization of each of these compounds is subject to anomalous dispersion, it is of interest to correlate molecular structure with some temperature characterizing the rise of the dispersion. To this end the temperature t_1 at which $\tau = 10^{-6}$ second was obtained by interpolation from the dielectric data for each of these compounds. The results are listed in the sixth column of Table I. They appear to exclude dipole interaction as a determining factor; t_1 declines if anything with increasing dipole moment. Figure 14 shows, however, that considerable regularity appears when t_1 is plotted against the number of chlorine atoms in the molecule, indicating in terms of the theory[21] that the height of the potential

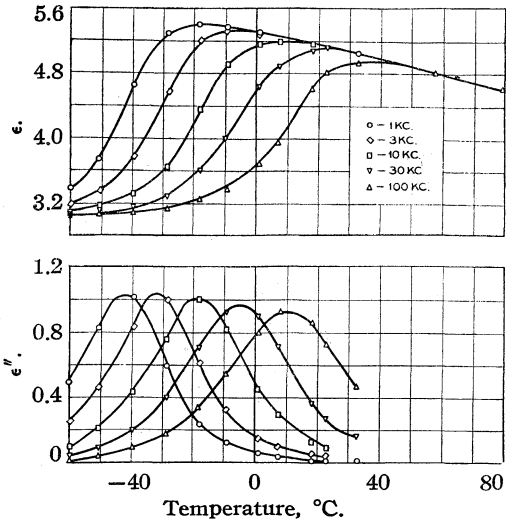

Fig. 13.—Dielectric properties of methylpentachlorobenzene.

hill between equilibrium orientations is increased by replacing a methyl radical in a molecule with a chlorine. The points fall within 7° of the straight line of Fig. 14 for each case except that of pentamethylchlorobenzene, whose point lies 53° above the line. A clue to the cause of its anomalous behavior is found in its crystal habit; it crystallizes from alcohol in plates, while all other members of this series crystallize in fine needles. Hexamethylbenzene, whose system is triclinic,[9] crystallizes from alcohol in plates; while hexachlorobenzene, whose system is monoclinic,[9]

crystallizes in fine needles. Although attempts to grow large single crystals for goniometric measurement have failed, it is reasonable to suppose that all compounds represented in Fig. 14 crystallize in the monoclinic system except pentamethylchlorobenzene, whose crystal is triclinic. Any regularity of behavior of t_1 would certainly be destroyed by such a change of crystal system.

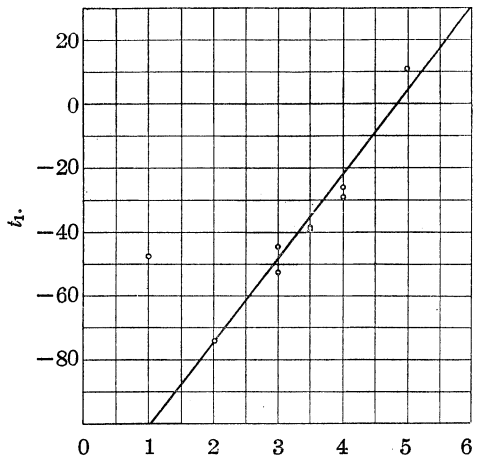

Fig. 14.—Temperature t at which $\tau = 10^{-6}$ seconds *vs.* number of chlorine atoms in hexasubstituted methylchlorobenzenes.

One striking feature of these results is the regular behavior of the relaxation time of 1,2,3-trimethyl-4,5,6-trichlorobenzene in the face of the very large reduction of ϵ_s. This argues in favor of a model in which the reduction factor and t_1 are determined by intrinsically independent features of the potential function, as in Fig. 9.

As a further test of the relation exhibited by Fig. 14, an equimolecular solid solution of methyl pentachlorobenzene and 1,2,3,4-tetramethyl-5,6-dichlorobenzene was prepared. This mixture was first melted and then cooled very slowly through the freezing range, in order to produce as far as possible an equilibrium distribution of the two molecular species throughout the specimen. The dielectric properties of pressed sheets of this solid solution are represented in Fig. 15. The value of t_1 thus observed is −38°, which as represented by the square in Fig. 14 is about what would be expected of a hexasubstituted methylchlorobenzene crystal each of whose molecules contained 3.5 chlorine atoms. Furthermore, the distribution of relaxation times about the principal value is not noticeably broader in the mixture than in the pure crystals, as may be seen by comparing the ratios $\epsilon''_m/(\epsilon_s - \epsilon_\infty)$, where ϵ''_m is the maximum value of ϵ'' at the temperature in question.[23] In the ideal case of a dielectric all of whose molecules have the same relaxation time, this ratio is 0.50; the observed values are 0.42 in methylpentachlorobenzene, 0.35 in 1,2,3,4-tetramethyl-5,6-dichlorobenzene, and 0.34 in the mixture. If any property of the individual molecule, such as moment of inertia, were of controlling importance in determining the frequency with which rotational motion could occur, a broadening of the distribution of relaxation times or possibly two separate principal relaxation times would have been expected in this solid solution. The absence of any such detectable inertia effect is, on the other hand, to be expected if these molecules pass over the potential hill classically as suggested by Frank[21] instead of passing through it in the quantum-mechanical tunnel effect as suggested by Mueller.[22]

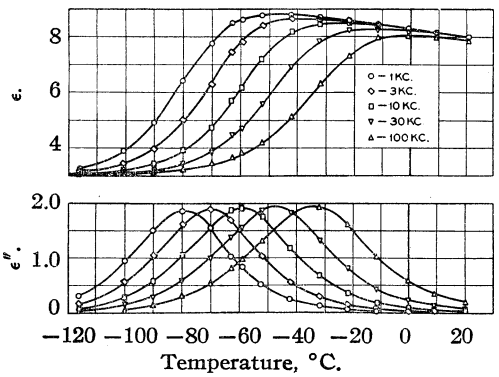

Fig. 15.—Dielectric properties of equimolecular mixture of 1,2,3,4-tetramethyl-5,6-dichlorobenzene and methylpentachlorobenzene.

Among the compounds of Figs. 1 to 4, in whose crystals molecular rotation sets in at a transition, only *o*-dinitrotetramethylbenzene is completely substituted. Among the compounds of Figs. 5 to 13, where there is molecular rotation but no transition, all are completely substituted. Diagrams of these molecules have been drawn to scale.[24] While it is difficult to evaluate the volumetric symmetry about the molecular center of gravity from such a drawing, the hexasubstituted compounds are in general much more symmetrical than the pentasubstituted, with 1,2,3-trimethyl-4,5,6-trichlorobenzene and *o*-dinitrotetramethylbenzene falling close to the dividing line. The

(23) Yager, *Physics*, **7**, 434 (1936).

(24) The procedure was similar to that employed by Smyth in his diagram of *o*-dichlorobenzene, reference 16, p. 111.

appearance of transitions in pentasubstituted benzenes and the derivatives of camphane, cyclohexane and ethane may be pictured in terms of the reduction of rotational energy with declining temperature, which eventually permits the crystal to collapse into a dense form in which "interlocking" of molecules eliminates their rotation without changing the closest distance of approach of the peripheral atoms of nearest neighbors. The more symmetrical hexasubstituted benzene molecules appear to require about the same amount of space in the crystal whether they rotate or not. Hence when the energy (or frequency) of molecular rotation is reduced with the temperature, there is little or no tendency for the crystal to collapse into a denser form. At room temperature the molar volume of tetrachloro-*o*-xylene is about 145 cc., while that of the high-temperature form of 3,4,5-trichloro-*o*-xylene is 143 cc., indicating that when rotating the volume required by corresponding hexa- and pentasubstituted molecules is about the same. At almost the same temperature but in the absence of rotation, the molecules of 3,4,5-trichloro-*o*-xylene require a molar volume of only about 136 cc.

The above explanation of the absence of transitions in certain crystals whose molecules rotate is obviously incomplete. Anomalous dispersion in the 1–100 kc. frequency range has been observed in a number of derivatives of camphane and cyclohexane,[5,6] although usually a transition is also found or there is reason to suspect that the state is one of metastable equilibrium.

Further evidence of the influence of symmetry in determining the ability of molecules to rotate is supplied by the negative results for other compounds in Table I. For example, pentamethylnitrobenzene differs from pentamethylchlorobenzene in that the nitro group is larger than chlorine and in that it projects out of the plane of the flat hexagonal ring. These factors apparently result in a sufficient distortion of the symmetry of the molecule or in sufficient interference between nitro groups of neighboring molecules to prevent rotation. The table shows that ethylpentachlorobenzene also is not sufficiently symmetrical to permit rotation. Consideration of models indicates that the ethyl group projects out of the plane of the ring more than the nitro group and thus that rotation is less likely. Pentaethylacetophenone also illustrates the requirement that the symmetry be in the plane of the ring. The decrease in symmetry in going to the tetrasubstituted compounds is so great that no rotation is to be expected among them. For the 1,2,3,4-tetrachlorobenzene, the most asymmetrical, and for the 4,5-dichloro-*o*-xylene, the most symmetrical tetra-substituted compound, there is no molecular rotation.

The authors are indebted to Mr. W. A. Yager for making his measurements of 1,2,4-trimethyl-3,5,6-trichlorobenzene available to them.

Summary

The dielectric data supply two kinds of evidence of molecular rotation in certain aromatic crystals: (1) the dielectric constant of the solid behaves like that of the corresponding liquid, and (2) among these solids, ϵ may be correlated with the dipole moment of the molecule. Although each of the molecules involved possesses considerable volumetric symmetry about one axis through its center of gravity, the less symmetrical of them cease rotating abruptly at transitions, while the more symmetrical exhibit reduced frequency of rotation but no transitions as temperature declines. Among the symmetrical hexasubstituted methylchlorobenzenes, the temperature at which the relaxation time reaches a given value depends with one exception on the number of chlorine atoms per molecule. A function recently proposed by one of the authors to describe the interaction of a molecule with its neighbors is used to explain the peculiar temperature variation of the static polarization of 1,2,3-trimethyl-4,5,6-trichlorobenzene.

The Partial Vapor Pressures of Water and Ammonia from the System Water–Phosphoric Acid–Ammonia

BY CLAYTON S. HUEY AND H. V. TARTAR

Introduction

This investigation of the ammonium orthophosphates was undertaken because of the growing importance of these salts commercially and the lack of precise information concerning their behavior.

Even such a fundamental property as the extent of hydrolysis of solutions of these salts has been investigated only partially previous to this work. Ball[1] measured the acidity of solutions of mono- and diammonium phosphates. Buchanan and Winner,[2] when studying the solubility of the above salts, found that only the latter was hydrolyzed. Ross, Merz and Jacob[3] discuss the dissociation of the three ammonium orthophosphates both in solution and in the solid form. The hydrolysis of solutions of the related compounds, disodium ammonium phosphate ($Na_2NH_4PO_4$) and sodium ammonium hydrogen phosphate ($NaNH_4HPO_4$), was investigated by Abbott and Bray.[4]

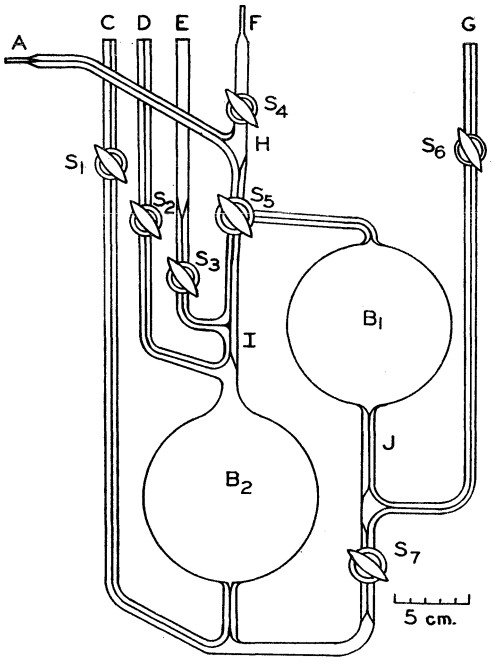

Fig. 1.—Sketch of the vapor pressure apparatus.

(4) Abbott and Bray, THIS JOURNAL, **31**, 729 (1909).

The dissociation pressures of some of the salts of this system have been studied by Warren[5] (mono-, di- and tri-ammonium phosphates), by Britzke and Dunaev[6] (diammonium phosphate) and by de Passille[7] (di- and tri-ammonium phosphates). The present work supplies the dissociation pressures of ammonia and water from triammonium phosphate trihydrate, $(NH_4)_3PO_4 \cdot 3H_2O$.

Vapor Pressure Apparatus

A static method for measuring vapor pressure was devised which permitted the determination of the composition of the two phases in equilibrium. The principal part of the equipment was the Pyrex glass apparatus shown in Fig. 1. The bulbs B_1 and B_2 were of 500 and 700 ml. capacity, respectively. The apparatus was supported by a frame made of brass angle strips, the bulbs resting on brass rings covered with rubber tubing. The frame was fastened in the thermostat at two points only so that it could be rocked about an almost vertical axis through the center of B_1. Bulb B_2 could then be moved through an arc of approximately 1.3 cm. twice per second by an eccentric arm from an electric motor. The glass tubing H to A and the rubber tube connection at A were wrapped with auxiliary heating coils to maintain a temperature somewhat higher than that of the thermostat. The volume of B_1 from S_5 to a mark on J was determined carefully. A scale fastened to tube J was calibrated in terms of the volume of the tube.

The operation of the apparatus was typically as follows: B_1, from S_5 to G to B_2, was filled with mercury through G. Then B_2 was rinsed with carbon dioxide-free air. Next the desired solution was added through C and the apparatus submerged in the water-bath to bring the water level just above S_5. After reaching temperature equilibrium, S_2 was opened momentarily to reduce the inside pressure to atmospheric and the apparatus rocked to establish equilibrium between the liquid and vapor in B_2; this required from twelve hours to several days, the longer time being when solid phases were present. The temperature of the water-bath was maintained to $\pm 0.005°$ at 35° and below and to $\pm 0.015°$ above that range.

To remove the vapor sample for analysis, the mercury was allowed to flow (about 30 ml./min.) from B_1 to B_2, being displaced by the vapor from B_2 through S_5. The mercury was stopped in J to permit the determination of the volume of the sample, which was finally removed (by displacement to H with mercury from G) through the absorption train connected to A after the temperature of the water-bath was raised about 1° to prevent condensation.

(5) Warren, *ibid.*, **49**, 1904 (1927).
(6) Britzke and Dunaev, *J. Chem. Ind. U. S. S. R.*, **5**, 161 (1928).
(7) De Passille, *Compt. rend.*, **199**, 356 (1934).

Tube A was finally washed with a stream of purified air admitted at S_4.

The absorption train consisted of a small tube filled with barium oxide desiccant, for absorbing water, and the ammonia absorber which was made of two 125-ml. Erlenmeyer flasks fitted with glass tubes so that the gas stream bubbled through the liquid. Following this was a Mariotte flask adjusted to maintain the pressure at A a little below atmospheric. The rubber connections at F, A and between the water and ammonia absorbers were treated as suggested by Pregl.[8]

After absorption of the vapor sample, the temperature of the water-bath was lowered to its original value and a portion of liquid removed from B_2, by displacement with mercury, through S_2 into a weighed sampling bulb attached at D. Any liquid in the capillary tube outside the stopcock on the sampling bulb was removed and the bulb wiped and weighed. The long tube on the sampling bulb was broken under an excess of sulfuric acid, the liquid then diluted to volume in a volumetric flask and suitable aliquots taken for the determination of ammonia and phosphate content.

Reagents

The preparation and purification of the materials used in this research which are not specified elsewhere were as follows.

Phosphoric Acid.—A "reagent" grade phosphoric acid (85% H_3PO_4) was concentrated to near 97% and crystallized by seeding with a few crystals of the acid. The crystals were separated by centrifuging in porcelain cups, and dissolved in water to make a stock solution which contained approximately 45% phosphoric acid. This solution was diluted to the desired strength, as needed. A check on the purity of this acid solution was obtained by analyzing three of the diluted solutions both gravimetrically for phosphate content and acidimetrically, the two methods agreeing within the limits of experimental error. The stock solution was also found to be free of reducing substances.[9]

Diammonium Phosphate.—A "C. P." grade of diammonium phosphate was recrystallized twice, and dissolved in water to give an approximately saturated solution. Since there was loss of ammonia from the solutions during recrystallization, the stock solution was analyzed for both ammonia and phosphate content, and ammonia added until the analyses showed a value of two for the molar ratio of ammonia to phosphate ion. This solution was diluted suitably for use in the experiments on the hydrolysis of diammonium phosphate.

Ammonia.—The gas from a tank of liquid ammonia was led through a barium oxide tube before use to remove any water which might have been present.

Water.—The water used was distilled through a block tin condenser and stored in a tin tank. Its specific resistance was approximately 10^6 ohms, without removal of the carbon dioxide.

Ammonium Chloride.—This salt was purified by recrystallization.

Mercury.—The mercury was cleaned by allowing it to drop through a column of dilute nitric acid, in the conventional apparatus.

Analytical Methods, Calculation and Accuracy of Vapor Pressure Determinations

Determination of Water in the Vapor Phase.—A microtechnique was employed. A Kuhlmann balance and microabsorption tubes of the type described by Kemmerer and Hallett[10] were used. The method of weighing was essentially that described by Pregl,[11] except that only a single wiping with a slightly damp chamois was made.

The final choice of barium oxide as a desiccant in the absorption tube was reached after aluminum oxide, calcium oxide and potassium hydroxide had been found unsatisfactory. The barium oxide was pulverized and packed in the absorption tubes in layers separated by Pyrex fiber. The flow of the gas stream through the absorption train was 5 ml. per min., the maximum rate that could be used safely.

The increase in weight of the barium oxide was taken as the weight of water in the sample except at temperatures above 25°. In these cases, a correction was made for the vapor pressure of mercury; at 50° this correction was 0.057 mg.

Determination of Ammonia in the Vapor Phase.—Slightly acidulated water or 4% boric acid solution was used as an absorbent for ammonia. Forty ml. of the former was used and the ammonia content determined directly by Nesslerization[12] when the ammonia pressure was less than 0.3 mm. The lowest pressure that could be measured by this method was about 0.002 mm.

Twenty-five or 50 ml. of the boric acid solution was used for the higher pressures of ammonia, and the quantity determined by titrating with standard hydrochloric acid, using brom phenol blue indicator. The end-point of this titration was determined in such a manner as to obviate the effect of the salts and water on the indicator. This was accomplished through the use of a solution of ammonium chloride of the same normality as the hydrochloric acid. For each titration a similar amount of the boric acid solution was treated in just the same way as the portion with the sample, except that ammonium chloride solution was added in place of the acid, until the sample showed approximately the color of the end-point. Then standard acid was added to the duplicate until the colors matched, and this volume subtracted from the volume of acid added to the sample. This corrected volume represented the acid equivalent to the ammonia in the sample. The end-point was checked by adding more acid to one solution, and matching the color again by adding to the other. Usually the correction amounted to a few tenths of a ml. of 0.015 *N* acid. Under these conditions the color change caused by 0.01 ml. of the standard acid could be seen.

Determination of Ammonia in Solution.—The method of distillation from an alkaline solution into 4% boric acid solution, as used by Markley and Hann,[13] was employed.

(13) Markley and Hann, *J. Assoc. Off. Agr. Chem.*, **8**, 455 (1925).

The same principle of color matching, as applied in the previous determination, was utilized here.

Determination of Phosphoric Acid.—The phosphate analyses were performed by a double precipitation of magnesium ammonium phosphate and final ignition to magnesium pyrophosphate ($Mg_2P_2O_7$).[14] The phosphoric acid was titrated as a dibasic acid using phenolphthalein indicator.[15]

Standardization of Hydrochloric Acid.—This reagent was standardized using phenolphthalein indicator with carbonate-free sodium hydroxide, using recrystallized potassium biphthalate[16] as the primary standard.

Calculations and Constants Used.—Use was made of the perfect gas law to calculate partial pressures from the number of moles, analytically determined, of ammonia or water vapor. The value of the gas constant R was taken to be 1.9864 cal. The weighings were corrected to values *in vacuo* except in the case of solutions whose densities were unknown.

Accuracy of the Vapor Pressure Determinations.—Numerous determinations of the vapor pressure of water were made at 25° to develop the details of the procedure. The average of nine determinations was 23.778 mm.; average deviation was 0.018 mm.; the deviation of the mean from the accepted value[17] was −0.001 mm.

The partial pressures of ammonia and water from several aqueous solutions of ammonia were determined at 25° in an early part of this research to test the method. While the results were not as consistent as those obtained after the technique of the various operations had been improved, the data are shown in Table I, to indicate the accuracy at this stage of development.

[a] De Wijs, Thesis, Delft, 1923; "International Critical Tables," Vol. III, p. 259. [b] Perman, *J. Chem. Soc.*, **83**, 1168 (1903). [c] Wilson, *Univ. Ill. Exp. Sta., Bull.* 146 (1925). [d] This value was obtained by extrapolating de Wijs' curve with the aid of data from Morgan and Maass.[18]

To ascertain whether or not ammonia was absorbed by the barium oxide in the water absorption tube, the following experiment was performed. The barium oxide from one of these tubes, which had been used for six determinations and through which approximately 0.4 millimole of ammonia had passed, was divided into two parts, and each analyzed for ammonia. The part of the barium oxide which had absorbed the water in those six determinations, *i. e.* the front end, showed no ammonia, and the rest of it showed 6.5×10^{-8} millimole. The molar ratio of ammonia to barium oxide in the latter portion of the tube was calculated and found to be 1.9×10^{-4}. Hence absorption of ammonia by the barium oxide was considered to be negligible. The small residues of ammonia left in the barium oxide from each determination would introduce a very small error, since successive determinations were made on solutions with the same, or nearly the same, pressures of ammonia, and were made under similar conditions, thus making the residues approximately the same each time.

An estimate of the reliability and accuracy of the method was obtained from the last data taken, namely, those recorded in Table IV. The average deviation of the thirteen individual points from the straight line determined by the method of least squares was found to be 0.09 mm. for the water pressure and 0.03 mm. for the ammonia pressure, with about 60% of the variation due to four values in the first case, and two in the latter.

Partial Pressures of Ammonia and Water from Solutions of the Ammonium Orthophosphates at 25°.—Owing to hydrolysis, solutions of the secondary and tertiary ammonium phosphates would be expected to exhibit a pressure of ammonia. To study the extent of this reaction, solutions of phosphoric acid were titrated with anhydrous ammonia, and the partial pressures of both ammonia and water above the solutions determined at 25° as a function of the composition of the solution. The results of these experiments are shown in Table II, and graphically in Fig. 2.

Kabulkov and Zagwosdkin[19] have published the only available data with which these may be compared. Their values for the partial pressure of water from the 1.0 and 0.25 M solutions are 23.2 and 23.6 mm., respectively; the corresponding results reported herein are 23.16 and 23.55 mm.

A noteworthy point in Fig. 2 is on Curve E, where R equals 3. The fact that no break in the value of the ammonia pressure occurs here shows that triammonium phosphate is practically completely hydrolyzed in this solution.

Hydrolysis of Diammonium Hydrogen Phosphate at 25°.—Diammonium phosphate undergoes the following hydrolytic reaction

$$(NH_4)_2HPO_4 + H_2O \rightleftarrows NH_4OH + NH_4H_2PO_4 \quad (1)$$

[a] R represents the molar ratio of ammonia to phosphate ion.

The hydrolysis constant is defined by the equation

$$K_h = k_w/K_a K_b \qquad (2)$$

and can be formulated in terms of the experimental values as follows. We have

$$K_w = a_{H^+} a_{OH^-}/a_{H_2O}$$
$$K_a = a_{H^+} a_{HPO_4^{--}}/a_{H_2PO_4^-}$$
$$K_b = a_{NH_4^+} a_{OH^-}/a_{NH_4OH}$$

and substituting in equation (2) we obtain

$$K_h = \frac{a_{H_2PO_4^-} a_{NH_4OH}}{a_{HPO_4^{--}} a_{NH_4^+} a_{H_2O}}$$

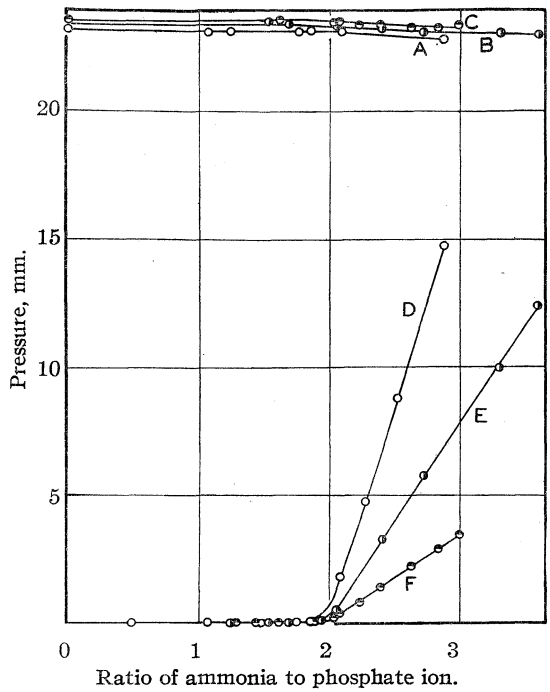

Fig. 2.—Partial pressures of ammonia and water from solutions of the ammonium orthophosphates at 25°. Curves A, B and C represent the partial pressure of water from solutions whose phosphate ion molalities are 1.0, 0.5 and 0.25, respectively. Curves D, E and F show the partial pressures of ammonia from the same solutions, respectively.

Consider a solution of diammonium hydrogen phosphate, of molality M_2, of which X is the fraction hydrolyzed. Then at equilibrium the molality of the $H_2PO_4^-$ ion and also that of the ammonium hydroxide is XM_2; also the molalities of the HPO_4^- and NH_4^+ ions are $(1 - X)M_2$ and $(2 - X)M_2$, respectively, assuming no appreciable ionization of the ammonium hydroxide. Then

$$K_h = \frac{X^2}{(1 - X)(2 - X)} \frac{\gamma_{H_2PO_4^-}\gamma_{NH_4OH}}{\gamma_{HPO_4^{--}}\gamma_{NH_4^+} a_{H_2O}}$$

Letting

$$K_h' = \frac{X^2}{(1 - X)(2 - X)} \qquad (3)$$

and expressing in logarithmic form

$$\log K_h = \log K_h' + \log \frac{\gamma_{H_2PO_4^-}\gamma_{NH_4OH}}{\gamma_{HPO_4^{--}}\gamma_{NH_4^+} a_{H_2O}}$$

Use was made of a correction factor similar to the Debye and Hückel expression for the activities of ions for evaluating the last term of the preceding equation. Doing this we obtain

$$\log \frac{\gamma_{H_2PO_4^-}}{\gamma_{HPO_4^{--}}\gamma_{NH_4^+}} = \frac{4A\sqrt{\mu}}{1 + B\sqrt{\mu}}$$

A has the value 0.506 at 25° and B is a semi-

TABLE III

HYDROLYSIS OF DIAMMONIUM HYDROGEN PHOSPHATE AT 25°

Diammonium hydrogen phosphate molality, (M_2)	Partial press., mm. Water	Ammonia	M_0	X	$-\log K_h'$	μ	$-\log K_h^*$

.4011		.144	.01077	.02685	3.4257	1.182	2.276

empirical constant related to the ionic radius, a, by the relation $B = 0.327 \times 10^8 a$, when the difference between the molality and normality is negligible.

Next, a quantity K_h^* was defined by the equation

$$\log K_h^* = \log K_h' + \frac{4A\sqrt{\mu}}{1 + B\sqrt{\mu}} \qquad (4)$$

If $\log K_h^*$ is plotted against μ, the ionic strength, the intercept at zero ionic strength is the logarithm of the hydrolysis constant.

The following procedure was employed to evaluate K_h'. Suppose that a membrane were available which would permit the passage of ammonia but which would be impermeable to water vapor. If this membrane were placed between a solution of diammonium phosphate and water, ammonia would distil from the former to the latter until the activity of the ammonia would become the same in all three phases. Let a_0 represent the activity and M_0 the molality of un-ionized ammonia in the ammonia solution. Let P_0 represent the partial pressure of ammonia. The ammonia solution would exhibit the equilibria

$$NH_{3(g)} \rightleftarrows NH_{3(soln.)}$$

$$NH_{3(soln.)} + H_2O \rightleftarrows NH_4OH$$

$$K_0 = \frac{(a_{NH_4OH})}{(a_{NH_3(soln.)})(a_{H_2O})}$$

$$NH_4OH \rightleftarrows NH_4^+ + OH^-$$

Then

$$a_0 = M_0\gamma_0 = (a_{NH_3(soln.)}) + (a_{NH_4OH}) = (a_{NH_3(soln.)})(1 + K_0 a_{H_2O})$$

and since the activity of ammonia in solution is proportional to its partial pressure above the solution

$$a_0 = M_0\gamma_0 = P_0K_2(1 + K_0a_{H_2O})$$

Therefore, the activity of the un-ionized ammonia in both solutions would be directly proportional to the pressure of ammonia, if the activity of water were the same in the two cases.

The value of M_0, the molality of un-ionized ammonia in the water solution, was calculated by using P_0, the ionization constant of ammonium hydroxide, and the pressure–composition curve for ammonia in water.[20] Since the activity of the un-ionized ammonia was essentially the same in the two solutions, M_0 was also taken as equal to XM_2, the molality of the un-ionized ammonia in the diammonium phosphate solution. This was based on two approximations: first, that the activity coefficients of the un-ionized ammonia in the two solutions were the same, and, second, that the activities of water in the two solutions were the same. X was calculated from this value of M_0 and the analytically determined M_2. These values were introduced into equation (3) and K_h' computed.

The molality of diammonium phosphate was varied approximately from 5.0 to 0.4 and the measured values of P_0 plotted against M_2. These values are shown in Table III, and graphically in Fig. 3, Curve A. Curve B gives the corresponding values of the partial pressure of water, with the addition of three values in the dilute solution from Fig. 2.

Table III also includes the calculated values for $-\log K_h^*$, arbitrarily taking B in equation (4) to be 0.84. No trend is apparent in the values of $-\log K_h^*$; the best value is probably 2.053 ($K_h^* = 8.86 \times 10^{-3}$), the average of the values given omitting the last one for the most dilute solution because of its evident inconsistency. K_h was found to be 8.87×10^{-3}, using the values 10^{-14} for K_w, 6.226×10^{-8} for K_a[21] and 1.81×10^{-5} for K_b.[22] Since the arbitrarily chosen value of B influenced the magnitude of K_h, the agree-

(20) The values for the partial pressures of ammonia from the ammonia–water solutions were those of de Wijs (see Note *a*, Table I).

(22) "International Crit. Tables," Vol. VII, McGraw-Hill Book Co., Inc., New York, N. Y., 1926, p. 240.

ment of the two values for this constant is not a complete check on the validity of the present work. Using the value 0.84 for B, however, the average ionic radius was calculated to be 2.56×10^{-8} cm., slightly lower than similarly obtained values[23] yet nevertheless quite reasonable. Hence the agreement of the value of K_h obtained from our experimental data with that calculated from the defining equation (2) is deemed to be satisfactory.

Dissociation Pressures of Triammonium Phosphate Trihydrate from 25 to 50°.—The measurement of the dissociation pressures corresponding to the reaction

$$(NH_4)_3PO_4 \cdot 3H_2O(s) \rightleftharpoons (NH_4)_2HPO_4(s) + 3H_2O(g) + NH_3(g) \quad (5)$$

was accomplished by preparing a solution saturated with respect to both solids and measuring the partial pressures of ammonia and water exerted by this solution over the temperature range 25 to 50°. This solution was prepared by adding gaseous ammonia to the 45% phosphoric acid solution until the above solids were present.

The phase rule shows that during the addition of ammonia the composition of the solution and the partial pressures of ammonia and water will not change as long as both triammonium phosphate trihydrate and diammonium phosphate are in equilibrium with the solution. This constancy of the partial pressures with changing total composition was taken as the chief criterion for determining when the two solid phases were present. The solubility curves of the system, known approximately at these temperatures[24,2] served to locate the approximate composition of the solution at this equilibrium. When nearly enough ammonia had been added to give the above equilibrium mixture, a vapor pressure determination was made, more ammonia or 45% phosphoric acid added, and the determination repeated, until at least two successive experiments gave the same values for the partial pressures. Proceeding in this manner, four determinations at 50° gave essentially the same partial pressures when the ammonia content of the mixture was varied about 3.2%. This variation was calculated from the weight of solution added and the time during which ammonia was added through a calibrated Venturi meter.

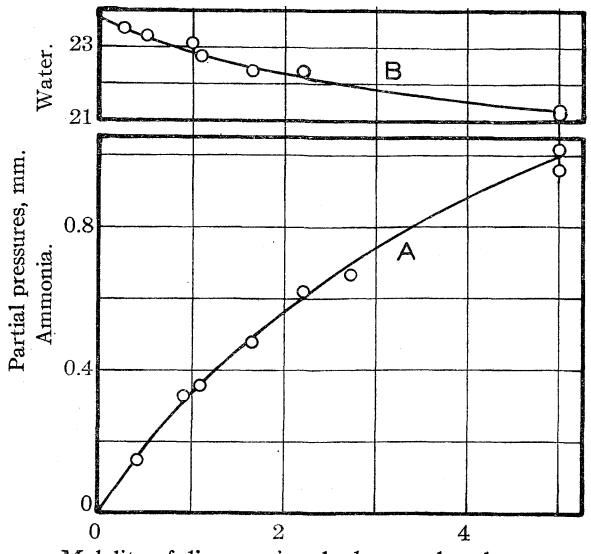

Fig. 3.—The hydrolysis of diammonium phosphate at 25°.

Then the temperature variations of the partial pressures were determined by changing the temperature of the apparatus to the values 40, 45, 35, 30, 25, 20 and 25°, respectively. The data obtained are given in Table IV. Figure 4 shows a graph of the logarithm of the pressure against the reciprocal of the absolute temperature.

TABLE IV

DISSOCIATION PRESSURES OF TRIAMMONIUM PHOSPHATE TRIHYDRATE FROM 25 TO 50°

Temp., °A.	Partial press., mm. Water	Ammonia	ΔR[a] %	$-\log K_p$	$K_p \cdot 10^7$	$\Delta F°$ calcd.	ΔS calcd.
298.14	21.26	3.995					
298.14	21.11	3.995					
298.14	21.14	4.012	+1.0	6.9440	1.138	9469	151.5
303.16	28.10	5.958		6.4017	3.966	8877	149.0
308.14	37.04	8.825		5.8714	13.45	8275	146.6
313.14	48.34	12.84					
313.14	48.39	12.82					
313.14	48.48	12.85	+0.5	5.3600	43.65	7677	144.3
318.14	62.89	18.55		4.8591	138.3	7071	142.0
323.14	80.51	26.39					
323.14	80.50	26.27	−0.1				
323.14	80.33	26.39	−3.0				
323.14	80.45	26.50	−0.1	4.3853	411.8	6482	139.8

[a] ΔR represents the increase in the value of the ratio of ammonia to phosphoric acid in the mixture from the value in the experiment immediately preceding the one for which the value is tabulated.

From the average values at each temperature the following equations were calculated by the method of least squares, where the pressures are

in mm. of mercury and T is the absolute temperature.

$$\log_{10}P_{NH_3} = (-3161.3/T) + 11.2045 \quad (25 \text{ to } 50°)$$
$$\log_{10}P_{H_2O} = (-2239.0/T) + 8.8353 \quad (25 \text{ to } 50°)$$

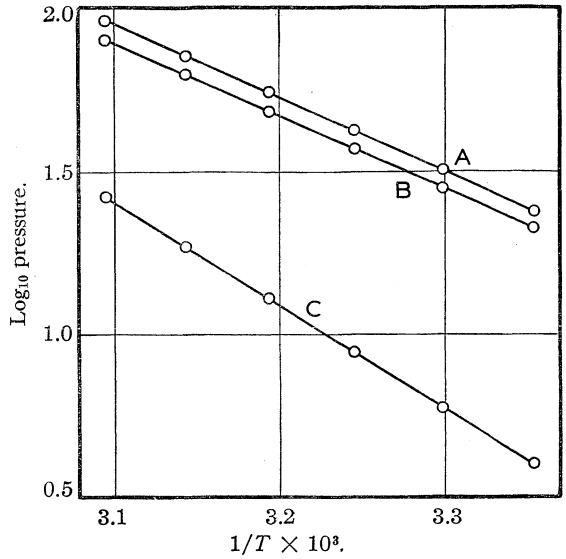

Fig. 4.—The dissociation pressures of triammonium phosphate trihydrate from 25 to 50°. Curve A shows the vapor pressure of pure water. Curves B and C represent the partial pressures of water and ammonia, respectively.

For equation (5) the following well-known thermodynamic quantities were evaluated

$$K_p = (P_{H_2O})^3(P_{NH_3})$$
$$\log_{10}K_p = (-\Delta H/2.3026RT) + C$$
$$\Delta F° = -RT \log_e K_p$$
$$\Delta S = \Delta H/T$$

The following equations were derived from the above after converting the unit of pressure to the atmosphere

$$\log_{10}K_p = (-9878.4/T) + 26.1870$$
$$\Delta F° = 45{,}183 - 119.78\ T \text{ cal.}$$
$$\Delta H = 4.518 \cdot 10^4 \text{ cal.}$$

The values of $\log_{10}K_p$, K_p, $\Delta F°$ and ΔS, which were computed directly from the experimental values, are listed in the last four columns of Table IV.

Samples of the solution were removed at both 25 and 50° and subsequently analyzed. The results of these analyses are given in Table V.

TABLE V

COMPARISON OF THE ANALYSIS OF THE SOLUTIONS SATURATED WITH DIAMMONIUM PHOSPHATE AND TRIAMMONIUM PHOSPHATE TRIHYDRATE AT 25 AND 50°

Temp., °C.	Found, % Ammonia in soln.	Found, % Phosphoric acid in soln.	Calcd., % Ammonia in soln.	Calcd., % Phosphoric acid in soln.	Source
25	10.79	30.08	11.03	31.0	D'Ans and
25	10.79	30.38			Schreiner[25]
50	12.08	34.10	12.7	34.7	Jänecke[26]

It is believed that the discrepancies in Table V are not due to lack of attainment of equilibrium conditions, because of the constancy of the ammonia pressure found. Whether or not the analytical values were in error due to a mistake in sampling is difficult to judge. On the other hand, the values of Jänecke are the result of an interpolation and can only be considered as approximate.

Parker's[24] investigation at 25° throws no light on this particular point and apparently is in error in this region. At least his data for this range are at variance with those of other investigations,[25,2] which are in fair agreement. None of these, however, except that of D'Ans and Schreiner, has included this point.

Summary

1. A method for determining the partial pressures of ammonia and water from solutions has been developed.

2. The partial pressures of these gases were measured at 25° from solutions of orthophosphoric acid containing varying amounts of ammonia.

3. These partial pressures were determined at 25° for solutions of diammonium phosphate of varying molality, and the hydrolysis constant of this salt was calculated.

4. The dissociation pressures of ammonia and water for the reaction: $(NH_4)_3PO_4 \cdot 3H_2O(s) \rightleftarrows (NH_4)_2HPO_4(s) + 3H_2O(g) + NH_3(g)$ were measured over the temperature range from 25 to 50°. From these measurements K_p, $\Delta F°$, ΔS and ΔH were computed for this reaction.

The Extraction of Ferric Iron from Hydrochloric Acid Solutions by Dichloroethyl Ether and the Formula of the Iron Compound in the Ether

BY JOSEPH AXELROD AND ERNEST H. SWIFT

Introduction

Although the extraction of ferric iron from hydrochloric acid solutions by ethyl ether has been an analytical procedure for over fifty years, only recently has the use of other than ethyl ether been investigated; furthermore, although there have been studies of the molecular condition of anhydrous ferric chloride in ethyl ether[1,2] only very recently does there appear to have been any experimental investigations to establish the molecular nature of the iron compound in the ether phase obtained in the extraction process.[3] Dodson, Forney and Swift[4] have shown recently that isopropyl ether possesses certain advantages over ethyl ether for the extraction of ferric iron from hydrochloric acid solutions, and unpublished experiments by Dodson have shown that the ferric chloride in the isopropyl ether phase was associated with hydrogen chloride. He found that with high initial concentrations of acid and of iron in the aqueous phase, two ether phases separated and obtained ratios of hydrogen chloride to ferric chloride of 1.25 and 1.32 in the two ether phases. In addition, it seemed necessary to assume polymerization of the iron in the ether layer in order to explain the dependence of the distribution ratio upon the concentration of iron.

This paper presents the results of studies of, first, the distribution of ferric iron between hydrochloric acid solutions and dichloroethyl ether, and, second, the nature of the ferric iron compound in the ether phase. Preliminary experiments by Mr. John Gates had shown that the mutual solubilities of this ether with hydrochloric acid solutions are small so that extractions are practical with even quite concentrated acid solutions, and, in addition, so little acid passes into the ether phase that conditions are favorable for studying the association of hydrogen chloride with the iron. Dichloroethyl ether also has a practical advantage over either ethyl or isopropyl ether for the extraction of iron in that it separates as the lower phase when shaken with hydrochloric acid solutions and repeated extractions from a single separatory funnel are therefore possible.

The Distribution of Iron between Dichloroethyl Ether and Hydrochloric Acid Solutions

Experimental.—The β,β'-dichloroethyl ether was a redistilled grade. It was found to have a boiling range of less than 3° and gave a negative test for peroxide. It was used repeatedly, being washed and distilled each time. Various solutions of ferric chloride in hydrochloric acid were prepared; both reagent grade hexahydrate and anhydrous sublimed ferric chloride were used. Standard solutions of sodium thiosulfate, ammonium thiocyanate, silver nitrate, hydrochloric acid and sodium hydroxide were prepared and standardized by conventional methods.

The distribution data were obtained by shaking equal volumes of the ether with iron and hydrochloric solutions of the desired concentrations in a thermostat at 25° for from thirty to sixty minutes in order to obtain thermal equilibrium. The equilibrium of the iron between the two phases appeared to be established very rapidly. The probable accuracy of the distribution ratios is indicated by the reproducibility of duplicate experiments and the conformity of the points to the curves of Fig. 1. The separatory funnel was then allowed to stand in the thermostat until the two layers separated and the ether layer drawn off. Duplicate twenty-five ml. portions of the acid phase were pipetted into conical flasks, the acid concentration made approximately one normal and the iron determined iodometrically.[5] Where the amount of iron present was small, a 0.01 normal thiosulfate solution was used. Duplicate twenty-five ml. portions of the ether phase were shaken with twenty-five ml. portions of water, the water layer separated and the iron determined as above. Experiments showed that the hydrochloric acid and iron were quantitatively extracted from the ether layer by an equal volume of water. In Table I below is shown the initial concentration of the acid in the aqueous phase and the acid concentration after equilibrium had been established. This latter value was calculated by correcting the original acid concentration for the hydrogen chloride dissolved as such and as $HFeCl_4$ by the ether, for dilution of the aqueous phase by dissolved ether, and for concentration by the water passing into the ether phase. The solubility of ether in 7.5 formal hydrochloric acid and in a solution 7.5 formal in hydrochloric acid and 1 formal in ferric chloride was found to be substantially the same. It should be

(3) Not until after this article was prepared for publication did the work of Kato and Isii, *Sci. Papers Inst. Phys. Chem. Research (Tokyo)*, **36**, 82–96 (1939), on the molecular formula of the iron compound in ethyl ether come to the attention of the authors. As the result of analytical and absorption spectra studies of the ether phase these investigators assign the compound in ethyl ether the formula $2[FeCl_3 \cdot HCl] \cdot 9H_2O \cdot 15(C_2H_5)_2O$.

(4) Dodson, Forney and Swift, THIS JOURNAL, **58**, 2573 (1936).

(5) Swift, THIS JOURNAL, **51**, 2682 (1929).

pointed out that the acid concentrations given are formal, not molal, concentrations as there is undoubted association of the iron and acid in the aqueous phase.[6]

The results of the distribution experiments are collected in Table I and curves showing the percentage extraction at various acid concentrations are shown in Fig. 1.

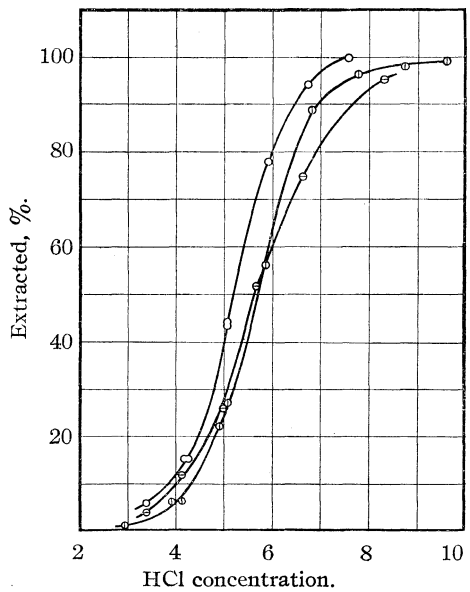

Fig. 1.—Iron extracted into dichloroethyl ether from HCl solutions: ○, initial iron concentration, 0.01 *F*; ⊕, initial iron concentration, 0.07 *F*; ⊖, initial iron concentration, 0.57 *F*.

An inspection of the data of Table I and the curves of Fig. 1 shows that, over the concentration range studied, the extraction of the iron by dichloroethyl ether becomes more effective the higher the hydrochloric acid concentration. This was confirmed by preliminary experiments which extended to 11.5 formal acid without showing any evidence of a decrease in the distribution ratio. This is contrary to the results of Dodson, Forney and Swift which show regions of maximum extraction at approximately 6 and 8 formal acid for ethyl and for isopropyl ether, respectively, and indicates that in the aqueous phase there is a continuous increase with increasing acid concentration of the concentration of the molecular compound passing into the ether phase.

The curves also show that dichloroethyl ether can be used for the practical extraction of iron from solutions in which the hydrochloric acid concentration is greater than seven formal. Mention should be made, however, that the time required for the separation of the two phases is somewhat longer than for either ethyl or isopropyl ether.

(6) Complex acids such as $HFeCl_4 \cdot 2H_2O$ and $H_2FeCl_5 \cdot 4H_2O$ have been prepared, as have salts such as $KFeCl_4$. In addition, studies of the heat of solution of ferric chloride in hydrochloric acid solutions show evidence of such compound formation. Kangro and Flugge, *Z. physik. Chem.*, **A175**, 187 (1935).

The unexpected behavior of the lower portion of the curve for the solutions 0.57 formal in iron may be due to the ferric iron causing an abnormal increase in the ionic strength of the solutions. When a large fraction of the iron is extracted into the ether, this effect diminishes and the upper portion of the curve conforms more nearly to the other two.

The Determination of the Formula of the Iron Compound in the Ether Phase.—In the determination of the formula of the iron in the ether phase the analytical procedure was essentially as follows, although minor refinements and modifications were made as the experiments progressed. Equal volumes of the ether and the iron–hydrochloric acid solutions were shaken together, allowed to separate and the ether layer was analyzed for chloride by shaking it with an equal volume of water, removing the water layer, adding an excess of standard silver nitrate, coagulating the precipitate, and titrating the excess silver nitrate

with a standard thiocyanate solution. A second portion of the ether layer was analyzed for acid and ferric iron by similarly shaking it with an equal volume of water, separating the water layer, titrating it with standard hydroxide until the ferric hydroxide could be coagulated by heating, then again titrating with the hydroxide to a phenolphthalein end-point. The titrated solution was then made approximately one normal in hydrochloric acid and the iron determined iodometrically. The amount of hydrogen chloride passing into the ether layer from pure hydrochloric acid solutions of various concentrations was determined by separate experiments and this amount subtracted from the total amount found with the iron extracts. The analytical data have been collected and are shown in Table II below; also the molecular ratios of chloride and of acid to iron in the ether phase are calculated and tabulated. It was not at first thought necessary to entirely free the water extracts (containing the iron and acid) from ether before heating the solution for the acid titration; however, upon heating 100 ml. of water with a small amount of the ether for an hour it was found that an acidity had developed roughly equivalent to one per cent. of the acid found in the previous analyses. In the last two experiments the water extracts were separated from the ether and then filtered through paper filters before making the titration for acid, thus removing suspended droplets of ether.

TABLE II

ANALYSES OF THE ETHER EXTRACTS

Concentration (moles liter)			Ratios	
Fe^{III}	Cl^-	$H^+ + 3Fe^{III}$	Cl^-/Fe^{III}	H^+/Fe^{III}

.1544	.6160	.6181	3.99	1.000

From the data of Table II it is seen that, exclusive of water and ether, the formula of the iron compound can be written as $HFeCl_4$. The closeness of the agreement of the ratios with this formula makes it appear reasonable to conclude that no other complex with a higher ratio of chloride to iron exists in appreciable amounts in the ether.

As Schwarz and Meyer[7] in their study of the various chloro acids found that they could not prepare anhydrous $HFeCl_4$, and as the evaporation of ethyl ether extracts containing iron gives evidence of more water than that normally dissolving in the ether, attempts were made to analyze dichloroethyl ether extracts for their water content. The presence of hydrogen chloride and ferric chloride cause interference with most chemical methods, so, in spite of obvious decomposition in the ether solution during the process, a distillation method was used. A 100-ml. round-bottomed flask was sealed to a fractionating column connected by a ground-glass joint to a condenser which drained into a 15-ml. graduated centrifuge tube initially containing 5 ml. of petroleum ether. Decomposition in the solution in the distilling flask began after approximately 40% of the water was collected and by the time complete recovery was obtained (as shown by the analysis of artificially prepared solutions) a dark viscous mixture was left. Probably because of this decomposition the analysis of the artificial solutions of known content gave an excess of water which was independent of the amount of water originally present and varied in volume from 0.62 to 1.05 ml. with an average value of 0.89 ml.; this volume was subtracted from the total volume of water obtained in the subsequent distillation, as was also the volume of water found to be dissolved by the ether from pure hydrochloric acid solutions. Hydrogen chloride also was distilled over and collected with the water; therefore, the distillate was titrated to determine the acid concentration and the volume corrected accordingly. The data obtained from analyses of ether extracts of iron from 7.5 formal hydrochloric acid solutions are shown in Table III. In the first column are shown the millimoles of iron present in the 50.0 ml. of ether solution; in column two is shown the total volume of water obtained by the distillation procedure outlined above; in column three the corrected volume; and in the last column the calculated molal ratio of water to iron.

The data of Table III show that from four to five molecules of water are associated with each

molecule of iron. The average ratio is 4.52; this value and the formula assigned to the iron compound in the ethyl ether phase by Kato and Isii[3] suggests the possibility that at least two iron atoms are associated in the molecule existing in the ether phase; however, because of the large corrections applied in obtaining the water volumes, and because a water determination was made with only one concentration of acid and of iron, too great significance should not be placed on the ratio values.

No attempt was made to determine the extent to which the ether may be associated with the iron compound. That there may be such association is indicated by the fact that the compounds $FeCl_3 \cdot (C_2H_5)_2O$[2] and $FeCl_3 \cdot HCl \cdot 2(C_2H_5)_2O$[8] have been prepared, and by the results of Kato and Isii. Although the first of the compounds mentioned is stated to be immediately decomposed by water, this does not preclude the possibility of the existence in an ether solution of a mixed compound containing both water and ether molecules. Because of the uncertainty regarding the association of ether molecules, an exact formulation of the compound or its structure cannot be made. It seems probable that the four chlorides are bonded tetrahedrally to the iron and that the waters are held by hydrogen bonds to the chlorides. As previously stated, Schwarz and Meyer could not prepare anhydrous $HFeCl_4$, which indicates that these hydrogen bonds are needed to stabilize the tetrahedral complex.

Acknowledgment: The authors are greatly indebted to Mr. John Gates and Mr. R. C. Jones for carrying out an extensive series of preliminary experiments. These experiments were of value in showing the dependence of the distribution ratio on the acid concentration and in establishing the ratio of acid and of chloride to iron in the ether solution.

Summary

The distribution of ferric iron between hydrochloric acid solutions and β,β'-dichloroethyl ether has been studied for various concentrations of acid and iron. Dichloroethyl ether can be used for the quantitative extraction of ferric iron from solutions greater than 7 formal in hydrochloric acid.

Chemical analyses of the ether solution have shown that one molecule of hydrochloric acid and from four to five molecules of water are present for each molecule of iron present in the ether layer. Neglecting polymerization and the possible presence of ether in the molecule, the empirical formula can be written as $HFeCl_4 \cdot 4\text{–}5H_2O$.

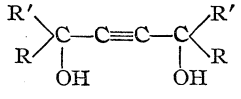
Cycli-Alkylation of Aromatic Compounds by the Friedel and Crafts Reaction

BY HERMAN ALEXANDER BRUSON AND JOHN W. KROEGER

The method recently described by Kazarian[1] for preparing acetylenic alcohols by the interaction of calcium carbide, potassium hydroxide and a ketone, has made more readily available, many acetylenic tertiary glycols heretofore obtainable only with considerable difficulty and expense. These acetylenic tertiary glycols have the general formula (I)



I

Upon catalytic hydrogenation with Raney nickel at 60–85° and 100 lb. pressure/square inch (7 atm.), the acetylenic bond of these glycols can be completely saturated with hydrogen, thus making available in quantity 1,4-ditertiary glycols (II) having unique interest for further synthetic work.

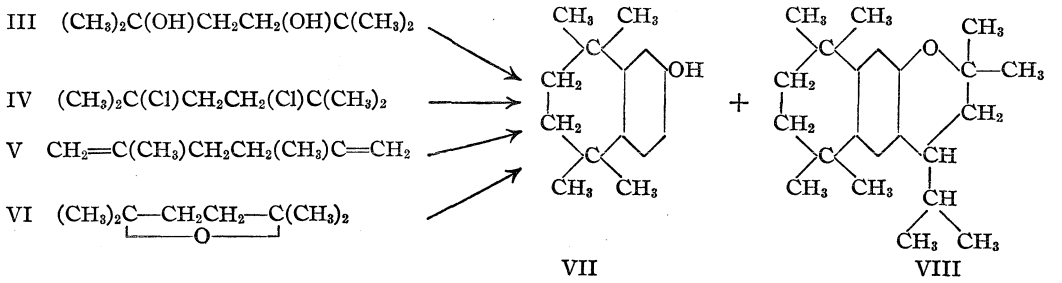
II

The glycol in which R and R′ are each methyl groups, namely, 2,5-dimethylhexane-2,5-diol (III) and a number of its derivatives, namely, 2,5-dichloro-2,5-dimethylhexane (IV), 2,5-dimethyl-1,5-hexadiene (V), and 2,2,5,5-tetramethyl-tetrahydrofuran (VI), were each condensed with various aromatic compounds in the presence of anhydrous aluminum chloride, boron trifluoride, and sulfuric acid as the condensing agents.

Reactions with Phenols and Aluminum Chloride.—It was found that phenol condenses with compounds III, IV, V, and VI in the presence of anhydrous aluminum chloride to give, in each case, the same crystalline compound, m. p. 145°, which is a tetramethyltetrahydronaphthol derivative having the configuration (VII). A small amount of a crystalline non-phenolic compound, m. p. 240–241°, was also isolated, which appears to be a benzo-chromane derivative (VIII). The reactions involved may be formulated as shown



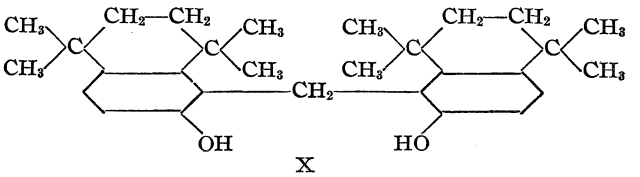
VII VIII

In accordance with known alkylation reactions of phenol with tertiary aliphatic alcohols, tertiary alkyl halides, or tertiary olefins to yield para tertiary alkylphenols, it is very probable that compounds III, IV and V first alkylate phenol in the para position to form mono-alkyl derivatives which immediately undergo either cyclo-dehydration, cyclo-dehydro-halogenation or cyclo-addition, respectively, to form the β-naphthol derivative (VII) which, in turn, may react with another molecule of the alkylating agent to form the chromane derivative (VIII). In the case of compound (VI), the furan ring must open up for cyclo-dehydration to occur. In no case was it possible to isolate the open chain mono-alkylation products, nor was there any evidence of the presence of a diphenolic alkane which could conceivably be formed.

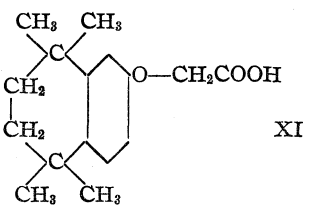
Since alkylation with these compounds proceeds at each end of a difunctionally reactive open chain to form a new cycle by attachment of a saturated divalent alkyl group to the aromatic nucleus, it is proposed that the term "*cycli-alkylation*" be applied to this form of condensation reaction.[2]

Upon oxidation with potassium permanganate, compound (VII) yielded 1,1,4,4-tetramethyladipic acid, (IX), thus proving that no rearrangement of the entering group had occurred during the condensation with aluminum chloride. Attempts to definitely establish the position of the hydroxyl group in (VII) through conversion to a hydroxyphthalic acid by oxidation of the hydroaromatic ring with fused potassium hydroxide were unsuccessful. However, like β-naphthol, compound (VII) condenses readily with formaldehyde in acid solution to yield a crystalline methylene dinaphthol derivative (X) melting at 232°.

With chloroacetic acid in sodium hydroxide solution, compound (VII) yields an oxyacetic acid derivative (XI) melting at 164–165°. The same compound is obtained by condensing (IV) in the presence of aluminum chloride with phenoxyacetic acid. Similarly, ethylation of (VII) gives an ethyl ether, b. p. 132° (5 mm.), identical with the



X



XI

(2) The term "*cyclo*-alkylation" already has been applied to reactions involving the introduction of a monovalent cyclo-aliphatic group, such as cyclohexyl, cyclopentyl, etc., into an aromatic nucleus, and is, of course, quite different from the above concept.

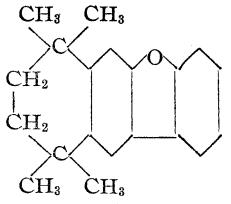
[a] This compound rapidly oxidizes in the air, which accounts for the low analysis.

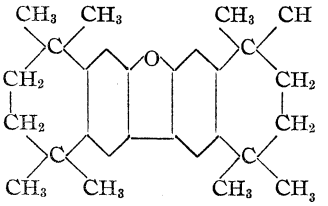
compound obtained by condensing (IV) with phenetole.

Most aromatic ethers, such as phenetole, guaiacol, ethyl *p*-cresyl ether, diphenyl ether, phenoxyacetic acid, and *m*-hydroxyphenoxyethoxy ethyl chloride, $HOC_6H_4OCH_2CH_2OCH_2CH_2Cl$, condense in the presence of aluminum chloride with compound (IV), so as to introduce one additional cycle in a manner analogous to that of phenol. The ether-phenol last mentioned gave two isomers, one, m. p. 107–108°, and the other, m. p. 71–75°.

Diphenylene oxide, however, gave both a monocycli-alkylated and a di-cycli-alkylated compound, represented, respectively, by the probable formulas (XII) and (XIII).



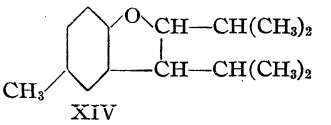
XII



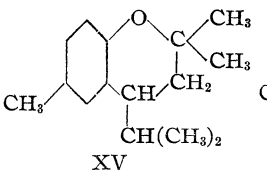
XIII

The following phenols were each condensed with (IV) in the presence of anhydrous aluminum chloride to produce the corresponding analogs of (VII), the properties of which are given in Table I.

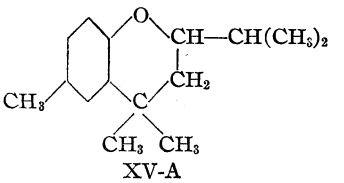
p-Cresol, however, reacted with 2,5-dichloro-2,5-dimethylhexane and aluminum chloride to give a mixture of two isomeric ether-like compounds having the empirical formula $C_{15}H_{22}O$, one of which is a liquid of faint minty odor, b. p. 107–108° (1 mm.), the other a crystalline compound, m. p. 100–101°. These compounds are believed to be coumaranes or chromanes which may be tentatively represented as (XIV), (XV) or (XV-A). A small quantity of a di-cycli-alkylated derivative, m. p. 193–195°, also was isolated.



XIV



XV

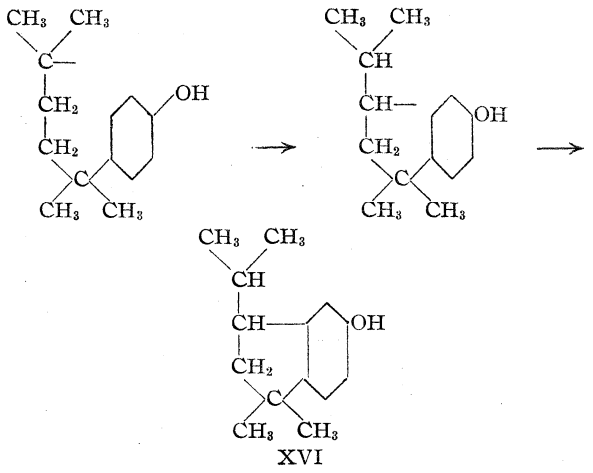


XV-A

Reactions with Sulfuric Acid or Boron Trifluoride.—In all of the above condensations, aluminum chloride was used as the condensing agent. When the aluminum chloride was replaced by sulfuric acid or boron trifluoride, phenol condensed with compounds (III), (V) or (VI) to give not the tetramethyltetrahydronaphthol (VII) but a phenolic compound isomeric therewith melting at 97–98°. This substance gave a crystalline oxyacetic acid derivative, m. p. 112–113°. It did not give a crystalline derivative with formaldehyde, nor did it yield any identifiable acid upon oxidation with permanganate. It is believed to be a hydroxy-indane[3] derivative (XVI) formed by rearrangement of the cycli-alkylating group, rather than an *alpha* isomer of compound (VII).

The formation of such a compound would result from the internal stabilization of an intermediate such as that shown below.

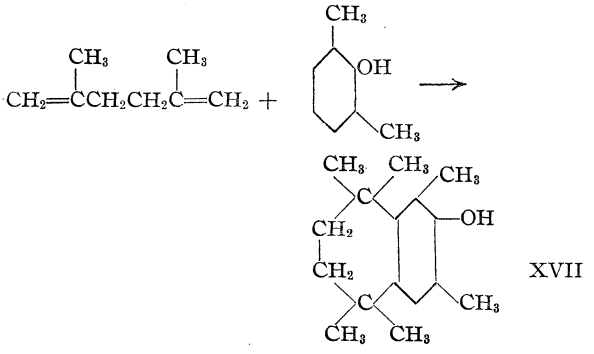
(3) Niederl, Niederl and Reznick, THIS JOURNAL, **58**, 657 (1936).



XVI

The net result of this stabilization is a shifting of a hydrogen atom from a secondary to a tertiary carbon atom[4] followed by ring closure on the depleted carbon atom.

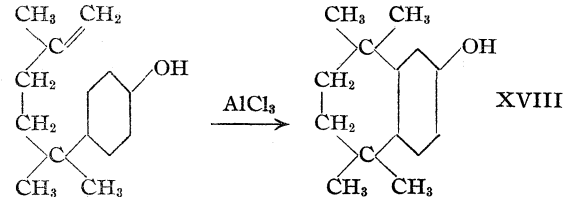
The possibility that compound (XVI) might be an *alpha* isomer of (VII) appears to be unlikely, since if the entering cycli-alkylene group did not rearrange, then a compound such as 2,6-dimethylphenol should condense to give only one compound (XVII), regardless of which catalyst was used.



XVII

However, 2,6-dimethylphenol behaves like phenol and gives two isomers, one with aluminum chloride (m. p. 165°) and the other with sulfuric acid (liquid, b. p. 156° (6 mm.)) as catalyst. Since two isomers are obtained, isomerism must occur in the entering group, unless the methyl groups of the phenol nucleus itself are assumed to wander. This appears unlikely under the conditions used.

That the second isomer in the case of phenol and of 2,6-dimethylphenol is not an open-chain para-substituted phenol, but a bicyclic structure, is shown by the fact that these compounds are unchanged by heating with aluminum chloride. If they had an open chain structure, aluminum chloride should cause cyclization to the higher melting isomer, as follows



XVIII

It has already been pointed out that in the alkylation of aromatic compounds with olefins, sulfuric acid shows a greater tendency to bring about rearrangements than does aluminum chloride.[5] The hydroxy-indane compound (XVI) was not obtained when aluminum chloride was employed as the condensing agent under a wide variety of conditions.

When boron trifluoride was used as a catalyst at 90° for condensing *p*-cresol and (V), the liquid isomer (XIV) previously mentioned, together with a crystalline di-cycli-alkylated product (XVIII) melting at 193–195°, was obtained. At 0°, however, the rearranging tendencies of boron trifluoride are greatly reduced, phenol, for example, reacting with (V) to give the tetramethyltetrahydronaphthol (VII), together with the hydroxyindane (XVI) and the benzochromane (VIII).

Reactions with Other Cycli-alkylating Compounds.—It was of interest to investigate the action of phenols in the presence of aluminum chloride upon 1,1,4,4-tetraphenylbutane-1,4-diol (made from benzophenone, calcium carbide and potassium hydroxide, followed by catalytic hydrogenation), since this compound might undergo internal ring closure before appreciable cycli-alkylation occurred. The reaction with phenol, or *o*-chlorophenol, led mainly to dehydration of the glycol with formation of 1,1,4,4-tetraphenyl-1,3-butadiene. With *o*-cresol, however, the reaction yielded, in addition to 1,1,4,4-tetraphenyl-1,3-butadiene, a definite compound, m. p. 330–332°, the analysis of which corresponds to the probable structure (XIX).

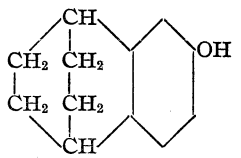
m-Thiocresol	$AlCl_3$	CH_3	IV	105–106	$C_{22}H_{30}S_2$	73.8	8.45	17.9	73.86	8.30	17.90
m-Thiocresol	$AlCl_3$	CH_3	V	105–106	$C_{22}H_{30}S_2$	73.8	8.45	17.9	...	..	...
p-Thiocresol	$AlCl_3$	CH_3	IV	128–129	$C_{22}H_{30}S_2$	73.8	8.45	17.9	73.80	8.48	17.85

An attempt was made to obtain a compound with an internal bridge such as shown in formula (XX) by condensing phenol in the presence of anhydrous aluminum chloride with 1,4-dichlorocyclohexane.

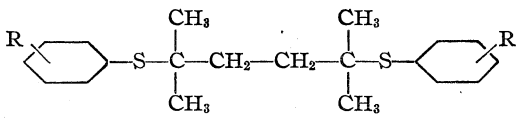


XX

A phenolic crystalline substance was obtained which melted at 124–127° and contained 0.35% chlorine. It appears probable that this is the desired compound (XX) in impure condition.

Finally, it should be pointed out that secondary aliphatic 1,4-glycols condense with phenol in the presence of 77% sulfuric acid to cycli-alkylate the aromatic nucleus. For example, 2,5-dihydroxyhexane and phenol gave a liquid phenolic product which appears to be a hydroxyindane derivative. 1,4-Dihydroxybutane, however, did not condense with phenol in the presence of 77% sulfuric acid to give tetrahydronaphthol.

Condensation with Thiophenols.—In contrast to phenol and its homologs, the thiophenols condense with compounds (IV) or (V) to form dithio ethers, instead of undergoing cycli-alkylation. The same dithio ethers are obtained, regardless of whether aluminum chloride or boron trifluoride is used as the catalyst. These dithio ethers are beautifully crystalline compounds of the general formula (XXI).

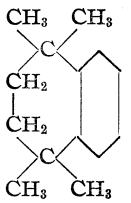


XXI

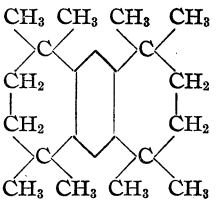
Their properties are given in Table II.

The unusual tendency for olefins and thiophenols to condense even in the absence of catalysts to form thiophenol ethers already has been pointed out by Ipatieff, Pines and Friedman,[6] and may thus account for the non-formation of cycli-alkylation products.

Cycli-alkylation of Aromatic Hydrocarbons.—The condensation of 2,5-dichloro-2,5-dimethylhexane with benzene in the presence of anhydrous aluminum chloride yields a liquid mono- and a crystalline di-cycli-alkylation product, (XXII) and (XXIII), respectively.



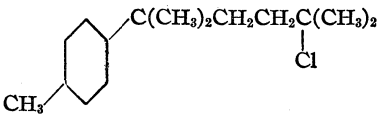
XXII

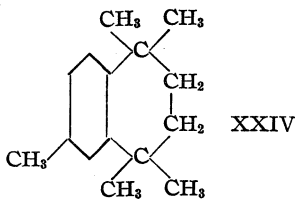


XXIII

It is assumed that the entering group in the case of hydrocarbons has the same configuration as in the case of phenols, since there was no difference in the method of preparation. The analytical data checked the formulas given.

When only catalytic quantities of aluminum chloride are used, nearly quantitative yields of compound (XXIII) are obtained. Larger amounts of aluminum chloride favor the formation of the mono-cycli-alkylation product. Toluene, however, gave only a liquid mono-cycli-alkylation product. It already has been pointed out[7] that in the cyclo-dehydration of *m*-$CH_3C_6H_4CH_2CH_2CH_2C(CH_3)_2OH$ ring closure occurs so that the entering group takes a position as far removed as possible from the substituent already present in the ring. It is highly probable that in the case of





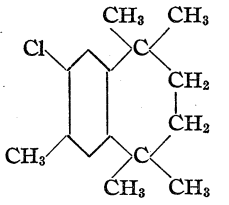
XXIV

(6) Ipatieff, Pines and Friedman, THIS JOURNAL, **60**, 2731 (1938).

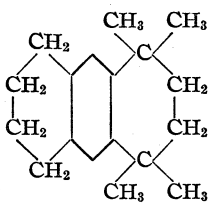
(7) Bogert, Davidson and Apfelbaum, *ibid.*, **56**, 959 (1934).

toluene the entering group is first introduced into the para position and immediately undergoes cyclo-dehydrohalogenation to give the mono-cycli-alkylation product (XXIV).

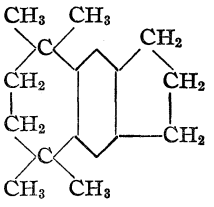
o-Chlorotoluene, tetralin and hydrindene each give crystalline mono-cycli-alkylation products with (IV) in the presence of aluminum chloride. These compounds may be represented by formulas (XXV), (XXVI) and (XXVII), respectively.



XXV

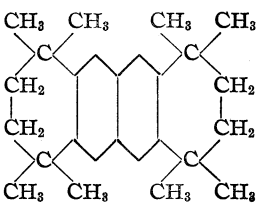


XXVI

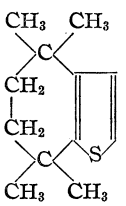


XXVII

Naphthalene, however, gave only a di-cycli-alkylated derivative. The high melting point of this compound (319–320°) and the tendency for naphthalene to alkylate first in the beta position, is indicative that the compound is probably a hydronaphthacene derivative (XXVIII).



XXVIII



XXIX

On the other hand, thiophene condenses with (IV) in the presence of stannic chloride as catalyst, to give only a mono-cycli-alkylation product (XXIX), which is believed to be a tetramethyltetrahydrobenzothiophene.

Although the exact formulas of these compounds have not as yet been proved, it is none the less certain that this simple method of introducing hydroaromatic rings into aromatic compounds may be of unusual interest at the present time, in connection with the synthesis of higher polynuclear structures in vitamin and hormone research.

Experimental

Preparation of Intermediates

2,5-Dimethyl-3-hexyn-2,5-diol.[1]—Technical calcium carbide (20–35 mesh, 80%) was powdered by grinding with benzene in a ball mill. Seven hundred grams of this suspension, containing 1.75 moles of calcium carbide, was diluted with 800 g. of benzene, and 196 g. (3.50 moles) of powdered potassium hydroxide was added. The mixture was stirred vigorously, while 305 g. of acetone (5.25 moles) was added during seven hours. The temperature was held at 21–24° by external cooling and by controlling the rate of addition of the acetone.

Stirring was continued for ninety-six hours at about 20°; then the pasty mass was hydrolyzed by slow addition of 750–800 g. of 37% hydrochloric acid, which left the mixture neutral or faintly acid. The aqueous layer was discarded and the organic layer was heated to boiling and filtered. The clear yellow filtrate deposited 183 g. of 2,5-dimethyl-3-hexyn-2,5-diol on cooling. This was filtered off and washed with a little benzene; then the combined filtrate and washings were distilled to recover the remaining glycol, b. p. 115–140° (30 mm.), 60 g. The total yield of white, crystalline product was 243 g. or 98%. The material was pure enough for preparative purposes. A sample recrystallized from petroleum ether melted at 94–95° and had the following analysis: calcd. for $C_8H_{14}O_2$: C, 67.55; H, 9.93. Found: C, 67.47; H, 10.09.

(III) 2,5-Dimethylhexane-2,5-diol.—This compound was prepared by hydrogenating 2,5-dimethyl-3-hexyn-2,5-diol dissolved in water or alcohol at 60–85° under 100 lb./square inch (7 atm.) pressure of hydrogen in the presence of Raney nickel. The product was obtained in excellent purity by simply evaporating the solvent *in vacuo*, m. p. (·$6H_2O$) 38°, m. p. (anhydrous) 88–89°; yield 95–99%.[8]

(IV) 2,5-Dichloro-2,5-dimethylhexane.—III was dissolved in concentrated hydrochloric acid and the solution was saturated with hydrogen chloride at room temperature. During this last operation, the product crystallized as small, white leaflets. This was filtered off, washed thoroughly with water, finally with a little methanol, then air-dried or dried *in vacuo*. The yield was quantitative. The dichloride melted at 63–64° and had a strong menthol-like odor.[9]

(V) 2,5-Dimethyl-1,5-hexadiene.—This compound was prepared by the usual Grignard technique from methallyl chloride and magnesium[10] in a molar ratio of 2 to 1, b. p. 114.5° (763 mm.).

(VI) 2,2,5,5-Tetramethyltetrahydrofuran.—This compound was obtained, together with a small amount of 2,5-dimethyl-2,4-hexadiene, by distilling (III) in the presence of 3% of aniline hydrobromide. It boiled at 112–114° (768 mm.).[9]

Cycli-alkylated Products

(VII) 5,5,8,8-Tetramethyl-5,6,7,8-tetrahydro-2-naphthol. (a) (From phenol and IV).—Twenty-nine grams of phenol, 55 g. of (IV) and 3 g. of anhydrous aluminum

(8) Dupont, *Ann. chim. phys.*, (8) **30**, 485 (1913); *C. A.*, **8**, 1579 (1914).

(9) Henry, *Compt. rend.*, **143**, 497 (1906).

(10) Schales, *Ber.*, **70**, 117 (1937).

chloride were suspended and partly dissolved in 30 g. of petroleum ether (b. p. 90–100°). This mixture was stirred at room temperature for about one hour or until the first vigorous evolution of hydrogen chloride had abated. The suspension was then heated on a steam-bath for two hours, 2 g. of aluminum chloride added, and heating continued for two hours more. The product was stirred with cold, dilute hydrochloric acid, and the light gray crystalline tetrahydronaphthol derivative which separated was filtered off (42 g.). Evaporation of the organic layer gave an additional 6 g.; total yield, 48 g., 80%.

The product was recrystallized to constant melting point from petroleum ether or benzene, and separated as long, thick, colorless prisms, m. p. 145.0–145.2° (uncorr.). It gave an emerald-green color with alcoholic ferric chloride, and had a hydroxyl number of 279.9; calculated value, 275. The oxyacetic acid derivative (XI) melted at 164–165°. *Anal.* Calcd. for $C_{16}H_{22}O_3$: C, 73.23; H, 8.46. Found: C, 73.08; H, 8.48.

The ethyl ether boiled at 132° (5 mm.). *Anal.* Calcd. for $C_{16}H_{24}O$: C, 82.70; H, 10.42. Found: C, 81.91; H, 10.06.

Attempted oxidation of this ether with dilute nitric acid gave a crystalline yellow mono-nitro derivative, m. p. 106–108°. *Anal.* Calcd. for $C_{16}H_{23}O_3N$: C, 69.3; H, 8.37; N, 5.05. Found: C, 68.90; H, 7.92; N, 5.70.

(X), m. p. 232°, was prepared by condensing the substituted naphthol with aqueous formaldehyde in the presence of hydrochloric acid. *Anal.* Calcd. for $C_{29}H_{40}O$: C, 82.79; H, 9.59. Found: C, 82.91; H, 9.30.

Oxidation of (VII) with neutral potassium permanganate gave a small quantity of 1,1,4,4-tetramethyladipic acid, m. p. 190–193° (uncorr.). *Anal.* Calcd. for $C_{10}H_{18}O_4$: C, 59.36; H, 8.97. Found: C, 58.73; H, 8.05.

From the combined recrystallization liquors of several preparations of (VII), a small amount of a disubstituted derivative, the benzochromane (VIII) was isolated. This crystallized from petroleum ether in large, oblique hexahedra, m. p. 240–241°. Its hydroxyl number was zero. *Anal.* Calcd. for $C_{22}H_{34}O$: C, 84.00; H, 10.90. Found: C, 84.42; H, 10.68.

(b) **(From Phenol and III).**—Twenty-one grams of (III), 54 g. of phenol, and 50 g. of anhydrous aluminum chloride were suspended in 200 cc. of petroleum naphtha and stirred at 85–90° for eight hours. The mixture was hydrolyzed with cold, dilute hydrochloric acid, then the organic layer was taken up in benzene, washed with 5% sodium carbonate solution, and distilled. The fraction boiling from 150–165° (3 mm.) weighed 21 g. and crystallized on standing. Recrystallization from petroleum ether gave the pure compound, m. p. 145°.

(c) **(From Phenol and VI).**—Thirteen grams of phenol, 12.8 g. of (VI) and 13 g. of aluminum chloride were suspended in 30 g. of petroleum ether (b. p. 90–100°) and cooled for five minutes. The mixture was then stirred at room temperature for five hours and refluxed for two hours. The mixture was then hydrolyzed and filtered, giving 16 g. of crude product. After one recrystallization from petroleum ether, it melted at 143–145°.

(d) **(From Phenol and V).**—Forty grams of phenol and 4 g. of anhydrous aluminum chloride were suspended in 20 g. of 90–100° petroleum ether and cooled to 0° or below. Forty-four grams of (V) was then added slowly with stirring, while the temperature was kept below 0°. The temperature was then allowed to rise slowly, the mixture was stirred at 25° for sixteen hours, and finally at 50° for one hour. The product was worked up as in (b). The fraction boiling from 128–150° (1 mm.) crystallized partly. On recrystallization from petroleum ether, the solid melted at 145°.

Mixed melting points of products (a), (b), (c) and (d) showed no depressions.

(XI) **5,5,8,8-Tetramethyl-5,6,7,8-tetrahydro-2-naphthoxyacetic Acid.**—Four grams of (IV), 3.5 g. of phenoxyacetic acid, and 3.5 g. of anhydrous aluminum chloride were suspended in 30 g. of ethylene dichloride and stirred for one hour at room temperature. The mixture next was refluxed for five hours and then hydrolyzed with dilute hydrochloric acid. The organic layer was separated and the solvent was evaporated by a stream of air, leaving 5.5 g. of greenish crystals. The solid was dissolved in petroleum ether and boiled with Norite for an hour. On cooling, the product separated in glistening white plates. A second crystallization from petroleum ether and two from 33% alcohol gave the pure compound, m. p. 164–165°. The melting point was not raised by the last recrystallization, and showed no depression when mixed with the oxyacetic acid derivative prepared by heating chloroacetic acid with an aqueous sodium hydroxide solution of (VII).

The properties of other substituted naphthols prepared in the manner described in (a) above are given in Table I.

***m*-Hydroxyphenoxyethoxyethyl Chloride.**—This compound was obtained as a crystalline solid, m. p. 46–47°, by condensing resorcinol in aqueous potassium carbonate solution with β,β'-dichlorodiethyl ether.[11]

Six grams of *m*-hydroxyphenoxyethoxyethyl chloride, 5 g. of (IV) and 0.5 g. of anhydrous aluminum chloride were mixed and heated at 65° for four hours. Hydrolysis with dilute hydrochloric acid gave a dough-like mass which crystallized partly on macerating with water. The organic material was dissolved in 90–100° petroleum ether, and cooled, giving crystals which melted at 102–103°. Concentration of the mother liquor gave a second compound, m. p. 69–71°. Both these compounds were recrystallized twice more and the first was decolorized with Norite. The final melting points were 107–108° and 71–75°, respectively.

(XVI) **1,1-Dimethyl-3-isopropyl-5-hydroxyindane.**—Twenty-five grams of phenol and 54.5 g. of (III) were melted together and the melt was dropped slowly into 96 g. of 77% sulfuric acid, which was well stirred and held at 10°. The temperature was allowed to rise slowly to 35°, the mixture was stirred at room temperature for twenty-two hours, and at 85–95° for one hour, then was poured into 200 ml. of cold water. The oil was extracted with benzene, washed with water and dilute sodium carbonate solution, and distilled. The fraction boiling from 145–170° (5 mm.) (b. p. 160–165° (5 mm.)), weighing 30 g., solidified on standing. After several recrystallizations from petroleum ether, the pure compound was obtained as tiny needles, m. p. 97–98°. *Anal.* Calcd. for $C_{14}H_{20}O$: C, 82.29; H, 9.87. Found: C, 82.60; H, 9.70.

(11) Bruson, U. S. Patent 2,098,204 (1937).

This compound, like (VII), gave an emerald-green color with alcoholic ferric chloride, and formed a sparingly soluble sodium salt when dissolved in warm 10% sodium hydroxide. It did not give a crystalline methylene derivative with formaldehyde, but treatment of the sodium salt with chloroacetic acid gave an oxyacetic acid derivative, m. p. 112–113°. It was unchanged by warming with aluminum chloride in petroleum ether.

2,6-Dimethylphenol was condensed similarly with 2,5-dimethylhexane-2,5-diol in the presence of 77% sulfuric acid to give a compound of b. p. 156° (6 mm.). *Anal.* Calcd. for $C_{16}H_{24}O$: C, 82.69; H, 10.42. Found: C, 82.66; H, 10.34.

(XIX) 5,5,8,8-Tetraphenyl-3-methyl-5,6,7,8-tetrahydro-2-naphthol.—Eight grams of 1,1,4,4-tetraphenylbutane-1,4-diol, 10 g. of *o*-cresol, and 8 g. of anhydrous aluminum chloride were suspended in 100 ml. of petroleum ether (b. p. 30–60°) and refluxed for fourteen hours. After hydrolysis with 200 ml. of dilute hydrochloric acid, the product was filtered out (6 g.). Two recrystallizations from toluene gave the pure compound, m. p. 330–332°, as glistening, white needles. *Anal.* Calcd. for $C_{35}H_{30}O$: C, 90.08; H, 6.48. Found: C, 89.81; H, 5.94.

Evaporation of the mother liquors gave a small amount of 1,1,4,4-tetraphenyl-1,3-butadiene. After several recrystallizations from toluene, it was obtained as pale violet needles, m. p. 195–196° (uncorr.). *Anal.* Calcd. for $C_{28}H_{22}$: C, 93.80; H, 6.19. Found: C, 93.67; H, 6.24.

(XX) 5,8-Endoethylene-5,6,7,8-tetrahydro-2-naphthol (?).—Fourteen grams of 1,4-dichlorocyclohexane (*cis* and *trans*), 8 g. of phenol, 1 g. of aluminum chloride, and 20 g. of petroleum ether were stirred for a half hour and refluxed for six hours; 9 g. of aluminum chloride was added and the mixture was stirred for four hours, then hydrolyzed with ice and hydrochloric acid. The organic layer was washed and distilled and the fraction boiling from 110–180° (3 mm.) was saved. Two recrystallizations from di-isobutylene gave white needles, m. p. 124–127°. *Anal.* Calcd. for $C_{12}H_{14}O$: C, 82.70; H, 8.10. Found: C, 81.00; H, 8.77; Cl, 0.35%.

2,5-Dimethylhexane-2,5-bis-(*p*-tolyl sulfide).—Nine g. of (IV), 6.2 g. of *p*-thiocresol, and 1.0 g. of anhydrous aluminum chloride were suspended and partly dissolved in 30 g. of petroleum ether (b. p. 90–100°), and refluxed for four hours. The product was hydrolyzed with dilute hydrochloric acid and the organic layer was cooled and evaporated to give 4 g. of the crystalline dithio ether. This was recrystallized to constant melting point from petroleum ether, giving long, white needles, m. p. 128–129°. Data on this compound and other dithio ethers prepared in the same manner are given in Table II. The compounds were insoluble in hot 5% sodium hydroxide.

(XXII) 1,1,4,4-Tetramethyl-1,2,3,4-tetrahydronaphthalene.—Thirty-six grams of (IV) was dissolved in 78 g. of benzene and stirred at 30° or lower, while 16 g. of anhydrous aluminum chloride was added in small portions. The thick suspension was then stirred at room temperature for twenty-one hours, refluxed for two hours, and poured into ice and dilute hydrochloric acid. The organic layer was washed with water and dilute sodium carbonate solution and distilled. A 61% yield (22.5 g.) of crude (XXII) was obtained, boiling from 95–125° (4 mm.). The pure compound was a water-white oil and had the following properties: b. p. 82–84° (3 mm.); 248° (760 mm.); $n^{27}D$ 1.5278; d^{27}_4 0.9482; MR_D calcd., 61.06; found, 61.09.

(XXIII) 1,1,4,4,5,5,8,8-Octamethyl-1,2,3,4,5,6,7,8-octahydroanthracene.—Thirty-six grams of (IV), 78 g. of benzene, and 1 g. of anhydrous aluminum chloride were stirred and refluxed for four hours. The product was hydrolyzed without cooling by adding warm, dilute hydrochloric acid; then the hot organic layer was separated and chilled. The substituted anthracene separated in large, white prisms which were filtered off and the filtrate was evaporated to recover the remainder (total, 26 g.). It was purified by recrystallization to constant melting point from benzene or carbon tetrachloride–methanol mixture (2:1) and melted at 220–222° (uncorr.). In the evaporation mentioned above, a small amount of oil remained, which contained 3.5 g. of the substituted naphthalene (XXII).

When treated with nitric and sulfuric acids (2:1), this compound formed a nitro derivative, m. p. 259–261°.

(XXVI) 1,1,4,4-Tetramethyl-1,2,3,4,5,6,7,8-octahydroanthracene.—Thirteen grams of tetralin, 18 g. of (IV) and 1 g. of anhydrous aluminum chloride were suspended in 30 g. of petroleum ether (b. p. 90–100°) and refluxed for five hours. The product was hydrolyzed with ice-cold, dilute hydrochloric acid, filtered, then the organic layer was taken up in benzene, washed and distilled. Two fractionations gave 7 g. of yellow sirup boiling from 150–160° (4 mm.) which crystallized on standing for four days. The solid was recrystallized four times from methanol containing a few drops of ethyl acetate, m. p. 90–91°.

(XXVII) 5,5,8,8-Tetramethyl-5,6,7,8-tetrahydro-β-naphthindane.—Fifteen grams of hydrindene, 18 g. of (IV) and 1 g. of aluminum chloride were suspended in 30 g. of petroleum ether and stirred at room temperature for two hours. The mixture was then refluxed for four hours and worked up as in the previous experiment. The fraction boiling from 110–150° (3 mm.) weighed 3 g. and crystallized in the receiver. The product was recrystallized four times from a mixture of methanol and ethyl acetate and finally separated as large square plates, m. p. 93–94°.

(XXVIII) 1,1,4,4,7,7,10,10-Octamethyl-1,2,3,4,7,8,9,10-octahydronaphthacene.—Thirty-eight grams of naphthalene, 55 g. of (IV) and 5 g. of aluminum chloride were suspended in 100 g. of petroleum ether (b. p. 90–100°) and refluxed for four hours. The product was hydrolyzed with cold, dilute hydrochloric acid and filtered. The crystalline solid was then washed with four 50-cc. portions of cold benzene to remove unchanged naphthalene, and air-dried; yield, 42 g., 80.5%. Two recrystallizations from toluene gave the pure product in the form of beautiful white needles, m. p. 319–320°.

Other hydrocarbons prepared in this way are described in Table III.

(XXIX) Thiophene and (IV).—Nine grams of (IV) and 8.4 g. of thiophene were dissolved in 30 g. of petroleum ether and 2.0 g. of anhydrous stannic chloride was slowly dropped in. The solution was stirred for one hour at room temperature, refluxed for three hours, then the product hydrolyzed, washed, filtered from a trace of black impurity, and distilled. The fraction boiling from 90–130° (6 mm.) was saved and redistilled. The pure compound had a boiling point of 94° (6 mm.). *Anal.* Calcd. for

***p*-Cresol and IV.**—Thirty-three grams of *p*-cresol, 55 g. of (IV) and 3 g. of aluminum chloride were suspended and partly dissolved in 50 g. of petroleum ether. The mixture was then stirred for a half hour at room temperature and at 85–90° for two hours. Two grams of aluminum chloride was added and heating and stirring was continued for two hours more. The product was hydrolyzed, washed and distilled. The fraction boiling from 91–115° (2 mm.) (26.5 g.) gave the liquid isomer (A) as a water-white oil, having a pleasant, minty odor. It had the following properties: b. p. 107–108° (1 mm.); $n^{25}D$ 1.5137; d^{25}_4 0.953.

The fraction boiling from 115–140° (2 mm.) (6 g.) crystallized partly when diluted with petroleum ether and chilled. Recrystallization to constant melting point gave small prisms, m. p. 100–101° (B).

The above experiment was repeated, using (V) as a cycli-alkylating agent and boron trifluoride as a catalyst. Small amounts of the liquid isomer (A) and a disubstituted derivative (C) melting at 193–195° were obtained. The analytical data are as follows: calcd. for $C_{15}H_{22}O$ (XIV and XV): C, 82.50; H, 10.16. Found (A): C, 83.02; H, 10.09. Found (B): C, 82.81; H, 9.92. Diphenylene Oxide and IV.—Nine grams of (IV), 8.5 g. of diphenylene oxide, and 1 g. of anhydrous aluminum chloride were suspended in 30 g. of petroleum ether (b. p. 30–60°) and stirred for eight and one-half hours at room temperature. The mixture was then refluxed for one hour, hydrolyzed, washed and distilled. The fraction boiling from 170–240° (4 mm.) (5.5 g.) was a thick yellow sirup (XII) and was analyzed. Calcd. for $C_{20}H_{22}O$: C, 86.27; H, 7.97. Found: C, 86.91; H, 8.38. From this it appeared the compound (XII) was contained in this fraction.

The residue of the above distillation was recrystallized three times from an ethyl acetate–methanol mixture as colorless crystals, m. p. 201–202°. *Anal.* (XIII) Calculated for $C_{28}H_{36}O$: C, 86.53; H, 9.34. Found: C, 87.00; H, 9.50.

Acknowledgment.—We are indebted to Dr. C. W. Nash of this Company for microdeterminations of carbon, hydrogen, sulfur and chlorine.

Summary

1. Di-tertiary 1,4-glycols condense in the presence of aluminum chloride with aromatic hydrocarbons, phenols, or phenol ethers, so as to introduce a new hydroaromatic cycle into the aromatic nucleus. The use of boron trifluoride or of 77% sulfuric acid as condensing agent in place of aluminum chloride, gives isomers of the above compounds. Phenols which are blocked in the para-position give chromanes or coumaranes.

2. Similar condensation products are obtained by using di-tertiary 1,4-dichlorides, 1,5-diolefins, and 2,2,5,5-tetraalkyltetrahydrofurans in place of the 1,4-glycols.

3. Thiophenols behave differently from phenols and give diaryl dithio ethers. Thiophene takes up a hydroaromatic cycle.

4. Certain aromatics, notably benzene, naphthalene and diphenylene oxide, readily take up two hydroaromatic cycles.

5. The term "cycli-alkylation" has been proposed for these reactions.

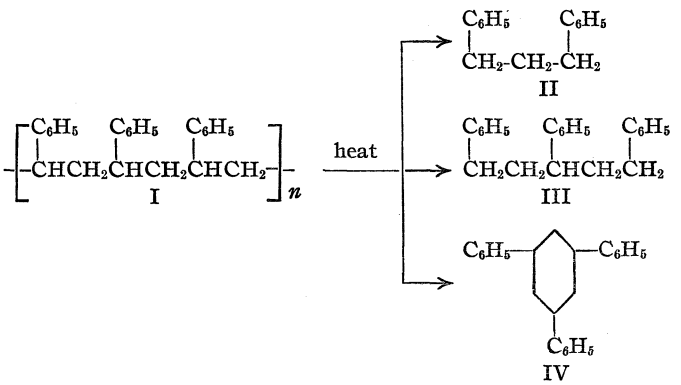
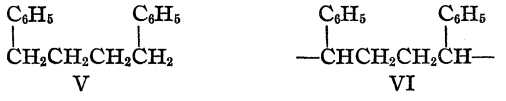
The Structure of Vinyl Polymers. VIII.[1] Polystyrene and Some of its Derivatives

BY C. S. MARVEL AND NEIL S. MOON

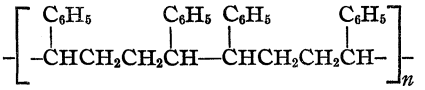
The destructive distillation of polystyrene (I) has been shown by Staudinger and Steinhofer[2] to produce a rather complex mixture of hydrocarbons from which, among other things, 1,3-diphenylpropane (II), 1,3,5-triphenylpentane (III) and 1,3,5-triphenylbenzene (IV) have been isolated and identified. These products furnish excellent evidence that the aryl groups are on alternate carbon atoms in the polymer chain (I).[3]



Midgley, Henne and Leicester[4] found that treatment of styrene with sodium and alcohol yielded 1,4-diphenylbutane (V) and a polymer of styrene which appeared to be identical with that obtained by the polymerization of styrene in the presence of peroxides.



The formation of 1,4-diphenylbutane in this reaction was interpreted as evidence that the biradical (VI) was an intermediate in the polymerization of styrene and that polystyrene might have the "head to head, tail to tail" type of structure (VII).



In the present work we have prepared a number of derivatives of styrene containing various functional groups both in the ring and in the side chain with the aim of producing polymers whose chemical reactions would be useful in determining the relative positions of the aryl groups in the polymer chain. Ortho-, meta- and para-bromostyrenes were synthesized and polymerized. Meta- and para-bromostyrenes have been reported previously[5] but the ortho-compound apparently is new. It was prepared readily by dehydration of *o*-bromophenylmethylcarbinol. All three of these bromostyrenes polymerized more readily than styrene itself to give hard, brittle, colorless, transparent products which gradually assumed an amber color on aging for a few months.

A poly-*o*-bromostyrene which has the 1,2-arrangement (VIII) of the aryl groups along the polymer chain should react with metals to give a dihydrophenanthrene (X) type of polymer in a manner similar to

(2) Staudinger and Steinhofer, *Ann.*, **517**, 35 (1935).

(3) Allen (Gibson Island Conference on Synthetic Resins, July 12, 1939) reported the identification of toluene and isopropenylbenzene as products of the pyrolysis of polystyrene. The formation of isopropenylbenzene is most readily explained on the basis of structure I for this polymer.

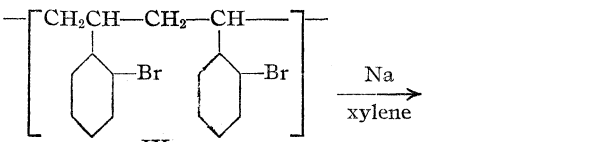
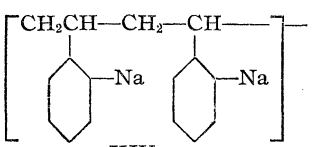
the conversion of 1,2-di-(*o*-bromophenyl)-ethane (XI) to dihydrophenanthrene (XII). Kenner and Wilson[6] have shown that at least a 12% yield of cyclic product results from the action of sodium on 1,2-di-(*o*-bromophenyl)-ethane although debromination to 1,2-diphenylethane (XIII) accounts for most of the product.

When poly-*o*-bromostyrene in dioxane solution was treated with zinc, very little halogen was removed. Neither did copper remove halogen from a nitrobenzene solution of the polymer. Sodium did remove halogen from the hot solution of the polymer in benzene or toluene and when xylene was used as a solvent, the removal of halogen became essentially quantitative. The viscosity of the solution did not change appreciably during this treatment, showing that the polymeric material was not coupling to give a higher molecular weight product and there was no separation from solution as should occur if cross linking of chains had occurred. These facts led to the belief that ring closure must be taking place. However, it was impossible to obtain any evidence of a cyclization reaction. Oxidation of the debrominated polymer gave neither diphenic acid nor a phenanthraquinone derivative. Dehydrogenation and cracking of the polymer over hot selenium gave no phenanthrene derivatives.

The reaction of poly-*p*-bromostyrene in xylene solution with sodium was next tried. This polymer was as readily debrominated by the treatment as the ortho compound and there was no evidence of cross linking in the reaction. Obviously, then, sodium had reacted with these two polybromostyrenes to give polymeric organometallic materials (XIV) which were hydrolyzed by water during the subsequent steps in the working up of the reaction mixtures. This was confirmed by treating the reaction mixture of poly-*o*-bromostyrene and sodium in xylene with dry carbon dioxide. Some alkali soluble material was



IX



XIV

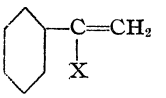
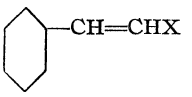
produced showing that carbonation had taken place. It seems probable that the *o*-bromophenyl groups are on alternate carbon atoms in the chain (IX) for this formation of the sodium derivative to proceed so smoothly. If the aryl groups are on adjacent carbon atoms (VIII) in the polymer chains some evidence that a Wurtz–Fittig reaction had occurred should have been found.

α-Chlorostyrene (XV, X = Cl) was prepared by the method of Dufraisse and Viel[7] and attempts



XV



XVI

were made to polymerize it with heat, ultraviolet light, benzoyl peroxide, ascaridole, stannic chloride and the boron fluoride complex with ethyl acetate. No polymer was obtained although the boron fluoride catalyst did convert α-chlorostyrene into 1,3,5-triphenylbenzene (IV).

α-Methoxystyrene[8] (XV, X = OCH_3), β-bromostyrene (XVI, X = Br), α-acetoxystyrene (XV, X = $OCOCH_3$) and β-acetoxystyrene[9] (XVI, X = $OCOCH_3$) failed to give polymers with peroxide catalysts or under the influence of ultraviolet light. β-Nitrostyrene (XVI, X = NO_2) was polymerized by the method of Vorländer and Herrmann[10] but the polymer was too insoluble to permit the attack of any reagents.

Experimental

o-Bromophenylmethylcarbinol.—A suspension of methylmagnesium chloride was prepared by passing commercial methyl chloride, dried by passing through a calcium chloride tower, into ice cold anhydrous ether covering 100 g. of magnesium turnings. When the ether was saturated with methyl chloride the cooling bath was removed and the temperature of the mixture allowed to rise to room temperature. Usually the reaction between methyl chloride and the magnesium started readily when this was done. Occasionally it was necessary to repeat the cooling and saturating with methyl chloride. Once the reaction had started another 500 cc. of dry ether was added and methyl chloride was slowly passed into the mixture until the magnesium had dissolved. A grayish precipitate separated during the reaction. If the loss of ether became too great more was added to the reaction mixture.

When the formation of the Grignard reagent was complete, a solution of 600 g. of *o*-bromobenzaldehyde in 1200 cc. of dry ether was added slowly to the cooled solution. After all of the aldehyde had been added, the reaction mixture was warmed slowly and finally refluxed gently for

about an hour. Usually the addition product separated from solution at this stage but if it did not appear the reaction mixture was allowed to stand until it did separate. The reaction mixture was then worked up in the usual manner. The yield was 568 g. (87%) of a colorless, viscous liquid boiling at 91–98° (2 mm.). A sample was redistilled for analysis. It boiled at 108.5° (6.5 mm.); d^{27}_{27} 1.470; $n^{20}D$ 1.5702; $n^{25}D$ 1.5678.

Anal. Calcd. for C_8H_9OBr: C, 47.76; H, 4.51. Found: C, 47.39, 47.99; H, 4.40, 4.51.

When methylmagnesium iodide was used in place of methylmagnesium chloride, the product was red and it seemed impossible to remove iodine completely even by washing with sodium bisulfite, as the red color always reappeared when the product was heated.

o-Bromostyrene.—In a 50-cc. Claisen flask were placed 30 g. of *o*-bromophenylmethylcarbinol, 5 g. of freshly fused and powdered potassium acid sulfate and 0.3 g. of hydroquinone. The mixture was heated under a pressure of 21–30 mm. in an oil-bath at 155–160°. To the distillate was added a little hydroquinone and ether, the water was separated, the ether dried and the mixture distilled. The yield was 9 g. (33%) of product of b. p. 60–65° (3 mm.); 65° (4 mm.); d^{27}_{27} 1.468; $n^{25}D$ 1.5893.

Anal. Calcd. for C_8H_7Br: C, 52.47; H, 3.86. Found: C, 52.75; H, 4.22.

The product was slightly lachrymatory and polymerized on standing even in the presence of hydroquinone.

o-Bromo-α-chloroethylbenzene.—This was prepared by adding dropwise 201 g. of *o*-bromophenylmethylcarbinol to 292 g. of thionyl chloride in the cold. After the evolution of hydrogen chloride and sulfur dioxide had slowed down, the reaction mixture was warmed to 50° for about an hour. Distillation gave 183 g. (83%) of a product boiling at 63–65° (2 mm.). A sample purified by redistillation had the following constants: d^{20}_{20} 1.499; $n^{20}D$ 1.5693.

Anal. Calcd. for C_8H_8BrCl: C, 43.77; H, 3.67. Found: C, 43.70; H, 3.77.

Attempts to remove hydrogen chloride from this product by treatment with quinoline were ineffective.

Poly-o-bromostyrene.—*o*-Bromostyrene containing 1–2% of hydroquinone polymerized slowly and a solid product was obtained in a matter of months. Heating alone or especially in the presence of peroxides such as benzoyl peroxide greatly accelerated the polymerization. Freshly distilled *o*-bromostyrene was polymerized in three to five minutes at 175°, whereas at 160° several hours were required to produce the same result.

Most of the polymer used in these experiments was produced by adding 0.2% of benzoyl peroxide to *o*-bromostyrene and heating the mixture to about 140–150° in an oil-bath. The reaction was exothermic and once started proceeded rapidly. It was complete in a few minutes. The end-point could be detected by noting the cessation of the evolution of bubbles. The product as first formed was a hard, brittle, colorless transparent mass. Even if the *o*-bromostyrene used was yellow, the polymer was colorless. On standing, however, an amber color developed in the polymer in a few months.

The polymer was soluble in benzene, toluene, xylene, dioxane and nitrobenzene. It was insoluble in ether, ethyl and methyl alcohols, ethyl acetate, glacial acetic acid and acetone. By dissolving the polymer in benzene or dioxane and pouring this solution into a large excess of ether or methyl alcohol, a colorless amorphous powder was obtained.

A sample of polymer prepared at 140–150° in the presence of benzoyl peroxide had an approximate molecular weight of 24,000 as indicated by viscosity measurements[11]; $n^{25}D$ 1.6333 ± 0.003.[12]

Anal. Calcd. for $(C_8H_7Br)_x$: Br, 43.67. Found: Br, 43.35, 43.73.

Poly-m- and p-Bromostyrenes.—These products were prepared in the same general manner and their properties were essentially the same as recorded for poly-*o*-bromostyrene. Dr. H. R. Moulton of the American Optical Company has kindly determined the refractive indices of these two polymers for us. The meta isomer has a refractive index of 1.63 and the para isomer 1.62.

Reaction of Poly-o-bromostyrene with Metals.—A solution of 1 g. of poly-*o*-bromostyrene in 500 cc. of dioxane was refluxed for seven days with 5 g. of activated zinc.[13] The solution took on an orange-yellow color. About half of the dioxane was removed by distillation and the remaining solution was filtered to remove the zinc. The polymer was precipitated as a buff powder by pouring this solution into water. Analysis of the polymer showed 35.54 and 35.37% bromine remaining.

An attempt to carry out an Ullmann reaction by treating 1 g. of poly-*o*-bromostyrene in 500 cc. of nitrobenzene with 3 g. of copper bronze produced a black, tarry intractable material.

Boiling a solution of 5 g. of poly-*o*-bromostyrene in 2 liters of dry benzene with an excess of clean sodium shavings for fifty hours gave a polymer which contained 37.59–36.99% bromine. After three days of treatment in boiling toluene a polymer was formed containing 34.62–35.54% bromine. Using boiling xylene with sodium, almost complete removal of bromine resulted in 300 to 400 hours. The details of such an experiment follow.

A solution of 2 g. of poly-*o*-bromostyrene in 1 liter of dry technical xylene (which had been purified by refluxing with sodium followed by distillation) was refluxed in an all-glass apparatus with about 7 g. of freshly sliced, clean sodium. The reaction mixture turned yellow in about an hour and gradually assumed an orange color and became somewhat opaque. After about three hundred hours of boiling, part of the xylene was distilled and water was added carefully to destroy the excess sodium. The mixture was then steam distilled to remove the remaining xylene. The polymer which remained was a white or gray, porous, brittle mass. It was dissolved in dioxane and precipitated by pouring the solution into water. The polymer was analyzed for bromine and all of the solutions were saved and analyzed for bromide ion. Many experiments were performed before the time necessary for the removal of bromine was found. In three hundred

hours 97% removal of bromine was obtained and in a four hundred and fifty hour run 100% of the bromine was removed.

Carbonation of the Reaction Product of Sodium and Poly-*o*-bromostyrene.—A solution of 15 g. of poly-*o*-bromostyrene in 1 liter of xylene was heated under a reflux condenser for twenty days with 50 g. of sodium. Solid carbon dioxide was then introduced into the reaction mixture. The excess sodium was removed mechanically, the xylene by steam distillation and the insoluble polymer by filtration. The water layer (about 1.5 liters) on acidification gave about 0.23 g. of acidic material. The water layer was then made alkaline, concentrated to about 300 cc. and again acidified. About 1.5 g. of acidic material was obtained. This fraction was a very complex mixture and melted over the range of 90–225°. There was some crystalline material which must have been formed by degradation of the polymer. The neutral equivalent was 76–78.

Anal. Found: C, 69.54; H, 5.87; Br, none.

No definite products were isolated but the experiment did establish the fact that an alkali metal derivative was formed by the reaction of sodium and the poly-*o*-bromostyrene.

Attempts to Oxidize the Debrominated Polymer.—The debrominated polymer was treated with hot chromic acid in glacial acetic acid, with hot nitric acid and with potassium dichromate in dilute sulfuric acid but none of these procedures gave products which could be characterized.

Heating 2 g. of the debrominated polymer with 6 g. of selenium to 400° for twenty hours gave no crystalline products but only gummy solids and brownish powders.

Action of Sodium on Poly-*p*-bromostyrene.—A reaction mixture containing 2.5 g. of poly-*p*-bromostyrene, 1 liter of xylene and 4.7 g. of sodium was heated under a reflux condenser for about five hundred and fifty hours as described for the ortho isomer. Analysis of the water solution showed that 99% of the bromine was removed. The polymer remaining was soluble in xylene and dioxane.

α-Chlorostyrene and Boron Trifluoride–Ethyl Acetate Complex.—A reaction mixture containing 2 cc. of α-chlorostyrene, 3 drops of boron trifluoride–ethyl acetate complex[14] and 2 cc. of ethyl alcohol was sealed and set aside. After two years a mass of long plate-like crystals had separated. The tube was opened and these crystals were recrystallized from absolute alcohol. They melted at 171.5–173.5° whereas the 1,3,5-triphenylbenzene is reported to melt at 172°.[15]

Anal. Calcd. for $C_{24}H_{18}$: C, 94.07; H, 5.93. Found: C, 93.90; H, 6.01.

Other attempts to polymerize α-chlorostyrene with ultraviolet light, benzoyl peroxide, ascaridole, anhydrous stannic chloride and large amounts of the boron trifluoride–ethyl acetate complex[14] gave colored products but no definite polymeric compounds. In one experiment α-chlorostyrene was heated to 130–140° with ascaridole and an impure 1,3,5-triphenylbenzene was obtained.

α-Acetoxystyrene.—Several attempts to add acetic acid to phenylacetylene under various conditions failed to give this product. It was then prepared from styrene bromohydrin obtained by the method of Read and Reid.[16] To 181 g. of styrene bromohydrin was added in small portions 141 g. of acetyl chloride.[17] Heat was evolved during the addition. The reaction mixture was refluxed for ten hours after the addition was complete and then allowed to stand overnight. The excess acetyl chloride was destroyed by pouring the mixture on cracked ice. The organic layer was collected in ether, separated, washed with sodium bicarbonate solution, dried and distilled. The yield was 199.5 g. (91%) of a product of b. p. 105–107° (3 mm.); d^{20}_{20} 1.386; $n^{20}D$ 1.5380.

Anal. Calcd. for $C_{10}H_{11}O_2Br$: C, 49.40; H, 4.56. Found: C, 49.59; H, 4.63.

A mixture of 48.6 g. of α-acetoxy-β-bromoethylbenzene, 51.5 g. of quinoline and 0.2 g. of hydroquinone was heated to 145–155° for one hour and then distilled under reduced pressure. The yield of product boiling at 80–90° (2 mm.) was 49 g. The quinoline was removed by washing with dilute hydrochloric acid and the product was then fractionated several times through a modified Widmer column. Some decomposition occurred during distillation and analysis of the product showed it to be slightly impure. The yield of product was about 11 g. (34%) boiling at 87.5–89.5° (3.5 mm.); 57.5–58° (0.5 mm.); d^{20}_{20} 1.074; $n^{20}D$ 1.5533.

Anal. Calcd. for $C_{10}H_{10}O_2$: C, 74.04; H, 6.21. Found: C, 72.84; H, 6.41.

The dibromide was prepared by treating a sample of the above product with bromine in dry carbon tetrachloride. After recrystallization from 95% ethyl alcohol the dibromide melted at 93.5–94.5°.

Anal. Calcd. for $C_{10}H_{10}O_2Br_2$: C, 37.20; H, 3.13. Found: C, 37.23; H, 3.20.

Attempts to Polymerize Various α- and β-Substituted Styrenes.—A variety of catalysts under different conditions were used with α- and β-acetoxystyrene, β-bromostyrene and α-methoxystyrene but no true polymers were obtained. Details of the experiments are therefore not recorded.

Summary

1. Poly-*o*-bromostyrene prepared by peroxide polymerization reacted with sodium in boiling xylene to give replacement of bromine by sodium and no evidence for a Wurtz–Fittig reaction was obtained. This indicates a 1,3-structure for the polymer.

2. Poly-*p*-bromostyrene also reacted with sodium in xylene to give complete removal of halogen without cross linking the polymer chains.

3. α-Chlorostyrene under the influence of boron trifluoride was slowly converted to 1,3,5-triphenylbenzene.

4. α-Acetoxystyrene has been prepared from

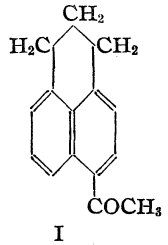
Further Observations on the Use of Hydrogen Fluoride in Acylations and Cyclizations

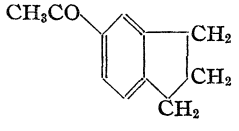
BY LOUIS F. FIESER AND E. B. HERSHBERG[1]

In a first paper[2] on this subject it was reported that acenaphthene can be acylated smoothly by reaction with various free acids, acid anhydrides and acid chlorides in the presence of liquid anhydrous hydrogen fluoride at room temperature. Under the same conditions, entirely negative results were obtained with benzene, naphthalene, phenanthrene, anthracene and 1,2-benzanthracene. These observations have now been extended, partly in the hope of casting further light on the remarkable specificity of acenaphthene in the reaction, and partly to see if any additional examples could be found of unusual orientations of practical synthetic value, as encountered in the acetylation of the above hydrocarbon by the hydrogen fluoride method.[2] We may state at the outset that no such applications have been discovered and that the theoretical interpretation still seems obscure.

Two other aromatic hydrocarbons which, like acenaphthene, contain an alicyclic side ring, have been found amenable to acylation under the above conditions. Perinaphthane reacted fairly readily with either acetic acid or acetic anhydride to give as the chief product a substance identified as the 4-aceto derivative I by oxidative degradation.



I



II

The orientation is thus the same as in the benzoylation of the hydrocarbon by the Friedel and Crafts (Perrier) method.[3] Satisfactory condensation also occurred in the presence of hydrogen fluoride between hydrindene and either acetic acid or benzoyl chloride, and again substitution took the normal course and gave the 5-derivatives, such as II. The direct substitution of an α-naphthoyl group in the 4-position of hydrindene would give a known ketone[4] which is easily convertible into cholanthrene, but the total ketonic reaction product obtained with α-naphthoic acid and hydrogen fluoride yielded no hydrocarbon on pyrolysis and afforded on purification a crystalline substance which evidently is the 5-derivative.

It was next found that certain of the hydrocarbons which do not react at room temperature and atmospheric pressure can be acylated by conducting the condensation in an iron pressure vessel under reflux at temperatures up to that of the steam-bath. The acetylation of acenaphthene under these conditions was investigated for comparison and because of the usefulness in syntheses of the 1-aceto compound made available by this reaction. The condensation proceeded smoothly and 1-acetoacenaphthene was obtained in even better yield (37%) than at room temperature. The ketone was converted through the acid to the new 1-acenaphthaldehyde by the Rosenmund reaction. Using the pressure apparatus naphthalene and acetic anhydride gave a mixture of the α- and β-aceto compounds somewhat richer in the β-isomer than that obtained by the Friedel and Crafts method in carbon bisulfide solution[5]; the hydrocarbon did not react with succinic anhydride at moderate temperatures and tar formation occurred on attempting to push the reaction. At 50–55° phenanthrene and acetic anhydride gave a mixture from which the 2- and 3-acetyl compounds were isolated, as with aluminum chloride.[6] A condensation of the hydrocarbon with crotonic acid was also effected giving an oil which appears to be a mixture of isomeric methylketo-

cyclopentenophenanthrenes. The special susceptibility shown by acenaphthene, perinaphthane and hydrindene in the acylation reaction, while still appearing rather remarkable, is thus seen to be a matter of degree rather than of kind.

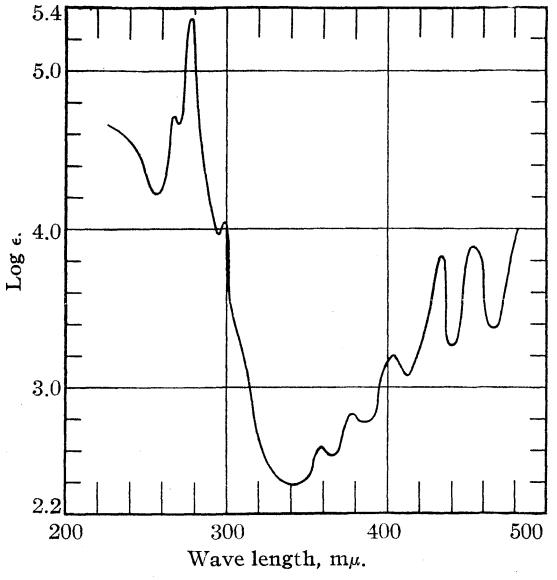

Fig. 1.—1′,10-Dimethyl-2,3-benzanthracene in absolute alcohol. Principal maxima in mμ (log ε values in parentheses): 278 (5.33), 299 (4.03), 359 (2.61), 378 (2.82), 403 (3.20), 433 (3.82), 454 (3.90).

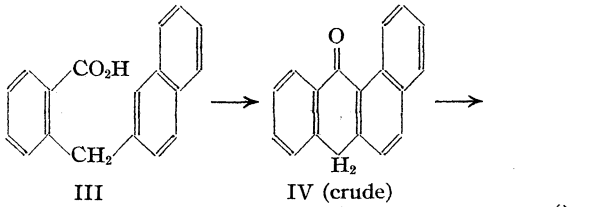
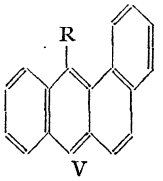
The hydrogen fluoride method[2] of cyclizing aromatic compounds with acidic side chains has found many useful applications.[7] In view of the success in the preparation of 1,2-benz-10-anthrones by this method in a condition suitable for the introduction of 10-alkyl substituents by the Grignard reaction,[2] we have investigated this possible route to 9-alkyl-1,2-benzanthracenes, with particular reference to the unknown 1′,9-dimethyl compound. *o*-(β-Naphthylmethyl)-benzoic acid (III) was found to undergo rapid cyclization in hydrogen fluoride at room temperature, but the anthrone IV proved to be a very sensitive substance and was not isolated as such. By pumping the mixture to dryness decomposition and isomerization attendant upon the manipulation of the material was minimized, and on treating the crude residue with Grignard reagent it was possible to obtain substituted hydrocarbons in significant if low yields. The known 9-methyl-1,2-benzanthracene[8] was isolated in 14% yield, and the 9-allyl compound was obtained in 35% yield.

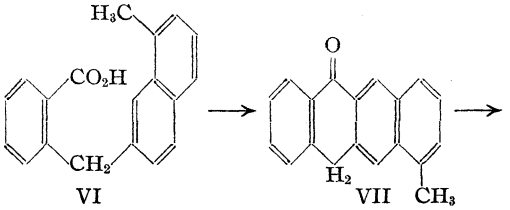


III IV (crude)

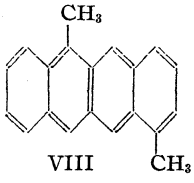


V

These results seemed sufficiently promising to warrant a further attempt to synthesize 1′,9-dimethyl-1,2-benzanthracene from the previously described intermediate VI.[9] It had been established that on cyclization with zinc chloride and acetic anhydride this acid gives a 1,2-benzanthranyl-10-acetate, but this could not be converted satisfactorily into the corresponding anthrone. On using hydrogen fluoride in the hope of obtaining the anthrone directly we were surprised to find that ring closure largely takes the alternate course and gives chiefly the naphthacene derivative VII and only a very small amount of the angular isomer (characterized as the quinone). The anthrone VII, like the parent substance,[10] is stable in the ketonic form and easily purified, and on reaction with methylmagnesium chloride it gave a hydrocarbon which crystallized either in bronze plates or in the form of fiery red needles of striking beauty.



VI VII



VIII

That the substance has the linear rather than the angular structure was at once apparent from the ultraviolet absorption spectrum, kindly de-

termined by Mr. D. M. Bowen. The curve (Fig. 1) bears no resemblance to that of 1,2-benzanthracene but corresponds well in form with the absorption curve of naphthacene as reported by Radulescu and co-workers[11] and by Clar.[12] Compared with the parent hydrocarbon, the maxima for the dimethyl compound VIII are shifted about 7–8 mμ (av.) in the direction of longer wave lengths. The extinction coefficients found for VIII correspond with the values for naphthacene given by Clar rather than the distinctly lower values reported by Radulescu. Chemical evidence for the linear structure was also obtained, for the anthrone VII gave on oxidation a quinone isomeric with the known 1′-methyl-1,2-benzanthraquinone[9] and exhibiting the resistance to alkaline hydrosulfite characteristic of naphthacenequinone.[10]

Experimental Part[13]

3-Acetoperinaphthane (I).—A mixture of 10 g. of perinaphthane[3] in 5 cc. of dry ether, 6.1 g. of acetic anhydride, and 200 g. of hydrogen fluoride was stirred mechanically for sixty hours at room temperature, fresh hydrogen fluoride being added to replace that lost by evaporation. The solution was then evaporated on the steam-bath and the product taken up in benzene, washed with dilute alkali, and distilled. A fore-run of 1.3 g. (perinaphthane) was collected up to 160° (2 mm.) and the ketone fraction boiled at 170–175°; yield 9.1 g. (71%).

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.69; H, 6.72. Found: C, 85.28; H, 6.66.

Acetic acid gave similar results. Trial runs with no solvent to serve as a diluent were less satisfactory.

The ketone forms an easily dissociated picrate in ether–ligroin and no complex was obtained in methanol.

The **trinitrobenzene derivative** separated from methanol in yellow needles of m. p. 114–114.5°.

Anal. Calcd. for $C_{15}H_{14}O \cdot C_6H_3O_6N_3$: N, 10.22. Found: N, 9.82.

Oxidation to **4-aceto-1,8-naphthalic anhydride** was accomplished by warming a solution of 1.0 g. of the ketone and 7.5 g. of anhydrous sodium dichromate in 25 cc. of acetic acid to 75–90° until the first vigorous reaction was over and then refluxing for two hours. The anhydride slowly separated after cooling and three crystallizations from benzene–ligroin gave yellow micro-needles, m. p. 193–195°. The substance has been reported as melting at 189°[14] or 191–192°[15]; the 2-aceto isomer[7b] melts considerably higher.

3-Perinaphthoic acid was obtained by shaking the ketone with potassium hypochlorite solution until dissolved. The acid after four crystallizations from benzene–ligroin formed pale yellow needles, m. p. 188.4–189°.

Anal. Calcd. for $C_{14}H_{12}O_2$: C, 79.25; H, 5.70. Found: C, 78.89; H, 5.83.

Acylation of Hydrindene. (a) 5-Aceto Compound.—From 46.4 g. of hydrindene, 27 g. of acetic acid, and 600 g. of hydrogen fluoride there was obtained after a reaction time of sixty-four hours at room temperature 46.2 g. (73%) of 5-acetohydrindene, b. p. 134–137° (8 mm.). A 2-g. portion of the material, oxidized with hot hypochlorite solution, gave 1.3 g. of hydrindene-5-carboxylic acid, m. p. 172–178°; recrystallized from dilute alcohol, m. p. 179.5–181.5° (compare 178–179°[16]; the 4-isomer melts at 152.5–153.5°).[17]

(b) **Benzoylation.**—Treated with one equivalent of benzoyl chloride and excess hydrogen fluoride at room temperature for thirty-six hours, 11.6 g. of hydrindene gave 16.5 g. (75%) of a colorless ketone, b. p. 203–204° (8 mm.) and 1.75 g. of benzoic acid was recovered from the alkaline extract. The material seems to consist very largely of 5-benzoylhydrindene, for 1.0 g. of the ketone treated with hydroxylamine in pyridine–alcohol gave 1.1 g. of once crystallized oxime which, after a second crystallization from benzene–ligroin, melted at 149–152° (compare 153–154°).[18]

(c) **5-(α-Naphthoyl)-hydrindene** was prepared as above from the hydrocarbon (7 g.) and α-naphthoic acid (9.8 g.). After seventy-two hours at room temperature, 2.1 g. of α-naphthoic acid was recovered and the ketone, b. p. 255–265° (8 mm.), obtained as a pale yellow oil amounted to 11.0 g. (90%, allowing for the recovered acid). The oil crystallized after standing for several weeks and on recrystallization from ether–petroleum ether it formed rosets of colorless needles, m. p. 71–72°.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.21; H, 5.92. Found: C, 88.23; H, 6.14.

Pyrolysis of the total distilled ketone under conditions suited for the Elbs reaction gave only tars and no cholanthrene could be detected.

Acetylation of Acenaphthene under Pressure.—The reaction vessel used was a welded steel cylinder with 1/8 in. (3-mm.) walls. This was connected to a stainless steel condenser tube carrying a glass water jacket by means of a wrought steel union with a brass seat (large stainless steel unions could not be as easily disconnected after exposure to hydrogen fluoride). A tee connection at the top of the condenser tube carried a 200-lb. (13 atm.) pressure gage, but this did not withstand corrosion very well and was used only in pilot runs and then disconnected and a plug substituted. To the horizontal opening of the tee connection there was fitted a stainless steel needle valve leading, through a second wrought steel union, to a steel receiver which could be closed by a separate brass needle valve. A mixture of 61.6 g. of acenaphthene, 22 cc. of acetic anhydride, and 120 g. of hydrogen fluoride was heated in this pressure vessel under reflux on the steam-bath for one and one-half hours at a gage pressure of 60 lb. (4 atm.). The hydrogen fluoride was then allowed to distill into the receiver and the residue was taken up in

benzene, washed thoroughly but rapidly with water in a glass separatory funnel and distilled. The total ketone fraction, b. p. 190–200° at 6 mm., weighed 54.7 g. (78%) and on two crystallizations from methanol afforded 23.6 g. of 1-acetoacenaphthene, m. p. 103–104.5°, and 2.3 g., m. p. 101.5–104.5° (yield, 37%). A fore-run of 6.7 g. consisted largely of acenaphthene.

1-Acenaphthaldehyde.—A solution of 7.5 g. of 1-acenaphthoyl chloride in 75 cc. of xylene, to which was added 0.35 g. of 2% palladium catalyst on barium sulfate and 0.075 cc. of the quinoline–sulfur reagent,[19] was stirred mechanically at 150–160° while passing in hydrogen. The evolution of hydrogen chloride continued for five and one-half hours, when 88% of the theoretical amount had been produced. After filtration and removal of the solvent at reduced pressure the product was distilled and the crude aldehyde (5 g., b. p. 150–165° at 2 mm.) dissolved in ether–benzene and stirred overnight with 75 cc. of saturated sodium bisulfite solution. The solid addition product was collected by centrifugation and decomposed with sodium carbonate solution, giving 4.5 g. (72%) of aldehyde, m. p. 93–99°. After five crystallizations from ether–roleum ether, the substance formed faintly yellowish dles, m. p. 99.5–100.5°.

Anal. Calcd. for $C_{13}H_{10}O$: C, 85.72; H, 5.54. Found: C, 85.29; H, 5.56.

β-Naphthaldehyde was obtained by the same procedure in 84% yield.

Naphthalene and Acetic Anhydride.—The hydrocarbon (12.8 g.) and anhydride (10.2 g.) were heated with hydrogen fluoride (100 g.) in the pressure bomb at 50–60° for sixty-eight hours. Distillation of the recovered and washed product gave a small fore-run of naphthalene and 4.9 g. of acetonaphthalene mixture, b. p. 155–165° (9 mm.). Oxidation with hypochlorite afforded 4.7 g. of naphthoic acid mixture, m. p. 145–168°, and on two crystallizations from dilute alcohol 2.9 g. of β-naphthoic acid, m. p. 182–184°, was obtained.

Phenanthrene and Acetic Anhydride.—From 35.6 g. of phenanthrene, 11 cc. of the anhydride, and 150 g. of hydrogen fluoride heated one hundred hours at 50–55° there was obtained 25.8 g. of recovered hydrocarbon and 9.3 g. (77% based on material consumed) of ketone, b. p. 180–210° (3 mm.). Crystallization from ether and from benzene–ligroin afforded 1.2 g. of 2-acetophenanthrene, m. p. 144–145°; the mother material when purified from methanol gave 3.6 g. of the 3-isomer, m. p. 70.5–71.5°. The latter substance gave a large depression when mixed with 9-acetophenanthrene (m. p. 74°).

Phenanthrene (17.8 g.) and crotonic acid in equivalent amounts were heated with hydrogen fluoride (100 g.) for forty-three hours at 40–50 lb. (3 atm.) pressure. The reagent was evaporated, the product taken up in benzene, and the blue organic layer washed with alkali and distilled, giving 8.4 g. of phenanthrene, b. p. 140–200° (2 mm.), and 6.4 g. of ketone, b. p. 210–240°. The redistilled material was an orange oil, b. p. 215–225° (2 mm.).

Anal. Calcd. for $C_{18}H_{14}O$: C, 87.78; H, 5.73. Found: C, 87.42; H, 5.88.

(19) Rosenmund and Zetzsche, *Ber.*, **54**, 425 (1921).

o-(β-Naphthoyl)-benzoic acid was prepared from 29 g. of β-bromonaphthalene and 23 g. of phthalic anhydride by the Grignard procedure[20] in 37% yield. It crystallized from benzene in small needles containing combined solvent; this complex melted at 129–131° with loss of benzene, resolidified and melted at 166–167° (compare 168°).[20]

Anal. Calcd. for $C_{18}H_{12}O_3 \cdot {}^1/_2C_6H_6$: C, 80.00; H, 4.79. Found: C, 80.14; H, 5.01.

o-(β-Naphthylmethyl)-benzoic Acid (III).—The keto acid (9 g.) was refluxed for sixteen hours with 200 cc. of water containing 20 g. of sodium hydroxide, 12 g. of zinc dust and a trace of copper sulfate. Capryl alcohol (2–3 cc.) was helpful in preventing foaming and was distilled off prior to filtration and acidification. The product was taken up in ether–benzene and the solution extracted with soda; precipitation gave 7.3 g. (97%) of good acid, m. p. 134–138°. After two crystallizations from dilute acetic acid the substance formed glistening white leaflets melting at 134–136°, and remelting after solidification at 139.5–140°.

Anal. Calcd. for $C_{18}H_{14}O_2$: C, 82.42; H, 5.34. Found: C, 82.59; H, 5.47.

The acid was previously prepared in poor yield by another method by King[21] (m. p. 136–137°).

9-Methyl-1,2-benzanthracene.—The best procedure found consisted in dissolving 2.5 g. of the acid III in 18 g. of hydrogen fluoride in a platinum cylinder, allowing the solution to stand at room temperature for one hour, and removing the reagent by placing the cylinder in a large glass test-tube and evaporating at the water pump. An ethereal solution of methylmagnesium chloride from 2.5 g. of metal was then added to the residue in the platinum container and after suitable time for reaction the mixture was worked up in the usual manner[22] and the hydrocarbon obtained as bright yellow prisms, m. p. 136–137.5°; yield 0.32 g. (14%). This did not depress the melting point of Newman's material.[8]

9-Allyl-1,2-benzanthracene was prepared from 3.8 g. of III as above but allowing only twenty minutes for cyclization before evaporating the hydrogen fluoride and adding the Grignard reagent (16 g. allyl bromide). The yield of hydrocarbon, m. p. 111–115°, was 1.4 g. (35%). The purified substance separated from ligroin in pale yellow aggregates, m. p. 115–116°.

Anal. Calcd. for $C_{21}H_{16}$: C, 94.00; H, 6.01. Found: C, 94.26; H, 6.23.

o-(8-Methyl-2-naphthylmethyl)-benzoic Acid (VI).[9]—In repeating the previous synthesis **1-methyl-7-bromonaphthalene** was prepared from 100 g. of the dihydride according to Fieser and Seligman,[9] and after fractionation the naphthalene derivative was isolated from the mixture as the **trinitrobenzene derivative.** The complex forms yellow blades from methanol, m. p. 92.5–93°.

Anal. Calcd. for $C_{11}H_9Br \cdot C_6H_3O_6N_3$: N, 9.70. Found: N, 9.35.

This was cleaved by reduction with stannous chloride in hydrochloric acid, giving 10.9 g. of pure 1-methyl-7-

(20) Weizmann, Bergmann and Bergmann, *J. Chem. Soc.*, 1367 (1935).

(22) Fieser and Hershberg, *ibid.*, **59**, 1028 (1937).

bromonaphthalene (liquid). On reaction with magnesium and then phthalic anhydride, this afforded 11.4 g. of hydrated keto acid, m. p. 110–120° (76%, assuming the substance to be a monohydrate). Reduction as above gave the acid VI, m. p. 142–143.5°, in 60% yield.

1'-Methyl-2,3-benz-10-anthrone (VII).—One gram of the methylnaphthylmethylbenzoic acid VII was treated with hydrogen fluoride at room temperature and after seven minutes was poured onto ice and the light yellow solid was quickly collected and washed. A portion was crystallized from acetone and obtained in two polymorphic forms of the same m. p. 174–176°. Prisms separated when a saturated solution was cooled rapidly in the ice box, while slow crystallization at room temperature gave rise to needles. Recrystallized slowly, the anthrone formed pale yellow needles, melting at 175–176° when heated slowly but liquefying when immersed in a bath at 171°.

Anal. Calcd. for $C_{19}H_{14}O$: C, 88.35; H, 5.46. Found: C, 88.80; H, 5.63.

With alcoholic alkali the anthrone gives a characteristic[10] purplish color which fades on shaking with air.

1'-Methyl-2,3-benzanthraquinone was obtained by oxidation of 100 mg. of the anthrone with 55 mg. of chromic anhydride in acetic acid. The substance crystallized from this solvent in orange-yellow needles, m. p. 227–229°. It gave no red color with aqueous hydrosulfite–alkali.

Anal. Calcd. for $C_{19}H_{12}O_2$: C, 83.80; H, 4.45. Found: C, 83.68; H, 4.66.

1',10-Dimethyl-2,3-benzanthracene (VIII).—After treatment of the crude anthrone VII with excess methylmagnesium chloride the collected product was passed in benzene solution through a tower charged with alumina mixed with Super-cel. On slow crystallization from absolute alcohol the hydrocarbon then formed brilliant, fiery red needles, m. p. 138–139°. When the alcoholic solution is cooled rapidly by cooling in ice the hydrocarbon separates in another modification which forms small, bronze-colored plates. This form melts when inserted in a bath at 133° and then solidifies and remelts at the higher temperature. The solution in concentrated sulfuric acid is olive-green.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.29. Found: C, 93.82; H, 6.35.

The **picrate** forms purplish-black needles from absolute alcohol, m. p. 164–165°.

Anal. Calcd. for $C_{20}H_{16}\cdot C_6H_3O_7N_3$: N, 8.66. Found: N, 8.59.

The **trinitrobenzene derivative** resembles the picrate in appearance, m. p. 166.5–167.5° (absolute alcohol).

Anal. Calcd. for $C_{20}H_{16}\cdot C_6H_3O_6N_3$: N, 8.94. Found: N, 9.04.

When the total crude product of cyclization was treated with Grignard reagent there was obtained in addition to the hydrocarbon a small amount of 1'-methyl-1,2-benzanthraquinone.[9]

Summary

Perinaphthane and hydrindene can be acetylated in the presence of hydrogen fluoride at room temperature, and the acylation of naphthalene and phenanthrene can be accomplished in a pressure bomb at somewhat higher temperatures.

9-Methyl- and 9-allyl-1,2-benzanthracene were synthesized successfully by cyclizing *o*-(β-naphthylmethyl)-benzoic acid with hydrogen fluoride and treating the crude anthrone with Grignard reagent, but when this process was applied to *o*-(8-methyl-2-naphthylmethyl)-benzoic acid ring closure occurred chiefly in the alternate direction, giving rise to the linear isomer. 1',10-Dimethyl-2,3-benzanthracene exists in two modifications, one of which has a striking red color.

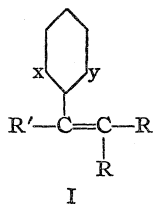
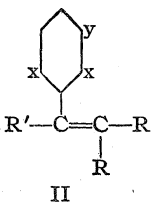
Restricted Rotation in Aryl Olefins. I. Preparation and Resolution of β-Chloro-β-(2,4,6-trimethyl-3-bromophenyl)-α-methylacrylic Acid

BY ROGER ADAMS AND M. W. MILLER[1]

Molecular dissymmetry due to restricted rotation between the ring and the olefinic carbon in appropriately substituted aryl olefins of types I and II was postulated in a previous communication.[2] Synthetic difficulties in preparing such compounds proved to be great and no procedure was found which gave successful results. The



I



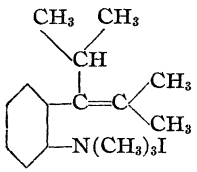
II

introduction of an atom or group other than hydrogen for the R' was complicated when R, x and y represented substituents other than hydrogen.

(1) Portion of a thesis submitted in partial fulfilment of the requirements for the degree of Doctor of Philosophy in chemistry; Eastman Kodak Fellow, 1939–1940.

(2) Maxwell and Adams, THIS JOURNAL, **52**, 2960 (1930).

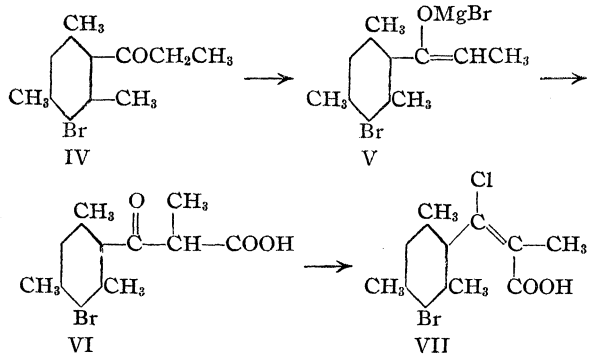
In the last few years several compounds have been prepared in which restricted rotation between an aryl group and an aliphatic nitrogen or carbon atom has been demonstrated.[3] The probability of resolution of properly substituted aryl olefins was thus made to appear more likely. Just recently, Mills and Dazeley[4] have succeeded in synthesizing and resolving *o*-(β,β-dimethyl-α-isopropylvinyl)-phenyltrimethylammonium iodide (III), thus verifying the correctness of the original



III

postulation. They observed also that a hydrogen atom on the olefin carbon not attached to the ring resulted in a compound which they were unable to obtain in enantiomorphic forms.

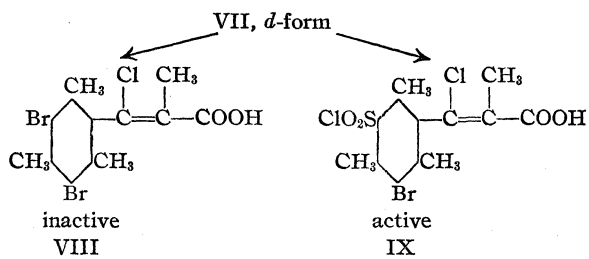
Search has been continued in this Laboratory to find a procedure for synthesizing molecules of types I and II, especially a procedure which would make feasible the preparation of several closely related compounds and thus allow a study of the effect of different groups around the point of restricted rotation. Such a procedure has now been devised. The first compound to be prepared and resolved is β-chloro-β-(2,4,6-trimethyl-3-bromophenyl)-α-methylacrylic acid. In its synthesis, advantage has been taken of the reports of Kohler[5] that hindered ketones react with ethylmagnesium bromide to give ethane and the magnesium bromide derivative of the enol form, and the observation by Kohler and Baltzly as well as by Fuson, Fugate and Fisher[6] that such enol magnesium bromides and carbon dioxide give β-ketonic acids. Thus, bromopropiomesitylene (IV) gives the magnesium bromide derivative (V), which carbonates to α-methyl-(2,4,6-trimethyl-3-bromobenzoyl)-acetic acid (VI). Molecules of the type shown by VI enolize with great ease and it was possible, therefore, to convert the keto acid (VI) by means of a mixture of phosphorus pentachloride and phosphorus oxy-



IV V VI VII

chloride into the chloro olefin (VII), β-chloro-β-(2,4,6-trimethyl-3-bromophenyl)-α-methylacrylic acid. Although VII should exist in *cis* and *trans* forms, only one of these isomers was obtained. This isomer was resolved readily through the quinine salt. The *d*-form from the less soluble salt gave $[\alpha]^{20}D$ +52.6° in ethanol and proved to be surprisingly stable. The *l*-form also was isolated. The optical activity of the *d*-form was not changed by refluxing for fifteen hours in ethanol or twelve hours in glacial acetic acid. A very rigid restriction of rotation in this molecule was thus demonstrated.

The necessity for unsymmetrical substitution in the benzene ring in order to produce asymmetry in VII was proved by bromination and by preparing a sulfonyl chloride derivative of the optically active forms. Bromination resulted in symmetrical substitution with formation of an optically inactive dibromo compound (VIII), identical with that prepared by bromination of the racemic form of VII. Chlorosulfonic acid, on the other hand, gave a molecule with unsymmetrical substitution which proved to be the optically active chlorosulfonyl derivative (IX).



VIII IX

The reactions by which VII was prepared are peculiarly suitable for synthesizing molecules in which the atoms or groups substituted in the benzene ring and on the olefin linkage may be varied. A study of such molecules and others containing two points of restricted rotation is now under way.

Experimental

Bromopropiomesitylene.—To a mechanically stirred mixture of 300 g. of carbon disulfide, 100 g. of bromomesitylene and 140 g. of aluminum chloride, was added 65 g. of propionic anhydride at such a rate that the solvent refluxed gently. After completion of the addition, stirring was continued for two hours and the reaction product was then poured into iced hydrochloric acid. The carbon disulfide layer was separated, the solvent removed and the residual oil dissolved in ether. This solution was washed with hydrochloric acid, water and finally with aqueous sodium carbonate. The product was a colorless liquid, b. p. 127–129° (3 mm.), $n^{20}D$ 1.5490, d^{24}_{24} 1.2956.

Anal. Calcd. for $C_{12}H_{15}OBr$: C, 56.50; H, 5.88. Found: C, 56.47; H, 6.08.

Dinitrobromomesitylene.—The structure of bromopropiomesitylene was proved by cleavage of the propionyl group with sirupy phosphoric acid[7] and nitration of the product to dinitrobromomesitylene. Following the same nitration procedure, bromomesitylene was converted to an identical product.

A mixture of 50 cc. of sirupy phosphoric acid and 5 g. of bromopropiomesitylene was refluxed for twelve hours and then steam distilled. The distillate was extracted with ether and the ether removed. The oil thus obtained was added slowly to 25 cc. of ice cold fuming nitric acid. After standing for twenty minutes, the mixture was poured on ice. The product was purified by crystallization from ethanol, m. p. 199.5–201.5° (cor.). Fittig and Storer[8] report m. p. of 189–190°.

Anal. Calcd. for $C_9H_9O_4N_2Br$: C, 37.37; H, 3.12. Found: C, 37.60; H, 3.31.

Bromomagnesium Enolate of Bromopropiomesitylene (V); α-Methyl-(2,4,6-trimethyl-3-bromobenzoyl)-acetic Acid (VI).—A solution of 25 g. of bromopropiomesitylene in 25 cc. of dry ether was added to 100 cc. of an ether solution containing slightly over one mole equivalent of ethylmagnesium bromide. The mixture was refluxed for thirty minutes, then transferred to a catalytic hydrogenation apparatus, cooled in an ice-bath, and carbon dioxide passed in at a pressure of 2–3 atm. After forty-five minutes, the temperature was allowed to come to that of the room and addition of carbon dioxide continued for six hours.

The reaction mixture was then chilled in an ice-bath, and poured slowly into iced hydrochloric acid. The ether layer was extracted with aqueous sodium carbonate and the aqueous extract acidified with iced hydrochloric acid. The product was purified by crystallization from benzene; white crystals, m. p. 123–124° (cor.) with decomposition. The crude product was satisfactory for conversion to the chloro compound; yield 15 g. (51%).

Anal. Calcd. for $C_{13}H_{15}O_3Br$: C, 52.17; H, 5.02. Found: C, 52.39; H, 5.55.

β-Chloro-β-(2,4,6-trimethyl-3-bromophenyl)-α-methylacrylic Acid (VII).—To a solution of 10 g. of α-methyl-(2,4,6-trimethyl-3-bromobenzoyl)-acetic acid in 50 cc. of ice cold phosphorus oxychloride, was added 25 g. of phosphorus pentachloride.[9] After warming on a steam cone for one hour, the solution was cooled and poured on 300 g. of ice. The product separated as an oil which solidified on standing. It was purified by crystallization from petroleum ether (b. p. 60–110°) as white crystals, m. p. 157–158° (cor.); yield 5.6 g. (53%).

Anal. Calcd. for $C_{13}H_{14}O_2BrCl$: C, 49.12; H, 4.42; neut. equiv., 317.5. Found: C, 48.95; H, 4.58; neut. equiv., 317, 314.

β-Chloro-β-(2,4,6-trimethyl-3-bromo-5-chlorosulfonylphenyl)-α-methylacrylic Acid (IX).—To 5 cc. of chlorosulfonic acid cooled to −10° was added slowly 0.20 g. of β-chloro-β-(2,4,6-trimethyl-3-bromophenyl)-α-methylacrylic acid. The reaction mixture was allowed to warm to room temperature and then poured on ice. The yellow solid was purified by recrystallization from petroleum ether (b. p. 60–110°): white crystals, m. p. 188–189° (cor.); yield 0.14 g. (53%).

Anal. Calcd. for $C_{13}H_{13}O_4BrCl_2S$: C, 37.59; H, 3.13. Found: C, 37.94; H, 3.26.

β-Chloro-β-(2,4,6-trimethyl-3,5-dibromophenyl)-α-methylacrylic Acid (VIII).—A mixture of 0.2 g. of β-chloro-β-(2,4,6-trimethyl-3-bromophenyl)-α-methylacrylic acid and 0.5 cc. of liquid bromine (cooled to 0°) was allowed to stand for twenty minutes. The excess bromine was evaporated and the residue treated with aqueous sodium bisulfite. The cream colored solid was purified by crystallization from ethanol; white needles, m. p. 228–229° (cor.).

Anal. Calcd. for $C_{13}H_{13}O_2Br_2Cl$: C, 39.39; H, 3.28. Found: C, 39.26; H, 3.26.

Resolution of β-Chloro-β-(2,4,6-trimethyl-3-bromophenyl)-α-methylacrylic Acid.—A solution of 10 g. of β-chloro-β-(2,4,6-trimethyl-3-bromophenyl)-α-methylacrylic acid in 75 cc. of warm absolute ethanol was added to a solution of 10 g. of quinine in 75 cc. of warm absolute ethanol. After filtration and cooling, 8.45 g. of salt (fraction A) crystallized. Evaporation of the filtrate to 100 cc. and cooling gave an additional 5.34 g. of salt (fraction B). The filtrate from the second fraction was diluted with 50 cc. of water whereupon 3.2 g. of oil separated (fraction C). Decantation of the solvent and slow evaporation yielded an additional crop of crystals (fraction D).

Fraction A was twice recrystallized from ethanol after which a constant rotation had been reached.

Rotation. Less soluble salt (*l*B·*d*A) 0.0995 g. made up to 25 cc. in absolute ethanol at 20° gave αD −0.37; *l*, 2; $[\alpha]^{20}D$ −46.8°.

Anal. Calcd. for $C_{33}H_{38}O_4N_2BrCl$: C, 61.73; H, 5.92. Found: C, 61.82; H, 6.05.

***d*-β-Chloro-β-(2,4,6-trimethyl-3-bromophenyl)-α-methylacrylic Acid.**—To a suspension of 5.2 g. of the purified salt (fraction A) in 100 cc. of water was added 10 cc. of concentrated hydrochloric acid. After stirring for thirty minutes, the product was filtered and washed with 5% hydrochloric acid until quinine-free and then with water. The product (2.4 g.) was purified by recrystallization twice from petroleum ether (b. p. 60–110°). Its rotation was the same after each crystallization; white crystals, m. p. 155–156° (cor.).

Rotation. (*d*-acid) 0.0998 g. made up to 25 cc. with absolute ethanol at 20° gave αD +0.42; *l*, 2; $[\alpha]^{20}D$

(7) Klages and Lickroth, *Ber.*, **32**, 1549 (1899).
(8) Fittig and Storer, *Ann.*, **147**, 8 (1868).

+52.6°. 0.1008 g. made up to 25 cc. with glacial acetic acid at 20° gave α_D +0.56; *l*, 2; $[\alpha]^{20}D$ +69.4°.

Anal. Calcd. for $C_{13}H_{14}OBrCl$: C, 49.12; H, 4.42. Found: C, 49.04; H, 4.04.

Decomposition of the oily fraction C in a similar manner gave *l*-acid which after two crystallizations gave a constant rotation; white crystals, m. p. 155–156° (cor.).

Rotation. (*l*-acid) 0.0994 g. made up to 25 cc. with absolute ethanol at 20° gave α_D −0.43; *l*, 2; $[\alpha]^{20}D$ −54°.

Anal. Calcd. for $C_{13}H_{14}O_2BrCl$: C, 49.12; H, 4.42. Found: C, 49.62; H, 4.52.

Racemization Experiments.—The *d*-acid was refluxed in absolute ethanol for fifteen hours and in glacial acetic acid for twelve hours with no change in rotation in either case.

Bromination of *d*- + *l*-Acids: *dl*-β-Chloro-β-(2,4,6-trimethyl-3,5-dibromophenyl)-α-methylacrylic Acid.—The procedure for bromination was exactly that used in bromination of the racemic compound. The product was optically inactive and proved to be identical with the dibromo compound previously prepared; white needles, m. p. 228–229° (cor.). Bromination of the *l*-acid gave the same compound.

Action of Chlorosulfonic Acid on *d*- and *l*-Acids. Preparation of *d*- and *l*-β-Chloro-β-(2,4,6-trimethyl-3-bromo-5-chlorosulfonylphenyl)-α-methylacrylic Acids.—The procedure in these preparations was identical with that used for the racemic acid. Both *d*- and *l*-forms consisted of white crystals from petroleum ether (b. p. 60–100°), m. p. 183–184° (cor.).

Rotation. (derivative from *d*-acid) 0.1018 g. made up to 25 cc. with benzene at 20° gave α_D −0.07; *l*, 2; $[\alpha]^{20}D$ −8.6°.

Anal. Calcd. for $C_{13}H_{13}O_4BrCl_2S$: C, 37.59; H, 3.13. Found: C, 37.96; H, 3.29.

Rotation. (derivative from *l*-acid) 0.1002 g. made up to 25 cc. with benzene at 20° gave α_D +0.08; *l*, 2; $[\alpha]^{20}D$ +10.0°.

Summary

1. β-Chloro-β-(2,4,6-trimethyl-3-bromophenyl)-α-methylacrylic acid has been synthesized. This substance was resolved into its enantiomorphic forms. They proved to be very stable to racemization.

2. The asymmetry of the molecule is undoubtedly due to restricted rotation between the carbon of the benzene ring and the olefinic carbon to which it is attached. Necessity for unsymmetrical substitution in the benzene ring was demonstrated by bromination of the active acids and introduction of a chlorosulfonyl group. Bromination which results in a dibromo compound with symmetrical substitution gave an inactive product. Chlorosulfonic acid, on the other hand, which results in a molecule still containing an unsymmetrically substituted benzene, gave an optically active product.

3. This compound is typical of a general class of aryl olefins which should be capable of resolution.

The Synthesis of 1,3-Diphenyldihydroisobenzofurans, 1,3-Diphenylisobenzofurans and *o*-Dibenzoylbenzenes from the Diene Addition Products to Dibenzoylethylene

BY ROGER ADAMS AND MARVIN H. GOLD[1]

In a recent paper, the addition of 1,4-dimethylbutadiene to *trans*-dibenzoylethylene was described and a number of the reaction products of this substance was prepared.[2] A more systematic study is now under way on the diene addition products to dibenzoyl and substituted dibenzoyl ethylenes. In this communication will be reported the substances formed by the action of butadiene, 2,3-dimethylbutadiene, and cyclopentadiene on dibenzoylethylene, and the transformations of these substances.

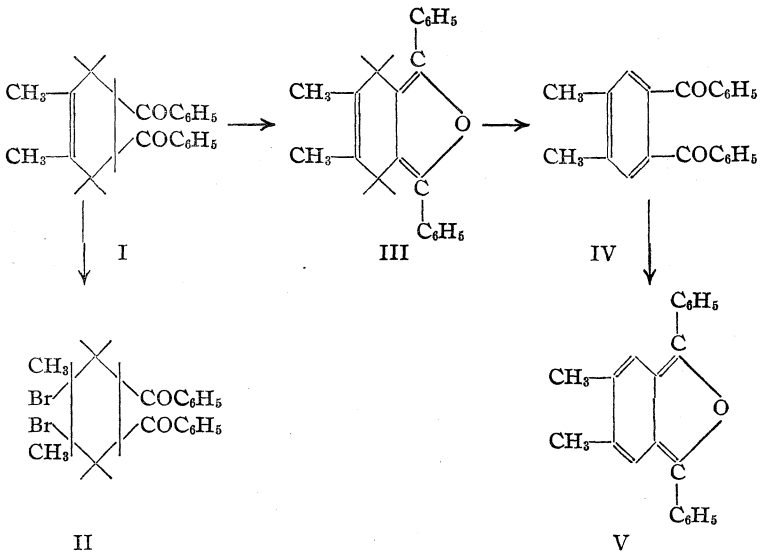
2,3-Dimethylbutadiene and *trans*-dibenzoylethylene react to give a quantitative yield of 1,2-dimethyl-4,5-dibenzoylcyclohexene (I), which adds a mole of bromine to give the expected dibromide (II).

The cyclohexene (I) is converted, by means of a few drops of sirupy phosphoric acid in acetic anhydride, into 1,3-diphenyl-5,6-dimethyl-4,7-dihydroisobenzofuran (III).

Compound III, on treatment with two molecules of bromine followed by sodium acetate in acetic acid, gives an excellent yield of 1,2-dimethyl-4,5-dibenzoylbenzene (IV). The exact mechanism of this reaction was not determined but it is probable that one mole of bromine adds to the cyclohexene double bond and one mole to the 1,4-position in the furan conjugated system

(1) An abstract of a thesis submitted in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry.

(2) Adams and Geissman, THIS JOURNAL, **61**, 2083 (1939).

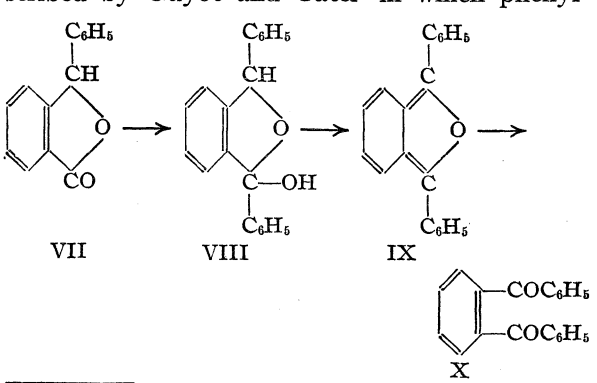


molecule of bromine to compound III was isolated and then treated with sodium acetate, a mixture of the *o*-dibenzoylbenzene (IV) and the isobenzofuran (V) was obtained.

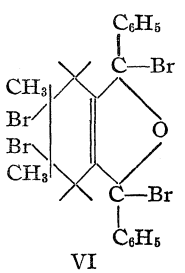
Butadiene in place of 2,3-dimethylbutadiene adds equally well to *trans*-dibenzoylethylene and by analogous reactions to those just described, compounds corresponding to I, II, III, IV, and V without the methyl groups were synthesized.

o-Dibenzoylbenzene and certain of its derivatives are known compounds but none of the methods of preparation is entirely satisfactory. A brief review of these methods is pertinent. It was first prepared by oxidation of *o*-dibenzylbenzene resulting as one of the products from the action of zinc dust on a mixture of benzyl chloride and benzene.[4] Beis[5] obtained it as one of the products from the reaction of phenylmagnesium bromide on N-phenylphthalimide. Bruhat and Thomas[6] used the Grignard reagent from *o*-diiodobenzene and two moles of benzonitrile followed by hydrolysis. Blicke and Patelski[3b,7] condensed *o*-benzoylbenzonitrile with phenylmagnesium bromide followed by hydrolysis. Clar, John and Hawran[8] replaced the two chlorines in *o*-phthalyl chloride with phenyl groups by the action of phenylmagnesium bromide.

The procedure most frequently used and unquestionably superior to the others is that described by Guyot and Catel[9] in which phenyl-



(VI). Two hydrogen bromides are then eliminated to form the benzene ring with simultaneous hy-



drolysis of the brominated furan ring to give two benzoyl groups.

o-Dibenzoylbenzene and one or two of its derivatives have been converted into 1,3-diphenylisobenzofuran by means of zinc dust and acetic acid.[3] This reaction, however, has not been extensively studied since the isobenzofurans have been in general more easily obtained than the *o*-dibenzoylbenzenes and have served as intermediates in the preparation of the latter compounds. Since in the reactions described in this paper the *o*-dibenzoylbenzenes are more easily obtained than the isobenzofurans, the conversion of the former to the latter was investigated. It was found that activated zinc and ethanolic sodium hydroxide was a superior reagent and resulted in a quantitative conversion of IV to the 1,3-diphenyl-5,6-dimethylisobenzofuran (V). The time of reduction of the *o*-dibenzoylbenzenes varies with the activity of the zinc dust.

If the product formed by the addition of one

phthalide (VII) was condensed with phenylmagnesium bromide. The initial product (VIII) was transformed by hydrochloric acid or acetic acid to 1,3-diphenylisobenzofuran (IX) which, on oxidation with chromic acid, gave *o*-dibenzoylbenzene (X).

The method for preparing *o*-dibenzoylbenzene through the butadiene addition to dibenzoylethylene unquestionably is better than these just described. It has the further advantage of being readily applicable to certain substituted dibenzoylbenzenes which would be very difficult to prepare by the other methods.

Thus, by using reasonably accessible 2,3-disubstituted butadienes and substituted dibenzoylethylenes, 4,5-dialkyl or diaryl 1,2-dibenzoyl or substituted 1,2-dibenzoylbenzenes can be synthesized.

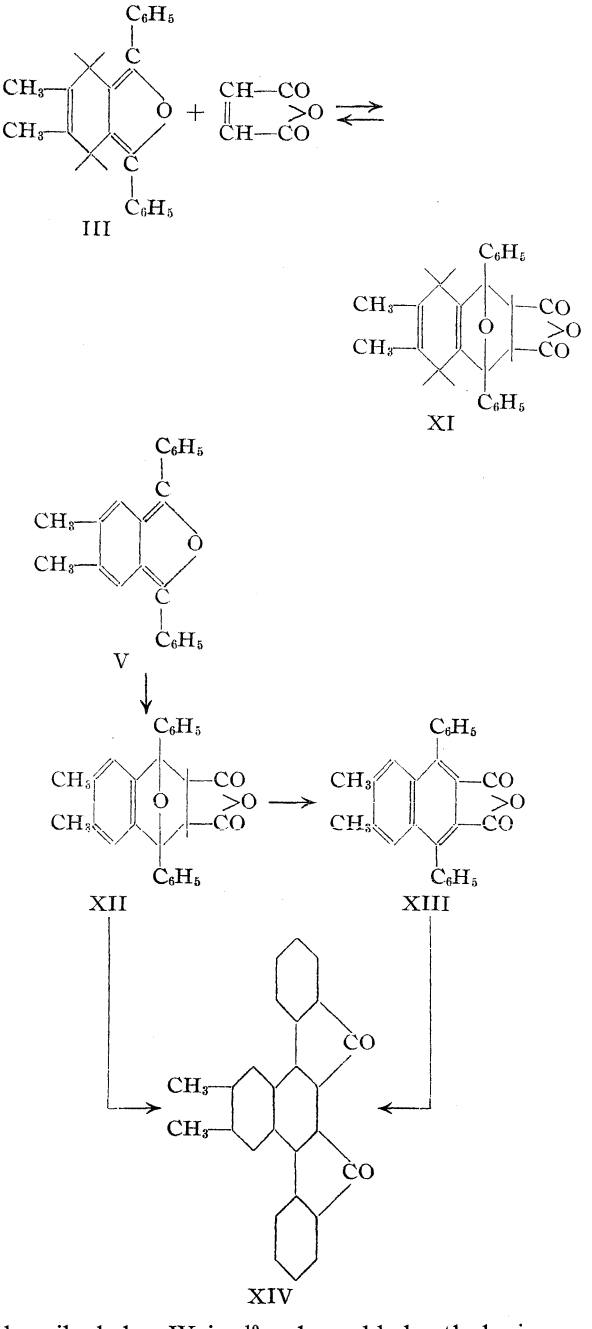
1,3-Diphenylisobenzofurans previously have been made by three processes: (1) the reduction of *o*-dibenzoylbenzenes by means of zinc and acetic acid,[3a,b] (2) the action of sulfuric acid on phthalins,[3b] (3) the action of arylmagnesium halides on aryl phthalides.[9] The unsubstituted compound has been made by the action of phenylmagnesium bromide on *o*-cyanobenzaldehyde.[3b] Since *o*-dibenzoylbenzenes can now be produced readily, the reduction of this type of compound seems the best procedure for arriving at the 1,3-diphenylisobenzofurans.

No 1,3-diphenyl-4,7-dihydroisobenzofurans (III) have been described previously.

The 1,3-diphenyl-4,7-dihydroisobenzofurans and the 1,3-diphenylisobenzofurans show marked fluorescence in dilute solution. The former are sometimes fluorescent even in the solid state. A quantitative study of the fluorescence of a series of these substances is now under way.

The isobenzofurans are useful as intermediates in various syntheses since they contain an active diene conjugated system. They add various compounds of the α,β-unsaturated carbonyl type. Thus, 1,3-diphenyl-5,6-dimethylisobenzofuran (V) is converted with maleic anhydride to 1,4-diphenyl-1,4-oxido-6,7-dimethyl-1,2,3,4-tetrahydronaphthalene-2,3-dicarboxylic acid anhydride (XII). The dihydroisobenzofurans also contain a similar active conjugated system but the reaction with maleic anhydride is so readily reversible that isolation of pure products was not accomplished (III $\rightleftarrows$ XI).

Additions of this type (V $\rightarrow$ XII) have been



described by Weiss,[10] who added ethyl cinnamate, indene, maleic anhydride and acrolein to 1,3-diphenylisobenzofuran, and maleic anhydride and acrolein to 1,3-di-α-naphthylisobenzofuran.

Barnett[11] added maleic anhydride and *p*-benzoquinone to 1,3-diphenylisobenzofuran and Dufraisse[12] *p*-benzoquinone and naphthoquinone.

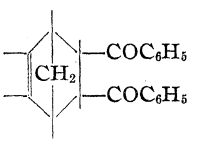
By treatment of these adducts with hydrogen chloride, napthalene derivatives are produced and the adducts or the corresponding napthalenes are converted by sulfuric acid to 1,2,3,4-dibenzoylenenaphthalenes. Thus, the adduct (XII) is converted by hydrogen chloride to 1,4-diphenyl-6,7-dimethyl-2,3-naphthalic anhydride (XIII) and by sulfuric acid to 6,7-dimethyl-1,2,3,4-dibenzoylenenaphthalene (XIV).

Because of the ease with which many 1,3-diphenylisobenzofurans can now be made, satisfactory syntheses of 1,4-diaryl or substituted diaryl 6,7-dialkyl or diaryl 2,3-mono- or disubstituted naphthalenes are made available. A further study is being made of the scope of these preparative procedures.

When cyclopentadiene was added to *trans*-dibenzoylethylene, a compound presumably with structure XV was produced.



XV

This isomer must represent a molecule in which the benzoyl groups are *trans* or on opposite sides of the ring. A second isomer with the two benzoyl groups on the same side was obtained by addition of cyclopentadiene to *cis*-dibenzoylethylene. Neither of these adducts could be converted to furans by the procedure used for the cyclohexene derivatives.

Experimental

1,2-Dimethyl-4,5-dibenzoylcyclohexene.—To a solution of 40 g. of *trans*-dibenzoylethylene[13] in 200 cc. of absolute ethanol was added 35 g. of crude 2,3-dimethylbutadiene (unredistilled dehydration product of pinacol with 48% hydrobromic acid). The mixture was refluxed for three hours on the steam cone and allowed to cool, whereupon the product crystallized; yield 54 g. Purifications by recrystallization from 95% ethanol gave large plate-like prisms, m. p. 111–111.5° (corr.). On the first recrystallization 1.5 g. of a less soluble product remained undissolved in the hot ethanol and was identified as the corresponding dihydroisobenzofuran described in a subsequent procedure. The adduct gives a lemon yellow color in concentrated sulfuric acid.

1,2-Dimethyl-4,5-dibenzoylcyclohexene Monodinitrophenylhydrazone.—The product separated from an ethanol solution of the reactants after standing overnight: orange crystals from ethanol; m. p. 226–228° (corr.) with decomposition.

Anal. Calcd. for $C_{28}H_{26}O_5N_4$: N, 11.25. Found: N, 11.20.

1,2-Dimethyl-1,2-dibromo-4,5-dibenzoylcyclohexane.—The addition product was prepared in glacial acetic acid: small white crystals from ethanol or petroleum ether (b. p. 60–110°); m. p. 170–171° (corr.) with decomposition.

Anal. Calcd. for $C_{22}H_{22}O_2Br_2$: C, 55.23; H, 4.60. Found: C, 55.37; H, 4.86.

1,3-Diphenyl-5,6-dimethyl-4,7-dihydroisobenzofuran.—To a nearly boiling solution of 5 g. of 1,2-dimethyl-4,5-dibenzoylcyclohexene in 75 cc. of acetic anhydride was added a few drops of sirupy phosphoric acid. The mixture was allowed to reflux for ten minutes, although the product started to come out after the first minute or two. After cooling the solution, the product was filtered, washed with water and recrystallized from benzene: yellowish-green fluorescent crystals, m. p. 225–226° (corr.); yield 4.7 g. (99%).

Anal. Calcd. for $C_{22}H_{20}O$: C, 88.00; H, 6.67. Found: C, 87.82; H, 6.79.

The furan exhibited a blue fluorescence in solution in organic solvents. With concentrated sulfuric acid, it gives an orange-brown color.

1,2-Dimethyl-4,5-dibenzoylbenzene.—A solution of 5 cc. of bromine in 30 cc. of glacial acetic acid was added slowly to a boiling suspension of 15 g. of 1,3-diphenyl-5,6-dimethyl-4,7-dihydroisobenzofuran in 200 cc. of acetic acid, 30 g. of sodium acetate and 15 cc. of water. Within a few minutes the bromine was completely absorbed and all of the furan dissolved. Reflux was continued for five minutes and then the solution was poured directly into 500–600 cc. of hot water, after which it was allowed to cool slowly for several hours. The product was filtered, dissolved in 300 cc. of ethanol and decolorized with norit: small white rectangular plates from ethanol, m. p. 143–144° (corr.); yield 14.2 g. (90%). The product gave a violet color in concentrated sulfuric acid.

Anal. Calcd. for $C_{22}H_{18}O_2$: C, 84.07; H, 5.73. Found: C, 83.81; H, 5.93.

2-Methyl-4,5-dibenzoylbenzoic Acid.—To a mixture of 25 cc. of pyridine, 35 cc. of water, 5 g. of potassium permanganate and 1 cc. of 10% aqueous sodium hydroxide was added 2 g. of 1,2-dimethyl-4,5-dibenzoylbenzene. The solution was refluxed for thirty minutes after which time all the permanganate was reduced. The solution was cooled, acidified with sulfuric acid and the manganese dioxide reduced with sodium bisulfite. The white precipitate was filtered, dissolved in 50 cc. of 5% aqueous sodium hydroxide, again filtered and reprecipitated with dilute sulfuric acid. The product was purified by recrystallization from benzene: small white crystals, m. p. 196–197° (corr.); yield 1.4 g. (64%).

Anal. Calcd. for $C_{22}H_{16}O_4$: C, 76.74; H, 4.65; neut. equiv., 344. Found: C, 76.50; H, 4.77; neut. equiv., 340.

1,3-Diphenyl-5,6-dimethylisobenzofuran.—A mixture of 3 g. of 1,2-dimethyl-4,5-dibenzoylbenzene, 3 g. of sodium hydroxide and 75 cc. of 95% ethanol was refluxed until the solution had turned dark brownish-red in color (usually about forty-five minutes). Then 3 g. of active zinc dust (prepared by suspending zinc dust in dilute hydrochloric acid, stirring well for one minute, decanting and washing with water until free of acid) was added and refluxing continued until the red solution became light yellow (usually five to forty-five minutes, depending on the activity of the zinc dust). The reaction should be discontinued as soon as the yellow color has appeared, otherwise the reduction proceeds too far. The hot solution was next filtered and poured into 70 cc. of glacial acetic acid and stirred to help precipitation. Within half a minute, the furan started to come out of solution. About 10 cc. of water was then added to ensure complete precipitation and the mixture was digested for about five minutes on the hot plate before allowing to cool. The product was purified from benzene or acetone: orange-yellow needles, m. p. 187–188° (corr.); yield 2.8 g. (97%).

Anal. Calcd. for $C_{22}H_{18}O$: C, 88.58; H, 6.04. Found: C, 88.13; H, 6.01.

The product exhibited a brilliant blue-green fluorescence in solution in organic solvents. It gave a reddish-orange color in concentrated sulfuric acid.

When an ethanolic solution of the benzofuran was illuminated by a strong lamp for a few days, it was reconverted completely to the 1,2-dimethyl-4,5-dibenzoylbenzene.[14]

A second procedure for preparing 1,3-diphenyl-5,6-dimethylisobenzofuran is from 1,3-diphenyl-5,6-dimethyl-5,6-dibromo-4,5,6,7-tetrahydroisobenzofuran. A solution of 1 g. of the dibromo compound in 30 cc. of glacial acetic acid and 10 cc. of acetic anhydride was heated nearly to boiling, then 8 g. of anhydrous sodium acetate and 10 cc. of glacial acetic acid was added, and the mixture refluxed for one-half hour. Upon cooling, the 1,3-diphenyl-5,6-dimethylisobenzofuran separated as yellow needles; yield 0.3 g. The mother liquor was then heated nearly to boiling and water was added until just turbid. Upon cooling, 0.36 g. of 1,2-dimethyl-4,5-dibenzoylbenzene precipitated.

1,3-Diphenyl-5,6-dibromo-5,6-dimethyl-4,5,6,7-tetrahydroisobenzofuran.—To a solution of 1 g. of 1,3-diphenyl-5,6-dimethyl-4,7-dihydroisobenzofuran in 80 cc. of chloroform was added a solution of 0.17 cc. of bromine in 15 cc. of chloroform over a period of ten minutes. The resulting solution was then evaporated to about 10 cc. and 5 cc. of petroleum ether (b. p. 60–110°) was added. The immediate precipitate consisting of unchanged dihydroisobenzofuran was filtered and the solution concentrated until the dibromo derivative crystallized. It was purified by recrystallization from ethanol: small light yellow crystals, m. p. 155–156° (corr.) with decomposition; yield 0.58 g. (38%; 60% based on unrecovered dihydroisobenzofuran).

Anal. Calcd. for $C_{22}H_{20}OBr_2$: C, 57.39; H, 4.35. Found: C, 57.76; H, 4.68.

1,4-Diphenyl-1,4-oxido-6,7-dimethyl-1,2,3,4-tetrahydronaphthalene-2,3-dicarboxylic Anhydride.—To a solution of 1.5 g. of 1,3-diphenyl-5,6-dimethylisobenzofuran in 75 cc. of benzene was added 0.5 g. of powdered maleic anhydride. Upon the addition of the anhydride there was a brilliant flash of red color which immediately disappeared, leaving a colorless solution which no longer fluoresced. The product soon separated. Purified from toluene, it gave tiny white crystals, m. p. (sealed tube) 254–255° (corr.) with decomposition; yield 2 g. (quant.).

Anal. Calcd. for $C_{26}H_{20}O_4$: C, 78.78; H, 5.05. Found: C, 78.65; H, 5.38.

The product gave a lemon yellow color in concentrated sulfuric acid.

1,4-Diphenyl-6,7-dimethyl-2,3-naphthalic Anhydride.—A suspension of 2 g. of the oxido compound in 150 cc. of absolute methanol was saturated with dry hydrogen chloride and then refluxed for two hours, while a slow stream of the hydrogen chloride was kept continuously bubbling through the reaction mixture. The oxido compound rapidly dissolved and the solution exhibited a faint fluorescence. After evaporation to dryness, 25 cc. of water, 5 g. of sodium hydroxide and 100 cc. of ethanol were added and the mixture refluxed for four hours. The solution was then cooled and acidified to congo red. The resulting white precipitate was filtered and dissolved in 10% aqueous sodium hydroxide, filtered and reprecipitated with acid. Upon purification by recrystallization from benzene, it gave tiny white crystals, m. p. 324–325° (corr.) with decomposition and some sublimation; yield 1.3 g. (68%).

Anal. Calcd. for $C_{26}H_{18}O_3$: C, 82.80; H, 4.76. Found: C, 83.06; H, 4.85.

The product gave a greenish-yellow color in concentrated sulfuric acid.

6,7-Dimethyl-1,2,3,4-dibenzoylenenaphthalene.—A mixture of 10 cc. of concentrated sulfuric acid and 0.5 g. of 1,4-diphenyl-1,4-oxido-6,7-dimethyl-1,2,3,4-tetrahydronaphthalene-2,3-dicarboxylic anhydride was allowed to stand for three and one-half hours. After this time the solution, which had turned from a light yellow to a deep green, was poured over 30 g. of ice. The red precipitate was purified by recrystallization from boiling acetic acid: tiny red needles, m. p. >325°; yield 0.2 g.

Anal. Calcd. for $C_{26}H_{16}O_2$: C, 86.67; H, 4.44. Found: C, 86.58; H, 4.56.

4,5-Dibenzoylcyclohexene.—To a cooled solution of 15 g. (1.5 moles) of butadiene in 200 cc. of benzene was added 40 g. of *trans*-dibenzoylethylene. The mixture was heated in a pressure bomb for two hours at 100°. The benzene was evaporated to 75 cc. and 125 cc. of methanol was added. Upon cooling, the product separated. It was purified by crystallization from ethanol: fine white crystals, m. p. 111.5–112° (corr.); yield 49 g. (quant.).

Anal. Calcd. for $C_{20}H_{18}O_2$: C, 82.75; H, 6.21. Found: C, 82.81; H, 6.47.

1,2-Dibromo-4,5-dibenzoylcyclohexane.—The procedure used was the same as for the bromination of the dimethyl homolog. The product was obtained in 90% yield and was purified from petroleum ether (b. p. 60–110°): small white crystals, m. p. 148–149° (corr.).

Anal. Calcd. for $C_{20}H_{18}O_2Br_2$: C, 53.33; H, 4.00. Found: C, 53.61; H, 4.22.

(14) Guyot and Catel, *Bull. soc. chim.*, [3] **35**, 1127 (1906).

1,3-Diphenyl-4,7-dihydroisobenzofuran.—The procedure used was that employed for preparation of the dimethyl compound: yellowish-green crystals from petroleum ether (b. p. 60–110°), m. p. 120–121° (corr.); yield 99%.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.23; H, 5.88. Found: C, 88.04; H, 6.28.

1,3 - Diphenyl - 5,6 - dibromo - 4,5,6,7 - tetrahydroisobenzofuran.—To a solution of 4 g. of 1,3-diphenyl-4,7-dihydroisobenzofuran in 30 cc. of glacial acetic acid was added dropwise a solution of 0.76 cc. of bromine in 10 cc. of acetic acid. The mixture was cooled and 4 g. (67%) of product separated. It was purified by crystallization from petroleum ether (b. p. 60–110°): yellow crystals, m. p. 150–151° (corr.) with decomposition.

Anal. Calcd. for $C_{20}H_{16}OBr_2$: C, 55.55; H, 3.72. Found: C, 55.01; H, 3.77.

This compound is relatively unstable and consequently difficult to obtain in an absolutely pure state. For this reason, the analysis does not agree with the theoretical as closely as is usually expected.

***o*-Dibenzoylbenzene.**—This was prepared in the same manner as the 4,5-dimethyl derivative; yield 85%. It was purified by recrystallization from ethanol or petroleum ether (b. p. 60–110°): white crystals, m. p. 145–146° (corr.); previously reported melting points are Zincke,[4] 145–146°; Beis,[5] 149°; Bruhat and Thomas,[6] 148°; Boyd and Ladhams,[3a] 145°.

1,3-Diphenylisobenzofuran.—This was prepared in the same manner as the dimethyl homolog. After the zinc dust reduction of 1 g. of dibenzoylbenzene, the filtered solution was treated with 5 cc. of concentrated hydrochloric acid with stirring. In a few seconds, the product separated in the form of yellow flakes. The product was purified by crystallization from petroleum ether (b. p. 60–110°): yellow crystals, m. p. 125–126° (corr.); yield 69%; previously reported melting points, Guyot and Catel,[9] 125°; Boyd and Ladhams,[3a] 120–125°.

Addition of Maleic Anhydride to 1,3-Diphenyl-4,7-dihydroisobenzofuran and to 1,3-Diphenyl-5,6-dimethyl-4,7-dihydroisobenzofuran.—These addition reactions were carried out in benzene solution. Mixing of the reactants was followed immediately by formation of an orange-red color which slowly faded. The characterisric fluorescence of the furans disappeared after refluxing for a short time. By concentration of the solvent products crystallized which, however, could not be purified owing to reversal to the furan and maleic anhydride.

2,3 - Dibenzoyl - 1,4 - endomethylene - 1,2,3,4 - tetrahydrobenzene.—To a solution of 10 g. of *trans*-dibenzoylethylene in 45 cc. of dry benzene was added 10 g. of cyclopentadiene. Heat was evolved and the yellow color faded. The mixture was refluxed for several hours, then well cooled, whereupon an oil separated. Concentration to a small volume, addition of ethanol, scratching and cooling resulted in the formation of crystals. These were purified by recrystallization from methanol: white crystals, m. p. 78–79° (corr.); yield 11 g. (89%).

Anal. Calcd. for $C_{21}H_{18}O_2$: C, 83.11; H, 5.96. Found: C, 83.00; H, 6.15.

A solution of 0.5 g. of *cis*-dibenzoylethylene in 15 cc. of absolute ethanol was refluxed with 1 g. of cyclopentadiene for four hours. This gave white needles on cooling. Purified by recrystallization from ethanol, m. p. 160–161° (corr.). This compound was a second isomer.

Anal. Calcd. for $C_{21}H_{18}O_2$: C, 83.11; H, 5.96. Found: C, 82.70; H, 6.12.

Summary

New and unusually satisfactory methods for preparing dihydroisobenzofurans, isobenzofurans and *o*-dibenzoylbenzenes are described.

Butadiene and 2,3-dimethylbutadiene have been condensed with *trans*-dibenzoylethylene to give 4,5-dibenzoylcyclohexene and its 1,2-dimethyl derivative. These dibenzoyl compounds are quantitatively converted by means of a little phosphoric acid in acetic anhydride to dihydroisobenzofurans. These, in turn, by bromine and sodium acetate give excellent yields of *o*-dibenzoylbenzenes.

It has been shown that the *o*-dibenzoylbenzenes can be converted quantitatively to isobenzofurans by ethanolic sodium hydroxide and activated zinc dust.

Both the dihydroisobenzofurans and the isobenzofurans add maleic anhydride and the adducts of the latter may be converted to naphthalene derivatives.

Cyclopentadiene also adds to *trans*- and *cis*-dibenzoylethylenes with formation of isomeric adducts.

Condensations Brought about by Bases. VIII. The Conversion of Ethyl Benzoyldimethylacetate to Ethyl Benzoate and Ethyl Isobutyryl-isobutyrate in the Presence of Sodium Ethoxide and Triphenylmethane. The Reversibility of the Claisen Type of Condensation[1]

BY CHARLES R. HAUSER AND BOYD E. HUDSON, JR.

Recently[2] it was shown that ethyl isobutyrate condenses with ethyl benzoate in the presence of sodium triphenylmethyl to form ethyl benzoyldimethylacetate, but in order to obtain this product it was necessary to stop the reaction by acidification within a short time (thirty minutes). When the reaction mixture was allowed to stand for several days before acidification no ethyl benzoyldimethylacetate could be isolated. This indicated that ethyl benzoyldimethylacetate, although first formed by the condensation of ethyl isobutyrate with ethyl benzoate, was cleaved later by the sodium ethoxide and triphenylmethane which were produced during the reaction. This has now been definitely established.

It has been found that ethyl benzoyldimethylacetate (synthesized from the enolate of ethyl isobutyrate and benzoyl chloride[3]) on standing in ether solution with sodium ethoxide and triphenylmethane at room temperature decomposes completely within five days. On working up the reaction mixture after this time, none of the original ethyl benzoyldimethylacetate could be isolated; instead ethyl benzoate and ethyl isobutyryl-isobutyrate were obtained.

The condensation of ethyl isobutyrate with ethyl benzoate, in the presence of sodium triphenylmethyl, to form ethyl benzoyldimethylacetate, as well as the cleavage of the latter and the condensation of ethyl isobutyrate with itself, may be represented by the following equations.

(I) $H—C(CH_3)_2COOC_2H_5 + (C_6H_5)_3CNa \rightleftharpoons Na[C(CH_3)_2COOC_2H_5] + (C_6H_5)_3CH$

(II) $C_6H_5COOC_2H_5 + Na[C(CH_3)_2COOC_2H_5] \rightleftharpoons$
Component A Component B
$C_6H_5C(ONa)(OC_2H_5)C(CH_3)_2COOC_2H_5 \rightleftharpoons C_6H_5COC(CH_3)_2COOC_2H_5 + NaOC_2H_5$

(III) $H—C(CH_3)_2COOC_2H_5 +$
Component A
$Na[C(CH_3)_2COOC_2H_5] \rightleftharpoons$
Component B
$H—C(CH_3)_2C(ONa)(OC_2H_5)C(CH_3)_2COOC_2H_5 \rightleftharpoons H—C(CH_3)_2COC(CH_3)_2COOC_2H_5 + NaOC_2H_5$

These reactions are regarded as essentially ionic.[4] The ethyl isobutyrate is converted into its sodium derivative (enolate) by means of sodium triphenylmethyl as represented by equation (I). The anion of the sodium enolate is undoubtedly a resonance structure, its two resonance forms being represented by (IV) (a) and (b); the mesomeric form of the anion may be represented by (c).

(IV)
(a) $(CH_3)_2\overset{\ominus}{C}—COOC_2H_5$
(b) $(CH_3)_2C=\underset{\ominus}{C}(O)OC_2H_5$
(c) $CH_3—\overset{\ominus}{C}(—O)—C(CH_3)(OC_2H_5)$

The condensations represented by equations (II) and (III) may be considered to involve the addition of the enolate anion to the carbon atoms of the carbonyl groups of the esters, ethyl benzoate and ethyl isobutyrate, to form intermediate anions with the charge on the oxygen atoms; the intermediate anions release ethoxide ion giving the β-keto esters.

When equimolar quantities of ethyl isobutyrate, ethyl benzoate and sodium triphenylmethyl are used, reaction (II) at first predominates over reaction (III). This is the case even though the ethyl isobutyrate and the sodium triphenylmethyl are allowed to react for a few minutes before adding the ethyl benzoate. After a time, however, reaction (III) becomes predominant, reaction (II) being reversed completely. This illustrates the reversibility of the Claisen type of condensation.[5]

The fact that reaction (II) at first predominates was anticipated on the basis that not only is the carbonyl group of ethyl benzoate probably more reactive than that of ethyl isobutyrate, but the

(5) In this connection see Dieckmann, *Ber.*, **33**, 2670 (1900); *ibid.*, **41**, 1260 (1908); see also Arndt and Loewe, *ibid.*, **71**, 1636 (1938).

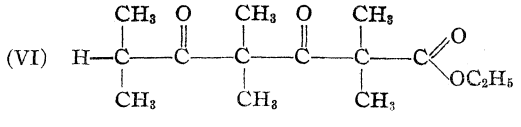
concentration of the latter, which may serve as component A, is much lower than that of ethyl benzoate; this is so because most of the ethyl isobutyrate is soon converted by the sodium triphenylmethyl into its enolate which is incapable of serving as component A.

The reason why ethyl benzoyldimethylacetate, in the presence of sodium ethoxide and triphenylmethane, is converted completely into ethyl benzoate and ethyl isobutyryl-isobutyrate is not entirely clear, but this change appears to be connected with the capacity for enolization of the latter and its existence in the reaction mixture in the form of its enolate. The formation of this enolate from the reactants used may be illustrated thus

$$\text{(V)}\quad 2C_6H_5COC(CH_3)_2COOC_2H_5 + NaOC_2H_5 \xrightarrow{(C_6H_5)_3CH} 2C_6H_5COOC_2H_5 + Na[C(CH_3)_2COC(CH_3)_2COOC_2H_5]$$

The formation of ethyl isobutyryl-isobutyrate from ethyl benzoyldimethylacetate presumably involves the cleavage of the latter and the condensation of two isobutyrate residues as represented in (III). The reversal of equation (II) gives the enolate of ethyl isobutyrate but apparently the only way the free ester, required for reaction (III), could be formed from ethyl benzoyldimethylacetate is by the reaction of the enolate of ethyl isobutyrate (formed by the reversal of II) with the proton donor, triphenylmethane (the reverse of reaction I). This gives the strong base sodium triphenylmethyl, which readily can convert the ethyl isobutyryl-isobutyrate as it is formed in reaction (III) into its enolate.

Experimental evidence has been obtained that at least most of the ethyl isobutyryl-isobutyrate, produced by the action of sodium ethoxide on ethyl benzoyldimethylacetate in the presence of triphenylmethane, is in the form of its enolate. The evidence has been obtained as follows. The reaction mixture of ethyl benzoyldimethylacetate, sodium ethoxide and triphenylmethane, after standing five days (during which time the cleavage is complete) was treated with isobutyryl chloride. On working up the resulting mixture, there was obtained, in addition to ethyl benzoate and ethyl isobutyryl-isobutyrate, a 32% yield of the compound represented by formula (VI).



Presumably, compound (VI) could have resulted only if the ethyl isobutyryl-isobutyrate were in the form of its enolate,[6] since the free β-keto ester does not condense with acid chlorides. Previously,[6] a yield of 46% of compound (VI) has been obtained from the enolate of pure ethyl isobutyryl-isobutyrate and isobutyryl chloride. Judging from this yield of compound (VI), it would appear that most of the ethyl isobutyryl-isobutyrate obtained from ethyl benzoyldimethylacetate (in the presence of sodium ethoxide and triphenylmethane) was in the form of its enolate. The passage from ethyl benzoyldimethylacetate (which is incapable of enolizing) to the enolate anion of ethyl isobutyryl-isobutyrate, which is a resonance structure, might furnish a driving force for the reaction.[7]

That the proton donor, triphenylmethane, is necessary for the conversion of ethyl benzoyldimethylacetate to ethyl benzoate and ethyl isobutyryl-isobutyrate is shown by the fact that the former ester may be recovered unchanged after standing for five days with sodium ethoxide in ether. Stronger proton donors, such as water or alcohol, cause ethyl benzoyldimethylacetate to be cleaved into acids or esters.[8]

In connection with the results presented above it is of interest to consider the reaction of sodium ethoxide with certain other β-keto esters. Dieckmann[5] reported that ethyl α,α-diethylacetoacetate with sodium ethoxide gave the acetyl derivative of this β-keto ester. We have obtained similar results with ethyl α,α-dimethylacetoacetate (VII). In the presence of sodium ethoxide, compound (VII) gave a good yield of ethyl isobutyrate, a fair yield of ethyl γ-acetyl-α,α-dimethylacetoacetate (VIII), and some ethyl acetate; also, some unchanged compound (VII) was recovered.

$CH_3COC(CH_3)_2COOC_2H_5$
(VII)
$CH_3COCH_2COC(CH_3)_2COOC_2H_5$
(VIII)

It is assumed that compound (VII), in the presence of sodium ethoxide, is cleaved to form ethyl

(6) Similar evidence has been obtained that the ethyl isobutyryl-isobutyrate, produced by the self-condensation of ethyl isobutyrate by means of sodium triphenylmethyl, is in the form of its sodium enolate. See Hudson and Hauser, THIS JOURNAL, **61**, 3567 (1939).

(7) The over-all reaction may depend upon the relative acidities (including the "activities" of the carbonyl groups) and basicities of the starting materials and of the products formed.

(8) In the presence of sodium ethoxide and alcohol, β-keto esters undergo "ester cleavage" giving two moles of ester (see ref. 5). Ethyl benzoyldimethylacetate in the presence of aqueous sodium hydroxide probably forms sodium benzoate and ethyl isobutyrate, the latter undergoing hydrolysis giving sodium isobutyrate.

acetate and the sodium enolate of ethyl isobutyrate. The latter, which is a strong base, immediately enolizes unchanged ethyl α,α-dimethylacetoacetate (VII). The enolate thus produced condenses with the ethyl acetate formed by the cleavage of (VII) giving compound (VIII) which is converted into its enolate by sodium ethoxide.

It is of interest to note that no appreciable amount of ethyl acetoacetate, which might have resulted by the self-condensation of the ethyl acetate, was obtained from the reaction. This is in agreement with theoretical considerations. One should expect that the enolate of ethyl isobutyrate, practically as rapidly as it is formed, should enolize unchanged ethyl α,α-dimethylacetoacetate (VII) rather than the ethyl acetate. The keto ester is not only the stronger acid but it is present in higher concentration than ethyl acetate, since the equilibrium of the cleavage reaction is probably far on the side of the unchanged β-keto-ester.

Finally, it should be noted that the original keto-ester, ethyl α,α-dimethylacetoacetate (VII), is not enolized appreciably by sodium ethoxide, whereas the final keto-ester, ethyl γ-acetyl-α,α-dimethylacetoacetate (VIII), is enolized by this base.

Experimental[9]

The Reaction of Ethyl Benzoyldimethylacetate with Sodium Ethoxide in the Presence of Triphenylmethane.—A solution of sodium triphenylmethyl was prepared as described previously[10,11] from 63 g. of triphenylchloromethane (m. p. 112–113°), 1500 cc. of dry ether (dried with sodium), and 2000 g. of 1% sodium amalgam. The average concentration of the base in solutions prepared from recrystallized[12] triphenylchloromethane has been found to be about 0.13 mole per liter. Approximately 1150 cc. of this solution was delivered by means of a nitrogen siphon to a previously calibrated 2-liter Pyrex glass-stoppered bottle filled with dry nitrogen. By means of a bent tube, an atmosphere of dry nitrogen was maintained in the bottle while the solution was neutralized with absolute alcohol[13] from a siphon-filled buret. The red color of the sodium triphenylmethyl became lighter as the alcohol was added, and finally, on the addition of a single drop of alcohol, there was a definite color change from orange to light yellow. This was considered to be the equivalence point of the neutralization. To this suspension of sodium ethoxide in an ether solution of triphenylmethane was added 33 g. (0.15 mole) of ethyl benzoyldimethylacetate (b. p. 146–148°) prepared from the enolate of ethyl isobutyrate and benzoyl chloride.[3] The stopper was lubricated with a little "Lubriseal," inserted immediately, and clamped in place. The mixture was allowed to stand for two weeks at room temperature with occasional shaking. At the end of that time, the stopper was removed and the mixture poured with vigorous shaking into 25 cc. of glacial acetic acid. The resulting mixture was extracted once with water and twice with 300-cc. portions of 10% sodium carbonate solution. The ether solution was dried with anhydrous sodium sulfate followed by "Drierite." The solution was filtered and the ether distilled off until the volume of the residue was approximately 75 cc. The residue was chilled overnight in the refrigerator and the supernatant solution decanted from the crystallized triphenylmethane, the latter being washed with a little ether and the washings added to the solution. After a final removal of ether by distillation at atmospheric pressure, the remaining liquid was vacuum-distilled, collecting up to 180° at 18 mm., at which point triphenylmethane began coming over. The distillate was redistilled and yielded 18 g. of material, presumably a mixture of ethyl benzoate and ethyl isobutyryl-isobutyrate, boiling at 96–116° at 18 mm. No ethyl benzoyldimethylacetate could be recovered. The fraction obtained was hydrolyzed by refluxing with 200 cc. of 8% potassium hydroxide; at the end of five hours, 8 g. additional alkali was added and refluxing continued three hours longer. The resulting mixture was cooled and extracted with four 50-cc. portions of ether. The combined ether extract was washed with a small quantity of water and dried with anhydrous sodium sulfate. The ether was distilled off. The residue yielded, on distillation at atmospheric pressure, 0.5 g. of di-isopropyl ketone boiling at 123–126°, which is the boiling point recorded previously[14] for this ketone. An additional 0.5 g. of the ketone boiling a few degrees above and below this range was obtained. The semicarbazone of the ketone melted at 159–160° in agreement with the melting point reported by Hauser and Renfrow.[4a] The alkaline solution, after the ether extraction, was boiled to remove dissolved ether. When cool, it was acidified with excess hydrochloric acid and chilled in the refrigerator. The precipitated benzoic acid was filtered by suction and air-dried; yield, 9.0 g., m. p. 118–120°. After one recrystallization from water, the melting point was 121–122° and was not lowered by the addition of an authentic specimen of benzoic acid.

A similar experiment was carried out using 10 g. (0.045 mole) of ethyl benzoyldimethylacetate and the corresponding amount of neutralized sodium triphenylmethyl solution. The reaction mixture was allowed to stand only five days and on working up yielded a fraction boiling at 91–111° at 15 mm. and weighing 6.0 g. There was no evidence of unchanged ethyl benzoyldimethylacetate.

Treatment of the Reaction Mixture of Ethyl Benzoyldimethylacetate, Sodium Ethoxide, and Triphenylmethane with Isobutyryl Chloride.—A suspension of sodium ethoxide in an ether solution of triphenylmethane was prepared as described above by neutralizing 1050 cc. of sodium triphenylmethyl solution (containing about 0.14 mole of base) with alcohol. To this suspension was added 30 g.

(9) All melting points and boiling points given are corrected.

(0.136 mole) of ethyl benzoyldimethylacetate, the bottle being stoppered and allowed to stand five days at room temperature with occasional shaking. At the end of that time, the mixture was poured into a solution of 17.5 g. (0.16 mole) of isobutyryl chloride (Eastman Kodak Co.) in 500 cc. of dry ether vigorously agitated by a mechanical stirrer. After the mixture had stood an hour in a closed vessel, 3 cc. of glacial acetic acid was added and the mixture extracted with water. The resulting ether solution was washed with 10% sodium carbonate solution and dried with anhydrous sodium sulfate followed by "Drierite." The solution was filtered and most of the ether distilled off. The residue was chilled overnight in the refrigerator and the crystallized triphenylmethane filtered off and washed with a small quantity of ether, the washings being added to the filtrate. After the ether was removed by distillation at atmospheric pressure, the filtrate was distilled at 15 mm., a fraction boiling up to 50° and another boiling from 50–180° being collected. The low-boiling fraction (approximately 3 g.) consisted presumably of ethyl isobutyrate (probably formed from isobutyryl chloride and sodium ethoxide); on redistillation at atmospheric pressure it boiled at 110–120°. The higher boiling material was refractionated at 15 mm., the following fractions being obtained: (a) 95–115° at 15 mm., 17.8 g.; (b) 115–130° at 15 mm., 2 g.; (c) 130–140° at 15 mm., 5.5 g. (Most of this fraction distilled at 135–138°.)

Fraction (a) was shown to be a mixture of ethyl benzoate and ethyl isobutyryl-isobutyrate by hydrolysis as described in the preceding experiment. A yield of 5.5 g. of benzoic acid (m. p. 121–122°) and 1 g. of di-isopropyl ketone (b. p. 115–125°) was obtained. The latter was converted into its semicarbazone, which melted at 158–159°.

Fraction (c) undoubtedly consisted largely of ethyl 2,2,4,-4,6-pentamethyl-3,5-diketoheptanoate, which boils at 136–138° at 15 mm.[6] It was cyclized to hexamethylphloroglucinol, which was identified by the mixed melting point method.[6] The yield (5.5 g.) of the heptanoate obtained corresponds to 32% of the theoretical amount, based on the quantity of ethyl benzoyldimethylacetate used.

Preparation of Ethyl Benzoyldimethylacetate by the Oxidation of Ethyl β-Phenyl-β-hydroxypivalate.—Fifty grams of ethyl β-phenyl-β-hydroxypivalate[15] (m. p. 39–40°) was dissolved in 100 cc. of glacial acetic acid on a water-bath. The solution was maintained at 80–100° while 17.3 g. (a 15% excess over the equivalent quantity) of chromic anhydride was added in 0.5-g. portions. After each addition, the mixture was stirred until reaction was complete and no chromic anhydride remained on the bottom of the flask. When all the chromic anhydride had been added, the solution was heated on the water-bath an hour longer, at the end of which time it was poured into 500 cc. of water and shaken vigorously. The resulting mixture was extracted with three 100-cc. portions of ether. The combined ether extract was washed once with water and several times with 10% sodium carbonate solution, and was dried with anhydrous sodium sulfate followed by "Drierite." The solution was filtered and the ether was removed by distillation at atmospheric pressure. The residue was vacuum-distilled and the portion of ethyl benzoyldimethylacetate boiling at 146–148° at 15 mm. collected; yield, 36 g., 72% of the theoretical amount.

Treatment of Ethyl Benzoyldimethylacetate with Sodium Ethoxide in the Absence of Proton Donors.—Fifteen grams (0.068 mole) of ethyl benzoyldimethylacetate, prepared by the oxidation of ethyl β-phenyl-β-hydroxypivalate, was dissolved in 500 cc. of dry ether and added to 4.65 g. (0.068 mole) of alcohol-free sodium ethoxide contained in a glass-stoppered flask. Several pieces of glass tubing 1 cm. long were dropped in the flask, and a glass stopper well lubricated with "Lubriseal" was inserted and clamped in place. The flask was shaken vigorously until all the caked sodium ethoxide was changed to a fine suspension. The reaction mixture was allowed to stand for five days with occasional shaking. At the end of that time, the mixture was poured with vigorous shaking into 5 cc. of glacial acetic acid, extracted with water, and washed twice with 10% sodium carbonate solution. The resulting ether solution was dried with anhydrous sodium sulfate followed by "Drierite." The solution was filtered and the ether distilled off. The residue was vacuum-distilled at 15 mm., yielding two fractions, 90–115° (2.3 g.) and 140–148° (9.8 g.). The lower boiling fraction was presumably a mixture of ethyl isobutyryl-isobutyrate and ethyl benzoate. The higher boiling fraction was shown to be ethyl benzoyldimethylacetate by conversion into its isoxazolone, which melted at 69–70° in agreement with the melting point reported in the literature.[16] The recovered ethyl benzoyldimethylacetate (9.8 g.) represents 65% of the initial quantity and 81% of the recovered products. These results indicate that ethyl benzoyldimethylacetate is essentially unaffected by sodium ethoxide in the absence of appreciable quantities of proton donors.

Reaction of Ethyl α,α-Dimethylacetoacetate with Sodium Ethoxide.—A solution of 50 g. (0.136 mole) of ethyl α,α-dimethylacetoacetate[17] (b. p. 75–76° at 15 mm.) in 1000 cc. of dry ether was added to 22 g. (0.32 mole) of alcohol-free sodium ethoxide contained in a glass stoppered flask. The flask was stoppered and allowed to stand three days with frequent shaking. At the end of that time, the mixture was acidified with 25 cc. of glacial acetic acid and extracted with water. The resulting ether solution was washed three times with 10% sodium carbonate solution and dried with anhydrous sodium sulfate. Ether was removed up to 40°. The remaining liquid was distilled through a short Widmer column up to 120°. Redistillation of the distillate and vacuum fractionation of the residue gave the following fractions:

(a)	60–80° at atm. press.	3.5 g. ethyl acetate (b. p. 77°)
(b)	80–108° at atm. press.	1.5 g. mid-fraction
(c)	108–112° at atm. press.	18.5 g. ethyl isobutyrate (b. p. 111°)
(d)	up to 75° at 15 mm.	1.2 g. mid-fraction
(e)	75–80° at 15 mm.	3.5 g. unchanged ethyl α,-α-dimethylacetoacetate
(f)	80–95° at 15 mm.	1.4 g. mid-fraction
(g)	95–121° at 15 mm.	3.5 g. largely ethyl γ-acetyl α,α-dimethylacetoacetate
(h)	121–123° at 15 mm.	5.3 g. ethyl γ-acetyl α,α-dimethylacetoacetate

(15) Blaise and Hermann, *Ann. chim. phys.*, [8] **23**, 532 (1911).

(16) See ref. 2, p. 464.

(17) Frankland and Duppa, *Ann.*, **138**, 328 (1866).

Ferric chloride tests with fractions (d) and (e) were negative, with fraction (f) faintly positive, and with fractions (g) and (h), strongly positive. Fraction (g) was shown to consist largely of ethyl γ-acetyl-α,α-dimethylacetoacetate by conversion (by means of concentrated ammonia) into the lactam of 2,2-dimethyl-3-keto-5-amino-4-hexenecarboxylic acid, melting at 139–140°; this is the melting point reported in the literature[18] for this lactam. Fraction (h) presumably consisted entirely of ethyl γ-acetyl-α,α-dimethylacetoacetate.

Summary

1. In the presence of sodium ethoxide and triphenylmethane, ethyl benzoyldimethylacetate is converted completely into ethyl benzoate and ethyl isobutyryl-isobutyrate, the latter being converted into its enolate.

2. In the complete absence of proton donors, ethyl benzoyldimethylacetate is apparently stable toward sodium ethoxide.

3. In the presence of sodium ethoxide, α,α-dimethylacetoacetic ester is converted into γ-acetyl-α,α-dimethylacetoacetic ester and ethyl isobutyrate.

4. These results illustrate the reversibility of the Claisen type of condensation.

5. The mechanisms for these reactions are discussed.

The Synthesis of Certain Oligosaccharide Acetates in the Mannose Series[1]

BY DELBERT D. REYNOLDS AND WM. LLOYD EVANS

In a recent publication, the authors[2] discussed certain improvements in the well-known Königs and Knorr reaction as it was applied to the synthesis of α- and β-gentiobiose octaacetates. Our present paper contains an account of the first successful use of this reaction in the synthesis of certain acetates in the mannose series of saccharides.

Several epimeric pairs of mono- and disaccharides have been prepared by other workers and the properties of these compounds have been studied carefully. As far as the authors are aware such an epimeric pair in the trisaccharide series has never been reported. Anticipating the interesting problems that would arise from such a synthesis, acetobromogentiobiose was condensed with β-*d*-mannose-1,2,3,4-tetraacetate, a reaction which gave rise to 6-β-gentiobiosido-β-*d*-mannose hendekaacetate. This new hendekaacetate and that of 6-β-gentiobiosido-β-*d*-glucose prepared by Helferich and co-workers[3] make available the first known epimeric pair of trisaccharides. An application of Hudson's isorotation rules has been made to these two compounds.

By another application of the improved Königs and Knorr reaction, 6-β-*d*-glucosido-α-*d*-mannose octaacetate was prepared by the condensation of acetobromoglucose with α-*d*-mannose-1,2,3,4-tetraacetate. This method of preparing this disaccharide is to be preferred to the oxidation of gentiobial by the procedure of Bergmann and Schotte[4] which was utilized previously in this Laboratory[5]; the new method involves fewer steps and gives higher yields.

During the progress of this work it became necessary to prepare ethyl gentiobioside heptaacetate, the synthesis of which is herein described, together with an application of the isorotation rules to its rotation.

Experimental Part

Purification of Reagents.—Chloroform was purified by the method described in an earlier paper.[2] The mannose was prepared according to the method of Levene.[6] Acetobromogentiobiose was prepared from gentiobiose octaacetate by the method of Brauns.[7]

6 - Trityl - β - *d* - mannose - 1,2,3,4 - tetraacetate.—The method of Helferich and Leete[8] was modified in such a way that the yield of 6-trityl-β-*d*-mannose-1,2,3,4-tetraacetate was doubled. One hundred grams of dry mannose and trityl chloride (161 g.) were added to anhydrous pyridine (500 cc.). The mixture was shaken in a thermostat at 50° until solution was complete (four hours). Without cooling, three hundred cc. of acetic anhydride was then

added in one portion. After standing at room temperature for about eighteen hours, the reaction mixture was poured slowly into seven liters of mechanically stirred ice water. The reaction product separated as a white amorphous solid. The water was changed twice in order to remove the pyridine. The crude product was separated by filtration, washed well with cold water and dried in the open air. It was then dissolved in hot 95% ethanol, decolorized with Carboraffin and the β-isomer allowed to crystallize. It was recrystallized from the same solvent; yield 150 g.; m. p. 204–206° (corr.).

β - *d* - Mannose - 1,2,3,4 - tetraacetate.—β - *d* - Mannose-1,2,3,4-tetraacetate was prepared according to the directions of Helferich and Leete[8] except for the method of crystallization.

Forty-six grams of 6-trityl-β-*d*-mannose-1,2,3,4-tetraacetate was dissolved in glacial acetic acid (200 cc.) by warming on a water-bath. The solution was cooled to 10°. Acetic acid (18 cc.) saturated with hydrogen bromide at 0° was added and the solution shaken for about forty-five seconds. The trityl bromide was removed at once by filtration and the filtrate poured into one liter of cold water. The tetraacetate was extracted with chloroform (250 cc.). The chloroform layer was washed twice with ice water and then dried over anhydrous sodium sulfate. After filtration, the chloroform was partially removed by a stream of dry air. The last traces were removed under reduced pressure. Anhydrous ether (100 cc.) was added and the sirup rubbed with a glass rod. Crystallization took place instantaneously. The product was purified by dissolving it in a minimum amount of U. S. P. chloroform and then adding anhydrous ether until crystallization began; yield 19.3 g.; m. p. 135.5–136.5° (corr.).

6-β-Gentiobiosido-β-*d*-mannose Hendekaacetate.—Sixteen grams (1.2 mol) of β-*d*-mannose-1,2,3,4-tetraacetate, silver oxide (26 g.), Drierite (100 g.) preheated at 240° for two hours, and dry, alcohol-free chloroform (150 cc.) were placed in a 500 cc. three-necked, round-bottomed flask equipped with a mercury-sealed mechanical stirrer, a calcium chloride drying tube and a dropping funnel. The flask was wrapped in black paper. The contents of the flask were stirred for about one hour to ensure the complete absence of water. Iodine (5 g.) was then added to the reaction mixture. Acetobromogentiobiose[7] (26.6 g., 1 mol) was dissolved in dry, alcohol-free chloroform (100 cc.) and then added through the dropping funnel to the reaction mixture over a course of about one hour. The stirring was then continued for an additional twenty-four hours. The reaction mixture was filtered through a layer of "Filter-Cel" and the residue washed well with U. S. P. chloroform. The filtrate was blown down by a stream of dry air and finally concentrated to a sirup under reduced pressure. The sirup was then dissolved in 95% ethanol. Crystallization began after a short time at room temperature. After standing in the refrigerator overnight, the crystals were filtered and dried; yield 27 g. (73.4%), m. p. 116–118° (corr.); after six recrystallizations, m. p. 122–123° (corr.) and $[\alpha]^{25}D$ −21.02° (*c*, 3.92; *l*, 2; $CHCl_3$).

Anal. Calcd. for $C_{18}H_{21}O_{16}(COCH_3)_{11}$: (a) acetyl, 11.39 cc. of 0.1 *N* sodium hydroxide per 100 mg. sample; C, 49.66; H, 5.63; mol. wt., 966. Found: (b) acetyl, 11.41 and 11.42; C, 48.55; H, 5.62; mol. wt., by Rast method, 935 and 1000.

Ethyl Gentiobioside Heptaacetate.—The preparation of 6-β-gentiobiosido-β-*d*-mannose hendekaacetate was repeated several times. In one instance crystalline ethyl gentiobioside heptaacetate was isolated as a result of insufficiently purified chloroform. Ethyl gentiobioside heptaacetate has not been recorded in the literature. For identification and characterization, it has been prepared by the method described for 6-β-gentiobiosido-β-*d*-mannose hendekaacetate. A mixture of absolute ethanol (100 cc.), silver oxide (10 g.), Drierite (50 g.) and dry chloroform (75 cc.) was stirred for one hour. One gram of iodine was added. Acetobromogentiobiose (15 g.) was dissolved in dry chloroform (25 cc.) and then added to the reaction mixture over a period of about one hour. After stirring for twenty-four hours, the reaction mixture was treated as previously described for 6-β-gentiobiosido-β-*d*-mannose hendekaacetate. Crystallization began as soon as the chloroform was removed. The product was filtered and recrystallized from 95% ethanol; yield 11.7 g. (82%) m. p. 158–159° (corr.); $[\alpha]^{25}D$ −23.06° (*c*, 4.12; *l*, 2; $CHCl_3$).

Anal. Calcd. for $C_{14}H_{19}O_{11}(COCH_3)_7$; acetyl, 10.54 cc. of 0.1 *N* sodium hydroxide per 100 mg. of sample. Found: acetyl, 10.51 cc.

6-Trityl-α-*d*-mannose-1,2,3,4-tetraacetate.—A mixture of dry mannose (20 g.), trityl chloride (32.2 g.) and anhydrous pyridine (100 cc.) was shaken mechanically at room temperature. Solution was effected within four hours. The solution was placed in the refrigerator at 0° for fifteen hours and then poured slowly into two liters of mechanically stirred ice water. This water was changed three times. The granular precipitate was then filtered and dried, after which it was dissolved in pyridine and placed in the refrigerator for twelve hours. It was then kept at a temperature of 0–5° while 60 cc. of acetic anhydride was added and then placed in the refrigerator overnight. Ice water was added to turbidity and the solution poured slowly into three liters of mechanically stirred ice water. The water was changed twice. The dried precipitate (48 g.) was taken up in absolute ethanol (300 cc.), decolorized with Carboraffin and filtered. Crystallization began when the solution was blown down by a stream of dry air; yield 15 g. After one recrystallization $[\alpha]D$ +73.5° ($CHCl_3$); m. p. 123–124° (corr.).

6-β-*d*-Glucosido-α-*d*-mannose Octaacetate.—6-Trityl-α-*d*-mannose-1,2,3,4-tetraacetate (34 g.) was dissolved in glacial acetic acid (100 cc.). After cooling to 10° a saturated solution of hydrogen bromide in glacial acetic acid (18 cc.) was added. The solution was shaken for about one minute, filtered and the filtrate poured into one liter of water (25°). This water was stirred for one hour, in order to dissolve the α-*d*-mannose-1,2,3,4-tetraacetate and then filtered. The filtrate was extracted with U. S. P. chloroform (500 cc.), the chloroform portion washed three times with three 400-cc. portions of ice water, dried over anhydrous sodium sulfate and blown down to a sirup. This sirup was finally concentrated under reduced pressure and taken up in anhydrous alcohol-free chloroform.

To this chloroform solution were added Drierite (15 g.), and silver oxide (8 g.). After stirring for one-half hour,

iodine (0.5 g.) was added and then acetobromoglucose (8 g.), dissolved in anhydrous alcohol-free chloroform (35 cc.), was added over a course of one hour. The apparatus used was the same as that for the preparation of 6-β-gentiobiosido-β-*d*-mannose hendekaacetate. The reaction mixture was stirred for a total of twenty-four hours, filtered and concentrated to a sirup. This sirup was dissolved in 95% ethanol (50 cc.) and placed in the refrigerator. Crystallization began immediately; yield 6 g. (45.5%); after one recrystallization $[\alpha]_D$ +26.01° (*c*, 2.96; *l*, 2; $CHCl_3$), the same value as that recorded by Dauben and Evans.[5]

Discussion

The isorotation rules of Hudson[9] afford a means of arriving at the approximate rotation of the trisaccharide acetate. If it is assumed that the epimeric difference of the molecular rotation between 6-β-gentiobiosido-β-*d*-glucose hendekaacetate and 6-β-gentiobiosido-β-*d*-mannose hendekaacetate has the same value as that between β-*d*-glucose pentaacetate and β-*d*-mannose pentaacetate under the experimental conditions indicated by the symbol, $[\alpha]^{25}D$, then by the relation

$$[\alpha_A]M_A[10] - [\alpha_B]M_B = [\alpha_{A'}]M_{A'} - [\alpha_{B'}]M_{B'}$$

it is possible to calculate the approximate rotation of 6-β-gentiobiosido-β-*d*-mannose hendekaacetate (B) from the known values of the molecular rotations of 6-β-gentiobiosido-β-*d*-glucose hendekaacetate (A),[3] β-*d*-glucose pentaacetate (A)[11] and β-*d*-mannose pentaacetate (B)[11] all measurements referring to chloroform solutions. Thus

$$\begin{aligned}[\alpha_B]M_B &= [\alpha_A]M_A - [\alpha_{A'}]M_{A'} + [\alpha_{B'}]M_{B'}\\ &= (-7728) - (1482) + (-9828)\\ &= -19{,}038\\ \therefore [\alpha_B] &= -19.7^\circ \text{ (The observed value is } -21.0^\circ.)\end{aligned}$$

Hudson[12] and Isbell[13] have shown previously that the values for the epimeric difference in the α-derivatives of the mannose series are entirely different from those of the β-derivatives. This is illustrated for the acetates in Table I.

Haworth and Hirst[14] have pointed out that the values of "the epimeric differences required by Hudson's scheme are not found in 4-glucosidomannose octaacetate and cellobiose octaacetate." However, it may be observed from Table I, as was shown by Dauben and Evans,[5] that the epimeric differences of α-gentiobiose octaacetate and 6-β-*d*-glucosido-α-*d*-mannose octaacetate agree very well with that of α-*d*-glucose pentaacetate and α-*d*-mannose pentaacetate. Further observation shows that the epimeric difference for 6-β-gentiobiosido-β-*d*-glucose hendekaacetate and the newly synthesized 6-β-gentiobiosido-β-*d*-mannose hendekaacetate agree in a satisfactory way with that of β-*d*-glucose pentaacetate and β-*d*-mannose pentaacetate. It thus appears that the epimeric relationships hold for the 6-linked sugar acetates, although they fail for the 4-linked acetates. Since the epimeric difference is twice the rotational value of carbon 2, the farther the glucosido portion is removed from carbon 2 the less influence it seems to have on the value of the epimeric difference.

TABLE I

EPIMERIC DIFFERENCES OF MOLECULAR ROTATION IN THE GLUCOSE AND MANNOSE SERIES

Sugar acetates	$[\alpha]_D$	Mol. epimeric diff.
α-Glucose pentaacetate	+101.6°	
α-Mannose pentaacetate	+ 55.0°	+18,200
α-Gentiobiose octaacetate	+ 52.4°	
α-6-Glucosidomannose octaacetate	+ 26.0°	+17,900
α-Cellobiose octaacetate	+ 42.0	
α-4-Glucosidomannose octaacetate	+ 36.2	+ 3,260
β-Glucose pentaacetate	+ 3.8	
β-Mannose pentaacetate	− 25.2	+11,300
β-Gentiobiosido-β-*d*-glucose hendekaacetate	− 8.0	
β-Gentiobiosido-β-*d*-mannose hendekaacetate	− 21.0	+12,600
β-Cellobiose octaacetate	− 14.6	
β-4-Glucosidomannose octaacetate	− 13.0	− 1,940

The rotation of the new β-ethyl gentiobioside heptaacetate may be calculated from the known values for

β-methylgentiobioside heptaacetate[15] ($[M]_D$ = (−18.9)-(650) = −12.300)

β-methylglucoside tetraacetate[16] ($[M]_D$ = (−18.3)(362) = −6600)

β-ethylglucoside tetraacetate[17] ($[M]_D$ = (−22.7)(374) = −8535)

The isorotation rules give the augmentation of the molecular rotation from the methyl to the ethyl compound as 8535−6600 = 1935; hence

the $[\alpha]_D$ value for β-ethylgentiobioside heptaacetate is calculated to be $(-12{,}300-1935)/664 = -21.4°$, which agrees satisfactorily with the observed value, $-23.1°$.

Acknowledgment.—The authors wish to acknowledge the assistance given by William G. Dauben and Harold D. McDowell during the progress of this work.

Summary

1. A new crystalline 6-β-gentiobiosido-β-*d*-mannose hendekaacetate has been synthesized by the improved Königs and Knorr reaction and its physical properties determined. This is the first time that a crystalline 6-linked oligosaccharide acetate containing mannose has been synthesized by this method.

2. The epimeric difference relationships of the new 6-β-gentiobiosido-β-*d*-mannose hendekaacetate and the known 6-β-gentiobiosido-β-*d*-glucose hendekaacetate have been correlated with others of the mannose series. The specific rotation as calculated by Hudson's rules is $-19.7°$. The observed specific rotation is $[\alpha]^{25}D$ $-21.0°$. It has been pointed out that the values of the epimeric differences as required by Hudson's scheme seem to hold for 6-linked sugars although they do not hold for 4-linked sugars.

3. The known 6-β-*d*-glucosido-α-*d*-mannose octaacetate has been made more available by the improved Königs and Knorr reaction. Its preparation represents the second synthesis of a crystalline 6-linked oligosaccharide acetate containing a mannose unit.

4. Ethylgentiobioside heptaacetate has been synthesized and its physical properties determined, m. p. 158–159° (corr.); $[\alpha]^{25}D$ $-23.1°$. This rotation agrees with that which is calculated $(-21.4°)$ from Hudson's rules.

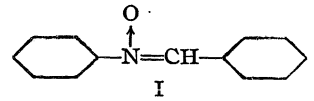
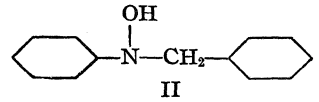
Secondary Amines from Nitro Compounds

BY WILLIAM S. EMERSON AND H. W. MOHRMAN

Since most aromatic primary amines are prepared by the reduction of nitro compounds, it seemed possible that the procedure for reductive alkylation of these amines[1] could be adapted to apply directly to the original nitro compounds. Vavon and Crajcinovic,[2] reduced a mixture of nitrobenzene and benzaldehyde with hydrogen and platinum. By suitably interrupting the reduction they obtained the nitrone I or the alkylarylhydroxylamine II.



I



II

They postulated the course of the reaction as (1) reduction of the nitrobenzene to phenylhydroxylamine, (2) condensation of the phenylhydroxylamine with the benzaldehyde to give the nitrone I and (3) reduction of the nitrone to the substituted hydroxylamine II.

In order to obtain secondary amines it, therefore, appeared necessary to determine satisfactory conditions for the reduction of the hydroxylamine II. From the work of Major[3] it seemed likely that hydrogen and a catalyst would be suitable. He reduced *p*-nitrophenol with hydrogen and platinum in acetone solution to obtain good yields of *p*-hydroxy-N-isopropylaniline. Later he extended the reaction to obtain N,N′-diisopropyl-*p*-phenylenediamine in good yield from *p*-nitroaniline, but states he was unable to obtain alkylation with nitrobenzene and acetone or with *p*-nitrophenol and formaldehyde or acetaldehyde. Benzaldehyde, however, gave *p*-hydroxydibenzylaniline with *p*-nitrophenol. For these reactions Major postulated the same mechanism as that proposed by Vavon and Crajcinovic.

We have found that when an alcoholic solution of an aromatic nitro compound and an aldehyde is reduced with hydrogen and Raney nickel in the presence of sodium acetate as a condensing agent, the corresponding secondary amine is formed in good yield. The reaction is apparently general

for aromatic nitro compounds and aliphatic or aromatic aldehydes. Our results are summarized in Table I.

Experimental

General Procedure.—All of the reactions were carried out in a machine for catalytic reduction[4] using Raney nickel[5] as the catalyst. In each experiment 0.1 mole of the nitro compound, 0.3 mole of the aldehyde and 2.0 g. of sodium acetate were dissolved in 150 cc. of alcohol. From 3.0 to 6.0 g. of Raney nickel was then added and the mixture placed in the machine at an initial pressure of 40 lb. It was shaken until no more hydrogen was absorbed, usually from twelve to twenty-four hours, 0.42 to 0.62 mole of hydrogen being taken up. After the catalyst had been removed by filtration, the solvent was distilled on the steam-bath. The remaining oil was steam distilled and the residue or distillate, depending on the amine, fractionated to obtain the pure product.

N-Alkylarylamines.—Using the general procedure described above, we have prepared twelve N-alkylarylamines in yields of from 31 to 96%. The compounds prepared, yields, and derivatives used in their identification are shown in Table I. Four of these amines are new and their characterization is summarized in Table II. In all cases except the toluidines the yield of tertiary amine was negligible. No appreciable quantity of high boiling material was isolated except in the case of N-*n*-amylaniline where there was 1.5 cc. of a high boiling oil.

In the case of *p*-nitrotoluene appreciable quantities of the tertiary amines were formed: 53% of N,N-di-*n*-butyl-*p*-toluidine in the first butyraldehyde run and 34% of N,N-di-*n*-heptyl-*p*-toluidine in the heptaldehyde run. The latter is a new compound and is included in Table II. Since our constants for N,N-di-*n*-butyl-*p*-toluidine differ from those previously recorded, this compound is also in Table II.

Summary

A procedure has been developed for preparing N-alkylarylamines from aromatic nitro compounds in 31 to 96% yields by treating an alcoholic solution of the nitro compound and an aldehyde with hydrogen and Raney nickel in the presence of sodium acetate.

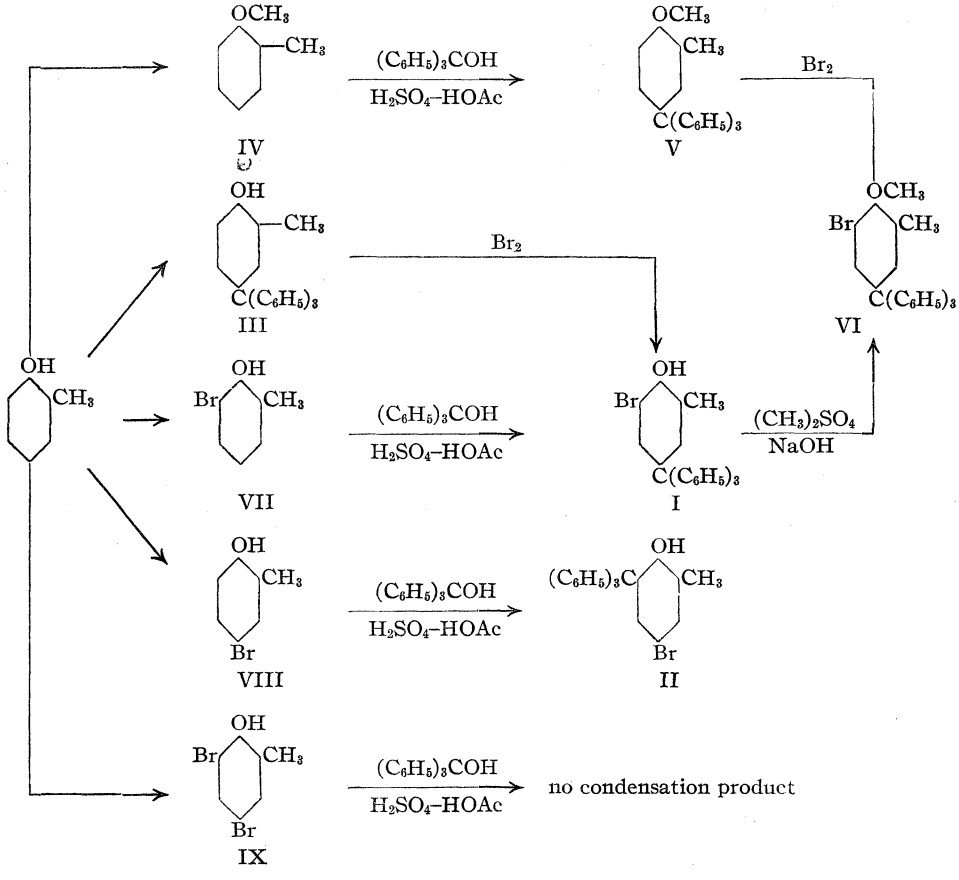
Rearrangement of the Triphenylmethyl Ethers of Ortho Cresol and Brominated Ortho Cresols

BY H. A. IDDLES, W. H. MILLER AND W. H. POWERS

In a previous communication[1] a derivative of the postulated rearrangement product[2,3] from the triphenylmethyl ether of *o*-cresol was reported. However, the synthetic α-2-methoxyphenyl-β,β,-β-triphenylethane possessed a lower m. p. of 142–143° than the methylated cryptophenol, m. p. 165°, which supported the interpretation[4] that the triphenylmethyl group had not migrated to the side chain of *o*-cresol.

To substantiate the alternate hypothesis that migration involves a ring position, certain positions in the *o*-cresol molecule were blocked by bromine atoms, thus limiting the possible positions which a triphenylmethyl group might enter in the ensuing ether rearrangement or direct condensation reactions. The products of these reactions were then compared with the brominated product from the cryptophenol under consideration. This is shown in the accompanying schematic set of reactions.



Parallel condensations were made using triphenylcarbinol, sulfuric acid and glacial acetic acid on 6-bromo-*o*-cresol, VII, 4-bromo-*o*-cresol, VIII, and 4,6-dibromo-*o*-cresol, IX. In the case of VII, in which a para position is free, a good yield (55%) of product I was obtained, whereas using VIII in which an ortho position is open, there was a low yield of product (6.75%) and no condensation product from IX could be recovered. Further by adding an equivalent of bromine to the cryptophenol III[2] in carbon tetrachloride solution, the same monobrominated product I was obtained, which indicates the entrance

(4) Boyd and Hardy, *J. Chem. Soc.*, 630 (1928).

of bromine into position 6 and indirectly that position 4 must be occupied by the triphenylmethyl group prior to bromination.

Since Boyd and Hardy[4] had condensed *o*-methoxytoluene with triphenylcarbinol in an acid medium and then brominated the resulting methyl ether to give a product, m. p. 180°, to which they assign structure VI, the present structure I was methylated and found to produce a material with the same m. p., 183–184°. Thus it is shown in preparing product I by two routes and product VI by two different sets of investigators and procedures, a common product was formed in each case.

In reactions[2,5,6,7] leading to the formation of the triphenylmethyl ethers of the three brominated *o*-cresols, an ether was produced from VIII but no ether formation occurred with VII and IX, apparently due to spacial hindrance. However, from VII a good yield of rearranged product I, m. p. 152°, was produced directly, agreeing with the compound prepared by the two procedures described above.

Experimental

Preparation of Brominated Cresols.—The 6-bromo-*o*-cresol VII was prepared by the procedure of Huston and Neeley.[8] The 4-bromo-*o*-cresol VIII was prepared as described by Goldschmidt, Schulz and Bernard.[9] The 4,6-dibromo-*o*-cresol IX was prepared similarly by dissolving 27 g. of *o*-cresol in 90 ml. of carbon tetrachloride and adding 80 g. of bromine in 10 ml. of carbon tetrachloride to the cooled, stirred solution during a two-hour period. After standing for fifteen minutes, yellow needles separated. These were filtered off and the mother liquor evaporated under reduced pressure to yield several further crops. Recrystallization from alcohol yielded a colorless product, m. p. 56.5–57.5°, in a 70% yield.

Condensation of *o*-Cresol and Triphenylcarbinol.—The rearranged product resulted as described previously.[1]

Condensation of 6-Bromo-*o*-cresol VII and Triphenylcarbinol.—Twenty grams of 6-bromo-*o*-cresol, 135 g. of glacial acetic acid, and 4.5 g. of triphenyl-carbinol were mixed and 23 g. of sulfuric acid was added dropwise, producing a deep reddish-brown coloration. After standing for three weeks, the solution was poured into 1500 ml. of water, producing a deep violet solution and a slight precipitate. The solution and solid were extracted with ether, washed with 10% sodium hydroxide to remove unreacted 6-bromo-*o*-cresol, then with water and dried over anhydrous sodium sulfate. After distilling off the ether the remaining amber oil was dissolved in 500 ml. of ligroin and extracted with Claisen's solution. The extract was acidified with hydrochloric acid, producing a precipitate which was recrystallized from alcohol or ligroin giving a 55% yield, m. p. 149–151°.

Anal. Calcd. for $C_{26}H_{21}OBr$: Br, 18.61. Found: Br, 18.39, 18.29.

Condensation of 4-Bromo-*o*-cresol VIII and Triphenylcarbinol.—4-Bromo-*o*-cresol, 26 g., was mixed with 135 g. of glacial acetic acid and 4.5 g. of triphenylcarbinol and 23 g. of sulfuric acid added slowly. No solid separated after standing for several weeks. Then the solution was poured into two liters of water, producing a black oil which was extracted with ether. After washing the ether extract with 10% sodium hydroxide, 21 g. of unchanged 4-bromo-*o*-cresol was recovered by acidifying the basic washings. The ether layer was dried and evaporated to yield a brown oil which was taken up in ligroin. Treatment with Claisen's solution, followed by acidification, gave a product which was recrystallized from alcohol with a yield of 0.5 g. or 6.75%, m. p. 208–209°.

Anal. Calcd. for $C_{26}H_{21}OBr$: Br, 18.61. Found: Br, 18.81, 18.57.

Attempted Condensation of 4,6-Dibromo-*o*-cresol IX and Triphenylcarbinol.—When the dibromo-*o*-cresol was carried through the usual condensation procedure, no significant condensation product could be recovered in the various steps of recovery.

Bromination of Schorigin's Cryptophenol III.—The simple cryptophenol (m. p. 180–183°), 7 g., was dissolved in 325 ml. of carbon tetrachloride, a few tacks were added and, while cooling and stirring, one equivalent (3.2 g.) of bromine dissolved in 25 ml. of carbon tetrachloride was added slowly. As the reaction proceeded the remaining cryptophenol dissolved and hydrogen bromide was evolved. After standing six hours, the reaction mixture was washed with water, dried with anhydrous sodium sulfate and then evaporated under reduced pressure. A creamy residue resulted which was recrystallized from ligroin (70–90°) and gave 7.35 g. or 85.7% yield, m. p. 149–151°. A mixed melting point with I obtained by the condensation of 6-bromo-*o*-cresol and triphenylcarbinol, also m. p. 149–151°, gave no depression and thus they were proved to be identical.

Methylation of Compound I.—One gram of the monobrominated cryptophenol I, dissolved in 50 ml. of benzene, was refluxed with 30 g. of sodium hydroxide in 60 ml. of water while adding 2 g. of dimethyl sulfate during a period of fifteen minutes. After one-half hour, another portion of alkali was added to destroy excess of dimethyl sulfate. Following ether extraction, washing with water and drying, the solvents were partially evaporated. Upon addition of ligroin (70–90°) crystallization resulted yielding 0.8 g. of product, m. p. 183–184°. By another synthesis[4] this product was found to melt at 180°.

Preparation of Rearranged Compound from 6-Bromo-*o*-cresol VII and Triphenylchloromethane.—In an attempt to prepare the triphenylmethyl ether of 6-bromo-*o*-cresol, 19 g. of the cresol was dissolved in 50 ml. of dry ether and 2.3 g. of sodium added. After complete reaction of the sodium, 15 g. of triphenylchloromethane dissolved in 200 ml. of dry ether was added and the reaction mixture refluxed for five hours. The cooled ether layer was washed with water and carried through the usual treatments with

10% sodium hydroxide and Claisen's extraction of a ligroin solution. Upon acidification of the two alkaline solutions, 9.5 g. (41.5%) of product, m. p. 150–152°, was obtained. This agreed by mixed melting point and analysis with the rearranged product I obtained by the direct condensation above. Further attempts to prepare the ether using potassium, potassium carbonate and acetone or a pyridine medium produced varying quantities of the same rearrangement product.

Attempted Preparation of Triphenylmethyl Ether of 4,6-Dibromo-*o*-cresol IX.—Ten grams of the 4,6-dibromo-*o*-cresol was treated with 1.5 g. of sodium in dry ether and 10 g. of triphenylchloromethane was added. After refluxing and carrying out the usual steps of recovery, no ether could be obtained but a large portion of the original brominated *o*-cresol and triphenylcarbinol was recovered.

Preparation of the Triphenylmethyl Ether of 4-Bromo-*o*-cresol VIII.—Eleven grams of 4-bromo-*o*-cresol was dissolved in 45 ml. of pyridine (dried and distilled from barium oxide) and 15 g. of triphenylchloromethane was added. After heating the mixture for ten hours, water and ether were added and the ether layer was washed with dilute hydrochloric acid, then with 10% sodium hydroxide and finally with water. After drying the ether layer and evaporation, the residue was taken up in ligroin (70–90°) and washed with Claisen's solution. No product was removed by the alkaline washing but from the ligroin layer, a product was obtained which was recrystallized from alcohol. A yield of 11.25 g. or 48.7%, m. p. 113.5–114°, was obtained.

Anal. Calcd. for $C_{26}H_{21}OBr$: Br, 18.61. Found: Br, 18.74, 18.65.

Attempted rearrangement of this ether in glacial acetic acid–sulfuric acid mixtures by dry hydrogen chloride or by zinc chloride was unsuccessful. Only small portions of triphenylcarbinol could be recovered in each case.

Conclusions

Condensation products have been obtained from the reaction in acid medium of triphenylcarbinol on 4-bromo-*o*-cresol VIII and 6-bromo-*o*-cresol VII. The latter product I agreed with the substance obtained by mono-bromination of Schorigin's cryptophenol. Methylation of product I gave a substance agreeing with the material prepared in a different series of steps by Boyd and Hardy[4] and postulated to have structure VI. Thus from these two reaction cycles the evidence places the triphenylmethyl group in the para position in the simple cryptophenol, as shown in structure III.

Sterols. LXXXII. Estrane Derivatives

BY RUSSELL E. MARKER AND EWALD ROHRMANN

Although the catalytic hydrogenation of estrone has been studied by a number of investigators,[1–5] the only reduction products which have been studied to any extent are the isomeric estradiols and an estranediol-3,17(α). This latter product is of considerable interest inasmuch as it is undoubtedly identical with one of the estranediols isolated from human non-pregnancy urine.[6,7] No information has been presented concerning the configurations at C-5 and at C-3 of this substance. The problem concerning the isomeric reduction products of estrone is complicated by the fact that the C-10 position becomes an asymmetric center during the course of the reduction. Thus the reduction of α-estradiol theoretically could give rise to eight isomeric estranediols. The fact that an isomeric estranediol, m. p. 242°, was isolated from human non-pregnancy urine[6,7] indicates that additional isomers exist. This particular estranediol-3,17 has not as yet been encountered in the *in vitro* reduction of estrone.

The fact that the catalytic hydrogenation of estrone in acidic medium results in the formation of mono-hydroxyestranes is of interest and in this respect it would appear to be analogous to equilenin, which readily yields a monohydroxy compound on reduction under similar conditions.[8,9,10] Dirscherl[4] has reported the isolation of two estranols from the reduction products of estrone in acidic ethanol. Butenandt[1] reported that in the hydrogenation of estrone acetate in neutral ethanol with platinum oxide catalyst the carbonyl group is reduced to a methylene group, the aromatic ring reduced and the acetate residue re-

moved to yield an estranol-3. This product was reported to be identical with the estranol obtained by the hydrogenation of 17-desoxyestrone in acidic ethanol[3] but unfortunately no direct comparison of the two products was reported in their experimental work.

In our experience the reduction of estrone in neutral ethanol under conditions apparently more drastic than used by Butenandt[1] gives rise to α-estradiol in over 90% yields and no evidence of the reduction of the aromatic ring was observed. The removal of the acetate residue by catalytic hydrogenation in neutral ethanol as observed by Butenandt is most probably due to the presence of a trace of alkali in the catalyst, a possibility demonstrated by the experiments of Miescher and Scholz.[11] In this Laboratory we have experienced no difficulty in hydrogenating estrone esters in ethanol solution with Adams catalyst to give the mono-esters of α-estradiol.[12]

That the predominant estranol obtained from the reduction of estrone in acidic ethanol is an estranol-17 seems most likely especially since the analogous reduction of equilenin gives high yields of estratriene-5,7,9-ol-17(α). By carrying out the reduction of the 17-mono acetate of α-estradiol with Adams catalyst in acetic acid, we have obtained an estranol apparently identical with that obtained by the catalytic hydrogenation of estrone in acidic ethanol. Inasmuch as the reduction of an acetoxy group at C-17 to a methylene group under the conditions of the hydrogenation is hardly probable, it would appear that the product is an estranol-17(α).

Further evidence that the hydroxyl group at C-3 is removed in the reduction is shown by the work of Butenandt and Westphal[3] on the catalytic hydrogenation of estriol in acidic medium. This reduction yielded two isomeric diols which upon dehydration with potassium bisulfate yielded ketonic compounds. This indicates a vicinal arrangement of the hydroxyl groups, which would be possible only in the C-17,C-16 positions.

The fact that estranediol-3,17(α) may be regarded as a *nor*-androstanediol or a *nor-etio*-cholanediol makes the substance of considerable interest because of its possible relationship to the androgenic hormones. Estranediol-3,17(α) on mild oxidation with chromic anhydride yields an estranedione-3,17 which we have now found to exist in two interconvertible polymorphic crystal forms, m. p. 146° and m. p. 180°. Estranedione readily reacts with bromine in acetic acid to yield a nicely crystalline bromo-estranedione. The removal of hydrogen bromide from this product with boiling pyridine proceeded smoothly to yield an estrenedione (*nor*-androstenedione). While the position of the ethylenic linkage in this substance is not proved, it appears probable that it is in the C-4,5 position, especially since the bromo compound behaves as a substance of coprostane configuration at C-5 in its reaction with pyridine.

An attempt to prepare crystalline *nor*-testosterone was unsuccessful. An estranol-17-one-3 was prepared by the reduction of the 17-monoacetate of α-estradiol and subsequent oxidation with chromic anhydride and hydrolysis with ethanolic alkali. The resulting ketone readily reacted with bromine to liberate hydrogen bromide but no crystalline bromide was obtained. Likewise, reaction with pyridine gave a non-crystalline product.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part

Estranediol-3,17(α), m. p. 205–206°, was prepared by the catalytic hydrogenation of estrone in acidic ethanol as described by Dirscherl.[4]

Estranedione.—This was prepared by the chromic anhydride oxidation of estranediol as described previously by us.[7] The product was crystallized from dilute acetone and dilute methanol to give a product of m. p. 176–178°.

The mother liquors remaining from the reduction of estrone after removal of part of the estranediol were evaporated and the residual sirup taken up in acetic acid and oxidized with chromic anhydride at room temperature for two hours. The crude oily oxidation product was sublimed in high vacuum. The first fraction sublimed at 80–90° and evidently consisted of mono-ketones which could not be crystallized. The higher fraction subliming at 125–140° consisted of estranedione which was crystallized from dilute acetone to give a product, m. p. 144–146°.

Anal. Calcd. for $C_{18}H_{26}O_2$: C, 78.8; H, 9.6. Found: C, 78.9; H, 9.6.

Upon another crystallization from ether–pentane white needles, m. p. 179–180°, were obtained. The mixture, with the lower melting form, melted at 160–178°. In another case the higher melting form was observed to revert to the lower form, m. p. 144–146.5°, on recrystallization from dilute acetone.

Estranol-17(α) from Estrone.—The material subliming at 80–90° obtained above was dissolved in a mixture of 300 cc. of absolute ethanol and 3 cc. of concentrated hydro-

(11) Miescher and Scholz, *Helv. Chim. Acta*, **20**, 263 (1937).
(12) Marker and Rohrmann, THIS JOURNAL, **61**, 1922 (1939).

chloric acid. The solution was shaken with Adams catalyst at two atmospheres hydrogen pressure at 25° for five hours. The reduction product was crystallized from aqueous methanol as white needles, m. p. 105–107°. This gave no depression with a sample of m. p. 106–108°, prepared by the direct catalytic hydrogenation of estrone.

Anal. Calcd. for $C_{18}H_{30}O$: C, 82.4; H, 11.5. Found: C, 82.2; H, 11.5.

An attempt to obtain a crystalline ketone on oxidation with chromic anhydride was unsuccessful.

Bromoestranedione.—To a solution of 700 mg. of estranedione in 20 cc. of acetic acid acidified with two drops of 48% hydrobromic acid was slowly added 5.3 cc. of 0.5 *M* bromine in acetic acid. Water was added and the precipitated solid collected, washed and dried. The product was crystallized from ether to give white crystals, m. p. 170–172°.

Anal. Calcd. for $C_{18}H_{25}O_2Br$: C, 61.2; H, 7.1. Found: C, 61.0; H, 7.1.

Estrenedione.—A solution of 400 mg. of bromoestranedione in 5 cc. of dry pyridine was refluxed for nine hours. The solution was diluted with water and the precipitated solid taken up in ether and freed from pyridine by washing with dilute hydrochloric acid. The ether was removed and the residue sublimed in high vacuum at 130–140°. The sublimate was crystallized from pentane as white leaflets, m. p. 146–148°.

Anal. Calcd. for $C_{18}H_{24}O_2$: C, 79.5; H, 8.9. Found: C, 79.2, 79.4; H, 8.9, 8.9.

Hydrogenation of Estrone in Neutral Medium.—Estrone (m. p. 259°) (5 g.) was shaken in absolute ethanol (300 cc.) with Adams catalyst (0.5 g.) and hydrogen at 3 atm. pressure at room temperature for eighteen hours. The reduction product was crystallized from aqueous acetone to give α-estradiol (4.6 g.), m. p. 173–175°. The mother liquors upon being subjected to sublimation in high vacuum gave no evidence of the presence of substances other than the isomeric estradiols.

17-Mono-acetate of α-Estradiol.—This was prepared in almost theoretical yields by the hydrolysis of α-estradiol diacetate with methanolic potassium carbonate at 20° as described by Miescher and Scholz[11] for the preparation of the 17-mono-*n*-butyrate of α-estradiol. The product formed white crystals, m. p. 215–217°. Miescher and Scholz[11] prepared the compound by carrying out the partial hydrolysis with Adams catalyst in ethanol in the presence of alkali and in an atmosphere of carbon dioxide. They report a m. p. of 215–217.5°.

Reduction of 17-Mono-acetate of α-Estradiol.—A mixture of 4 g. of the 17-monoacetate of α-estradiol, 250 cc. of glacial acetic acid, 70 cc. of absolute ethanol and 800 mg. of Adams catalyst was shaken with hydrogen at 10 pounds pressure at room temperature for fourteen hours. The catalyst was filtered and the filtrate diluted with water. The milky mixture was shaken with ether and the ethereal layer washed well with water and the ether removed. The residual sirup was dissolved in 100 cc. of glacial acetic acid and to this solution was added a solution of 2 g. of chromic anhydride in 25 cc. of 80% acetic acid. After standing at room temperature for two hours the mixture was diluted with water and the precipitated solid taken up in ether. The ether was removed and the residual sirup hydrolyzed with ethanolic potassium hydroxide.

The ketonic fraction was separated by means of Girard's reagent. After sublimation in high vacuum at 120–130° the product was crystallized from ether–pentane and aqueous acetone as white needles, m. p. 102–104°.

Anal. Calcd. for $C_{18}H_{28}O_2$: C, 78.2; H, 10.2. Found: C, 78.0; H, 10.1.

The product readily absorbed a mole of bromine in acetic acid solution acidified with a trace of hydrobromic acid. Hydrogen bromide was liberated. The bromination product could not be obtained crystalline. Heating with pyridine gave a non-crystalline product.

The neutral fraction (non-ketonic) from the chromic anhydride oxidation was sublimed in high vacuum and the fraction subliming at 100° was collected. This was crystalized from aqueous methanol as white needles, m. p. 106–108°. This gave no depression with a sample of estranol, m. p. 106–108°, obtained in the direct catalytic hydrogenation of estrone in acidic medium.

Anal. Calcd. for $C_{18}H_{30}O$: C, 82.4; H, 11.5. Found: C, 82.3; H, 11.4.

Summary

Estrenedione has been prepared from estranedione-3,17.

The major monohydroxyestrane resulting from the reduction of estrone in acidic medium appears to be an estranol-17(α).

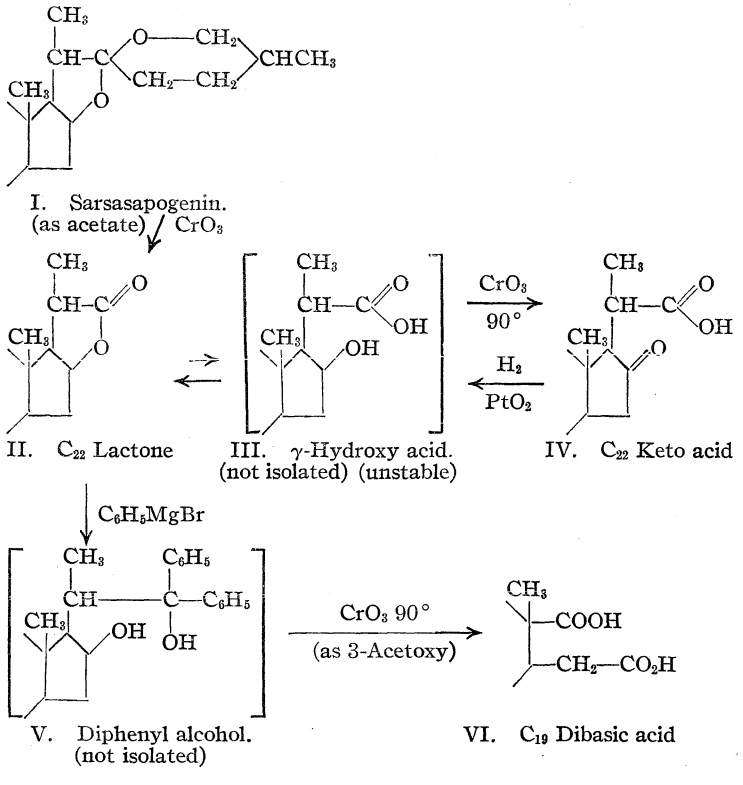
Sterols. LXXXIII. Oxidation Products of Sarsasapogenin. Studies on the C_{22} Lactone

BY RUSSELL E. MARKER AND EWALD ROHRMANN

Perhaps one of the most striking characteristics common to all of the more extensively studied steroid sapogenins is the formation of lactones upon rather vigorous oxidation with chromic anhydride (after adequate protection of the nuclear hydroxyl groups).[1] Sarsasapogenin,[2] smilagenin,[3] tigogenin,[4] chlorogenin,[5] gitogenin[6] and digitogenin,[6] have thus been oxidized to C_{22} lactones.



While all these lactones undoubtedly contain the same number of carbon atoms, it should be pointed out that many of the analyses reported for the substances do not distinguish between a C_{22} and a C_{23} compound. Our analytical results on the sarsasapogenin lactone and its various derivatives are in accord with the C_{22} composition. However, it is evident, as we pointed out previously,[7] that the final proof of the structure and composition of the lactone will depend upon its *stepwise* degradation to a known sterol derivative, an achievement not yet reported.

That the lactone (II) has a very slight tendency to exist as a γ-hydroxy acid (III) is indicated by the fact that the lactone acetate upon rather vigorous oxidation with chromic anhydride gives rise to some of the C_{22} keto acid (IV) which was previously obtained from a similar oxidation of sarsasapogenin acetate.[8]

The most fruitful process of degrading the sarsasapogenin lactone to a known product has been by the method of Tschesche and Hagedorn[4] involving the oxidation of the diphenyl Grignard addition product (V) of the lactone. By this method Farmer and Kon[3] degraded the desoxy lactone to *etio*-bilianic acid. We have carried out a similar degradation of the hydroxy lactone to obtain the C_{19} dibasic acid identical with that previously obtained by the chromic anhydride oxidation of the acetates of sarsasapogenin,[9] sarsasapogenoic acid[9] and dihydrosarsasapogenin.[10] This acid is most likely 3-hydroxy-*etio*-bilianic acid. The fact that we were unable to oxidize the C_{22} keto acid with chromic anhydride after acetylation with boiling acetic anhydride is of interest. This suggests that the γ-keto acid has a tendency to exist in a lactone form which would be stabilized to oxidation by acetylation (*cf.* levulinic acid).

Simpson and Jacobs[11] observed that sarsasapogenin upon oxidation with sodium hypobromite yielded a dibasic acid which upon further oxidation with nitric acid yielded a lactone dibasic acid. We have obtained a similar acid by the oxidation

TABLE I

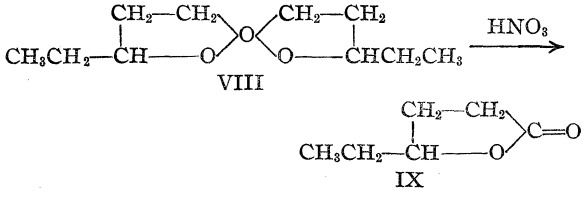
Substance	Composition	M. p., °C.	Analysis Calcd. C	Calcd. H	Found C	Found H
Lactone acetate[a]	$C_{24}H_{36}O_4$	184.5–185.5	74.15	9.37	74.26	9.30
Lactone benzoate[b]	$C_{29}H_{38}O_4$	207.5–209	77.28	8.49	77.16	8.49
Hydroxylactone	$C_{22}H_{34}O_3$	199–200	76.25	9.89	76.35	10.04
3-Keto lactone	$C_{22}H_{32}O_3$	184–185	76.69	9.37	76.55	9.37
Desoxy lactone	$C_{22}H_{34}O_2$	128–129	79.93	10.37	79.88	10.37

[a] The acetate was purified by sublimation in high vacuum at 130–140°. [b] The benzoate was prepared in pyridine solution with benzoyl chloride at room temperature and crystallized from acetone–pentane.

of sarsasapogenin lactone with chromic anhydride. The same acid was obtained by the direct oxidation of sarsasapogenone with nitric acid. While no comparison was made between our acid and that of Simpson and Jacobs the substances are very probably identical, as the melting points of the free acids and of the methyl esters are in good agreement. While this lactone dibasic acid is undoubtedly either a 2 || 3 or a 3 || 4 diacid there is insufficient evidence at present to distinguish between the two possibilities, especially in view of recent work[12] on the acids of the coprostane series resulting from the oxidation of ring A.

The question regarding the origin of the C_{22} lactones is of great interest but there is little information available on the course of the oxidation. However, it is now fairly certain that the sapogenoic acids are not intermediates in the formation of the lactone.[13,14,15]

The fact that nitric acid exerts a specific action on the side chain to yield lactones[11,15,16] is of considerable interest. In this connection it is probably significant that diethyl oxetone (VIII), a substance of the ketone spiro acetal type and consequently analogous to our proposed structure of the sapogenin side chain[7] (I), is oxidized by nitric acid to yield caproic lactone (IX) and propionic acid.[17]



In previous work concerning the hydrogenation of the C_{22} keto acid[8] a C_{22} lactone was obtained in two forms, m. p. 188° and m. p. 198°, which appeared to be polymorphic or possibly steroisomers. That the two forms are polymorphic is indicated by the fact that they yielded the same acetates and upon oxidation gave the same 3-keto-lactones.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part

Sarsasapogenin Lactone (II).—The lactone and its derivatives were prepared as described by previous workers. Our analytical data are summarized in Table I.

An attempt to reduce the hydroxylactone with phosphorus and hydriodic acid (sp. gr. 1.7) at 160° gave only non-crystalline neutral products. The products were very insoluble in methanol and distilled in high vacuum at 90°, suggesting substances of a hydrocarbon nature. The lactone showed no tendency to esterification when allowed to stand for several days with absolute ethanol and concentrated sulfuric acid.

***epi*-Lactone.**—A mixture of 500 mg. of the keto lactone, 500 mg. of Adams catalyst, and 80 cc. of 98% ethanol was shaken with hydrogen at 3 atmospheres pressure at room temperature for three hours. The mixture was filtered and the filtrate evaporated *in vacuo*. The residue was taken up in 10 cc. of hot 95% ethanol and to this solution was added a hot solution of 500 mg. of digitonin in 15 cc. of 80% ethanol. The mixture after standing at 0° was filtered. The filtrate was diluted with water and the precipitated solid taken up with ether. Evaporation of the ether gave a residue which crystallized from ether–acetone–pentane as white needles, m. p. 198–200°. This gave a 10° depression with the 3-β-hydroxylactone, m. p. 199–200°.

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.25; H, 9.89. Found: C, 76.33; H, 9.95.

The *epi*-lactone when refluxed for twenty minutes with acetic anhydride yielded the *epi-lactone acetate* which crystallized from ether–pentane as white crystals, m. p. 159–160°.

Anal. Calcd. for $C_{24}H_{36}O_4$: C, 74.2; H, 9.35. Found: C, 73.9; H, 9.2.

Oxidation of Hydroxylactone to Lactone Dibasic Acid.—To a well-stirred solution of 2 g. of hydroxy lactone in 50 cc. of glacial acetic acid heated at 50–55° was added a solution of 3 g. of chromic anhydride in 20 cc. of 80% acetic acid over a period of three hours. The solution was stirred for an additional two hours at 55°. The mixture was then evaporated *in vacuo* to a volume of 30 cc. The residual material was diluted with water and the precipi-

(12) Marker, Plambeck, Wittle, Rohrmann, Krueger and Ulshafer, THIS JOURNAL, **61**, 3317 (1939).
(13) Fieser and Jacobsen, *ibid.*, **60**, 2753 (1938).
(14) Marker and Rohrmann, *ibid.*, **61**, 2072 (1939).
(15) Windaus and Linsert, *Z. physiol. Chem.*, **147**, 275 (1925).
(16) Jacobs and Simpson, *J. Biol. Chem.*, **105**, 501 (1934).
(17) Fittig and Dubois, *Ann.*, **256**, 141 (1889).

tated solid extracted with ether. The ethereal extract was washed well with water and the solution evaporated to a volume of 30 cc., compact white crystals separated. These were recrystallized from methanol–ether to give a product with m. p. 285–288° dec.

Anal. Calcd. for $C_{22}H_{32}O_6$: C, 67.3; H, 8.2. Found: C, 67.0; H, 8.4.

When treated with an ethereal solution of diazomethane the acid yielded a *dimethyl ester* which crystallized from ether–pentane as fine white needles, m. p. 170–171°.

Anal. Calcd. for $C_{24}H_{36}O_6$: C, 68.5; H, 8.6. Found: C, 68.2; H, 8.7.

Oxidation of Sarsasapogenone with Nitric Acid.—To a suspension of 1 g. of sarsasapogenone in 9 cc. of glacial acetic acid was added 15 cc. of nitric acid (d. 1.50). Brown fumes were liberated and the solid dissolved almost at once. The mixture was heated at 90° for one hour. The solution was diluted with water and the precipitated solid collected and washed with water. The solid was dissolved in ether and shaken with 3% sodium hydroxide solution.

The neutral fraction which would not crystallize was not investigated further. The sodium hydroxide extract was acidified with hydrochloric acid and extracted with ether. Evaporation of the ether gave compact white crystals which were recrystallized from ether–acetone, m. p. 285–289° dec. This gave no depression with the sample of dibasic lactone acid obtained previously, m. p. 285–288° dec.

Anal. Calcd. for $C_{22}H_{32}O_6$: C, 67.3; H, 8.2. Found: C, 67.0; H, 8.3.

With diazomethane the acid yielded a product which crystallized from ether–pentane as fine white needles, m. p. 170–171.5°. This gave no depression with the sample obtained above, m. p. 170–171°.

Oxidation of Lactone Acetate to C_{22}-Keto Acid.—To a solution of 800 mg. of lactone acetate, m. p. 183–184°, in 30 cc. of glacial acetic acid was added a solution of 2 g. of chromic anhydride in 40 cc. of 80% acetic acid. The resulting solution was heated on the steam-bath at 90° for three hours. The mixture was diluted with water and extracted with ether. The ethereal extract was washed well with water and then extracted with 3% sodium hydroxide solution. The sodium hydroxide extract was heated for twenty minutes on the steam-bath, cooled, acidified with hydrochloric acid and the solid acid extracted with ether. The ether upon slow evaporation deposited compact white crystals. These, after crystallization from ether–methanol, melted at 285–287° dec. and gave no depression with a sample of the C_{22} keto acid, m. p. 285–287°.

Anal. Calcd. for $C_{22}H_{34}O_4$: C, 72.9; H, 9.5. Found: C, 73.0; H, 9.6.

The neutral fraction consisted of unchanged lactone acetate.

Degradation of Hydroxylactone to C_{19}-Dibasic Acid.—To a Grignard reagent prepared from 1.25 g. of magnesium, 9 g. of phenyl bromide and 45 cc. of ether was added a solution of 2 g. of hydroxy lactone, m. p. 199–201°, over a period of ten minutes. The mixture was refluxed on the steam-bath for two hours after which the solvent was removed. The residue was dissolved in 50 cc. of dry pyridine and treated with 5 cc. of acetic anhydride at room temperature for eighteen hours. The mixture was decomposed with water and extracted with ether. After washing well with dilute hydrochloric acid the ether was evaporated to give a yellow non-crystalline sirup.

This was dissolved in 50 cc. of acetic acid and to the resulting solution heated at 90–95° was added 8 g. of chromic anhydride in 70 cc. of 80% acetic acid over a period of one hour. The mixture was heated for an additional two hours, the excess oxidizing agent was destroyed with ethanol and the mixture concentrated *in vacuo* to a volume of about 50 cc. The residual mixture was diluted with water and the precipitated solid taken up in ether. The residue remaining upon evaporation of the ether was refluxed for thirty minutes with an excess of ethanolic potassium hydroxide. The solid which separated upon dilution with water was taken up in ether and discarded. The alkaline water layer was acidified with hydrochloric acid and the acids taken up in ether. Evaporation of the ether gave a residue which crystallized from chloroform as white crystals, m. p. 218–220°; yield, 150 mg. This gave no depression in melting point with a sample of the C_{19}-dibasic acid, m. p. 220–222°.

Anal. Calcd. for $C_{19}H_{30}O_5$: C, 67.4; H, 8.9. Found: C, 67.2; H, 8.8.

Further Characterization of C_{22} Keto Acid.[8]—Treatment of the methyl ester of the keto acid with boiling acetic anhydride for thirty minutes followed by decomposition of the excess acetic anhydride with water yielded a *methyl ester acetate* which crystallized from ether–pentane as compact white crystals, m. p. 198–199.5°.

Anal. Calcd. for $C_{25}H_{38}O_5$: C, 71.7; H, 9.1. Found: C, 71.5; H, 9.1.

Treatment of the acid with hydroxylamine hydrochloride under the usual conditions gave an *oxime* which crystallized from aqueous methanol as small compact white crystals, m. p. 206–208° dec.

Anal. Calcd. for $C_{22}H_{35}O_4N$: C, 70.0; H, 9.3; N, 3.7. Found: C, 69.8; H, 9.2; N, 3.8.

Acetylation of the acid with boiling acetic anhydride gave a non-crystalline product. Oxidation of this product with chromic anhydride in acetic acid at 90–95° followed by alkaline hydrolysis of the total products yielded largely the original acid and none of the C_{19} dibasic acid was isolated.

The lactone, m. p. 186–188°, obtained by the catalytic hydrogenation of the C_{22} keto acid in ethanol–hydrochloric acid solution upon refluxing with acetic anhydride gave an acetate, m. p. 183–184°. This gave no depression with an authentic sample of the normal lactone acetate, m. p. 184.5–185.5°. Oxidation of the lactone with chromic anhydride at 25° gave the 3-ketolactone, m. p. 184–185°. This gave no depression with an authentic sample of the 3-ketolactone, m. p. 184–185°.

Summary

Oxidation of the acetate of the C_{22} lactone from sarsasapogenin with chromic anhydride yielded the C_{22} keto acid.

The C_{22} lactone has been degraded to the C_{19} dibasic acid.

Sterols. LXXXIV. Progesterone from Hyodesoxycholic Acid

BY RUSSELL E. MARKER AND JOHN KRUEGER

Preferential reactions in the sterol series have been widely used. Thus, Marker and co-workers acetylated the 3-position in both desoxycholic acid[1] and *allo*-pregnanediol,[2] leaving intact the 12-hydroxy group and the 20-hydroxy group, respectively. Half-hydrolysis of the diacetate of pregnanediol-(α),(α) gave pregnanol-20(α)-one-3[3] and Ellis and Petrow[4] obtained 6-acetoxycholestane-3,5-diol from 3,6-diacetoxycholestane-5-ol. Ruzicka and Wettstein[5] and Butenandt and Hanisch[6] utilized the difference in hydrolytic rate between acetoxy groups substituted in the 3- and 17-positions in the preparation of testosterone.

We assumed that, in analogy to the hydrolytic reactions previously cited, the main product in the partial hydrolysis of a 3,6-diacetoxy derivative would be a 3-hydroxy-6-acetoxy compound. We investigated the series of reactions I to VI using cholestanediol-3,6. Cholestanediol-3,6 of m. p. 216° has been described by Windaus[7] as the product of the sodium–alcohol reduction of 6-keto-cholestanol. We found platinum oxide in alcohol solution a more convenient reagent for the hydrogenation of 6-keto-cholestanol. Under these conditions a practically quantitative yield of a cholestanediol-3,6 of m. p. 190° was obtained. This substance VIII is stereoisomeric with the compound of m. p. 216° described by Windaus.

VIII

The diacetate (I) of cholestanediol-3,6 was preferentially hydrolyzed at position-3 either by potassium hydroxide in methanol at 20° or by refluxing with sodium bicarbonate in methanol a short time to yield the hydroxy acetate (II) which was not isolated but oxidized to 6-acetoxycholestanone (III). Hydrolysis of the 6-acetoxycholestanone and dehydration of the resulting 6-hydroxycholestanone by distillation over fused potassium bisulfate produced cholestenone (VI) in good yield.

We have now utilized the above reactions for the preparation of progesterone from hyodesoxycholic acid. The side chain of hyodesoxycholic acid was degraded by the Barbier–Wieland method to produce a keto group at C-20. The procedure used was similar to the directions of Hoehn and Mason[8] for the degradation of desoxycholic acid and the yields obtained were comparable to theirs. The 3,6-diacetoxy-*etio*-cholanyl methyl ketone was hydrolyzed preferentially at position 3. The resulting product was oxidized to a ketone which, after hydrolysis and sublimation from potassium bisulfate, yielded progesterone.

We wish to thank Parke, Davis and Company for their generous support and assistance in the various phases of this work.

Experimental Part

Cholestanediol-3,6.—6-Ketocholestanol,[9] m. p. 143°, (25 g.), 1.0 g. of platinum oxide catalyst and 300 cc. of methanol were shaken under 3 atm. of hydrogen. Reduction was complete within forty-five minutes. The catalyst and solid diol was filtered off, and the precipitate was then dissolved in warm alcohol and was filtered from the catalyst. The combined filtrates were concentrated by evaporation. The solution on cooling deposited 20 g. of white crystals which melted at 188°. The diol crystallized from methanol as large transparent prisms of m. p. 190°.

Anal. Calcd. for $C_{27}H_{48}O_2$: C, 80.1; H, 12.0. Found: C, 80.3; H, 12.0.

The diacetate was prepared by refluxing the diol for a short time in acetic anhydride. It crystallized from methanol as white flakes, m. p. 138°.

Anal. Calcd. for $C_{31}H_{50}O_4$: C, 76.5; H, 10.4. Found: C, 76.3; H, 10.5.

6 - Acetoxycholestanone.—Cholestanediol - 3,6 - diacetate, m. p. 138° (10 g.), was dissolved in 3 liters of methanol by warming, then cooled to 25° and a solution of 0.92 g. of potassium hydroxide in 177 cc. of methanol was added. The solution was allowed to stand at 20° for forty-eight hours. It was then exactly neutralized by addition of 16.9 cc. of 0.96 normal sulfuric acid. The solution was evaporated *in vacuo* and the residue was dissolved in 250 cc. of acetic acid. Chromic oxide (1.2 g.) dissolved in 50 cc. of 90% acetic acid was added to the reaction mixture. After standing at room temperature for three hours, water was added and the oily precipitate was extracted with ether. The ethereal solution was washed with water and then was evaporated. Remaining acetic acid was evaporated *in vacuo*. 6-Acetoxycholestanone crystallized from petroleum ether as thick white needles and from methanol as fine white needles of m. p. 101°.

Anal. Calcd. for $C_{29}H_{48}O_3$: C, 78.4; H, 10.9. Found: C, 78.3; H, 10.9.

6-Acetoxycholestanone also was prepared by refluxing 1.0 g. of the diacetate of cholestanediol-3,6 for one and one-half hours with 1.0 g. of sodium bicarbonate in a solution of 10 cc. of water and 250 cc. of methanol. The reaction mixture was poured into water and was extracted with ether. The residue left by evaporation of the ether was treated as described above, although in this case Girard's reagent was used to purify the product which melted at 100° and showed no depression with an analyzed sample of 6-acetoxycholestanone, m. p. 101°.

6-Hydroxycholestanone.—6-Acetoxycholestanone (3.7 g.) was refluxed for one and one-half hours with 150 cc. of 2% methanolic potassium hydroxide. Water was added and the precipitated product was allowed to stand overnight. The crystals collected by filtration weighed 3.0 g. and melted at 183–187°. Recrystallization from methanol gave white leaflets of m. p. 190°.

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 80.5; H, 11.5. Found: C, 80.3; H, 11.6.

Cholestenone.—6-Hydroxycholestanone (100 mg.) and 0.5 g. of fused potassium bisulfate were pulverized together and heated for two hours at 125°, then at 185° for five hours under 4 mm. pressure. The distilled substance after crystallization from methanol melted at 80° and showed no depression in melting point when mixed with an authentic sample melting at the same temperature.

Methyl Ester of Hyodesoxycholic Acid.—The acid was refluxed for two hours with 1% methanolic hydrogen chloride. The solvent was evaporated *in vacuo*. Addition of benzene to the oily residue caused crystallization. It melted at 86°.

Anal. Calcd. for $C_{25}H_{42}O_4$: C, 73.8; H, 10.4. Found: C, 74.2; H, 10.0.

***nor*-Hyodesoxycholic Acid.**—The methyl ester from 200 g. of hyodesoxycholic acid was added in hot benzene solution to 16 moles of phenylmagnesium bromide in ether. The thick gray suspension was refluxed for two hours, then most of the solvent was distilled off. Dry benzene (or toluene) was added and the mixture was heated overnight on a steam-bath. The suspension was decomposed by pouring it on ice and hydrochloric acid. It was then extracted with ether. The ethereal extract was washed with dilute hydrochloric acid, dilute potassium hydroxide, and then finally with water. The solvents were completely evaporated and the crystalline diphenyl alcohol was refluxed for two hours with 600 cc. of acetic anhydride. This solvent was evaporated *in vacuo* and the oily residue was refluxed for six hours with acetic acid. Evaporation of the acetic acid left an oil which did not crystallize but which was oxidized by chromic oxide in acetic acid–chloroform–water mixture exactly as described by Hoehn and Mason.[8] After addition of water and reduction of the excess chromic anhydride with sulfur dioxide, the mixture was extracted with ether. The ethereal extract was well washed with water and was then extracted with 2 *N* potassium hydroxide solution. The basic solution was boiled one and one-half hours and was poured slowly on a stirred mixture of ice and hydrochloric acid. The flocculent white precipitate could be easily filtered and washed with water. It was crystallized from a large amount of ethyl acetate to give a product melting at 198°; yield 110 g. The mixed melting point with hyodesoxycholic acid was 175–180°.

Anal. Calcd. for $C_{23}H_{38}O_4$: C, 72.9; H, 10.1. Found: C, 72.6; H, 10.1.

The methyl ester was prepared by refluxing *nor*-hyodesoxycholic acid in 1% methanolic hydrogen chloride solution. The substance crystallized from benzene with benzene of crystallization. It melted at 95°. After drying in a vacuum at room temperature the analysis showed it to contain 1 mole of benzene.

Anal. Calcd. for $C_{24}H_{40}O_4 \cdot C_6H_6$: C, 76.5; H, 9.8. Found: C, 76.8; H, 9.6.

***bis-nor*-Hyodesoxycholic Acid.**—This acid was prepared in yields of 42 g. from 100 g. of *nor*-hyodesoxycholic acid by the method described for the preparation of *nor*-hyodesoxycholic acid. A crystalline diphenyl alcohol of m. p. 222° (from toluene) was obtained.

Anal. Calcd. for $C_{35}H_{45}O_3$: C, 81.3; H, 9.4. Found: C, 81.3; H, 9.4.

bis-nor-Hyodesoxycholic acid crystallized from a large volume of ethyl acetate as white crystals of m. p. 240°.

Anal. Calcd. for $C_{22}H_{36}O_4$: C, 72.5; H, 10.0. Found: C, 72.4; H, 10.0.

Methylation of this acid in methanolic hydrogen chloride yielded an unsharply melting substance. Methylation with excess diazomethane in ether alcohol solution furnished a quantitative yield of the methyl ester of *bis-nor*-hyodesoxycholic acid of m. p. 146°.

Anal. Calcd. for $C_{23}H_{38}O_4$: C, 72.9; H, 10.1. Found: C, 72.7; H, 10.1.

3,6-Diacetoxy-*etio*-cholanyl Methyl Ketone.—The methyl ester of *bis-nor*-hyodesoxycholic acid was added in benzene solution to 16 moles of phenylmagnesium bromide. The reaction was carried out as described for the

preparation of *nor*-hyodesoxycholic acid. The alcohol was acetylated with acetic anhydride and pyridine at 100° for twenty hours. The solvents were evaporated *in vacuo* and the residue was taken up in ether. The ethereal solution was washed with dilute hydrochloric acid and sodium carbonate and was then evaporated to dryness. The residue was dehydrated for six hours by refluxing it with acetic acid. The solvent was evaporated *in vacuo*. The crude ethylenic compound was ozonized in chloroform solution at 0°. The ketones were separated by Girard's reagent and crystallized from ether–pentane. 3,6-Diacetoxy-*etio*-cholanyl methyl ketone melted at 100°.

Anal. Calcd. for $C_{25}H_{38}O_5$: C, 71.7; H, 9.2. Found: C, 72.0; H, 9.0.

Progesterone.—To 0.9 g. of 3,6-diacetoxy-*etio*-cholanyl methyl ketone in 200 cc. of methanol at 20° was added 42 cc. of methanolic potassium hydroxide containing 0.8 mole of base. The solution was allowed to stand at 20° for forty-eight hours. It was then exactly neutralized by addition of 1.7 cc. of 0.96 *N* sulfuric acid. The solvent was completely evaporated *in vacuo*, and the oily residue was oxidized in one hour at room temperature in 25 cc. of acetic acid with a solution of 5 cc. of 90% acetic acid containing 0.5 g. of chromic oxide. Water was added and the precipitated material was extracted with ether. The ethereal solution was washed with water, and then concentrated. This product was refluxed with 40 cc. of 2% methanolic potassium hydroxide for seventy-five minutes. Water was added and the organic material was extracted with ether. The ethereal solution was washed with water and was then evaporated to dryness. The solid remaining was covered with 5.0 g. of fused potassium bisulfate and was heated at 4 mm. at 130° for an hour and a half. The temperature was then raised to 180° for four hours. The ethereal solution of the distillate on evaporation left a pale, mobile oil, which, when crystallized from acetone–water, yielded greasy crystals. Recrystallization from ether–pentane produced small white crystals of m. p. 120°, which gave no depression in melting point with an authentic sample of progesterone.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6. Found: C, 80.4; H, 9.6.

Summary

The Barbier–Wieland degradation applied to hyodesoxycholic acid produced 3,6-diacetoxy-*etio*-cholanyl methyl ketone. This compound was converted into progesterone by a method described for the conversion of 3,6-cholestanediol diacetate into cholestenone.

The Peroxide Effect in the Addition of Reagents to Unsaturated Compounds. XXIV. The Addition of Hydrogen Iodide to Propene, 1-Bromopropene, Allyl Chloride, and Allyl Bromide

BY M. S. KHARASCH, JAMES A. NORTON,[1] AND FRANK R. MAYO

The work here reported was undertaken in extension of the previous studies of Kharasch and Hannum,[2] and for the purpose of discovering, if possible, the reasons for the discordance between the results of those studies and that of Ingold and Ramsden.[3]

The consensus among the earlier workers has been that isopropyl iodide is the sole product of the addition of hydrogen iodide to propene.[4] The cited work of Kharasch and Hannum confirms that opinion. Ingold and Ramsden, however, report addition products comprising as much as 25% of normal propyl iodide. The highest yields of the normal iodide were obtained in the absence of solvent and in the presence of the typically non-polar solvent propane. Relatively polar solvents, such as nitrobenzene, acetic acid, and water, were said to give rise to relatively smaller yields of the normal iodide. According to Ingold and Ramsden, the "solvent effect" varies with the "mean molecular fraction of hydrogen iodide in its mixture with the solvent (if any) during the course of the reaction." Unfortunately the "mean molecular fraction" is not precisely defined, nor are complete details of the experiments given. Their method consisted in breaking a sealed tube of propene within a sealed tube of hydrogen iodide (and solvent, if any) at a temperature of 18 ± 2°, which was maintained throughout the reaction.

Discussion

The Addition of Hydrogen Iodide to Propene.—A series of experiments performed in accordance with our usual technique (i. e., with exclusion of air, moisture, and light), and with hydrogen iodide–propene ratios varying from 0.36/

1.0 to 3.51/1.0 (the majority at approximately 1/1), at temperatures from −80° to room temperature (the majority at 0°), and with reaction times varying from one to twenty-one hours, yielded only isopropyl iodide as the addition product. To obtain 90% or more of addition product under the conditions indicated, about three hours were required at 0° or one hour at room temperature.

In order to make sure of the stability of normal propyl iodide under these experimental conditions at room temperature, about one-third mole of normal iodide per mole of propene was added in one experiment, and about one mole in another. In both cases the normal iodide added was unchanged, and the addition product was exclusively the secondary iodide.

The homogeneity of the reaction at 0° was tested by an experiment in which 0.5 g. of powdered Pyrex glass was present during the reaction of 5 g. of propene with an equimolecular quantity of hydrogen iodide. The direction of addition was not altered, and there was no appreciable change of rate.

The admission of air to reactions otherwise similarly conducted at 0° and at 10° did not materially affect the rate of addition, and did not alter the product (100% secondary iodide). Moisture in the ratio of 0.05 mole of water to one mole of propene had no marked catalytic effect, and did not alter the direction of addition.

Since the results of these experiments gave no clue to the discrepancy in the observations of Ingold and Ramsden and of this Laboratory, an attempt was made to reproduce some of their experiments as closely as the available description would permit. Three experiments were carried out in the absence of a solvent, using 1.01 to 1.11 moles of hydrogen iodide. One of these reaction tubes contained air; the other two did not. A fourth otherwise similar reaction mixture contained 0.78 mole of propane as solvent and no air. All of these experiments gave more than 90% yield of addition products which were exclusively isopropyl iodide. Other experiments in which propane, pentane, acetic acid, and nitrobenzene[5] were employed in similar proportions as solvents, but in which the reactants were not mixed by the Ingold procedure, also gave isopropyl iodide as the exclusive addition product.

(5) Some reduction of the nitrobenzene with precipitation of crystalline hydroiodide was observed; *cf.* Baumhauer, *Ann., Supp.*, **7**, 208 (1870).

In several experiments there was a small amount of high-boiling residue, in accord with the previous observation of Michael and Leighton.[6] However, the index of refraction was lower than that of isopropyl iodide, indicating that the normal iodide could not have been present in significant amount. The quantity of high-boiling material available was too small for conclusive identification, but it is suspected to be a hexyl iodide.

Catalysis of Hydrogen Iodide Addition to Propene.—It was previously reported by Kharasch and Hannum[2] that peroxides accelerate the addition of hydrogen iodide to olefins without affecting the direction of addition. In the present study it was found that with our usual technique equimolecular quantities of hydrogen iodide and propene react completely at 0° in about two hours. Under similar conditions, in the presence of 0.005 mole of ascaridole, the addition is complete in less than one minute at −80°. Since ascaridole must react with hydrogen iodide to liberate iodine (as is further indicated by the color of ascaridole reaction solutions), a similar experiment was conducted in the presence of 0.005 mole of iodine (without ascaridole). Again the addition was complete in less than a minute at −80°. (At higher temperatures peroxide- or iodine-catalyzed reactions proceed with almost explosive violence.) It seems likely, therefore, that peroxide catalysis of hydrogen iodide additions is essentially iodine catalysis.

A possible mechanism of iodine catalysis is found in the observation of Malbot[7] that hydrogen iodide reacts with propene iodide to give iodine and isopropyl iodide

$$C_3H_6 + I_2 \longrightarrow CH_3CHICH_2I$$
$$CH_3CHICH_2I + HI \longrightarrow CH_3CHICH_3 + I_2$$

Mercuric iodide also proved to be an effective catalyst. In experiments similar to those just described, in the presence of about 0.015 mole of mercuric iodide (per mole of olefin), the reaction of equimolecular quantities of propene and hydrogen iodide was complete in less than ten minutes at 0°. An addition reaction carried out in a tube in which a mercury mirror had previously been deposited was complete in about one-half hour.

Antioxidants do not appear to inhibit or otherwise affect the reaction. Thus, the presence of 0.005 mole of diphenylamine was without effect.

(6) Michael and Leighton, *J. prakt. Chem.*, [2], **60**, 445 (1899).
(7) Malbot, *Ann. chim.*, [6] **19**, 345 (1890).

In the presence of ethyl mercaptan (0.27 mole), however, there was thioether formation, with consequent reduction in yield (59%, as compared with the usual 95–98%). In all cases investigated the sole addition product was isopropyl iodide.

Two additional experiments show that hydrogen iodide can prevent the peroxide-catalyzed addition of hydrogen bromide. Ascaridole promotes the "abnormal" addition of hydrogen bromide to propene. In the presence of ascaridole (0.4 mole %) and (11 mole %) of hydrogen iodide, 1.02 moles of hydrogen bromide added to propene to give only the "normal" addition product (isopropyl bromide). In a similar experiment conducted for a month at room temperature, vinyl chloride and hydrogen bromide gave a 38% yield of the "normal" addition product, together with unchanged reactants; no ethylene chlorobromide was formed. The logical inference is that either peroxides are immediately and completely destroyed in the presence of hydrogen iodide or that hydrogen iodide inhibits the abnormal addition of hydrogen bromide.

Addition of Hydrogen Iodide to Allyl Bromide.—The addition of hydrogen iodide to allyl bromide yielded 1-bromo-2-iodopropane as the sole addition product but this reaction was accompanied by an oxidation–reduction reaction which yielded iodine and addition products of propene. The latter consisted of isopropyl bromide and iodide and contained no normal propyl halides. To reduce the reduction reaction to a minimum, only a small excess (1–10%) of hydrogen iodide and temperatures of 0° and below were usually employed. Air, moisture, and light were generally excluded. Observations of volume changes of reaction mixtures indicated that in reaction at 0° there is an induction period of about one hour during which little or no adddition takes place but iodine is slowly liberated. As iodine accumulates, addition becomes more rapid and reaches completion in two to four hours, with a yield of 70–90% of addition product and weights of recovered allyl and isopropyl halides ranging up to 30% of the initial allyl bromide used. Both addition and reduction take place more slowly at −33°, and at −80° no reaction was observed during twenty-one hours.

That iodine catalyzes the addition reaction at 0° is shown by the fact that addition of 0.5 to 1 mole % of iodine eliminated the induction period, and caused the reaction to take place in a few minutes. At −33°, addition was also accelerated by iodine but a day was required for complete reaction. No reduction was observed under these conditions and yields as high as 96% are readily obtained. At −80°, addition took place at the rate of 30–35% a day in the presence of iodine. The iodine catalysis may be due to the easy reduction of the unknown 1-bromo-2,3-diiodopropane by hydrogen iodide.

These experiments and the fact that the addition product, 1-bromo-2-iodopropane, is fairly stable toward hydrogen iodide at 0°, suggest that it is allyl iodide, formed by halogen exchange between allyl bromide and hydrogen iodide, or its hydrogen iodide addition product, which is reduced to isopropyl iodide by hydrogen iodide.[7,8] The effect of 6 mole per cent. of water in shortening the induction period at 0° is ascribed to facilitation of the halogen interchange necessary for formation of iodine.

Ascaridole had about the same effect as iodine in eliminating the induction period and accelerating the addition. The best result at 0° was obtained with the smallest proportion of peroxide, 0.7 mole per cent., when the yield of addition product was 93% within one hour. Equally good results were obtained with a sample of allyl bromide which gave a strong peroxide test. Use of larger amounts of ascaridole resulted in tar formation and reduction, probably because of rapid reaction and overheating.

Attempts to obtain an addition product from allyl bromide other than 1-bromo-2-iodopropane were made. Thus, additions were carried out in the presence of 0.7 mole per cent. of diphenylamine at 0°, and by adding hydrogen iodide and ascaridole very slowly at room temperature (and in the presence of air) to allyl bromide mixed with 1.68 moles of pentane.

The Addition of Hydrogen Iodide to Allyl Chloride.—The addition of hydrogen iodide to allyl chloride differs from the addition to allyl bromide chiefly because of the slower halogen exchange to give allyl iodide. Since the iodine formed by the interaction of this product with hydrogen iodide is the controlling factor in the rate of addition, the reaction is slow compared to that with allyl bromide. The addition of hydrogen iodide to allyl chloride gave exclusively 1-chloro-2-iodopropane in yields of 90–100%. Fur-

(8) Simpson, *Ann.*, **129**, 127 (1864).

thermore, since this dihalide is more stable to hydrogen iodide than that formed from allyl bromide, the extent of formation and reduction of the allyl halide by hydrogen iodide could be determined conveniently by titration of the iodine formed. All the reactions with allyl chloride were carried out at 0°, using a 10 to 20% excess of hydrogen iodide.

In the absence of air, peroxides, iodine, moisture, and light, the induction period was about twelve hours. The reaction proceeded to completion in the next twenty-four hours, and 0.3 to 0.4% of iodine was formed. Six mole per cent. of water decreased the induction period so that reaction was complete in six to twelve hours, and increased the iodine formed to nearly 3%.

One-half mole per cent. of iodine eliminated the induction period so that reaction was complete in six hours or less. One mole per cent. of mercuric iodide appeared to shorten the induction period without markedly affecting the rate of the subsequent addition reaction. The addition of 19–27 mole per cent. of reduced iron[9] to one addition reaction carried out at room temperature and to another at −33° was without effect on the direction of addition.

Addition of Hydrogen Iodide to 1-Bromopropene.—Previous work in this Laboratory[10] has shown that the addition of hydrogen chloride and hydrogen bromide to 1-bromopropene gives rise to mixtures of 1,1- and 1,2-dihalides. It was concluded that such mixtures represent the "normal" addition products and that the directing influences of the bromine atom and methyl group on the ethylene bond are nearly balanced. Although this work indicated that ferric chloride catalyzes the "normal" additions of both acids without influencing the direction of addition, the necessity for the use of this catalyst in both additions (to attain practical addition rates), and the extreme sensitivity to peroxides of the hydrogen bromide addition, suggested the desirability of confirming earlier conclusions by the addition of hydrogen iodide. The latter reagent should add sufficiently rapidly without a catalyst, and the direction of addition to unsaturated compounds is not affected by peroxides.

Three experiments were carried out with hydrogen iodide and a mixture of the *cis* and *trans* isomers of 1-bromopropene, at 0°, in the absence of air, moisture, and light, and using about 1.15 moles of hydrogen iodide per mole of 1-bromopropene. In one experiment, 17.6 g. of 1-bromopropene giving a strong peroxide test was used. At the end of two days, a 76% yield of addition product was obtained along with unchanged bromopropene. The product was shown to contain 36% of 1-bromo-1-iodopropane and 64% of 1-bromo-2-iodopropane, in excellent agreement with the proportion of 1,1-dihalide found[10] in hydrogen chloride (35, 36%) and hydrogen bromide (33, 33, 41%) additions. The other two experiments (10 g. peroxide-free 1-bromopropene) gave 21 and 24% 1,1-dihalide. The rates of all of these reactions were about the same, and iodine (1.4 mole %) apparently had little effect on the rate of the reaction. In no experiment was there evidence of much reduction.

Conclusions

It has been established in this paper that only one product results from the addition of hydrogen iodide to propene, allyl bromide, and allyl chloride. A similar conclusion was drawn by Kharasch and Hannum[2] from their work on propene, 1-butene, neopentylethylene, vinyl chloride, and allyl bromide. In view of the extent of the work, these data provide strong evidence that the direction of addition of hydrogen iodide to olefins cannot be reversed. The present paper elucidates the accelerating effect of peroxides on this addition. It shows that peroxides are immediately destroyed by hydrogen iodide with the liberation of iodine, and that the latter catalyzes the normal addition reaction. It is noteworthy that the direction of addition of hydrogen iodide, hydrogen chloride, and the normal addition of hydrogen bromide to unsaturated compounds of several types, including 1-bromopropene which yields a mixture, is the same, within the experimental error, for all three halogen acids.

Experimental

Materials and Reagents.—Propene and propane of higher than 99% purity were obtained from commercial sources. The pentane was a commercial *n*-pentane–isopentane mixture. Allyl bromide[11] and allyl chloride[12] were prepared from allyl alcohol and the concentrated halogen halides in the presence of 1–2% of the corresponding cuprous halides. Before use they were agitated with

acidulated ferrous sulfate solution to destroy peroxides, dried rapidly over phosphorus pentoxide, and distilled. 1-Bromopropene was prepared by treatment of propylene bromide with alcoholic sodium ethoxide.[10] The crude product was washed with dilute sulfuric acid to remove unsaturated ethers, which were inseparable by fractionation.

Hydrogen iodide was prepared by the convenient method of Houben, Boedler and Fischer.[13] The gas was collected in a large trap containing some phosphorus pentoxide and a mercury mirror (prepared by heating a drop of mercury in the empty trap). The trap was cooled by dry ice–acetone. After collection, the gas was distilled in the absence of air into the storage vessel, which was a large 30-mm. glass tube mirrored with mercury and equipped with ground joint and stopcock. The usual high-vacuum technique was employed for this purpose; air was not permitted to come in contact with the hydrogen iodide. The storage vessel was kept in dry-ice–acetone when not in use.

Experimental Procedure.—The usual apparatus employed in most of the propene addition experiments, as well as in the allyl bromide, and 1-bromopropene additions, consisted of a series of tubes attached to a vacuum line. In most cases the olefin and volatile solvent (if any) were weighed into a tube containing a little phosphorus pentoxide, which was then sealed to the vacuum line for degassing and eventual distillation of the contents into the reaction tube. When nitrobenzene and acetic acid were used as solvents, the solvent and the propylene were dried and degassed in separate tubes. When water, iodine, diphenylamine, ascaridole or other relatively non-volatile addenda were used, these were weighed into the tube that was eventually to become the reaction tube, which was then sealed to the line. Hydrogen iodide was distilled from a storage reservoir through a ground-glass joint into a tube already attached to the vacuum line. Rough estimation of quantity was made by volume calibration of one tube; exact amounts used were determined by weighings of the storage reservoir. Transfer of reactants to the reaction tube was effected by high-vacuum distillation with appropriate manipulation of stopcocks and cooling baths. Except in the experiments expressly designed to investigate the effect of air upon the addition, the reaction tube was sealed off without access of air, and was maintained at the desired temperature throughout the reaction period.

In about one-fourth of the propene, and in all of the allyl chloride experiments, hydrogen iodide and olefin were stored in the absence of air, in containers attached to the vacuum line. Hydrogen iodide and propylene were measured as gases, allyl chloride as a liquid, in calibrated bulbs, from which they were condensed in an empty tube before distillation into the reaction tubes. This procedure removed small amounts of non-condensable gases, mercury (from manometers), and mercuric iodide (from the hydrogen iodide storage vessel). High-boiling materials were placed in the bomb tube directly, as before.

About 0.1 mole of unsaturated compound usually was employed. The techniques described ordinarily gave colorless reaction mixtures, but a faint iodine color appeared in a few hours in propylene experiments, faster in others.

(13) Houben, Boedler, and Fischer, *Ber.*, **69B**, 1773 (1936).

In attempts to reproduce the experiments of Ingold and Ramsden, the following procedure was employed. Propene was condensed in a small bomb tube in the absence of air, using high vacuum technique. The end of this tube was drawn out to a long capillary, and sealed, and the tube was slipped into a larger bomb tube. The open end of the large bomb tube was drawn down (meanwhile the other end, containing the propene bomb tube, occasionally was cooled in liquid nitrogen), and was sealed onto the vacuum line. Then, after evacuation, hydrogen iodide (and solvent, if used) were distilled into the large bomb tube and the whole was sealed from the line. The bomb was allowed to warm to room temperature, and by suitable manipulation the long capillary was shattered and the contents mixed. Evacuation was omitted in one experiment.

Analysis of Reaction Products.—In most of the propene experiments the bomb contents (after completion of the reaction) were washed with aqueous sodium sulfite and aqueous potassium carbonate to remove iodine and hydrogen iodide, dried over potassium carbonate, and distilled through a Podbielniak column. A single fraction of boiling point corresponding to the "normal" addition product (isopropyl iodide) was obtained in each case. These products were later combined and refractionated. The index of refraction of the principal fraction was that of isopropyl iodide (n^{20}D 1.4988). The relatively small forerun and residue had lower indices of refraction, excluding the possibility of the presence of appreciable amounts of normal iodide (n^{20}D 1.5052). In the propene experiments involving the presence of added normal iodide, and in several others, the bomb contents were distilled at 10 mm. into a trap cooled by dry-ice–acetone. The distillate was then analyzed by index of refraction, the index being a linear function of the composition of iso–normal propyl iodide mixtures.

In some of the propene and all of the allyl bromide experiments the first procedure was modified in that the distillate was cut into several fractions of which the indices of refraction were determined separately. The addition product of allyl bromide was distilled at 20 mm. pressure. The 1-bromo-2-iodopropane was found to boil at 66.8° at this pressure and to have the refractive index n^{20}D 1.5916.

In the allyl chloride experiments free iodine was first titrated with standard thiosulfate solution, and the product was then dried and fractionated at 40 mm. pressure. The 1-chloro-2-iodopropane boiled at 66.2° at 50 mm., n^{20}D 1.5472.

Reduction Products of Allyl Bromide.—The low-boiling materials from a number of allyl bromide experiments were combined and fractionated through a Podbielniak column. They comprised about 40% allyl bromide and a like amount of iospropyl iodide together with about 10% isopropyl bromide. The last was identified by halogen analysis and preparation of isopropyl 3,5-dinitrobenzoate.

1-Bromo-1-iodopropane.—The various fractions from the 1-bromopropene experiments were combined and fractionated to obtain a sample of 1-bromo-1-iodopropane. The amount of available material was too small to permit isolation of a pure sample, but the index of refraction was estimated from those of several fractions: n^{20}D 1.5826;

b. p. 61.3° at 20 mm. Fractions having indices both above and below the estimated value were obtained, and it is believed that the error in the index of refraction is less than ±0.0010.

Structure of 1-Chloro-2-iodopropane.—The structure of the addition product of hydrogen iodide and allyl chloride was established by the action of zinc and hot alcohol on the addition product. An 87% yield of propylene (identified by its addition of hydrogen iodide to give nearly the theoretical yield of isopropyl iodide) was obtained. Had the product been a 1,3-dihalide, cyclopropane (which yields *n*-propyl iodide upon treatment with hydrogen iodide) would have been produced. A 1,1-dihalide would have given 3-hexene. It was then shown that the 1,2-dihalide was 1-chloro-2-iodopropane by adding to it an equimolecular proportion of warm alcoholic sodium ethoxide. The product was a mixture of propene with the *cis* and *trans* isomers of 1-chloropropene.[10] The latter were identified by boiling point and index of refraction.

Summary

1. In a thorough investigation of the addition of hydrogen iodide to propene, allyl bromide and allyl chloride only one (the "normal") addition product was obtained in each case.

2. The addition of hydrogen iodide to 1-bromopropene yields a mixture of approximately one-third 1,1- and two-thirds 1,2-dihalides.

3. It is shown that iodine is a catalyst for the addition of hydrogen iodide, and that peroxides accelerate this addition because they liberate iodine from hydrogen iodide.

4. 1-Chloro-2-iodopropane and 1-bromo-1-iodopropane have been prepared in the pure and nearly pure states, respectively.

An Investigation of the Exchange between a Metal and Ions in Solution by Using Radioactive Indicators

BY B. V. ROLLIN

In experiments using the naturally radioactive isotope of lead, Hevesy and Biltz[1] have shown the existence of an exchange of atoms between the surface of a sheet of metallic lead and a solution of a plumbous salt in contact with it. In one hour, under the conditions of their experiment, they found that the quantity of lead which had exchanged with the solution corresponded to a depth of about a thousand atomic layers of the metal. The study of this type of exchange is interesting because it is important in understanding the mechanism of corrosion processes and so it was considered worth while to continue the investigation with other metals using, as indicators, artificially radioactive isotopes produced by bombardment in the cyclotron.

A. Inactive Metal Shaken with Active Solution

(1) Zinc.—For a preliminary experiment radioactive zinc was prepared by deuteron bombardment of zinc followed by chemical separation. The zinc was used in the form of the chloride in a solution of about 300 mg. of chloride in 30 cc. of water acidified to a *p*H of about 5. The total activity of the solution was about 10 microcuries. The metal, in the form of a powder, was first shaken for one hour with a concentrated solution of inactive zinc chloride, then filtered and washed, and about 1 g. of the powder then shaken with the active solution for one hour. The solution was filtered off and the powder very carefully washed. On testing the powder with an electroscope it was found to be quite appreciably radioactive. No quantitative results could be deduced from this experiment because the metallic zinc was slowly attacked by the solution during the period of shaking.

(2) Silver.—Silver was chosen because (in the absence of oxygen) it is only dissolved to a negligible extent by water and because it forms stable ions in solution which are not reduced to a lower valence state by contact with the metal. It would, for example, have been impossible to study the exchange between copper and cupric ions because the results would be obscured by the exchange brought about by the reaction

$$Cu^{++} + Cu \rightleftarrows 2Cu^{+}$$

Preparation of the Radioactive Silver.—The isotope used was Ag^{106} having an eight-day half-life and was obtained by bombarding palladium with 8 Mev. deuterons. The palladium was digested with fuming nitric acid and 9 *N* perchloric acid and 100 mg. of silver added as carrier. The silver was precipitated as chloride, washed and dissolved in excess of ammonium hydroxide, then precipitated with ammonium sulfide, filtered and the precipitate dissolved in hot nitric acid. The solution was evaporated to dryness and the silver nitrate residue dissolved in 30 cc. of water. The total (β-ray) activity of the solution was 10 microcuries.

(a) A sheet of silver of area 20 sq. cm. was polished with crocus cloth, washed with nitric acid and water, shaken with inactive silver nitrate solution for two hours and then shaken with the active silver nitrate solution for twenty-four hours. At the end of this time it was care-

(1) G. von Hevesy and M. Biltz, *Z. physik. Chem.*, **B3**, 271 (1929).

fully washed, then shaken with water for several hours and its activity tested. It was found to have acquired an activity corresponding to an exchange with the solution of about 150 atomic layers of the metal (assuming the actual surface of the metal is the same as the measured surface).

(b) The experiment was repeated using sheets of gold and platinum instead of silver. These were also found to have acquired an activity representing the transference of about 100 atomic layers from the solution. The activity was apparently not due to simple contamination with ions as it was not appreciably reduced by further washing with water for forty-eight hours.

(c) In this experiment the solution was shaken with a different type of surface. The surface was a silver mirror deposited on the inside of a glass flask by evaporation of silver in a vacuum from a heated tungsten strip. After evaporation of the mirror the flask was filled with nitrogen and the solution introduced. The flask was then evacuated again and shaken so that the solution was in contact with the mirror for one hour. After careful washing the solution was found to have an activity corresponding to the transference of about twenty atomic layers.

B. Active Surface Shaken with Inactive Solution.— The radioactive silver was obtained by electrolysis of the active nitrate solution. The surface was prepared by evaporation of a few milligrams of the silver in vacuum as in (c) above. Before evaporation the silver was carefully washed to free it from silver ions. After deposition of the mirror the flask was filled with nitrogen and the mirror washed several times with distilled water. The mirror was then shaken for one hour with distilled water (under vacuum), this water then discarded, a fresh quantity introduced and the shaking repeated. In this way the mirror was freed from all radioactive contamination as shown by testing the second water washing by adding silver ions (as carrier), precipitating the silver as bromide and testing the bromide with a Geiger counter. The mirror was now shaken for two hours with a solution of silver nitrate (containing 1 g. of silver nitrate in 20 cc. of water). On precipitating the silver as bromide it was found to contain an activity corresponding to the exchange of ten atomic layers.

To investigate whether the nitrate ion had any influence on the exchange, the mirror was now shaken for one hour with a solution of sodium nitrate (0.5 g. sodium nitrate in 20 cc. of water). Following the usual procedure of adding silver ion as carrier and then precipitating the silver as bromide and testing its activity, it was found that no activity had been taken up by the solution.

On washing the mirror again with silver nitrate solution for one hour and measuring the activity taken up by the silver solution, an unexpected result was found. The activity was now very high corresponding to the transference of about 150 atomic layers from the mirror. On washing the mirror with water and then shaking with silver nitrate solution again for two hours it was found that the activity in the solution was now that of only ten layers again. To verify the effect of treatment of the mirror with sodium nitrate solution, the experiment was repeated and again an exchange of about 100 atomic layers was found.

The results are summarized in Table I.

TABLE I

Soln.	Time of shaking, hours	Activity (atomic layers)
Water	2	Not measd.
Water	1	Less than 1
Water	1	Not measd.
$AgNO_3$	2	10
$NaNO_3$	1	0
$AgNO_3$	1	150
$AgNO_3$	2	10
$NaNO_3$	1	Not measd.
$AgNO_3$	1	100

Discussion

The experiments with silver in a solution of silver nitrate show that there is an actual exchange of atoms between the metal and the solution. The exchange appears to involve from ten to a hundred atomic layers and, as one can completely neglect the diffusion over these distances in the metal, the only reasonable mechanism seems to be that of local electrolysis caused by the existence of irregularities on the surface of the metal. However this hypothesis does not account for the activity obtained by the gold and platinum sheets from the silver solution unless the surfaces of the metals contained considerable impurities, which seems unlikely. It is very difficult to explain why treatment of the silver surface with sodium nitrate should increase the activity obtained by the silver surface solution from the mirror. The phenomenon is perhaps due to some kind of activation of points on the surface of the silver by sodium ions but no reason can be seen why this should take place. It seems that further experiments will be needed before the mechanism of these effects can be explained.

It is a pleasure to record the advice and coöperation in these experiments of Dr. G. T. Seaborg and also of Dr. S. Ruben, who very kindly made all the Geiger counter measurements. I am especially indebted to Professor E. O. Lawrence for enabling me to use the cyclotron to obtain the radioactive substances.

Summary

Experiments using radioactive silver have shown that exchange takes place between a solution of silver ions and a surface of metallic silver. In two hours an exchange of silver corresponding to ten atomic layers was found. The exchange was increased by a factor of ten if the surface was pretreated with sodium nitrate solution.

The Heat Capacity of Nickel Oxide from 68–298°K. and the Thermodynamic Properties of the Oxide

BY HARRY SELTZ, BERNARD J. DEWITT AND HUGH J. MCDONALD

This paper describes the results of measurements of the heat capacity of nickel oxide, NiO, from 68–298.1°K., making use of the calorimeter described in a previous publication.[1] From these results the entropy has been evaluated at 298.1°K., and from published heats of formation and heat capacities at higher temperatures the complete thermodynamic properties of the oxide have been derived.

Material.—The nickel oxide used was a C. P. Baker analyzed grade containing less than 0.2% of impurities. Microscopic examination (×1000) showed the material to be made up of transparent cubic crystals of uniform size. This is the only form of the pure oxide which has been reported. The powder was dried for several days at 100°, and a sample then showed no ignition loss on heating to bright redness in a platinum crucible. The total charge of nickel oxide used in these measurements was 151.085 g. (*in vacuo*) or 2.0229 moles. Frequent checks of the calorimeter resistance against the calibrated thermocouple during the heat capacity measurements showed no significant changes in the calibration.

Experimental Results.—In Table I the experimental heat capacities for the oxide are given, and the results are plotted in Fig. 1. The overall accuracy of these measurements is estimated at ±0.2%.

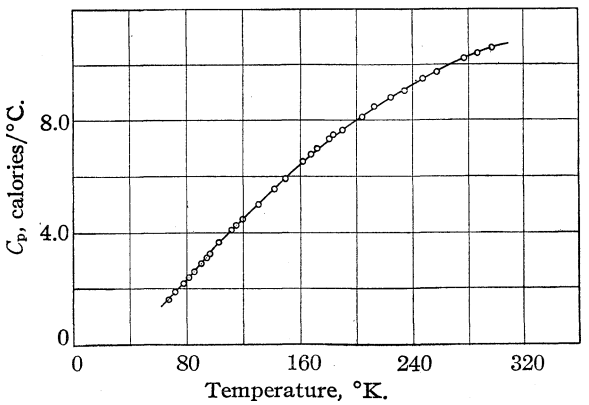

Fig. 1.—Molal heat capacity of NiO.

Calculations

The Entropy of NiO.—The method of Kelley[2] was used to extrapolate the heat capacity values from 68–0°K. It was found that

$$C_v = D\left(\frac{404}{T}\right) + E\left(\frac{620}{T}\right)$$

TABLE I

Temp. °K.	C_p, cal./mole	Temp. °K.	C_p, cal./mole
68.05	1.607	151.86	6.02
71.96	1.909	162.37	6.54
78.19	2.185	168.09	6.80
82.07	2.403	172.61	7.02
85.89	2.625	181.32	7.36
86.70	2.644	183.01	7.50
91.08	2.927	190.75	7.64
94.42	3.094	204.20	8.12
96.32	3.298	213.13	8.54
103.13	3.693	225.34	8.84
111.70	4.094	235.37	9.09
115.71	4.242	247.81	9.52
120.33	4.464	257.49	9.75
131.10	5.00	277.20	10.27
141.72	5.58	286.32	10.43
150.08	5.93	296.68	10.56

fitted the experimental curve very well up to 150°K. The contribution of the Debye function to the entropy was 0.648 e. u. at 68°K., while the contribution of the Einstein function was less than the experimental error. The entropy change from 68–298.1°K. was determined graphically and this amounted to 7.716 e. u. The rounded sum of the experimental and extrapolated entropies is 8.36 e. u. at 298.1°K. Since two moles of the oxide were used in these measurements, the accuracy of this value is estimated to be better than ±0.1 e. u.

Thermodynamic Properties of Nickel Oxide.—Using accepted[3] values for the entropies of nickel and oxygen, we calculate $\Delta S_{298.1} = -18.00$ for the entropy of formation of the oxide. The heat of formation given by several investigators varies greatly, but the most acceptable value seems to be that given by Bichowsky and Rossini[4] $\Delta H_{298.1} = -58{,}400$ cal. From this value and the entropy of formation we calculate $\Delta F^\circ_{298.1} = -53{,}034$ for the free energy of formation. We thus write

$$Ni(s) + {}^1/_2O_2(g) = NiO(s);\ \Delta S_{298.1} = -18.00;\ \Delta H_{298.1} = -58{,}400;\ \Delta F^\circ_{298.1} = -53{,}034$$

Watanabe[5] and Bogatskii[6] independently have studied the equilibrium

$$NiO(s) + CO(g) = Ni(s) + CO_2(g)$$

(3) Kelley, "Bureau of Mines Bulletin 394," 1935, p. 35.

(4) Bichowsky and Rossini, "The Thermochemistry of the Chemical Substances." Reinhold Publishing Corp., New York, N. Y.

(5) M. Watanabe, *Science Repts. Tôhoku Imp. Univ.*, **22**, 436 (1933).

(6) D. P. Bogatskii, *Metallurg.*, **13**, No. 2, 18 (1938).

From his measurements Watanabe calculates the free energy of formation of NiO(s) as $\Delta F^\circ_{298.1} = -50{,}333$ cal., while Bogatskii's results lead to a value $\Delta F^\circ_{298.1} = -52{,}092$ cal. Pease and Cook[7] have studied the reduction equilibrium with hydrogen at two temperatures, 485 and 600°, and from these data calculate for the formation of the oxide, $\Delta F^\circ_{298} = -56{,}497$ cal. It will be noticed that the value obtained in this paper represents about the mean of the three previous determinations.

Kapustinskii and Novosel'tsev[8] have measured the heat capacity of NiO at temperatures from 373 to 1373°K. Their results can best be represented by the equation

$$C_p = 13.69 + 0.83 \times 10^{-3}T - 2.915 \times 10^{5}T^{-2}$$

Using Kelley's[9] equations for Ni(α) up to 626°K. and for Ni(β) above this temperature, and his equation for O_2, we obtain

$$\mathrm{Ni}(\alpha) + {}^1/_2\mathrm{O_2(g)} = \mathrm{NiO(s)}: \quad \Delta F^\circ = -60{,}387 - 5.29T \ln T + 2.85 \times 10^{-3}T^2 + 0.988 \times 10^{5}T^{-1} + 52.84T$$

$$\mathrm{Ni}(\beta) + {}^1/_2\mathrm{O_2(g)} = \mathrm{NiO(s)}: \quad \Delta F^\circ = -59{,}692 - 2.55T \ln T + 0.102 \times 10^{-3}T^2 + 0.988 \times 10^{5}T^{-1} + 35.80T$$

Summary

1. The heat capacity of nickel oxide, NiO, has been measured from 68-298°K.

2. The entropy of the oxide is found to be 8.36 e. u., with an estimated accuracy better than ±0.1 e. u.

3. The free energy of formation of the oxide has been calculated, $\Delta F^\circ_{298.1} = -53{,}034$ cal., and has been expressed as a function of the temperature.

The Precision Conductivity Bridge Assembly

BY W. F. LUDER

I. Introduction

The papers of Jones and Josephs[1] and of Shedlovsky[2] marked the beginning of a new era in the investigation of various chemical phenomena by means of conductivity measurements. The precision which they obtained was, and still is, sufficient for most such investigations. However, the rapid development of communication engineering since the publication of their papers has now made it possible to effect several desirable improvements in the whole conductivity bridge assembly. Furthermore, by taking advantage of recent developments, the expense and difficulty of assembling a complete bridge can be greatly reduced.

At about the same time as the work of Jones and Josephs and Shedlovsky on the conductivity bridge, an increased interest in many other types of alternating current bridges was evident in the large number of papers which were published each year. According to Hague,[3] well over 250 papers on a. c. bridge methods must have appeared since 1928. There were 48 in 1932 alone. One of the most thorough of the recent papers is that of Astin.[4] Although his bridge is of the Schering type, Astin has used a Wagner ground, and certain conclusions reached by him are of value in conductivity bridge design. Following Ogawa,[5] Astin has brought a. c. bridge theory to a high degree of perfection. In surveying this large field, however, chemists will do well to keep in mind the fact that the requirements of such bridges as those of Astin and of Balsbaugh and Herzenberg[6] are considerably greater than similar requirements for a conductivity bridge. The conductivity bridge is one of the simpler alternating current bridges.

Communication engineering has more than kept pace with requirements of low frequency a. c. bridges. The application of inverse feedback to the problem of tuning an oscillator or an amplifier[7] probably will be of value in many cases. It is doubtful, however, whether much advantage is to be gained by using it with the ordinary conductivity bridge. This is especially true in

(1) Jones and Josephs, THIS JOURNAL, **50**, 1049 (1928).

view of the fact that a very simple and inexpensive, low output, low harmonic-content oscillator is now available.[8] Constant-frequency oscillators, degeneratively tuned amplifiers, cathode ray tube null indicating devices, vibration galvanometers and similar complicated and expensive instruments are increasingly necessary in communication engineering and for use with Schering and other types of bridges. It is questionable, however, whether chemists have anything to gain by using them with the conductivity bridge.

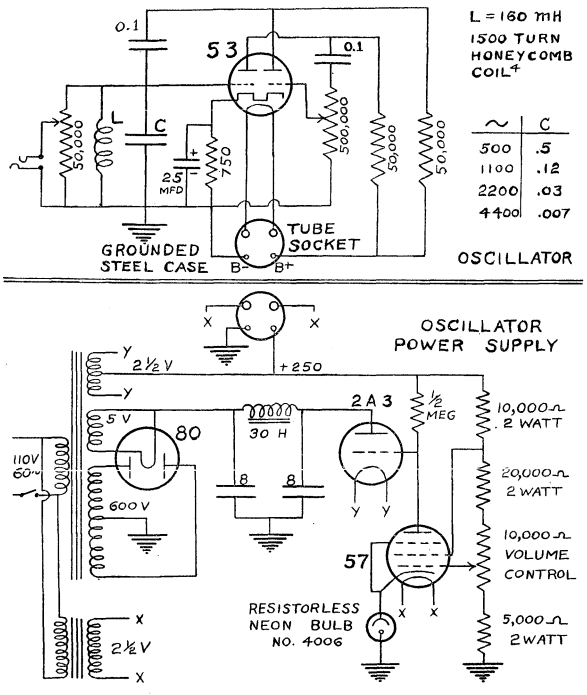

Fig. 1.

Securing the answer to this question was one of the objectives of the present investigation. Several different forms of the oscillator and its power supply, of the bridge network, and of the amplifier have been constructed and tested in this Laboratory. A preferred combination and several alternatives are suggested and discussed. Throughout the investigation the problem of easily duplicating the assembly as a unit has been kept in mind. Standard, readily-obtainable parts have been used. With the description given, any radio amateur or repair man should be able to complete the assembly in two or three days. This standardization has been secured with no loss in precision and with some gain in convenience in the operation of the bridge. Depending on the resistors chosen, it is possible to keep the cost of the whole assembly below $200.

(8) "Technical Service Bulletin TS-2," R. C. A. Manufacturing Co., Inc., p. 97.

II. The Oscillator

Headphones and a high gain amplifier make the most convenient detector in a bridge assembly where they can be used to good advantage. This is certainly true for the conductivity bridge. When bridge balance is indicated by zero amplitude of a 1000 cycle note, it is important to keep all other sounds at a minimum level. Undesired noise in the phones comes from four principal sources: (1) harmonics generated by the oscillator or introduced by transformers, (2) a. c. hum, (3) stray pickup, and (4) tube noise. The first two arise primarily in the oscillator and its power supply; the others will be discussed subsequently.

Oscillators are generally considered satisfactory for most purposes if their harmonic content is less than 2–3%. This value is too high for a precise bridge balance unless a filter is used in the detector. Such filters in the past have been rather unsatisfactory. (The question of whether or not a tuned amplifier should be used will be discussed in Part III.) The use of degenerative tuning[7] has made possible the construction of oscillators with remarkably low harmonic content.[9] Such oscillators have other good features, among which are low hum level and more easily controlled and constant frequency. They are, however, somewhat complicated and expensive, and offer no advantages, for conductivity bridge use, over the oscillator shown in Fig. 1.[10] By careful adjustment of the regeneration control of this oscillator, the harmonics can be reduced to 0.1%. This is not necessary, however. With ordinary care the percentage distortion will be approximately 0.3%. No harmonics can then be heard when the bridge is balanced using an untuned three-stage amplifier (two 6J7's and one 6C5).

An easy method of reducing a. c. hum is to make the power supply for the oscillator of the constant voltage type. The constant plate voltage probably contributes, also, to the observed stability of the regeneration control. The circuit of a simple constant voltage power unit is given

(9) For example, in one commercial model, the General Radio 608-A, the harmonic content may be kept under 0.1%.

(10) The use of this oscillator was suggested by Professor Carl F. Muckenhoupt, Chairman of the Physics Department of Northeastern University. Acknowledgment is due the R. C. A. Manufacturing Co., Inc., Harrison, N. J., for their kind permission to reproduce the diagram from page 97 of their Technical Service Bulletin TS-2.

in Fig. 1. When the bridge is balanced using the oscillator and power supply shown in Fig. 1, each in a separate steel case connected by cable and plugs, no a. c. hum can be heard in the output of a three-stage untuned amplifier.

Therefore the first two sources of unwanted noise can be eliminated easily without the use of a complicated oscillator or a tuned amplifier.

A further consideration in the design of an oscillator for conductivity bridge use is its output voltage. Most oscillators will supply too much power to a conductivity bridge. The output voltage of the oscillator described, 0.5 volt or less, is about the correct value.[11] If the noise level can be kept low enough, an oscillator voltage of 0.5 volt is sufficient to give a sensitivity in bridge reading of one or two parts per million using a two-stage amplifier consisting of one 6J7 and one 6C5.

The operating characteristics of the oscillator are given. (No alternative is suggested for the oscillator and its power supply, because there seems to be no more suitable combination for use with conductivity bridges at the present time. In addition to its having the correct operating characteristics, this oscillator is simple, inexpensive, and easy to construct and operate.)

Wave Form.—With the regeneration control properly adjusted[12] and the fundamental frequency set at approximately 1100 cycles per second, the harmonic content in the output voltage is less than 0.3%.[13]

Frequencies.—Approximately 500, 1100, 2200, 4400 c. p. s., are obtained by selecting different capacitances by means of a dial switch on the front panel.[14]

Output Voltage.—With the regeneration control properly adjusted and the oscillator connected to the bridge through a General Radio type 578-B bridge transformer, the maximum output voltage at the transformer secondary is approximately 0.5 volt.

Power Supply.—Controllable constant plate supply type. At 250 volts d. c. output the a. c. line voltage may be varied between 85 and 130 volts without causing a variation of more than one volt in the oscillator plate voltage.

(11) Jones and Bollinger, THIS JOURNAL, **51**, 2407 (1929).

(12) The adjustment is made by retarding the regeneration control until oscillation stops, then carefully advancing it until oscillation just begins again.

(13) A General Radio 736-A Wave Analyzer was used to make the distortion measurements. The author is indebted to Dr. Muckenhoupt for the use of the wave analyzer, a cathode ray oscilloscope, and a vacuum tube voltmeter.

(14) The inductance is a 1500 turn honeycomb coil (L = 160 mH) obtainable from the Radio Shack, 167 Washington St., Boston, Mass. Only rough observations were made on frequency stability, since conductivity measurements are not affected by small frequency changes.

III. The Amplifier

Since bridge balance is indicated by zero amplitude of the oscillator frequency, the useful gain of an amplifier is limited to a value not much greater than that at which the tube noise from the first tube becomes distinctly audible. This is true, of course, only if harmonics, hum, and stray pickup have been eliminated. Stray pickup will be discussed in Part IV.

The first amplifier constructed during this investigation was untuned and consisted of one 6J7 and one 6C5, supplied by batteries. Batteries were used because of the difficulties involved in preventing coupling between the oscillator and amplifier when both secure their power supply from a common a. c. source. "B" batteries are needed for a d. c. bridge with which to measure solvent conductance, at any rate. The same batteries may be used for the amplifier plate supply. The tube noise was just perceptible in this amplifier, which indicated that it had about the maximum useful gain that could be used without tuning. This gain was high enough to permit bridge balance to one or two parts per million in a quiet room. Therefore it is evident that when harmonics, hum, and stray pickup have been practically eliminated, such a two-stage untuned amplifier is sufficient for ordinary use of the bridge.

Little is to be gained by increasing the gain of the amplifier unless some means of tuning is employed. A three-stage untuned amplifier, constructed by adding another 6J7 tube to the two-stage amplifier, resulted in greatly increased volume of both the oscillator frequency and the tube noise. This may be of value if the bridge is to be used in noisy surroundings. However, in order to secure any great increase in sharpness of the bridge balance, a three-stage amplifier must be tuned. The best method seems to be degenerative tuning.[7] Inverse feedback is used to cancel all frequencies except that for which the degeneration network is balanced. Scott places the network around three direct coupled tubes in order to secure high selectivity. Direct coupling of three tubes, however, requires a very high voltage plate supply.

After some experimenting with degenerative

tuning, it seemed that the results in this case were not enough better than those obtainable by another method to justify the additional expense and difficulty of construction involved. This is particularly true with this assembly, since there is no need of suppressing harmonics from the oscillator. When noise other than tube noise has been practically eliminated from the assembly, the important requirement is a substantial reduction of tube noise with little decrease in signal strength. A simple method of tuning[15] which, although not extremely sharp, meets this requirement, is shown in the grid circuit of the 6C5 in Fig. 2.[16] Such an arrangement eliminates much of the background noise in the amplifier.

A number of such tuned circuits could be used for various frequencies by connecting them to a dial switch, but such an arrangement seems unnecessarily complicated. Most conductivity measurements are made at one frequency, usually 1000 cycles, so it seems best to include only one tuned circuit. A toggle switch is provided for

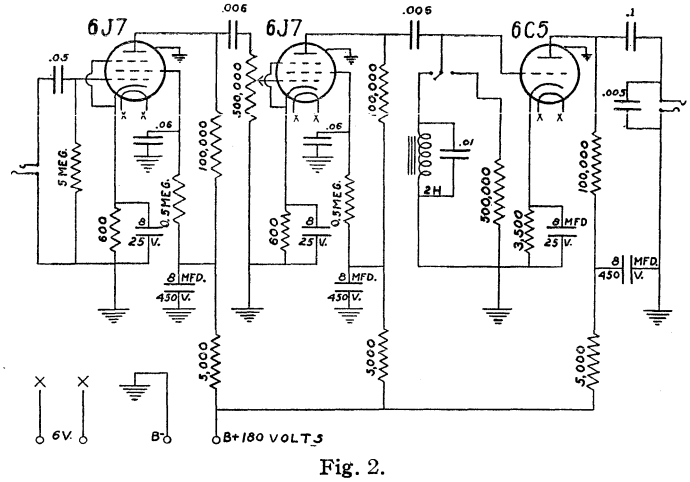

Fig. 2.

connecting a 500,000 ohm resistor in place of the tuned circuit. This permits the use of the amplifier as an untuned amplifier whenever measurements must be made at other frequencies.

An inductance of two henries is about right. This value can be obtained by increasing the separation between the I and E core pieces of a 10 henry, 50 milliampere, midget filter choke. If the frame is unclamped and seven strips of paper (cut to fit from typing paper) are inserted between the core pieces, the inductance will be about two henries. To tune this choke to 1,000 cycles a condenser of approximately 0.01 mfd. is needed. Since the inductance of the choke will not be exactly two henries, the correct value of the condenser should be chosen by experiment, starting with a value of 0.005 mfd. and adding 0.002 and 0.001 mfd. condensers in parallel until the correct value is reached. This is easily done by connecting the condensers while listening to the 1000 cycle note when the bridge is slightly off balance.

It seems that a two-stage amplifier is in many cases suitable. Where higher gain is necessary, sufficient tuning must be employed to reduce tube noise. Probably the most convenint method of tuning is the one described above.

IV. The Bridge Network

For most purposes there is no need of attempting to improve the precision obtained by Jones and Josephs.[1] There are, however, several refinements which may now be made. One of them involves a different method of connecting and balancing the Wagner ground circuit, called by Astin[4] separate balancing of the detector terminals to ground (Fig. 3). This method makes possible the elimination of the transformer usually employed between the bridge and the detector. A transformer in such a position is unsatisfactory for several reasons. Probably it is partly responsible for the fact that bridges using it show a great decrease in sensitivity as the resistance being measured is increased. At any rate, the bridge in the form now used in this Laboratory shows very little variation in balance sensitivity over its normal range of 1000 to 200,000 ohms. (Another factor in this nearly constant sensitivity will be referred to later.) A high impedance transformer is undesirable because of the effect stray fields may have upon it, thus making for a higher noise level.

If the more common form of Wagner ground described by Jones and Josephs[1] is to be retained, the elimination of the detector input transformer means that the amplifier cannot be grounded directly. Grounding a direct-coupled input amplifier makes the Wagner ground useless. An ordinary ungrounded amplifier, however, introduces

(15) This method is a common one in communication engineering. It will not attenuate adjacent harmonics sufficiently if they are present to any great extent in the oscillator output.

(16) For a two-stage amplifier, one of the 6J7's and the tuned circuit should be left out. The choke, condenser, and switch should be removed and the grid connected directly to the 500,000 ohm resistor.

an intolerable amount of stray noise. An ungrounded, doubly shielded amplifier[17] may be used, but involves unnecessary difficulties of construction. An alternative is to wire the amplifier so that the B minus line is isolated from the grounded chassis. A 0.5 mfd. condenser is connected from the midpoint of the bridge ratio arms to ground. The B minus side of the amplifier is connected to the midpoint. This arrangement functions satisfactorily[18] except that the volume is cut down considerably when the Wagner ground is being balanced. This is because the low impedance of the condenser is then directly across the amplifier input. Astin has shown that the only effect of the large admittance of the capacitance to ground is to make the bridge balance more dependent upon the Wagner ground adjustment. The requirement for non-critical adjustment is that the ground admittances from the detector terminals must be similar in ratio to the ratio between the admittances of the arms in either of the two pairs between the detector terminals. The large admittance to ground of the 0.5 mfd. condenser makes the Wagner ground adjustment nearly as critical as it is when the detector terminals are balanced separately to ground. Therefore it seems best to adopt the separate terminal balance since a conventional grounded amplifier can then be used.

Separate balancing of the detector terminals to ground requires that the Wagner ground balance be adjusted as carefully as the bridge proper. This is easily done by using verniers R_2 and C_2 as shown in the bridge network arranged for separate terminal balance (Fig. 3). The bridge is balanced roughly with S_1 upward. Then with S_1 downward the Wagner ground adjustment is made, first roughly with C_1 and R_1, then exactly with C_2 and R_2. Finally with S_1 upward again, the bridge is balanced exactly.[19] It is rarely necessary to repeat the procedure. (S_2, once set, is left untouched unless the oscillator leads are reversed.)

Jones and Josephs[1] and Shedlovsky[2] used 1,000-ohm resistors in the ratio arms and in the Wagner ground circuit of their bridges. It has

(17) Dye and Jones, *J. Inst. Elec. Engrs. London*, **72**, 169 (1933).

(18) No difference as great as 0.001% in measuring a resistance in the place of the cell can be detected when the frequency is changed from 500 to 4400 cycles.

(19) Those unfamiliar with separate terminal balance will be well repaid by a study of Astin's paper (ref. 4). (One of the Referees for this paper states that separate terminal balance was first proposed by Behr and Williams, *Proc. Inst. Radio Engrs.*, **20**, Fig. 13a, 985 (1932).)

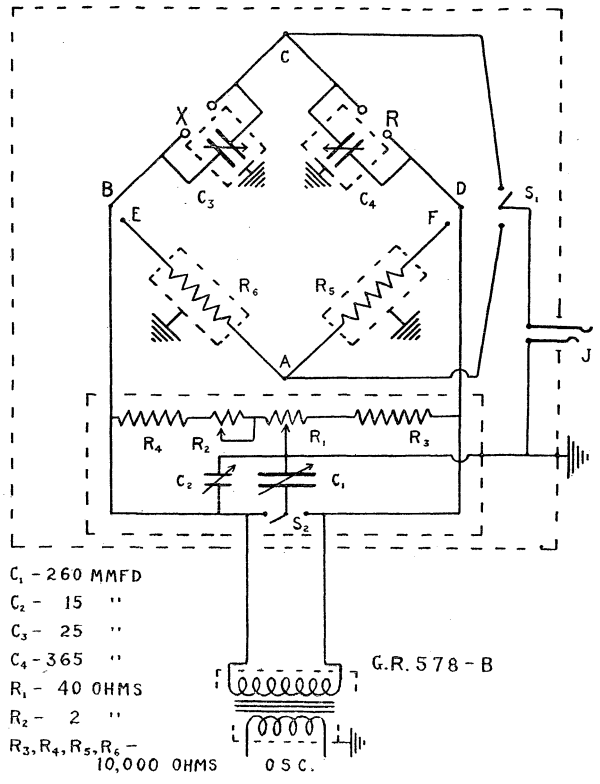

Fig. 3.

long been known[20] that one of the conditions for maximum balance sensitivity is to have the impedances of the four arms as nearly equal as possible. Therefore it seems desirable, for a bridge designed to cover the range of 1,000 to 200,000 ohms, to make the ratio arms and large Wagner ground resistances each equal to 10,000 ohms instead of 1000 ohms. When this combination is used with the readily available General Radio type 578-B bridge transformer step-up from oscillator to bridge, the oscillator–bridge impedance relationships are such as to give maximum energy transfer within the resistance range of the bridge.[21] This assists indirectly in making the bridge sensitivity comparatively constant. If the turns ratio of the transformer is such as to give maximum energy transfer from the oscillator to some impedance outside, or near one end of, the range represented by the bridge at the transformer secondary, considerable variation in apparent bridge sensitivity may be observed.

The chief source of stray pickup seems to be in the leads from the amplifier to the bridge and in the parts of the bridge connected directly to

(20) Reference 3, page 83.

(21) Different turns ratios of the transformer were tried, using a tapped telephone transformer.

these leads. For this reason, the shields around the ratio arms should be grounded directly instead of connected to the midpoint. Switch S_1 should be a toggle switch, the frame of which is connected to ground. The connections to the amplifier should be made by shielded plugs and cable.

From the above considerations it seems preferable: (1) that the Wagner ground be of the separate terminal balance type, (2) that 10,000 ohm resistances be used in the ratio arms and Wagner ground circuit, (3) that thorough shielding be employed. A description of the bridge control panel constructed by the author utilizing these features follows.

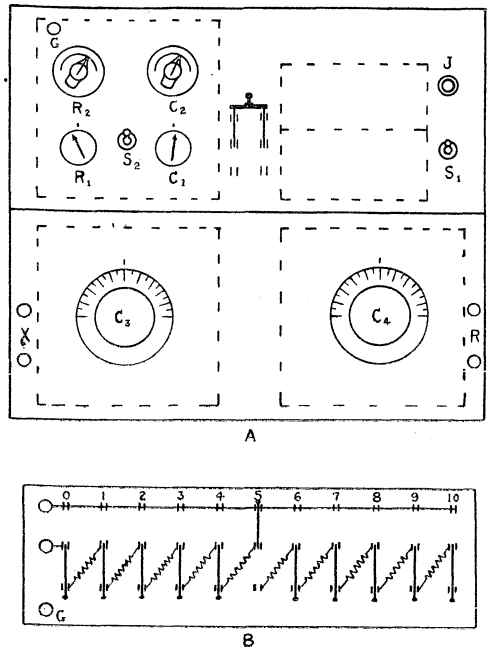

Fig. 4.

The panel itself consists of two $7'' \times 18'' \times 3/16''$ (18 × 45 × 0.5 cm.) hard rubber radio panels bolted together by means of a hardwood frame under the two panels (Fig. 4). The Wagner ground assembly is contained in one standard $6'' \times 6'' \times 6''$ (15 × 15 × 15 cm.) radio shield bolted to the panel underneath the farther left-hand corner. S_2 is a toggle switch. R_1 and R_2 are ordinary radio potentiometers. Each balancing condenser is contained by itself in a $6'' \times 6'' \times 6''$ shield. The farther right-hand section of the panel is shielded by copper sheet under the panel. It carries the ratio-arm shield, the jack for the amplifier plug and the toggle switch S_1. The ratio-arm shield is constructed of sheet copper just enough smaller than the other three shields to leave room for the switch and jack. The shield is divided into two compartments by a sheet of copper. Each compartment contains one of ratio arms. The reversing switch for the ratio arms[2] is a double-pole-double-throw knife switch mounted above the panel near the center. It is so connected as to reverse the connections E and F (Fig. 3) to B and D. The 10,000 ohm resistors are General Radio type 500-J without their cases. The two employed as ratio-arms should be so chosen (from the group to be used in constructing resistance boxes) as to have as nearly identical resistances as possible.

The walnut case which contains the control panel assembly is lined with thin sheet copper connected to the common ground. Shielded cable is used for the oscillator leads. The bridge transformer is connected step-up to the bridge from the oscillator. Its primary shield is grounded, its secondary shield is left floating. The transformer is placed about midway between oscillator and bridge. With this assembly it has not been found necessary to keep the bridge more than ten feet (3 meters) from the oscillator. The oscillator power supply is about five feet (1.5 meters) from the oscillator.

Suitable resistors are now produced by two companies: Leeds and Northrup and General Radio. General Radio resistors were used in this investigation. According to the General Radio catalog, their resistors have a higher temperature coefficient than Leeds and Northrup resistors, but are less expensive.[22] The temperature coefficient is not so high that thermostating is necessary, unless extreme precision is desired. Humidity changes sometimes cause greater changes in resistance than do temperature changes. In observations of the resistance of a sealed 10,000 ohm resistor measured against a combination of unsealed decade resistors no definite humidity effect could be noted. An extra precaution would be to dip the higher resistors in paraffin.[23]

A standard 602-F decade box is suitable for the three lowest decades (0.1, 1, 10 ohm steps). For the 100 ohm and 1000 ohm step decades, 510-D and 510-E decades were modified as follows. Each decade was removed from its close-fitting shield and mounted in a $6'' \times 6'' \times 6''$ radio shield. In the 1000 ohm step decade, in order to move them farther apart, alternate resistors were unsoldered and replaced projecting outward. The shields were then bolted together to make one two-dial decade box. Two 100,000 ohm resistance boxes were constructed using ten 10,000 ohm resistors in each.[24] The resistors were connected to small knife switches as suggested by Jones and Josephs[1] and shown in Fig. 4-B. Throwing only one switch gives the desired resistance without leaving any dead-end resistances. The wooden boxes are lined with grounded copper sheeting, but fortunately it is unnecessary to attempt to shield panel and switches. Unshielded leads are used between the resistance boxes.

(22) The temperature coefficient for Leeds and Northrup resistors is given as 0.0001% (Dike, *Rev. Sci. Instruments*, **2**, 393 (1931)). For General Radio resistors, the value is given as "less than 0.002%." Dike states that the Leeds and Northrup resistances are wound with manganin wire. In the specifications for their decade units, the General Radio catalog states that the lower resistors are wound with manganin wire and the 10,000 ohm cards with a combination of Nichrome and Ohmax to give "nearly zero" temperature coefficient. Therefore, in view of the fact that the General Radio Company is usually conservative in its performance claims, it seems probable that the temperature coefficients are considerably less than the value 0.002% given.

(23) Reference 3, p. 103.

(24) General Radio type 500-J resistances may be obtained without cases. Their a. c.-d. c. resistance difference is less than 0.1% at 50 kilocycles. Therefore, at one kilocycle it should be less than 0.001%.

Shielding of the network from stray pickup together with the absence of harmonics and hum from the oscillator have made it possible to balance the bridge to one or two parts per million using only the two-stage untuned amplifier described. When the bridge is at balance using this amplifier, no sound other than the barely perceptible hiss of the tube noise can be heard in the phones, even though the amplifier is untuned.

V. Summary

1. The conductivity bridge assembly has been investigated to determine to what extent it is advantageous for chemists to employ recent complicated and expensive developments in communication engineering in such a simple type of alternating current bridge.

2. Several different forms of the oscillator and its power supply, of the bridge network, and of the amplifier, incorporating recent developments in a. c. bridge methods and communication engineering, have been constructed and tested.

3. An adaptation of a new and simple low-distortion oscillator to conductivity bridge use is described. The oscillator plate supply is of the constant voltage type to reduce a. c. hum and stabilize the regeneration control.

4. Separate detector terminal balance to ground is suggested for conductivity bridges, and its adaptation and use described. The use of 10,000 ohm instead of 1,000 ohm resistors for the ratio-arms and Wagner ground circuit is proposed. Shielding to reduce stray pickup to a minimum is described.

5. A two-stage untuned amplifier with gain sufficient to permit balancing the bridge to one or two parts per million when oscillator harmonics, a. c. hum, and stray pickup have been practically eliminated is suggested for ordinary use of the bridge. A description of a three-stage tuned amplifier is also given.

6. Simplification, ease of construction, and lowered cost have been attained with no loss in precision and with some gain in convenience in the operation of the bridge.

The Magnetic Rotation of Praseodymium, Samarium, and Europium Chlorides in Aqueous Solution at 25°

BY CHARLES M. MASON, JOSEPH W. HICKEY AND WILFRED K. WILSON

Recently[1] this Laboratory has presented the results of an investigation of the magnetic rotation of lanthanum and neodymium chlorides in aqueous solution. In the present work this method of investigation has been extended to the aqueous solutions of praseodymium, samarium, and europium chlorides. The Verdet constants have been obtained for these solutions over a concentration range from zero (pure water) to 3.5 molal. The dispersion has been studied from 4811 to 6438 Å.

Experimental Details

The rotations were measured with a Franz Schmidt and Haensch model 55 Landolt–Lippich triple-shadow polarimeter with non-magnetic frame. The instrument could be read to one-hundredth degree of arc. The light sources used were a mercury Lab-Arc, sodium Lab-Arc, and a Zeiss electrical spectral lamp fitted with Osram zinc and cadmium-filled bulbs. Monochromatic light was obtained by means of a Winkel–Zeiss monochromator inserted in the optical path between the spectral source and the polarimeter. By this means it was possible to isolate the principal lines of the various spectra with enough intensity left to properly operate the polarimeter.

The solution, the rotation of which was to be measured, was placed in a water-jacketed cell of Pyrex brand glass equipped with optical windows of the same material fused to the ends of the cell. This cell, as placed in the magnet, is shown in Fig. 1. The magnet consisted of 17 layers of approximately 162 turns each of No. 16 B. and S. gage, silk-covered copper wire wound on a bakelite tube 3.5 cm. inside diameter and 24 cm. long. The total number of turns was 2753 and the length of the coil was 23.1 cm. The length of the light path through the solution was 20.08 cm. measured by calibrating the tube with carefully purified sucrose. These data enabled the computation of the field strength, H, of the coil at any point along the axis. The product of the effective field strength times the length of the light path in the cell was determined by integration between limits based on the diameter of the first and last layers of turns to be 11,089.4 gauss. Integration for each layer of turns and summation gave a value of 11,084.6 gauss, a check well within the experimental error of the methods used to measure the angle of rotation. This field strength, when used to compute the Verdet constant of water, gave a value of 13.11×10^{-3} for that constant at 25° and wave length 5893 Å. This com-

(1) C. M. Mason, R. D. Gray and G. L. Ernst, THIS JOURNAL, **58**, 1600 (1936).

pares very favorably with the value of 13.07×10^{-3} given for water under the same conditions by Rodger and Watson[2] when it is considered that an error of 0.01° in rotation is equivalent to 0.05×10^{-3} in the Verdet constant. The rotation of the end plates was corrected by the determination of their rotation when the cell was empty.

A current of 4.0 ± 0.001 amperes was used, supplied by storage batteries. Current regulation was obtained with a potential divider which was a modification of that described by MacInnes and Longsworth.[3] A potential drop of 0.4 volt was maintained across a standard tenth ohm resistor by controlling the potential divider in the circuit with the magnet so that the galvanometer in the potentiometer circuit showed no deflection during the course of a measurement.

All refractive indices were measured at 25° with a standard Pulfrich refractometer. Care was taken to eliminate or correct for any error due to evaporation during the measurement. The temperature was controlled with the same equipment described below for the electromagnet. The refractometer was checked with carefully prepared distilled water using the tables of Tilton and Taylor[4] as a source of standard values.

The temperature in the polarimeter cell was kept constant by circulating water from a thermostat through the jacket of the tube. The temperature of the thermostat was kept so that the temperature in the water jacket of the cell was 25.00 ± 0.03°. A mercury thermoregulator connected through a relay to an electric heater maintained the thermostat at a constant temperature. The actual temperature in the cell was taken as the average of the two thermometers at the ends of the cell, as shown in Fig. 1. All thermometers used were checked against a standard thermometer which had been calibrated by the United States Bureau of Standards.

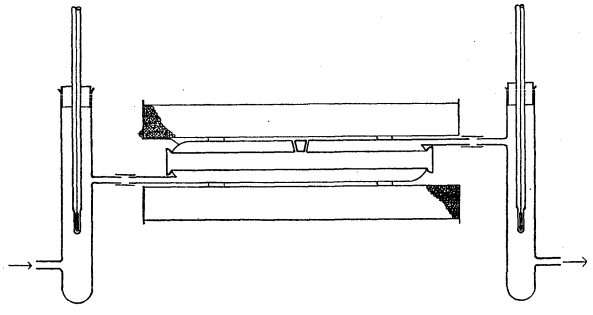

Fig. 1.—Cell, showing position in magnet.

The rare earth salts had been carefully prepared by repeated recrystallization. The samarium material had been obtained from the Maywood Chemical Co. and the praseodymium material from the estate of the late Charles James. The europium material was very kindly loaned to the department by Dr. Herbert N. McCoy. We wish at this time to thank Dr. McCoy for his generosity in loaning us this material. Its purification and purity is described elsewhere.[5] Since our sample of europium was from the same source, we used the atomic weight, 151.96, recently determined by Baxter and Tuemmler.[6] The chlorides were used as concentrated solutions prepared from the hydrates and analyzed for chloride ion and rare earth ion in the usual way.

The hydrated chlorides were prepared by the following procedure. The oxalate was ignited to the oxide in a muffle furnace at as low a temperature as possible and then dissolved in redistilled arsenic-free hydrochloric acid. It was found best to ignite the oxalate in small batches because it had a tendency to "boil" on decomposition and spatter out of the dish. The oxide was then cooled and added in small portions to the arsenic-free hydrochloric acid in a large beaker. Since some of the oxalate decomposed only to the carbonate, care was taken to prevent the solution from foaming over at this point. It was necessary in some cases to heat the solution for a time on a steam-bath to dissolve the last of the oxide. If, as often was the case, there was carbon remaining from the ignition, it was filtered out at this point. Igniting at high temperatures to remove all of the carbon often makes the oxide difficultly soluble and was to be avoided if possible.

After filtering, the solution was evaporated to a sirup on the steam plate or bath and the chloride shaken out at 0° with hydrogen chloride gas. This hydrated salt was then dried in a current of warm air in a hot-air drier until all of the hydrogen chloride seemed to be removed. The dried salt was then dissolved in a minimum amount of water, one or two drops of concentrated hydrochloric acid added to prevent hydrolysis, and evaporated to a thick sirup. This may be done either over a steam-bath or over a burner. In either case one must be careful to evaporate until just before the sirup begins to crystallize. Not enough evaporation will reduce the yield and too much will cause the whole to set to one solid mass which is of no value and must be dissolved in water and reworked. The sirup was quickly chilled to 0° while stirring very rapidly with a glass stirrer propelled by a motor. This action produced a mass of fine crystals of the hydrate which were easily filtered onto a fritted-glass plate and sucked free of mother liquor. The crystals were then washed with absolute ethanol and dried in a hot-air drier. A good test for the removal of hydrogen chloride was found to be as follows. The hydrate was placed in a glass-stoppered bottle for several days and then examined to see if any odor of the gas had collected in the top of the bottle. Its sharp penetrating odor was very easy to detect.

All of the water used was distilled in an ordinary electrically-heated laboratory still. Only about one-third of the vapor was condensed and collected, the rest being allowed to escape as steam. By employing this procedure, and protecting the water during cooling from the air, it was found that the water so obtained was free of carbon dioxide and other gases. The conductance of the water so obtained was of the order of 10^{-6} reciprocal ohms at 25°.

Results

The relationship of the magneto-optical rotation to the field strength and length of the light path is expressed by Verdet's law[7]

$$r = VHl \cos \alpha \qquad (1)$$

where r is the rotation in minutes, V is the Verdet constant, H is the field strength, l is the length of the light path in cm., and α is the angle between the path of light and the axis of the magnetic field. For the Faraday effect where the axis of the magnet and the rays of light are parallel, this law reduces to

$$r = VHl \qquad (2)$$

When an electromagnet of less than infinite length is used, this becomes

$$r = V \int H \, dl \qquad (3)$$

where $H\ dl$ is the average field strength over the light path used. If we choose to calibrate our cell with some pure liquid whose Verdet constant is known, such as water,[2] we find that

$$V = rV_s/r_s \qquad (4)$$

where r_s and V_s are the rotation and Verdet constants of the standard liquid used and r and V are those for the solution being measured. The Verdet constants of the rare earth solutions were obtained by measuring the magnetic rotation of the various solutions and then computed by means of equation (4). The results obtained are given in Table I.

It was also found necessary to determine the densities of the solutions used where they could not be found in the literature. These were determined in a 25-g. Regnault specific gravity bottle in duplicate and are given in Table III as a part of the calculation of the molecular and specific rotation. The refractive indices which were obtained have been expressed in terms of linear equations of the type $\eta = \eta_0 + am + bm^2$ where η is the refractive index, η_0 the refractive index of water, a and b are constants and m is the molality. The values of the constants of these equations are given in Table II, and the refractive indices reproduced by these equations are to within the experimental error, namely, ± 0.0002.

Discussion

Okazaki[8] has published a series of papers on the

(8) A. Okazaki, *Mem. Ryojun Coll. Eng.*, **6**, 181 (1933); *ibid., Inouye Commemoration Volume*, 209 (1934); **9**, 13, 101 (1936); **10**, 89, 115 (1937); **12**, 33, 45 (1939).

Faraday effect in solutions of electrolytes. He has used the following modification of the Schönrock mixture rule

$$(w) = t_1(w_1) + t_2(w_2) \quad (5)$$

where w, w_1 and w_2 are the specific rotations of the solution, solvent, and solute, respectively, and t_1 and t_2 are the weight percentages of the solvent and the solute. The molecular rotation, $M(w)$, may be obtained easily by multiplying the specific rotation by the molecular weight. We have used this formula to compute the molecular rotation of the solute, $M(w_2)$. The values so computed are included in Table III. We have also included the molecular rotation of aluminum, lanthanum, and neodymium chlorides calculated from data obtained previously.[1,9]

An examination of Table III shows that the mixture rule (equation 5) when applied to the data in Table I holds within limits of experimental error at concentrations below about 3 molal, which represents about 40% anhydrous salt in the solutions. There are some discrepancies in the more dilute solutions but in this region where the rotation is small the errors of measurement are magnified in the computation of the Verdet constant and further magnified in the computations of the molecular rotation. These results in general confirm and are consistent with the results obtained by Okazaki[8] for many other electrolytes.

Roberts, Wallace and Pierce[10] have calculated for cerium sulfate solutions a quantity Δ/W which they call the "specific rotation." This is defined in the equation

$$\Delta = \frac{nV}{(n^2+2)^2 d} - \frac{n_w V_w}{(n_w^2+2)^2 d_w}(1 - W/100) \quad (6)$$

where n is the refractive index of the solution, n_w that for water, and W is the number of grams of salt per 100 g. of solution. V is the Verdet constant for the solution and V_w is that for water. From the theory from which this equation is developed, the quantity Δ/W should be independent of the concentration for any given wave length. This constant is independent of the concentration for cerium nitrate[10] and an examination of the data given in Table IV will show if this be true for the salts studied in this investigation.

A study of the data in Table IV shows that the values of Δ/W obtained for solutions of praseodymium are constant within limits of error but that in the case of samarium and europium chlorides there seems to be a definite trend to decrease in the more concentrated solutions. It may also be noted that all specific rotations decrease with increasing wave length.

An interesting anomaly appears in the case of the results for europium chloride. Samarium is definitely less paramagnetic than cerium or praseodymium, as shown by the fact that the Bohr magneton number is about 3.6 for praseodymium and 2.5 for cerium, whereas for samarium it is only about 1.5,[11] and the decidedly less magnetic optical rotatory power of samarium might be explained on this basis. In the case of europium, however, the magneton number given by Van Vleck[11] and since recalculated by Schmidt[12] is about 3.4. Therefore, one might expect that europium would have magnetic optical rotatory powers of the order of those of cerium and praseodymium rather than of the order of magnitude of samarium which it does have. We are not able to offer an explanation of this apparent anomaly.

Summary

The magnetic rotations of the aqueous solutions of praseodymium, samarium, and europium chlorides have been measured at 25° for the wave lengths λ4810.5, λ5085.8, λ5460.7, λ5893, λ6362.4, and λ6438.47 Å. except in those cases where absorption interfered.

The refractive index of these aqueous solutions has been reported at 25°.

The Verdet constants have been calculated, those for samarium and europium solutions being positive and those for praseodymium solutions being negative when referred to water.

The specific and molecular rotations have been calculated and the variation of these properties with concentration noted and discussed.

An interesting anomaly has been observed in the comparison of the Verdet constants with the known magnetic moments of these ions.

Photochemistry of Diiodoacetylene and Tetraiodoethylene

BY JOHN W. TAMBLYN AND GEORGE S. FORBES

The present research represents a further attempt to correlate the mechanisms of photoiodination on either side of the convergence limit of iodine, 499 mμ. Brown[1] states that a continuum in the red, corresponding to production of normal atoms, is not visible below 50°. Bonhoeffer and Harteck[2] hold that this mode of dissociation is of minor importance photochemically. The data of Rabinowitch and Wood,[3] however, might lead to a contrary conclusion. Dickinson and Nies[4] re-evaluated the data of Schumacher and Steiger[5] in terms of the influence of absorbed light intensity. They found the relative efficiencies of quanta corresponding to λλ 578, 546 and 436 mμ to be 0.75, 0.87 and 1.00, respectively. The temperatures were 76.6 and 99°. On the other hand,

Forbes and Nelson[6] found that light of λ 644 mμ was much less efficient than light of λ 436 mμ in promoting iodination of *cis*-butene in chloroform. Quanta corresponding to λ 644 mμ are still substantially greater than the minimum requisite for production of normal atoms. Rollefson[7] has ably discussed the issues involved in this situation.

Diiodoacetylene represents a type of compound not yet investigated with the above stated problem in mind. The thermal addition of iodine takes place slowly in carbon disulfide[8] and rapidly in boiling toluene.[9] We found that the photochemical reaction proceeds smoothly in visible light, at 0°, without important thermal reaction. We varied light intensity, and concentrations, measured quantum yields and temperature coefficients, and set up rate equations valid for the different spectral regions.

Materials.—Diiodoacetylene was prepared according to Dehn[10] with the additional precaution that the acetylene was washed with lead acetate to remove hydrogen sulfide.[11] The product was twice recrystallized from petroleum ether. After storage at 0° in the dark for a period of nine months, no change in appearance or in melting point could be detected.

Tetraiodoethylene was prepared following the directions of Datta and Prosad,[12] also by boiling diiodoacetylene in toluene with purified iodine. The product was in each case recrystallized twice in toluene distilled from sodium.

Hexane, from Eastman Kodak Co., was shaken with portions of concentrated sulfuric acid until one remained colorless for several hours. Three or four treatments with fuming acid followed over a period of one to two days. A final washing with alkaline permanganate preceded distillation. Our criterion of purity was 99% transmission of light of λ254 mμ in a 5-mm. layer. The product, which boiled over the range 64 to 69°, was evidently a mixture of hydrocarbons, but it did not react thermally with iodine, nor photochemically even in light of λ254 mμ.

Apparatus and Method.—The quartz reaction cell previously used by Forbes and Nelson[6] had plane parallel faces 5 × 2 cm. in area and 1 cm. apart. It was surmounted by a quartz cylinder with a ground-in hollow Pyrex stopper through which passed sealed-in tubes for ingress and egress of nitrogen. For removal of oxygen, which retards many halogenation reactions, the best method found was to bubble nitrogen (said to be 99.93% pure) through the reaction mixture at dry-ice temperature, for an hour at the rate of two bubbles per second. After this, the solution was warmed to 0° and shaken to redissolve precipitated iodine. The following relative reaction rates were observed at 0° and in constant red light after an hour's treatment with the following mixtures of nitrogen and oxygen, respectively:

p_{O_2} (atm.)	0.0000[b]	0.0007[a]	0.028	0.21	0.995[c]
Rate, R	9.3	9.5	1.92	1.55	0.78

[a] Tank nitrogen. [b] Nitrogen treated with hot copper. [c] Tank oxygen.

In addition, R was found to be 3.9 in a solution prepared in air, frozen at liquid air temperature, pumped out, melted, again frozen, and so on, three times in all. Willard and Daniels[13] repeated such a cycle six or seven times before their reaction rates reached maximum values. Unless otherwise specified, all solutions mentioned below were freed from oxygen by tank nitrogen as described above.

The reaction cell[6] was lowered into an air thermostat[6] with a double quartz window to avoid condensation of moisture. Temperature was held at 0 ± 1° by a regulated current of chilled air. Whenever a prism monochromator was not employed, a light-filter cell one inch thick was in contact with the thermostat window. The solution was shaken as often as seemed desirable.

Since the quantum yields varied with incident light flux, the divergent beam from the exit slit of a monochromator, having a wide range of intensity over its cross section, would have been unsuitable in certain experiments. A tungsten lamp was employed with its U-shaped filament parallel to the cell window. Thanks to an efficient voltage regulator, the readings of an ammeter in series were constant within 3%. Known relative light intensities were realized by use of the inverse square law, valid within 1% except perhaps at the highest point of Graph II, Fig. 1.

Analytical.—Immediately after photolysis the solution was analyzed in dim light. Grease was carefully removed from the mouth of the cell, and the mixture was transferred to a flask containing 1 g. of potassium iodide in 5 cc. of water. The cell was rinsed into the flask with a little more potassium iodide solution, after which the iodine was titrated, while shaking, with 0.01 N thiosulfate. The thermal reaction, never more than 3% of the whole, was subtracted. The speed of this reaction was not measurably altered by packing the cell with quartz fragments, glass beads or glass wool.

Influence of Light Intensity.—To minimize undesirable thermal reactions, experiments were conducted at 0°. In Series I a 200-watt bulb was used. A ferric thiocyanate filter transmitted light, λ ≧ 600 mμ, according to visual observations with a Hilger wave-length spectrometer. No change in the absorption limit could be detected after exposure. In Series II, a 500-watt bulb was used behind a Corning filter H R Signal Red, λ ≧ 610 mμ. In Series III, blue light, λ ≦ 480 mμ, was transmitted by a cuprammonium sulfate filter. Exposure times varied from a few minutes to an hour. In Fig. 1, $\log_{10} R$ (reaction

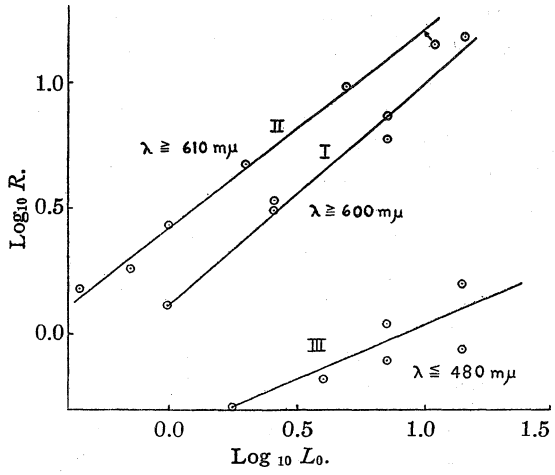

Fig. 1.—Influence of light intensity L_0 on reaction rate, R. The values of R on line II were multiplied by ten before plotting.

rate) is plotted against log L_0 (incident light flux), both in arbitrary units. As filter II had a relatively low transmission, and lamp distances were greater, all values of R_{II} were multiplied by ten before plotting. Drawing the best straight lines, $\Delta \log R_I = 0.90\ \Delta \log L_0$; $\Delta \log R_{II} = 0.78\ \Delta \log L_0$; and $\Delta \log R_{III} = 0.40 \log L_0$. Giving Series II slightly more weight than Series I, we wrote $R_{red} = k_{red} L_0^{0.8}$ and $R_{blue} = k_{blue} L^{0.4}$. An additional series, IV, was carried out with a dichromate filter, $\lambda \geqq 530$ mμ. Although the results are open to objection because air was not removed, it appears reasonable that $R_{yellow} = k_{yellow} L^{0.65}$; that is, the exponent lies between 0.8 and 0.4.

Influence of Diiodoacetylene Concentration.—This was varied from 8×10^{-4} to 8×10^{-2} M, and no visible light was absorbed. Lamp I with filters I and III was employed. Figure 2 gives the experimental data in comparison with curves plotted from the equations

$$R_{red} = \frac{[C_2I_2]}{0.038 + 4.0[C_2I_2]} \text{ and } R_{blue} = \frac{[C_2I_2]}{0.108 + 28[C_2I_2]}$$

which suffice to predict these data within experimental error.

Iodine concentration could not be varied widely, because saturation was reached at 10^{-2} M, and light transmission became excessive below 1.5×10^{-3} M. The solutions were made up determinate at 25° and a correction applied for the contraction to 0°. A mercury lamp[14] operated under atmospheric pressure, and the radiations λλ 578, 546 and 436 mμ were isolated by a monochromator having a large prism of extra dense

(14) Forbes and Heidt, THIS JOURNAL, **53**, 4349 (1931).

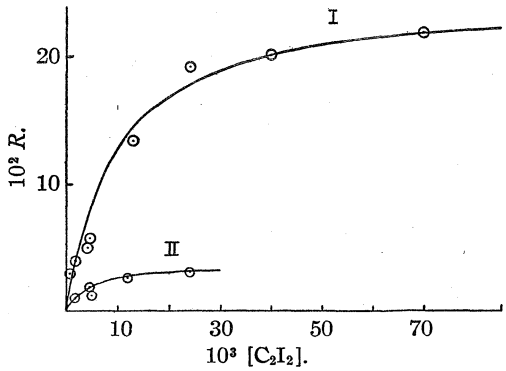

Fig. 2.—Influence of diiodoacetylene concentration on reaction rate, R. On Curve I, $\lambda \geqq 600$ mμ, and on Curve II, $\lambda \leqq 480$ mμ.

flint glass. Red light was similarly isolated from a constant spark[15] between cadmium bars. L_0 was measured radiometrically by the method of integration.[16] The extinction coefficients of iodine in hexane at 0° were obtained by interpolation of data by Groh and Papp[17] which we also checked at several points. Absorbed light energy was referred to average iodine concentration and average absorption in every case. The quantum yield ϕ is the ratio of m the number of iodine molecules reacting photochemically to q the number of quanta absorbed by iodine per second. Figure 3 summarizes these experiments. The temperature was

0°, and initial $[C_2I_2]$ was uniformly 0.005. Although measurements at λ 436 mμ were unexpectedly discordant, no trend in $\phi/[I_2]$ is anywhere apparent.

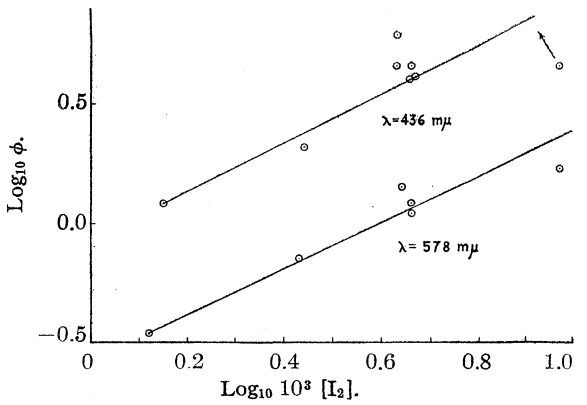

Fig. 3.—Influence of iodine concentration on quantum yield, ϕ.

Evidently $\phi/[I_2]$ increases slowly with decreasing wave length as the convergence limit is approached, and becomes considerably greater after this has been passed.

The ten-degree temperature coefficient Z of the photochemical reaction was found from eleven measurements at −32, 0 and 25°, behind the ferric thiocyanate and cuprammonium sulfate filters. The relative fractions of L_0 absorbed at each temperature were estimated by interpolation of data by Groh and Papp[17] on iodine at −53° and at room temperature. In red light Z = 1.11 between −32 and 0°, Z = 1.22 between 0 and 25°. In blue light both the corresponding values of Z were 1.18. Within experimental error all these values of Z can be considered identical.

To exclude the possibility of side reactions, a solution of average composition, free from oxygen, was exposed to red light until 5.23×10^{19} molecules of iodine had reacted. The hexane, together with the unchanged diiodoacetylene, was evaporated off. The residue, at constant weight, was 0.0450 g., *i. e.*, the weight of 5.16×10^{19} molecules of tetraiodoethylene. The melting point was 188° both before and after addition of a known sample of tetraiodoethylene. Apparently, therefore, the only important over-all reaction is $C_2I_2 + I_2 = C_2I_4$.

Experiments without removal of oxygen were performed at 0° and at 25° in purified hexane and in absolute ethanol. Both initial concentrations were 0.005 *M*. The only reaction product detected was tetraiodoethylene. In Table II, *d* is the extreme variation in ϕ_{air} within the group of experiments considered. In the last column, ϕ refers to experiments in solutions with the same initial concentrations but with oxygen removed. The second and third of these were performed at 0° but have been referred to 25° through multiplication by $(1.18)^{2.5}$.

The retarding effect of oxygen, in hexane solutions at least, seems to increase with decreasing wave length. The solvation of iodine in ethanol may well be responsible for the lower quantum yields there. Berthoud and Mosset,[18] likewise, found triiodide ions only one-fifth as effective as iodine molecules for iodination of allyl alcohol.

Photolysis of tetraiodoethylene was studied in hexane using an argon-filled mercury resonance lamp. About 83% of the total radiation was of wave length 254 mμ according to measurements by Leighton and Leighton.[19] Radiant flux was measured by actinometry with uranyl oxalate; the transmission of which for other wave lengths was much like that of tetraiodoethylene. Absorption of light by the iodine and diiodoacetylene formed by photolysis was shown to be negligible.

In absence of oxygen, two distinct reactions were observed: first a rapid liberation of 85% of the iodine corresponding to the equation $C_2I_4 = C_2I_2 + I_2$, then a (much slower) photolysis of diiodoacetylene, during which a characteristic odor different from that of diiodoacetylene was noticeable. In one experiment not carried to the second stage, liberated iodine was titrated; hexane and diiodoacetylene were evaporated off. The original weight of tetraiodoacetylene minus the weight of the residue corresponded within one milligram to the weight of iodine found by titration. Two other experiments (oxygen removed) gave ϕ = molecules of I_2 produced/quanta absorbed by C_2I_4 = 0.77 and 0.79. Parallel experiments without removal of oxygen gave ϕ = 0.81, 0.80 and 1.00 in hexane, also ϕ = 0.50, 0.57 and 0.58 in ethanol.

(19) Leighton and Leighton, *J. Chem. Education*, **12**, 139 (1935).

Photolysis of Diiodoacetylene in Hexane.—In absence of oxygen (λ = 254 mμ), two reaction stages were observed. At the start iodine appeared very slowly and the solution became somewhat milky. Later, but before the diiodoacetylene had been largely decomposed, iodine was released more rapidly. The milkiness tended to disappear, and a brownish deposit formed upon the cell window. Only about 55% of the original combined iodine could be liberated as such by light. The brown deposit evolved iodine when dried and heated, or when treated with alcohol or with potassium iodide solution. When the exposed solution was evaporated after extraction of iodine, a pale yellow oil remained having the odor already noted in the second stage of the photolysis of tetraiodoethylene. This oil turned brown upon exposure to air. If the photolysis was conducted in hexane or ethyl alcohol without exclusion of air, the liberation of iodine began at once. No milkiness or brown deposit was observed at any time, but carbon dioxide was detected when oxygen was bubbled first through the irradiated solution and then through barium hydroxide.

Attempts at photoiodination of tetraiodoethylene were unsuccessful in benzene, carbon disulfide, hexane and ethanol. Red, orange and white light was employed in succession, and temperatures ranged from −40 to 25°.

Reaction Mechanism in Blue Light.—A complete rate expression for addition of iodine to diiodoacetylene in blue light follows from the experiments described above, in which L_0, $[I_2]$, and $[C_2I_2]$ were varied one at a time. A suitable correction for incomplete absorption of incident light was made in each separate experiment.

$$-\left[\frac{d[I_2]}{dt}\right]_{\text{over-all}} = k_{\text{blue}} L_0^{0.4} [I_2]^{1.0} \frac{[C_2I_2]}{a_{\text{blue}} + b_{\text{blue}}[C_2I_2]}$$

Schumacher and Wiig,[15] for the iodine-sensitized decomposition of ethylene iodide, found a ten-degree temperature coefficient Z of 1.57, corresponding to an activation energy E of 11.8 kcal. per mole which they assigned to a reaction analogous to the reverse of equation (3) above. Since ΔH for this step should be nearly zero,[20] E should be nearly the same in both directions. We found for the iodination of diiodoacetylene Z = 1.18, corresponding to E = 2.5 kcal./mole. Then unless the formation of tetraiodoacetylene at λ 436 mμ proceeds mainly by way of the less probable step (5), E_3 must be much smaller than that of the analogous reaction for ethylene iodide. For the over-all dark reaction we found Z = 3, approximately, representing E = 20 cal./mole. By an argument similar to that of Polissar,[21] this should be equal to half the heat of dissociation of iodine (18 kcal./mole) plus E_3, which predicts E_3 = 2 kcal./mole in agreement with the over-all activation for the photochemical reaction calculated above.

Reaction Mechanism in Red Light.—The exponent of L_0 in red light is 0.8, in orange light between 0.7 and 0.6, and in blue light 0.4. This progression indicates either a continuous change in one particular mechanism or in the relative efficiencies of two mechanisms, as the convergence limit is passed. Several imaginable explanations are all open to well-recognized objections.

Direct addition to diiodoacetylene, of an excited iodine molecule is improbable in view of the observed dependence of ϕ upon $[I_2]$. Ogg[20] has argued against the addition, in a single act, of any halogen to an ethylenic linkage. Moreover, a chain mechanism initiated by molecules excited by red light cannot be seriously proposed, since about a thousand collisions with solvent molecules will on the average precede one with diiodoacetylene. As an exercise, we worked out a reaction scheme in harmony with our experimental results and plausible except for this fundamental objection. The same objection would impair any scheme assuming that the excited iodine atoms formed in blue light are more effective in starting chains than normal iodine atoms formed, exclusively, in red light.

Primary formation of halogen atoms need not in itself preclude linear dependence of reaction rate upon L_0. Booher and Rollefson[22] showed this for the photobromination of acetylene by omitting from their reaction scheme all steps involving reaction between two radicals. By analogous treatment of our reaction scheme proposed above for blue light, the results in red light could be made to appear reasonable, but those in blue light would then in turn become anomalous.

A remaining possibility, that atoms produced by a quantum of red light, less energetic at first than those produced by one of blue light, might recombine more rapidly in presence of third bodies, and thus lead to lower quantum yields, cannot be tested by the data of the present paper.

The Measure of Spectral Efficiencies.—Allmand,[23] also Dickinson and Nies,[4] have pointed out that when R is not proportional to $L_0^{1.0}$, ϕ_λ is no longer, in any simple sense, a measure of spectral efficiency, unless the variation of extinction coefficient is negligible over the spectral range considered. Usually there is considerable variation, and then a less simple but still practicable measure of efficiencies is found[4] in the specific rate constant k^* provided that a uniform rate expression is valid throughout the spectral region in question. The constant k^* may be obtained by an integration from front to back of the reaction mixture, of the rate expression taken as valid at any point in the light path. But when, as in the iodination of diiodoacetylene, the rate expression varies with wave length, the situation becomes more complex than that encountered by Dickinson and Nies. Consider a solution in which iodine is the only absorbent. In any layer of thickness dl perpendicular to the monochromatic light beam and l cm. behind the cell window, let L_l be the quanta per sec. absorbed per cc. Let L_0 represent quanta per second passing the cell window, as usual, and k_{I_2} the extinction coefficient of iodine for λ, the wave length employed.

$$L_l = -\frac{dL}{dl} = -\frac{d(L_0 10^{-k_{I_2}[I_2]l})}{dl}$$
$$= L_0 10^{-k_{I_2}[I_2]l} \ln 10\, k_{I_2}[I_2]$$

The reaction rate in such a layer is given by the equation

$$-\frac{d[I_2]}{dt} = k_\lambda^* L_l^x [I_2] \frac{[C_2I_2]}{a_\lambda + b_\lambda [C_2I_2]}$$

The relation between k_λ^* and ϕ_λ for negligible changes in $[I_2]$, is obtained by evaluating

$$\int_0^d -\frac{d[I_2]}{dt}\, dl$$

whereby we finally obtain

$$k_\lambda^* = \phi \left\{ x \frac{k_{I_2}^{1-x} L_0^{1-x}}{[I_2]^x} \frac{1-T}{1-T_x} \frac{a_\lambda + b_\lambda [C_2I_2]}{[C_2I_2]} \right\}$$

in which each variable, x included, has the value appropriate to λ, and

$$T = 10^{-k_{I_2}[I_2]d}$$

(23) Allmand, *J. Chem. Soc.*, 1557 (1929).

the transmitted fraction of incident light energy at depth d in the layer.

In this equation

$$\phi = -\left[\frac{d[I_2]}{dt}\right]_{\text{over-all}} \frac{V}{A[L_0(1-T)]}$$

where V = volume of reaction mixture in cm.^{3} and A = cross section of the light beam in cm.^{2}. It thus appears that relative efficiencies are not expressible in terms of any concept more simple than the equation for k_λ^*.

Summary

The photoiodination rate of diiodoacetylene in hexane, with careful exclusion of oxygen, was studied quantitatively in red and in blue light. A chain reaction is found to occur. Tetraiodoethylene is shown to be formed quantitatively.

The equation

$$-\frac{d[I_2]}{dt} = k^\lambda L_0^{x_\lambda} [I_2] \frac{[C_2I_2]}{a_\lambda + b_\lambda [C_2I_2]}$$

generalizes the data obtained. k_λ, x_λ, a_λ and b_λ must be evaluated separately for each spectral interval considered.

The mechanism of the reaction appears to vary with the wave length of light employed. In blue light the exponent of L_0 is 0.4, in orange light between 0.6 and 0.7, and in red light 0.8. It appears that the expedients hitherto employed for treatment of photochemical data here lead to difficulties.

A specific rate constant was obtained by integration which is valid at any given wave length provided that proper values for four constants dependent upon wave length are supplied.

Tetraiodoethylene in hexane was photolyzed in ultraviolet light, λ = 254 mμ (oxygen removed). At first one molecule of free iodine appears for each molecule of tetraiodoethylene which disappears, and the quantum yield is 0.8. In the late stages of the photolysis an unidentified product was observed.

The photolysis of diiodoacetylene in hexane was studied qualitatively. Apparently it is complicated by formation of polymeric substances.

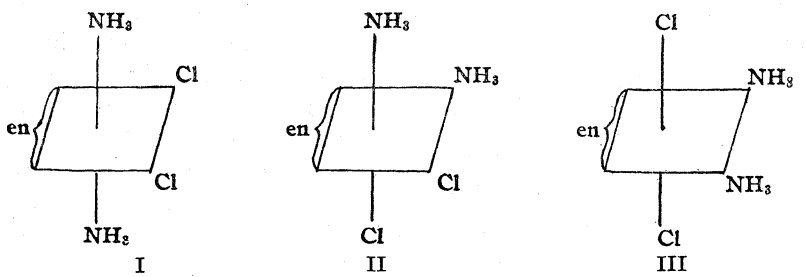
The Stereochemistry of Complex Inorganic Compounds. VI. A Study of the Stereoisomers of the Dichloro-diammino-ethylenediamine Cobaltic Ion

BY JOHN C. BAILAR, JR., AND DONALD F. PEPPARD[1]

The dichloro-diammino-ethylenediamine cobaltic ion can exist in three stereoisomeric forms



stable. The assignment of configurations is based upon the fact that ion II is asymmetric, while ion I is not. Attempts to resolve ion II itself were unsuccessful, but the carbonato salt derived from it was shown to be resolvable.

In attempting to prepare salts of these stereoisomeric ions, we first followed the directions given by Chaussy

$$NH_4[Co(NH_3)_2(NO_2)_4] \xrightarrow{NH_4OH} [Co(NH_3)_3(NO_2)_3] \xrightarrow{en} [Co\,en(NH_3)(NO_2)_3] \xrightarrow{HCl} [Co\,en(NH_3)(H_2O)Cl_2]Cl \xrightarrow{NH_4OH}$$

$$\xrightarrow{HCl} [Co\,en(NH_3)_2Cl_2]Cl\ (green) \xrightarrow{K_2CO_3} [Co\,en(NH_3)_2CO_3]Cl\ (red) \xrightarrow{HCl,\ NH_4Br} [Co\,en(NH_3)_2Cl_2]Br\ (violet)$$

Salts of two of these were prepared by Chaussy,[1a] who designated them as "*cis*" and "*trans*" (referring to the relative positions of the chloride groups) or simply as "blue" and "green." Chaussy made no mention of the fact that two *cis* series are possible. This is discussed, however, in a later account of Chaussy's work.[2]

cis-Dichloro-*trans*-diammino-ethylenediamine cobaltic ion (I) and *cis*-dichloro-*cis*-diammino-ethylenediamine cobaltic ion (II) would be expected to be violet, like *cis*-dichloro-tetrammino cobaltic ion and *cis*-dichloro-diethylenediamine cobaltic ion. The *trans*-dichloro-*cis*-diammino-ethylenediamine cobaltic ion (III) should be green, like its analogs in the ammino and ethylenediamine series. The colors of these ions determine the relative positions of the chloride groups with certainty but do not distinguish between the two *cis*-dichloro configurations.

This paper reports the preparation and a brief study of the properties of all three of the isomeric ions. It is shown that Chaussy's "blue" compounds are probably salts of the *cis*-dichloro-*cis*-diammino ion (II). This has almost exactly the same color as the *cis*-dichloro-*trans*-diammino ion (I), but its salts are much more soluble and less

The second step was very troublesome, always giving a product containing from 2–5% too much carbon. Trinitrotriammine cobalt prepared according to the directions of Riesenfeld and Klement,[3] however, gave a satisfactory product in good yield. This material, when treated with hydrochloric acid according to Chaussy's directions, did not yield a product exhibiting the properties of the dichloro-aquo-ammino-ethylenediamine cobalt described by him. There is no certainty, of course, that the trinitro-triammine cobalt used in the present study was the same stereoisomer as that used by Chaussy, as it was prepared by a different method. The problem is further complicated by the possibility of four stereoisomers of dichloro-aquo-ammino-ethylenediamine cobaltic chloride.

Chaussy's method finally was abandoned, and an entirely new approach was sought. The desired salts were prepared finally according to the following scheme:

$$\underset{cis\text{-disulfito}}{NH_4[Co(NH_3)_4(SO_3)_2]} \xrightarrow{en} \underset{cis\text{-disulfito-}trans\text{-diammino}}{NH_4[Co\,en(NH_3)_2(SO_3)_2]} \xrightarrow{HCl} [Co\,en(NH_3)_2Cl_2]Cl$$

Configurations were first assigned to $NH_4[Co(NH_3)_4(SO_3)_2]$ and $NH_4[Co\,en(NH_3)_2(SO_3)_2]$ by Klement,[4] on the basis of the fact that ethylenediamine replaces two of the ammonia molecules much more readily than the other two. If the

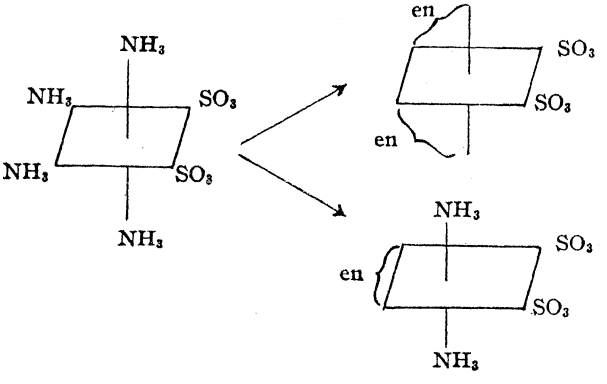
(4) Klement, *Z. anorg. allgem. Chem.*, **150**, 117–125 (1925).

sulfito groups are *trans* to each other, the four ammonia molecules are equivalent, and all of them would be replaced by ethylenediamine with equal ease. If the sulfito groups are *cis* to each other, however, the introduction of ethylenediamine may follow either of two paths; one of these allows the replacement of only two ammonia molecules:



Since only two ammonia molecules are replaced under the conditions used, Klement believed the product to be ammonium *cis*-disulfito-*trans*-diammino-ethylenediamine cobaltiate. The evidence to be presented in this paper confirms this view.

Treatment of ammonium *cis*-disulfito-*trans*-diammino-ethylenediamine cobaltiate with hydrochloric acid must produce *cis*-dichloro-*trans*-diammino-ethylenediamine cobaltic chloride, unless rearrangement takes place. That the experiment actually yields the green *trans* salt is not at all surprising, however, for the analogous *cis*-dichloro-diethylenediamine cobaltic chloride rapidly rearranges to the *trans* form in aqueous hydrochloric acid. Treatment of the disulfito salt with hydrogen chloride dissolved in absolute alcohol (in which these cobalt compounds are not soluble) yields a nearly pure violet dichloro salt, which can be purified by conversion to the slightly soluble *dextro*-α-bromocamphor-π-sulfonate and reconversion to the chloride by cold concentrated hydrochloric acid. This *cis* dichloro-salt could not be resolved by means of ammonium *dextro*-α-bromo-camphor-π-sulfonate, although it readily forms a nicely crystalline precipitate when treated with this reagent. This ion will later be shown to be the unresolvable *cis*-dichloro-*trans*-diammino form (I).

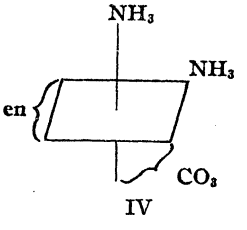
The *cis*-dichloro-*cis*-diammino isomer is most readily obtained through the following reactions:

$$[Co\,en(NH_3)_2Cl_2]Cl \xrightarrow{Ag_2CO_3} [Co\,en(NH_3)_2CO_3]_2CO_3 \xrightarrow{\text{alc. HCl}} [Co\,en(NH_3)_2Cl_2]Cl$$

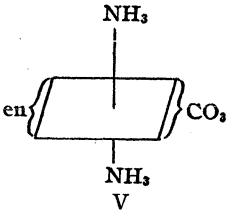
trans-dichloro-*cis*-diammino (III) — carbonato-*cis*-diammino

The product formed in the second of these reactions is a mixture of the *trans*-dichloro salt (III) and the *cis*-dichloro-*cis*-diammino salt (II). It seems impossible to prevent some rearrangement of this *cis*-dichloro form to the *trans* form.

The configurations of the two *cis*-dichloro forms were assigned through a study of the corresponding carbonato complexes. The carbonato salt prepared by treating *trans*-dichloro-*cis*-diammino-ethylenediamine cobaltic chloride with silver carbonate can be resolved partially by shaking a solution of it with optically active quartz[5] and yields, on treatment with alcoholic hydrogen chloride, a *cis*-dichloro isomer with some admixed *trans*-dichloro isomer. This *cis*-dichloro salt, when treated with silver carbonate, is again transformed into the carbonato complex which can be resolved partially by the use of active quartz. This carbonato complex must have configuration IV, and the related dichloro complex is



IV



V

almost certainly II. Since Chaussy prepared his "blue" dichloro salt from the carbonato chloride formed from the *trans*-dichloro chloride, it seems probable that his *cis*-isomer has the *cis*-dichloro-*cis*-diammino configuration.

On the other hand, the dichloro salt obtained by treating ammonium *cis*-disulfito-*trans*-diammino-ethylenediamine cobaltiate with alcoholic hydrogen chloride, when treated with silver carbonate, gives a carbonato complex which shows no resolution when shaken with active quartz (V). The original *cis*-dichloro salt, with no contamination of *trans*-dichloro-isomer, is obtained when this carbonato salt is treated with alcoholic hydrogen chloride.

It will be noted that the conversion of IV to the *trans*-dichloro salt requires the shift of one nitrogen–cobalt link, but the same conversion, in the case of V, requires the shift of two. The

(5) Tsuchida, Kobayashi and Nakamura, *Bull. Chem. Soc. Japan*, 11, 38-40 (1936).

fact that only one of the carbonato salts yields any *trans*-dichloro salt thus gives further evidence for the configurations assigned. By the same reasoning, it may be deduced that the *trans*-dichloro salt should form the carbonato complex IV.

Several reactions serving to distinguish the two *cis*-dichloro ions are summarized in Table I. In each case, the solid reagent was added to a nearly saturated solution of the dichloro-chloride and stirred vigorously.

TABLE I

Reagent	*cis*-Dichloro-*trans*-diammino (I)	*cis*-Dichloro-*cis*-diammino (II)
Ammonium dextro-α-bromocamphor-π-sulfonate	Purple crystals	No precipitate
Ammonium iodide	Dark purple crystals	Immediate precipitate of a brown and green gelatinous mixture
Sodium thiocyanate	Purple crystals	Slow deposition of a green powder

An attempt to prepare a *cis*-dibromo-diammino-ethylenediamine cobaltic salt by treating ammonium *cis*-disulfito-*trans*-diammino-ethylenediamine cobaltiate with alcoholic hydrogen bromide was unsuccessful. The *trans*-dibromo isomer was obtained under all conditions. This is not surprising, since it is difficult to prepare the *cis*-dibromo salt in the diethylenediamine series[6] and evidently impossible in the tetrammino series.

The *cis*-dichloro-*cis*-diammino-ethylenediamine cobaltic ion is asymmetric. If it were resolved it should afford some interesting studies on the Walden inversion, especially since the only cases of such inversion in inorganic complexes involve the cobalt atom with two ethylenediamine molecules attached.[7]

It may be that two such chelate groups are necessary to prevent complete loss of optical activity during substitution. On the other hand, inversion might occur more readily with only one ethylenediamine molecule in the complex, since the ammonia–cobalt link is probably ruptured more easily than the ethylenediamine–cobalt link.

Thus far, all attempts to resolve the *cis*-dichloro-*cis*-diammino-ethylenediamine cobaltic ion have failed, although the corresponding carbonato ion has been partially resolved by adsorption on active quartz.

Since the racemic dichloro complex could not be resolved directly, an attempt was made to isolate one of its optical antipodes indirectly. During a study of the active forms of chloro-aquo-diethylenediamine cobaltic ion (not yet published) it was found that if racemic *cis*-dichloro-diethylenediamine cobaltic chloride is allowed to stand in water solution until the requisite aquation has occurred and the solution then treated with a suitable resolving agent, active chloro-aquo-diethylenediamine cobaltic chloride can be obtained. The active salt also can be prepared by heating *trans*-dichloro-diethylenediamine cobaltic chloride in water solution, allowing the solution to stand for a few days, and adding a suitable resolving agent. This active chloro-aquo complex, when suspended in thionyl chloride, is transformed into active dichloro-diethylenediamine cobaltic chloride.

All attempts to isolate an active dichloro-diammino-ethylenediamine cobaltic ion in this way failed.

Experimental

Ammonium *cis*-disulfito-tetrammino cobaltiate is readily prepared by a modification of the method of Werner and Gruger.[8] Solutions of 160 g. of cobalt chloride hexahydrate in 240 cc. of water and 400 g. of ammonium carbonate in 2000 cc. of water are mixed with 1000 cc. of 28% ammonium hydroxide. Air which is first drawn through 14% ammonium hydroxide in three flasks connected in series is rapidly drawn through the solution for eight hours. Three hundred and ten grams of solid sodium bisulfite is added to the solution in the flask, and air is drawn through the solution for three or four minutes. The solution is poured into a large evaporating dish and allowed to stand open to the air for fifteen hours. It is then cooled in ice and salt for four hours, leaving the beakers open to the air and stirring occasionally. The brown salt forms in small crystals. These are filtered with suction, washed with a little cold water, absolute alcohol, and ether, and dried in air. The yield is 150 to 160 g. (62–66%). The salt is sufficiently pure without recrystallization.

Anal. Calcd. for $NH_4[Co(NH_3)_4(SO_3)_2]\cdot 3H_2O$: S, 17.83; N, 19.50; H, 6.13. Found: S, 17.74; N, 19.25; H, 6.14.

Ammonium - *cis* - disulfito - *trans* - diammino - ethylenediamine Cobaltiate.—The following method was found to give a much better yield than that of Klement.[4] Fifty grams of ammonium-*cis*-disulfito-tetramminocobaltiate and 50 or 60 glass beads are covered, in a round-bottomed flask, with a solution of 12 cc. of 60% ethylenediamine in 200 cc. of absolute ethanol. The flask is stoppered with a cork carrying a calcium oxide drying tube bent downward. The mixture is shaken continuously for one hundred and sixty hours. The suspension is drawn through a Büchner funnel without filter paper to free it from the glass beads; the powder is filtered from the liquid,

(8) Werner and Gruger, *Z. anorg. allgem. Chem.*, **16**, 398–423 (1898).

and washed with ethanol. The material from four such runs is combined and recrystallized by extracting at about 90° for eight or ten minutes with 400 cc. of water. After filtering, the residue is similarly extracted with 300 cc. of water. The filtrates from these extractions are cooled in ice. The precipitates are combined, washed with a little water, ethanol and ether, and dried in air. The yield of pure product is about 120 g. (56%). For analysis, the salt was dried over potassium hydroxide.

Anal. Calcd. for $NH_4[Co\ en(NH_3)_2(SO_3)_2]\cdot 2H_2O$: C, 6.54; H, 5.99; S, 17.44. Found: C, 6.48; H, 6.10; S, 17.26, 17.31.

Klement reported that the air-dried material contains three molecules of water.

***trans*-Dichloro-*cis*-diammino-ethylenediamine Cobaltic Chloride.**—Twenty-two grams of ammonium *cis*-disulfito-*trans*-diammino-ethylenediamine cobaltiate is covered with 27 cc. of concentrated hydrochloric acid. The mixture is kept at 70° until the solid dissolves and the solution becomes purple. Sixteen cubic centimeters of water is added and the solution warmed at 70° for one minute. After three days the green crystals are removed by filtration and purified by suspension in a little water. They are finally washed with 50% ethanol, absolute ethanol, and then ether. The yield is about 5 g. (32%) at best. The compound can be purified by recrystallization from concentrated hydrochloric acid, but the solution must not be heated to a temperature higher than 70°.

Anal. Calcd. for $[Co\ en(NH_3)_2Cl_2]Cl\cdot{}^1/_2H_2O$: C, 8.96; H, 5.60; N, 20.90; Cl, 39.40. Found: C, 8.95; H, 5.88; N, 20.87; Cl, 39.01, 39.12.

***trans*-Dichloro-*cis*-diammino-ethylenediamine cobaltic bromide, iodide, and thiocyanate** were prepared according to Chaussy's directions and conform to his descriptions.

***cis*-Dichloro-*trans*-diammino-ethylenediamine Cobaltic Chloride.**—Six grams of finely powdered ammonium *cis*-disulfito-*trans*-diamminoethylenediamine cobaltiate is covered with 90 cc. of absolute alcoholic hydrogen chloride (saturated at room temperature) and allowed to stand for twenty-four hours with occasional shaking. A blue salt contaminated with ammonium chloride is obtained. None of the *trans*-isomer is formed. The filtered salt is washed with absolute ethanol and ether to remove all of the hydrogen chloride. After being dried in air to remove most of the ether it is suspended three times in 3 cc. of water at room temperature, and filtered. The salt is washed with alcohol and ether.

Anal. Calcd. for $[Co\ en(NH_3)_2Cl_2]Cl\cdot H_2O$: C, 8.66; H, 5.78; N, 20.22; Cl, 38.27. Found: C, 8.76; H, 5.96; N, 19.98; Cl, 38.47, 38.59.

The salt can be purified more easily by conversion to the much less soluble *dextro*-α-bromocamphor-π-sulfonate. Two grams of the salt is stirred with 60 cc. of water at about 15° for two minutes. Five grams of ammonium *dextro*-α-bromocamphor-π-sulfonate is added to the filtered solution and the mixture stirred for thirty minutes at about 15°. The blue-purple salt is washed with absolute ethanol and ether and dried in air. It is then covered with 7 cc. of concentrated hydrochloric acid in an ice-cooled mortar and ground for a few seconds. Fourteen cubic centimeters of a mixture of equal volumes of absolute ethanol and ether are added and the grinding continued for several minutes. The blue salt is washed with absolute ethanol and ether.

The product is not optically active at the D line of sodium.

Several derivatives of the *cis*-dichloro-*trans*-diammino-ethylenediamine cobaltic ion were prepared to further characterize it. The bromide, $[Co\ en(NH_3)_2Cl_2]Br$, was obtained as follows. Slightly more than an equivalent amount of solid ammonium bromide is added with stirring to a filtered concentrated solution of *cis*-dichloro-*trans*-diamminoethylenediamine cobaltic chloride. After stirring and scraping the walls of the beaker, the blue-purple salt precipitates. It is purified by two or three suspensions in water and finally washed with alcohol and ether.

A product more easily purified is obtained by using slightly less than the calculated amount of ammonium bromide, but the yield is poorer.

Anal. Calcd. for $[Co\ en(NH_3)_2Cl_2]Br\cdot 2H_2O$: C, 7.06; H, 5.29; N, 16.47. Found: C, 6.98; H, 5.59; N, 16.95.

The iodide, prepared in similar manner, precipitates in good yield as beautiful purple crystals. In contrast to the iodide of the *cis*-dichloro-*cis*-diammino isomer, this salt is stable.

Anal. Calcd. for $[Co\ en(NH_3)_2Cl_2]I$: C, 6.84; H, 3.99; N, 15.95. Found: C, 7.17; H, 4.15; N, 16.11.

The purple thiocyanate, prepared in a similar way by the use of sodium thiocyanate, precipitates readily in good yield.

Anal. Calcd. for $[Co\ en(NH_3)_2Cl_2]SCN\cdot NaSCN$: C, 13.19; N, 23.14; S, 17.63. Found: C, 13.23; N, 23.13; S, 17.39, 17.51.

The formation of this double compound is reminiscent of the crystallization of *trans* $[Co\ en_2Cl_2]Cl\cdot HCl$ from hydrochloric acid.

***cis*-Dichloro-*cis*-diammino-ethylenediamine Cobaltic Chloride.**—Two grams of carbonato-*cis*-diammino-ethylenediamine cobaltic carbonate prepared from *trans*-dibromo-*cis*-diammino-ethylenediamine cobaltic bromide is covered with 40 cc. of alcoholic hydrogen chloride and a few glass beads added. The flask is fitted with a mercury seal allowing gases to escape but maintaining a pressure exceeding atmospheric. The apparatus is shaken for twenty-four hours, at the end of which time the light blue precipitate is filtered. It is suspended in a little water, filtered quickly from the green contamination, and 15 or 20 volumes of ethanol are added to the filtrate. A purple oil precipitates. The alcohol is decanted and the oil kept *in vacuo* over potassium hydroxide for twenty-four hours. The salt is then powdered and the drying continued.

Anal. Calcd. for $[Co\ en(NH_3)_2Cl_2]Cl$: C, 9.27; H, 5.45; N, 21.62; Cl, 40.93. Found: C, 9.47; H, 5.49; N, 21.36; Cl, 40.60, 40.71.

The bromide of the *cis*-dichloro-*cis*-diammino series is prepared by treatment of a concentrated solution of the chloride with the equivalent amount of solid ammonium bromide.

Anal. Calcd. for $[Co\ en(NH_3)_2Cl_2]Br$: C, 7.90; H, 4.64; N, 18.47. Found: C, 7.97; H, 4.71; N, 18.32.

***trans*-Dibromo-*cis*-diammino-ethylenediamine cobaltic bromide** was used in some of the preparations of the

carbonato-*cis*-diammino carbonate, as it is easier to purify than the dichloro salt. It is prepared as follows. Thirty-five cubic centimeters of 40% aqueous hydrobromic acid is heated to approximately 80° in a small beaker, and 5 g. of ammonium-*cis*-disulfito-*trans*-diammino-ethylenediamine cobaltiate is added with stirring. The heating and stirring are continued at approximately 80° until a dark green solution is formed. If the heating is continued longer than three minutes some decomposition takes place. The solution is allowed to stand at room temperature for three hours, then cooled in ice. The green crystals are filtered and purified once or twice by suspension in a little water. They are washed with absolute ethanol and ether. The yield from five such runs is 8 g. of pure product.

Anal. Calcd. for $[Co\ en(NH_3)_2Br_2]Br$: C, 6.11; H, 3.56; N, 14.25; Br, 61.07. Found: C, 6.29; H, 3.64; N, 14.01; Br, 60.73, 60.89.

The thiocyanate of the dibromo series was prepared as a pale green salt, in the same manner as the thiocyanate of the *cis*-dichloro-*trans*-diammino series.

Anal. Calcd. for $[Co\ en(NH_3)_2Br_2]SCN$: C, 9.70; N, 18.87; S, 8.63. Found: C, 9.63; N, 19.12; S, 8.76, 8.83.

Carbonato-*cis*-diammino-ethylenediamine Cobaltic Carbonate.—Eight grams of *trans*-dibromo-*cis*-diammino-ethylenediamine cobaltic bromide or 5.3 g. of the dichloro chloride, is ground with 8.4 g. of dry silver carbonate. The mortar is cooled in ice, 5 cc. of water is added and the grinding continued for half an hour. The solid is filtered and washed with a small amount of water. The combined filtrate and washings are evaporated *in vacuo*.

Anal. Calcd. for $[Co\ en(NH_3)_2CO_3]_2CO_3$: C, 17.26; H, 5.76; N, 23.05; C/N, 1.333. Found: C, 17.20; H, 6.15; N, 22.68; C/N, 1.319.

This salt was partially resolved by shaking it, in dilute solution, with optically active quartz, ground to 100-mesh. In each case, 80 cc. of the solution was shaken with 4 g. of quartz. At intervals, portions of the solutions were withdrawn, diluted, and the rotation at the sodium D line observed. The partially resolved salt is completely racemized in three minutes at 90°, or in three days at room temperature.

TABLE II

Concn. of soln., %	Time of shaking, minutes	Dilution H_2O:soln.	Rotation (*D* quartz)	Rotation (*L* quartz)
0.5	25	6/1	−0.03	+0.02
.5	120	6/1	− .03	+ .02
.5	980	6/1	− .03	+ .02
.2	60	1/1	− .04	+ .03
.2	120	1/1	− .04	+ .03
.2	300	1/1	− .04	+ .03

Aqueous hydrochloric acid converts the carbonato carbonate to *trans*-dichloro-*cis*-diammino-ethylenediamine cobaltic chloride.

Carbonato-*trans*-diammino-ethylenediamine cobaltic carbonate is prepared in the same way, using 4 g. of *cis*-dichloro-*trans*-diammino-ethylenediamine cobaltic chloride and 6.2 g. of silver carbonate. It is difficult to dry this salt completely.

Anal. Calcd. for $[Co\ en(NH_3)_2CO_3]_2CO_3 \cdot 3H_2O$: C, 15.56; N, 20.75; H, 6.30. Found: C, 15.67; N, 19.32; H, 6.02.

Its solutions, on being shaken with active quartz, show no sign of activity. Treatment of this salt with alcoholic hydrogen chloride converts it to the original *cis*-dichloro salt, while aqueous hydrogen chloride gives the green *trans*-dichloro salt.

Attempts to Prepare Chloro-aquo-diammino-ethylenediamine Cobaltic Chloride.—Two grams of *trans*-dichloro-*cis*-diammino-ethylenediamine cobaltic chloride, heated at 80–90° for sixteen hours to remove any traces of acid, was heated with 12 cc. of water in a test-tube at 85° for forty-five minutes. The solution became red a few minutes after the heating was begun. After twenty-four hours 3 g. of ammonium *dextro*-α-bromocamphor-π-sulfonate was added and the solution cooled to −5° for twelve hours. There was no precipitate. The use of ammonium *dextro*-camphor-π-sulfonate also gave only negative results.

One-half gram of *cis*-dichloro-*trans*-diammino-ethylenediamine cobaltic chloride was dissolved in 2 cc. of water at room temperature. At the end of forty-eight hours 0.6 g. of ammonium *dextro*-α-bromocamphor-π-sulfonate was added. After twenty minutes in an ice-bath the dark pink salt was filtered. It was ground with 0.5 cc. of cold concentrated hydrochloric acid, and 5 cc. of cold alcohol–ether mixture (1:1) was added. The pink-purple salt was filtered, keeping liquid on the solid at all times while washing with absolute ethanol and ether. As soon as the last of the ether was removed, the salt became sticky and assumed a deeper color. A solution of this substance exhibited no optical activity at the D line of sodium.

Summary

The three isomeric forms of the dichloro-diammino-ethylenediamine cobaltic ion have been prepared and some of their properties are described.

Improved methods of preparing several other compounds, which were obtained as intermediates, have been worked out.

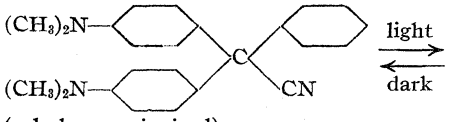
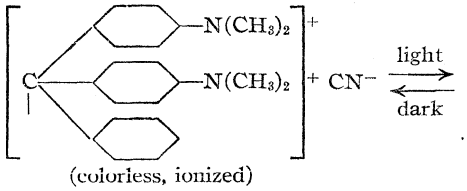
Studies on the Reactions of the Leucocyanides of the Triphenylmethane Dyes. I. The Mechanism of the Dark Reaction Following the Photolysis of Malachite Green Leucocyanide

BY FRANK E. E. GERMANN AND CHARLES LEROY GIBSON

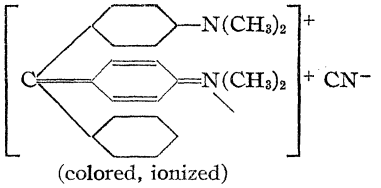
An alcoholic solution of malachite green leucocyanide has been shown to become deeply colored when exposed to ultraviolet light. This solution again becomes colorless when placed in the dark. Two mechanisms have been proposed for this "dark reaction." Lifschitz and his co-workers[1] proposed the following equation for the photolysis and dark reaction of malachite green leucocyanide in absolute alcohol



(colorless, un-ionized)



(colorless, ionized)



(colored, ionized)

The final product of the dark reaction was assumed to be the original leucocyanide.

Harris, Kaminsky and Simard[2] found that photolyzed and subsequently partially faded solutions of malachite green leucocyanide in alcohol containing some water recovered their color when treated with dilute hydrochloric acid. Leucocyanide solutions which had not been irradiated did not become colored when treated with the acid. They therefore suggested that the final product of the dark reaction may be the corresponding leucocarbinol, the hydroxyl ion being obtained from the water. This carbinol could be transformed into colored malachite green chloride when treated with hydrochloric acid. If exposed to ultraviolet light, this leucocarbinol would produce the colored ion of malachite green just as does the leucocyanide.

Villiger and Kopetschni[3] had at an earlier time reported that the acid always present in ordinary ethyl alcohol can quantitatively cause the removal of the ammonia from malachite green leucoamine upon warming. The end-product suggested for this reaction was $Ar_3C{\cdot}OC_2H_5$. Neutralization of the alcohol with sodium hydroxide prevented the reaction.

The purpose of the present investigation was to check these proposals of Harris, Kaminsky and Simard and of Villiger and Kopetschni by means of absorption studies of the photolyzed and then faded alcoholic solutions of malachite green leucocyanide which had been neutralized before irradiation. If the leucocarbinol were the end-product of the dark reaction, the absorption curve should shift from that of the pure leucocyanide to that of the leucocarbinol, in going from the photolyzed to the faded solutions, the amount of shift depending upon the time of irradiation.[4] Such results were not obtained.

Experimental

Preparation of Materials.—The malachite green leucocyanide was prepared from the oxalate by the Hantzsch[5] method and was purified as suggested by Harris, Kaminsky and Simard.[2] However, only five week-long extractions with ethyl alcohol were performed. The melting point of the purified crystals was found to be 174.6–175.8°. The measurements were made with a thermometer calibrated against a Bureau of Standards standard thermometer. In contrast to this Harris, *et al.*, state that they carried on extractions for ten weeks and obtained a melting point of 173.7–174.5°.

The "95%" ethyl alcohol used was the standard laboratory grade of grain alcohol. Density measurements showed the actual percentage of alcohol in the solution to be 92.6 to 92.8%. This alcohol was found to be definitely acidic. It was determined that 1 ml. of sodium hydroxide solution in "95%" alcohol of approximately 0.004 molarity was required to neutralize 50 ml. of the stock alcohol to the neutral tint of brom thymol blue. All the alcohol used in this experiment was neutralized in this manner except the absolute alcohol and the alcohol used in the purification of the leucocyanide.

(4) Darmois, *Compt. rend.*, **197**, 1120 (1933).

(5) Hantzsch and Osswald, *Ber.*, **33**, 307 (1900).

Procedure.—A Hilger E-3 quartz spectrograph with rotating sector was used for all spectrographic measurements. The light source was an under-water arc with tungsten electrodes. Wratten and Wainright Panchromatic plates were used for the photographs. A spectrum extending to a wave length of 2500 Å. was obtained with accurate comparisons possible to about 2700 Å. Absorption tubes one centimeter long were used throughout the experiment. The solution in the absorption tube was never allowed to be exposed to the light of the arc for more than twenty seconds, in order to avoid absorption due to the photocompound.

Fresh solutions of the leucocyanide in the neutralized 92.7% alcohol of 5×10^{-4}, 1×10^{-4}, 5×10^{-5} and 1×10^{-5} molarity were prepared in the dark and absorption spectra obtained. The absorption curve checked closely with that given by Harris, Kaminsky and Simard, which for comparison purposes has been reproduced in Fig. 1.

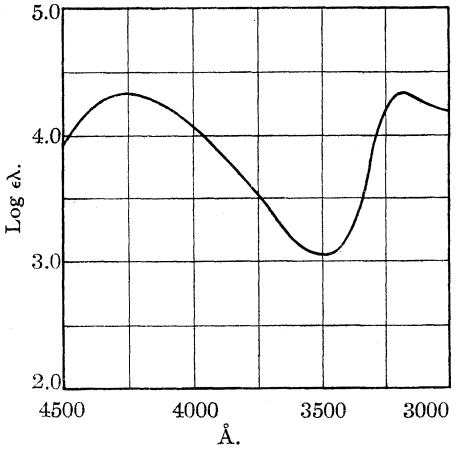

Fig. 1.—Section of curve of Harris, Kaminsky and Simard for photo-compound and chloride.

For the studies of the absorption spectra of the photocompound, the following solutions were used: (A) 5×10^{-5} *M* leucocyanide in 92.7% neutralized ethyl alcohol; (B) 5×10^{-5} *M* leucocyanide in 99.2% unneutralized ethyl alcohol; (C) 5×10^{-5} *M* leucocyanide in 84.6% ethyl alcohol (prepared by addition of water to 92.7% neutralized ethyl alcohol).

Different portions of these three solutions were illuminated for fifteen hours, ten hours, five hours and one hour in quartz flasks. The source of light was a "Bruleur Gallois" mercury vapor lamp (Type HG). After irradiation, the solutions were allowed to fade in the dark room for at least a week. At the end of that time all portions of solutions A and B were absolutely colorless. However, solutions C, even after only one hour of exposure to ultraviolet light, retained some green color after a month in the dark room. Absorption studies of solutions C were therefore not attempted.

Unfortunately, absorption bands for the faded photolyzed solutions were obtained only at low extinction (sector reading) and hence are not as accurate as they might have been. However, the appearance of a new absorption band in the region of 3400 Å. to 3700 Å. was quite evident for

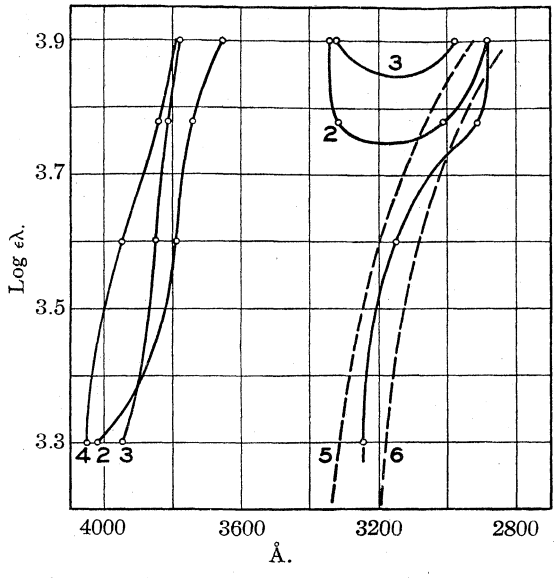

Fig. 2.—Absorption spectra of 0.00005 *M* malachite green leucocyanide in 92.7% ethyl alcohol completely faded after irradiation: curve 1, illuminated for one hour; curve 2, for five hours; curve 3, for ten hours; curve 4, for fifteen hours; curve 5, unilluminated cyanide; curve 6, unilluminated carbinol. Curves 5 and 6 are taken from the work of Harris, Kaminsky and Simard.

the solutions studied. The absorption curves obtained from the faded photolyzed solutions are shown in Figs. 2 and 3. In Fig. 2, we have inserted in curves 5 and 6 the absorption data for the leucocyanide and carbinol as taken from Harris, Kaminsky and Simard. These

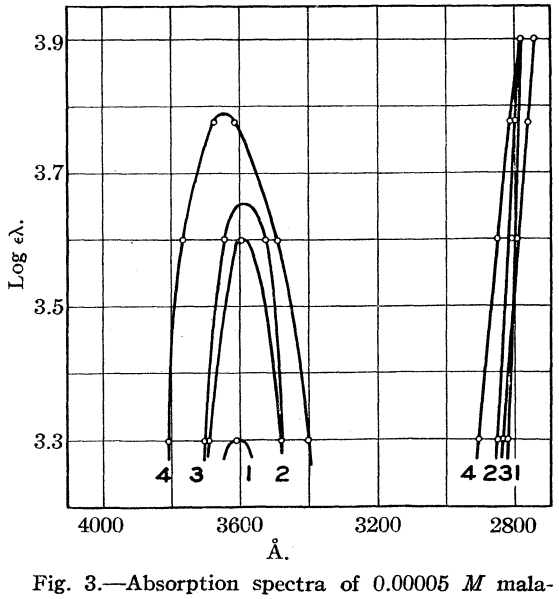

Fig. 3.—Absorption spectra of 0.00005 *M* malachite green leucocyanide in 99.25% ethyl alcohol completely faded after irradiation: curve 1, illuminated for one hour; curve 2, for five hours; curve 3, for ten hours; curve 4, for fifteen hours.

authors made no absorption measurements on the faded solutions, but refer to the colored solution as the photo compound. It will be observed that the maximum log ϵ of the faded solution between 3400 and 3700 Å. as given in Fig. 3 is about 3.8, whereas for the colored product (the photo compound of Harris, Kaminsky and Simard) at 3700 Å. in Fig. 1 it is only 3.5. This discrepancy is probably real and can hardly be accounted for by the lack of accuracy for the faded solutions at low extinction values since in this neighborhood the values are close together, the curves crossing almost at right angles. The inaccuracy of readings at low extinction would be in the horizontal direction (wave length) and not in the vertical direction (log ϵ). A comparison of curves 1 and 5 of Fig. 2 shows that our curve for the 5×10^{-5} M leucocyanide agrees with that of Harris, Kaminsky and Simard to within 50 Å. in all but point log ϵ 3.778 and wave length 2990, even at low extinction values.

When the faded solutions of A were treated with dilute hydrochloric acid they became uniformly dark green. No difference in intensity of color was apparent to the eye. The four solutions of B with similar treatment showed differences in intensities ranging from a very light green for the solution irradiated for one hour to a moderately deep green for the solution irradiated for fifteen hours. The depth of color was in the same order as the time of radiation. The darkest solution was not as heavily colored as the acidified portions of A. The solutions of C became uniformly dark green when acidified.

Discussion

The treatment of the irradiated and faded solutions with hydrochloric acid would seem to indicate that the neutralization of the alcohol used as a solvent had not changed the results previously reported in unneutralized alcohol,[2] except possibly in 84.6% alcohol.

The trend of the absorption curves as well as the results obtained with hydrochloric acid make it seem likely that the proposal of Lifschitz for the dark reaction would still be valid in 100% ethyl alcohol. In the presence of water, however, the end-product could not be the leucocyanide, the leucocarbinol, nor the photo-compound, since all of them show minima in their absorption curves at 3500 Å.

The experiment indicates that the end-product of the dark reaction of the photolysis of malachite green leucocyanide in ethyl alcohol containing some water has the following properties: (a) It is colorless, but has a peak in its absorption curve in the neighborhood of 3600 Å. (b) It is formed more easily as the amount of water in the solution increases, but it is unstable in as much as 15% water. (c) It is not as stable as the leucocyanide, being decomposed by dilute hydrochloric acid or excess water to produce the colored ion of malachite green. (d) When irradiated with ultraviolet light, it produces the colored ion of malachite green. (e) Although derived from the malachite green ion and easily reproducing this same ion, its absorption curve shows it to have a structure essentially different from the leucocyanide and leucocarbinol.

These properties would indicate that the end-product of the dark reaction must be the result of some reaction between the solvent and the malachite green ion. In analogy with the mechanism proposed by Villiger and Kopetschni,[3] this end-product might be the ether form: $Ar_3C{\cdot}OC_2H_5$. However, such a compound would be expected to be more stable than the substance produced here. Further investigation is necessary before the true identity of this end-product is established.

Summary

Absorption studies of photolyzed and subsequently faded solutions of malachite green leucocyanide in alcohol containing some water have shown that the dark reaction does not regenerate the leucocyanide as an end-product. The end-product is also shown not to be the leucocarbinol. The final product of the dark reaction is a colorless, light-sensitive substance with a peak in its absorption curve in the nieghborhood of 3500 Å. This end-product is decomposed by dilute hydrochloric acid to form a green solution similar to that of malachite green salts.

Hydrogen Exchange Reactions of Esters in Relation to Reactivity in Condensation Reactions

BY WELDON G. BROWN AND KENNETH EBERLY[1]

A study has been made of the base catalyzed hydrogen exchange reactions of representative esters of various types with deuteroalcohol in order to evaluate the effect on acidity[2] of structural variations and their consequent effect on reactivity in condensation reactions. Pertinent to the behavior of esters of monocarboxylic acids in the Claisen condensation, the effect of various alkyl groups has been investigated in some detail, and similarly, but less extensively, the effect of substitution has been traced in the phenylacetic and malonic ester series and correlated with the relative reactivities in alkylation reactions.

Preliminary experiments by W. R. Sprowls[3] indicated that the simple aliphatic esters do not undergo hydrogen exchange with deuteroalcohol in the presence of small amounts of sodium hydroxide either at room temperature or at 100° for long periods of time. Likewise no exchange was observed on addition of only a small quantity of metallic sodium (sufficient to form a 0.05 *M* sodium ethylate solution), evidently because of water present. We observed hydrogen exchange at a measurable rate even at room temperature, and without appreciable β-keto ester formation, on increasing the amount of sodium used to about 0.02 g. atom per mole of alcohol. A much weaker base, sodium salicylate, was required in the experiments on malonic ester and its derivatives.

Experimental Part

While the extent of hydrogen exchange has formerly been determined at this Laboratory[4,5] through density measurements on the water obtained by combustion of the alcohol recovered from reactions by distillation methods, the use of volatile esters in the present work precluded separations of the alcohol. Accordingly, in such cases, the reaction products were washed with saturated salt solution to remove the alcohol, samples (2 g.) of the separated esters were then burned and the water of combustion was collected in a cooled trap. The water, purified by heating with potassium permanagate and sodium carbonate at 180° for one hour and distilled twice *in vacuo*, was finally collected in a small tube (attached to the distilling apparatus through a ground joint) in which the density was determined with a quartz float and the deuterium content was then estimated by suitable interpolations.

Deuteroalcohol, with the C_2H_5OD content in the range 15–23 mole per cent. was prepared according to our previously described method.[4] The esters were obtained from commercial sources and purified, or were prepared according to directions in the literature.

TABLE I

HYDROGEN EXCHANGE REACTIONS OF ESTERS WITH DEUTERO-ALCOHOL[a]

Ethyl ester	M.-moles ester	Initial % D_2O[b]	Final % D_2O[c]	H at. exch.[d]	% completion
At 25°, four hours, with 38 ± 2 mg. sodium					
Acetic	51.1	3.13	1.70E	1.30	56

[a] The quantity of alcohol used in each experiment was 5 cc. (85.3 millimoles). [b] Data refer to deuterium content of water of combustion from stock deutero-alcohol. [c] Data refer to deuterium content of water of combustion from recovered alcohol or, where designated by "E," from the recovered ester. [d] Calculated on the assumption of statistical distribution of deuterium.

(1) Taken in part from the thesis of Kenneth Eberly submitted in partial fulfilment of the requirements for the Ph.D. degree at the University of Chicago, December, 1938.

(2) The term acidity is used throughout in the generalized sense. Since, in the condensation reactions to be considered, the anion concentration is maintained at the equilibrium value, the acid strength, not merely the rate of formation of anions as given by the rate of hydrogen exchange, is of importance. Brönsted and coworkers [see Brönsted, *Chem. Rev.*, **5**, 231 (1928)] have shown empirically, and Horiuti and Polanyi theoretically [*Acta Physicochimica, U. R. S. S.*, **2**, 505 (1935)], that the rate of proton transfer and the acid strength, in comparisons of acids of the same structural type, are directly and simply, though not linearly, related and undoubtedly the relative reactivities of similar esters in hydrogen exchange reactions will indicate correctly the order of acidity.

(3) W. R. Sprowls, Ph.D. Thesis, University of Chicago, 1938.

(4) Kharasch, Brown and McNab, *J. Org. Chem.*, **2**, 36 (1937).

(5) Brown, Kharasch and Sprowls, *ibid.*, **4**, 442 (1939).

Experiments in which the exchange reactions were substantially complete yielded values for the number of exchanging hydrogen atoms, assuming simple statistical distribution, of which the following are typical: ethyl acetate 2.25, propionate 1.74, butyrate 1.73, isobutyrate 0.91, β-dimethylacrylate 5.45, N-dimethylaminoacetate 1.98, phenylacetate 1.92, diphenylacetate 1.07, phenylmalonate 1.08. These limiting values, or estimated values in the absence of specific data, were then used in estimating the degree of completion of the exchange reaction in a series of experiments in which the reactions were interrupted before equilibrium was attained so as to obtain a quantitative comparison of the reactivities of the various esters. Typical results are given in Table I.

Discussion

The order of acidity in esters of the type RCH_2COOEt according to our results is as follows: $C_6H_5 > H > CH_3 > C_2H_5 > n\text{-}C_3H_7 > C_{10}H_{21}$, $C_{16}H_{33} >$ cyclo-$C_6H_{11} > i\text{-}C_3H_7$. Alkyl groups, relative to hydrogen, thus exert a de-activating effect which depends more upon whether the group is primary or secondary than upon the length of the chain. A second alkyl group (one example: ethyl isobutyrate) causes a further decrease in acidity, even after allowing for statistical effects. The phenyl group in phenylacetic ester appears strongly activating but a second phenyl group, as in diphenylacetic ester, fails to enhance the effect, and again, as a substituent in malonic ester, it has nearly the same (de-activating) effect as a methyl group.[6]

Vinylogic effects[7] in unsaturated esters diminish with increasing length of the conjugated bond system (*cf.* series, ethyl acetate, crotonate, sorbate) and are highly dependent upon geometrical configuration (*cf.* ethyl citraconate, mesaconate), the *trans* relationship between carbethoxy and β-methyl groups being more favorable.

The results for the esters of monocarboxylic acids are to be correlated with reactivity in the Claisen condensation, which, according to current theory,[8,9,10] involves anion formation by proton transfer as the first step, followed by reaction of the anion with another molecule of ester, etc., each step being reversible. The acid strength appears as a factor both in the rate and in the over-all equilibrium, and the failure of certain esters (notably ethyl isobutyrate and ethyl isovalerate) to undergo self-condensation under the usual conditions is ascribed to low acid strength, a conclusion supported by the observations[9,11] that condensation will occur if sufficiently powerful bases are used. Our results confirm this deduction regarding the acid strengths of ethyl isobutyrate and ethyl isovalerate, and the available data, chiefly of Roberts and McElvain[12] and Briese and McElvain,[13] on the rates and yields in condensations indicate close agreement throughout with the reactivity in hydrogen exchange. Quantitatively the correlation is less convincing, as we find, for example, the acid strength of ethyl laurate to be twice that of ethyl isovalerate, while in the acetoacetic ester condensation the former yielded 79%[13] and from the latter, under comparable conditions, "no trace of keto ester could be found."[12] The over-all equilibrium in the latter case is clearly much more unfavorable than by a factor of two, and we conclude that the variations in acidity, while similar in trend, are not wholly responsible for the variations in reactivity.[14]

In the malonic ester series we have but one example, methylmalonic ester, showing the effect of an alkyl group in decreasing the acidity but the effects of other alkyl groups are doubtless as characteristic as in the previous series, and the relative reactivity in alkylation reactions parallels that observed in the Claisen condensations of monocarboxylic esters. An outstanding example is the failure of isopropylmalonic ester to undergo further alkylation under the usual conditions, previously attributed to steric hindrance,[15]

(6) This apparently anomalous behavior of phenyl groups finds a ready explanation in the theory of damped resonance [Birtles and Hampson, *J. Chem. Soc.*, 10 (1937); Ingham and Hampson, *J. Chem. Soc.*, 981 (1939)]. The hydrogen lability of esters is due primarily to resonance stabilization of the anion and an α-phenyl group would normally reinforce this resonance by providing additional resonance forms, in which it appears doubly bonded to the α carbon, and which are therefore most effective if the benzene ring and the carbethoxy group can become coplanar. With two phenyl groups and one carbethoxy group (or one phenyl group and two carbethoxy groups) attached to the α carbon, the condition of coplanarity could not be fulfilled for steric reasons.

(10) Renfrow and Hauser, *ibid.*, **60**, 463 (1938).

(11) Spielman and Schmidt, *ibid.*, **59**, 2009 (1937).

(12) Roberts and McElvain, *ibid.*, **59**, 2007 (1937).

(13) Briese and McElvain, *ibid.*, **55**, 1697 (1933).

(14) Spielman and Schmidt (*loc. cit.*) attributed the failure of ethyl isovalerate and isobutyrate to undergo self-condensation (with sodium ethylate) to the low acidity, indicated by negative ferric chloride tests, of the β-keto esters derived from them, and, in our opinion, this should be admitted as a contributing factor. We considered the second step of the Claisen condensation (reaction of anion with another molecule of ester) as similar in form to the alkoxy group interchange reactions of esters, and we observed in such a reaction ($RCOOAm + OEt^- \longrightarrow RCOOEt + OAm^-$, Am = optically active amyl) that ethyl isobutyrate reacted only one-fifth as rapidly than ethyl *n*-butyrate. We believe, therefore, that the influence of structure on reactivity in the Claisen condensation is threefold, exerting itself, not only on the extent of the initial anion formation, but also on the rate at which the anion reacts with the ester, and the extent to which the equilibrium is shifted by salt formation of the β-keto ester.

(15) Fischer and Dilthey, *Ann.*, **335**, 337 (1904).

but which could now be interpreted, in view of the analogous behavior of isovaleric ester in the Claisen condensation, as due in part, at least, to low acidity.[16]

(16) The tacit assumption is made that decreased acid strength hinders the alkylation reaction through its effect in lowering the equilibrium anion concentration, and while this assumption appears to be valid in the malonic ester series, this will not be the dominant effect where the acidity is of such a high order that dissociation, under the conditions of alkylation, is practically complete. The introduction of alkyl groups in barbituric acid is known from ordinary acidometric measurements, to depress the acid strength, the isopropyl group being particularly effective [Preiswerk, *Helv. Chim. Acta*, **6**, 192 (1923)], but at the same time the ease of alkylation increases and the isopropyl derivative reacts with great ease. Less extreme illustrations are to be seen in the acetoacetic and cyanoacetic ester series, in which the isopropyl derivatives undergo alkylation readily [Fischer, Rohde and Brauns, *Ann.*, **402**, 364 (1913)] and which differ also from malonic ester in that a second alkyl group is introduced somewhat more readily than the first. In these instances the role of acidity is subordinate to the reactivity of the anions (or salts) toward alkyl halides which, as Conrad and Brückner pointed out [*Z. physik. Chem.*, **7**, 283 (1891)], varies inversely with the acid strength.

We take pleasure in acknowledging the active interest of M. S. Kharasch throughout this work.

Summary

Sodium ethylate catalyzed hydrogen exchange reactions of various types of esters with deutero-alcohol are reported, and the influence of structure on acidity, as determined by the exchange reaction, is correlated with reactivity in condensation reactions.

Mechanism of the Acid-catalyzed Dimerization of Anethole

BY WELDON G. BROWN AND ALEX H. WIDIGER

In connection with the possibility of obtaining evidence regarding the mechanism of the acid-catalyzed polymerization of olefins with the aid of deuterium, a study has been made of the dimerization of anethole catalyzed by deuterium chloride in methyl alcohol solution. This case was considered favorable for a test of the Whitmore[1] theory of acid catalyzed polymerizations because (1) the experimental conditions can be adjusted so as to yield almost exclusively the dimer, (2) the structure of the dimer is known and is in conformity with the Whitmore hypothesis, (3) the structure of the dimer is such that it contains no hydrogen atoms likely to be readily exchangeable under the influence of acids. It was recognized that the monomer contains at least one such hydrogen atom, namely, that attached to the β carbon atom, and that the exchange of this hydrogen with the deuterium of the medium, if fast in comparison with the polymerization process, would obscure the phenomenon we wished to observe.

The formation of isoanethole,[2] according to the mechanism of Whitmore, is shown in the equations

$$R{-}CH{=}CH{-}CH_3 + H^+ \longrightarrow R{-}CH^+{-}CH_2{-}CH_3 \quad (R = \text{anisyl}) \quad (1)$$

$$R{-}CH^+{-}CH_2{-}CH_3 + R{-}CH{=}CH{-}CH_3 \longrightarrow R{-}CH(C_2H_5){-}CH(CH_3){-}CH^+{-}R \quad (2)$$

$$R{-}CH(C_2H_5){-}CH(CH_3){-}CH^+{-}R \longrightarrow R{-}CH(C_2H_5){-}C(CH_3){=}CH{-}R + H^+ \quad (3)$$

It will be noted that the proton added becomes incorporated in the ethyl side-chain of the dimer and that the proton eliminated is derived from the second molecule of anethole. A polymerization carried out with a deutero acid should therefore yield, if no exchange reactions occur, a product containing one atom of deuterium per molecule of dimer. In the more likely event that a hydrogen exchange reaction of the monomer accompanies the polymerization reaction, but is not too rapid in comparison, it is still possible to predict that the proportion of deuterium in the dimer formed in any small interval of time during the polymerization should be greater than that present in the monomer.

Experimental Part

The polymerization of anethole (Eastman Kodak Co. product, redistilled, b. p. 225° (750 mm.)) was carried out by refluxing with 5 *N* hydrochloric acid in methyl alcohol, according to the procedure of Goodall and Haworth, except that the methyl alcohol and the hydrochloric acid were partly deuterated. The deuteration was accomplished by treating methyl alcohol with pure heavy water, thus permitting an exchange of the hydroxyl hydrogen of the alcohol with the deuterium of the water, then removing water by repeated treatment with calcium oxide. Dry hydrogen chloride was passed into the anhydrous alcohol to yield a 5 *N* solution. Analysis for deuterium was carried out by combustion, after having first removed halogen by treatment with dry silver oxide, the water of combustion

(1) Whitmore, *Ind. Eng. Chem.*, **26**, 94 (1934).

(2) The structure indicated for isoanethole is that established by Goodall and Haworth, *J. Chem. Soc.*, 2484 (1930).

being collected, purified, and analyzed for deuterium by the temperature-float method.

The dimer is of limited solubility in alcohol, and separates together with some unchanged anethole, making it possible to obtain samples by cooling and draining off the lower layer. The samples were taken up in ether, washed with aqueous alkali, then with water, and, after drying, the ether was allowed to evaporate. Fractional distillation at reduced pressure furnished samples of anethole and isoanethole which were analyzed for deuterium by combustion and density measurements on the water of combustion. The anethole fractions contained some chloride, evidently as a result of addition of hydrogen chloride but the extent of this addition was for our purposes negligible. During the period of heating a considerable part of the hydrogen chloride disappears by reacting with methyl alcohol.

In a typical experiment, a solution of 71 g. of anethole in 355 ml. (331 g.) of 5.30 *N* hydrogen chloride (HCl + DCl) in methyl alcohol was heated on a water-bath and samples were removed at intervals as described above. The deuterium present amounted to 8.90 mole per cent. of the total available hydrogen (hydroxyl hydrogen plus hydrogen chloride). The analytical results are given in Table I. The results are given in terms of mole per cent. of deuterium found in the water of combustion and in terms of the so-called exchange number.[3] In the present connection the exchange number may be considered simply as the number of deuterium atoms per anethole unit which would have been found had the available hydrogen of the medium been composed entirely of deuterium.

TABLE I

POLYMERIZATION OF ANETHOLE IN DEUTERO METHYL ALCOHOL–HYDROGEN CHLORIDE SOLUTION

Sample	Period[a] of heating, min.	Compn. of sample, g.	% D_2O in water of combustion	Exchange no.[b]
1	3	15 anethole	0.155	0.21
		7 isoanethole	.135	.18
2	6	7 anethole	.33	.45
		2 isoanethole	.18	.24
3	20	4 anethole	.61	.83
		7 isoanethole	.36	.48
4	120	4 isoanethole	.77	1.05

[a] Data in this column refer to time intervals. Thus the first sample was withdrawn three minutes after the start of the reaction, the second sample was withdrawn after a further period of six minutes, etc. [b] Atoms of deuterium per anethole unit.

(3) For the definition of the exchange number, and the method of calculation, see Brown, Kharasch and Sprowls, *J. Org. Chem.*, **4**, 442 (1939); Brown, Widiger and Letang, THIS JOURNAL, **61**, 2597 (1939).

Some information with regard to the position occupied by the deuterium in the dimer was obtained by oxidizing with alkaline permanganate, following the procedure of Goodall and Haworth, and analyzing the products for deuterium. The deuterium content of the isoanethole, expressed in terms of mole per cent. D_2O in the water of combustion (ordinary water being taken as zero), was 0.71%. The anisic acid contained 0.02%, and the ketone (3-anisylpentanone-2) contained 0.50%. Of the deuterium originally present 95% was found in the ketone. In view of the finding that deuterium is present only as a result of an exchange reaction of the monomer prior to polymerization, the conclusion was reached that virtually all of the deuterium present in the isoanethole is confined to the CH_2 group of the ethyl side chain.

Discussion

It is difficult to find any support in our results for the Whitmore mechanism of polymerization, or indeed for any mechanism involving an intermediate carbonium ion (or addition compound) in which the equivalence of the newly acquired hydrogen atom with hydrogen atoms previously present on the same carbon atom is to be assumed. The condition that there should not be a rapid interchange of hydrogen between the monomer and the medium is fulfilled, yet the predicted enrichment of the dimer with respect to deuterium is not observed. On the contrary, it is found that the dimer contains no more deuterium than can be accounted for as the result of a slow hydrogen exchange prior to its formation.

Summary

The dimerization of anethole in a partly deuterated medium of methyl alcohol and hydrogen chloride is accompanied by a slow hydrogen exchange reaction of the monomer and the dimer is found to contain no more deuterium than can be accounted for as a result of this exchange. The significance of this result for the mechanism of polymerization is pointed out.

The Rates of Reaction of Cyclopropyl Ketimines with Water[1]

BY JOHN B. CLOKE[2]

Ketimines react normally with water to give the corresponding ketone and ammonia as follows

$$R—C(=NH)R' + H_2O = RCOR' + NH_3$$

a reaction which ordinarily is accelerated greatly by the addition of one equivalent of acid. Our original interest in the behavior of the cyclopropyl ketimines with water was aroused by two strikingly different reports: first, that ethyl cyclopropyl ketimmonium chloride

$$\underset{\text{CH}_2\text{CH}_2\text{CH}}{\text{CH}_2\text{CH}_2\text{CH}}—C(=NH_2Cl)C_2H_5 \qquad (I)$$

appeared to be unaltered by hot water[3]; and, second, that the phenyl cyclopropyl analog,[4] $C_3H_5C(=NH_2Cl)C_6H_5$ (II), is instantly decomposed. The first of these reports became clear when the writer proved that de Booseré's stable compound is in reality the isomeric α-ethylpyrrolinium salt.[1] The present work shows, as was anticipated, that the real cyclopropyl compound (I) is even more readily saponified by water than (II).

Experimental

Phenyl Cyclopropyl Ketimmonium Chloride.—The salt was first prepared in the form of its chloroform compound as already described.[1] This crystalline compound, which was collected on a filter in a special moisture-proof housing, was therefore exposed in a desiccator over phosphorus pentoxide at 50° and under diminished pressure until weighings showed that all chloroform had been removed. Since the compound decomposed very readily, many recrystallizations and several repetitions of the initial preparation were necessary in order to maintain a supply of reasonably pure material.

Ethyl Cyclopropyl Ketimmonium Chloride.—Ethylmagnesium bromide was first prepared in the usual manner from 42.3 g. of ethyl bromide, 9.0 g. of magnesium and 150 cc. of anhydrous ether according to the procedure of Moureu and Mignonac.[5] To this ethereal solution 10.35 g. of cyclopropyl cyanide[6] in three times its volume of ether was added slowly from a dropping funnel. The material was then boiled gently for about twelve hours, when it was transferred to a separatory funnel from which it was added slowly to about 300 cc. of liquid ammonia[7] in a 500-cc. Dewar flask, which was then connected with a five-foot (1.5-meter) lime tower. From time to time during a twenty-hour period the mixture was agitated gently in order to disintegrate lumps. At this point about 200 cc. of dry ether was added carefully to the mixture, and about half an hour thereafter the solution was filtered through a Büchner in a moisture-proof apparatus. The residue on the filter was well washed with dry ether, and the combined filtrates were refiltered into a suction flask. In order to remove ammonia, a current of very dry air was aspirated through the ketimine solution, which was then diluted somewhat with ether and treated with dry hydrogen chloride.

The hydrogen chloride gave a white crystalline precipitate of the ethyl cyclopropyl ketimmonium chloride and a sticky material,[8] which collected on the walls of the flask. The entire precipitate was then dissolved in 50–60 cc. of a cold mixture of 100 cc. of glacial acetic acid[9] and 10 cc. of acetic anhydride, from which it was reprecipitated by the addition of 500 cc. of dry ether. At first a dusky, oily layer was obtained, but eventually this crystallized completely after the flask wall was scratched with a glass rod. Finally, the salt was collected on a suction filter in the absence of moisture, when it was exposed in a vacuum desiccator over sodium hydroxide and calcium chloride for a day, giving 10 g. or a 48.5% yield.

The substance appeared to shrink from 70–80°, but it did not melt until 95–97°, and then it gave a somewhat turbid liquid. Other cyclopropyl ketimmonium salts have behaved similarly, possibly because they pyrolyze to give pyrrolinium salts.

Anal. (micro) Calcd. for $C_6H_{12}NCl$: N, 10.49; Cl, 26.55. Found: N, 10.59, 10.47; Cl, 26.93.

When the salt was redissolved in dry chloroform containing a little acetic anhydride and reprecipitated by ether, neither properties nor composition were changed significantly. However, in a melting point determination begun at 87°, the compound melted at 98.5–100.5°.

Reaction Rate Measurements.—The rates with which the ketimmonium salts react with water were ascertained

(1) The data reported herein have been taken from the second part of a dissertation presented by J. B. Cloke to the University of Chicago in partial fulfilment of the requirements for the degree of Doctor of Philosophy. The first part was published in 1929, THIS JOURNAL, **51**, 1174 (1929).

(2) The problem discussed herein was suggested by Dr. Julius Stieglitz, whose inspiration, confidence and fatherly advice will always be treasured by the writer. For various reasons, Mrs. Stieglitz has suggested that her husband's name should be withheld from this second paper, which was his own wish in the case of the first.

(3) de Booseré, *Bull. soc. chim. Belg.*, **32**, 26 (1923).

(4) Bary, *ibid.*, **31**, 404 (1922).

(5) Moureu and Mignonac, *Compt. rend.*, **156**, 1801 (1913); *Ann. chim.*, [9], **14**, 322 (1920).

(6) Cloke, Anderson, Lachmann and Smith, THIS JOURNAL, **53**, 2791 (1931).

(7) The use of liquid ammonia for the decomposition of the bromomagnesium derivatives of ketimines was developed independently by Cornell, *ibid.*, **50**, 3314 (1928), and by Cloke and Van Wyck, *Thesis*, Rensselaer Polytechnic Institute, 1927. As a rule, the Grignard solution runs quite easily into the ammonia through a tube of precipitate formed at the tip of the funnel. Plugs may be removed with a wire.

(8) The formation of this viscous material, which has often been observed in connection with the precipitation of ketimine hydrochlorides, appears to be the result, in part at least, of the use of an excess of hydrogen chloride.

(9) Later work indicated that chloroform is better than the acetic acid.

by modifications of the method of Stieglitz and Derby[10] for the imido ester hydrochlorides. The method is based upon the fact that a ketimine can be liberated from its salt by the action of sodium hydroxide and that the free base, unlike ammonia, may be extracted from its aqueous solution by carbon tetrachloride. The reaction velocity constant, k, was calculated arithmetically and graphically from the equation for a monomolecular reaction

$$k = \frac{2.303}{t_2 - t_1} \log \frac{v_1}{v_2}$$

where v_1 and v_2 represent the relative concentrations of the ketimmonium salt at times t_1 and t_2.

Phenyl Salt.—In the work on the phenyl cyclopropyl ketimmonium chloride, special care was taken in order to prepare the aqueous solution rapidly at 0° and to maintain it at this temperature. Furthermore, the transfer pipet used for the removal of the samples was kept cold, when not in use, by allowing it to stand in a long tube, which was clamped in the well-stirred bath of water and cracked ice. Each sample was transferred at a noted time to a Squibb funnel containing a known volume of standard alkali and 30 cc. of purified carbon tetrachloride. At once the mixture was well shaken, the tetrachloride layer was drawn off and the extraction repeated three times with 25, 20 and 15 cc. portions of the immiscible solvent. Finally, the aqueous solution in the funnel was washed into a flask and titrated with standard acid with methyl orange as the indicator. Table I represents a typical run, wherein t is the time in minutes from the moment of preparation of 100 cc. of 0.05 M solution and v_b and v_a designate the volumes used of the 0.1 N sodium hydroxide and hydrochloric acid, respectively; samples of 17.6 cc. were taken.

TABLE I

t	$v_b - v_a$	k, min.$^{-1}$
2	8.06	.....
14	5.85	0.02669
33	3.75	.02469
44	2.87	.02460
55	2.13	.02510
70	(1.51)	.02463
	Average k	0.02514

The graphical computation of the data in Table I gives a value for k of 0.0246. Table II presents a summary of the constants, computed graphically, for several successive runs on the phenyl salt at 0° in 0.05 M and 0.1 M solutions. The grand averages for the average constants

computed arithmetically are 0.0252 and 0.0243 respectively, results for which the first points are generally responsible.

(10) Derby, *Am. Chem. J.*, **39**, 439 (1908).

Ethyl Salt.—Ethyl cyclopropyl ketimine differs from the phenyl analog in that it is decidedly more soluble in water and more reactive by far with water. In addition, it differs from all other ketimines thus far studied in that the base is more sensitive to saponification than the hydrochloride salt. These characteristics made it necessary to adopt the following modification of the analytical method used for the phenyl salt, and, even with the changes indicated, the results are not as accurate as might be desired.

A 100-cc. portion of purified carbon tetrachloride and a suitable volume of 0.5 N sodium hydroxide solution from a microburet were added in order to each of five Squibb funnels, which were suspended in the ice-bath. The ketimmonium salt solution was then prepared in a wide-necked, weighted Erlenmeyer flask, which stood in the bath, by the dropping of the proper weight of compound into the flask, which contained the proper volume of water measured at 0°. At once a definite volume of the well-mixed reacting solution together with a 5-g. portion of finely powdered sodium nitrate were transferred to one of the waiting funnels. The mixture was then shaken vigorously for a few moments, the lower layer was removed and at once the extraction was repeated with a 30-cc. and a 20-cc. portion of ice-cold tetrachloride, when the analysis was finished as in the case of the phenyl salt.

In the foregoing work, the very rapid extraction procedure, which was demanded by the great reactivity of the liberated base, undoubtedly removed some alkali mechanically. However, this error would be offset to some extent, especially in the first analyses, by the rapid decomposition of the base together with its significant solubility in water. The graphical computation of the results of three runs gave the following values of k: 0.0366, 0.0360, (0.0316).

Saponification of Ethyl Cyclopropyl Ketimine Base.—Since several unsuccessful attempts to prepare pure ethyl cyclopropyl ketimine indicated that this could only be accomplished with much effort, a general idea of its stability to saponification was obtained as follows. In short, the base was liberated from its hydrochloride salt at the moment when it was required by the dropping of the equivalent weight of the salt into a definite volume of 0.05 N sodium hydroxide solution at 0°. Without delay a 10-cc. portion of this solution was pipetted into a Squibb funnel containing 100 cc. of ice-cold tetrachloride and 5 g. of sodium nitrate, when the run was completed as above. The results of two runs, computed graphically, follow: k, min.$^{-1}$ = 0.46, 0.53.

The foregoing data, which indicate a half time value of about a minute and a half for the ketimine in water at 0°, are only of relative significance: first, on account of the haste necessary in the analytical work[11]; and, second, because a slight excess of sodium hydroxide, giving a high pH, might greatly accelerate the reaction. The last question may be ascertained in time.

Saponification of Phenyl Cyclopropyl Ketimine Base.—In view of the striking rate with which ethyl cyclopropyl ketimine base reacts with water in comparison with the rate for the salt, the work was extended to the phenyl analog. The procedure followed was analogous to that used for the ethyl compound with the exception that the

(11) In this connection the writer appreciates the aid of Dr. E. C. Knowles, Mr. R. J. Anderson and the Mrs. Sarah and Mary Cloke.

reaction was carried out in a special vessel provided with an efficient stirrer. The results of two runs are given in Table III. It is important to note that the reaction

TABLE III

Successive Values of $k \times 10^3$, min.$^{-1}$ at 0°

10.1	9.6	9.4	8.6	8.3	7.8	7.3
11.3	10.3	9.7	8.9	8.4	8.0	6.4

mixture was not strictly homogeneous and that the values obtained are therefore not truly comparable with other data in the paper. The drift in the values of k was probably the result chiefly of the reversing action of the ammonia, as in the saponification of diphenyl ketimine.[12]

The Retardation of Ketimmonium Salt Saponification by Acid.—The idea that the presence of an excess of acid would decrease the rate of reaction of ethyl cyclopropyl ketimmonium chloride with water, which was suggested by the foregoing data, has been confirmed for all ketimmonium salts thus far studied. Data on the two cyclopropyl compounds are given in Table IV. A study of these data shows that the rate with which these two

TABLE IV

Cyclopropyl ketimmonium chloride	HCl, N	Av. k, min.$^{-1}$ at 0°
Ethyl	0.05	0.00284
Ethyl	.20	.00118
Phenyl	.01	.00747
Phenyl	.05	.00435
Phenyl	.20	.00189

ketimmonium salts react with water decreases remarkably as the hydrogen-ion concentration increases. The imido ester salts are much less sensitive to changes in pH, as shown by the work of Stieglitz and Derby.[10]

Discussion

By analogy with ethyl phenyl ketimmonium chloride, $C_2H_5C(=NH_2Cl)C_6H_5$,[13] and the diphenyl compound, $C_6H_5C(=NH_2Cl)C_6H_5$,[12,14] the ethyl cyclopropyl ketimmonium chloride (I) is less reactive with water than would be expected. This deduction is also supported by the great reactivity of the ethyl cyclopropyl ketimine base with water, for ketimine bases are normally less reactive with water than their salts.[5] The foregoing considerations are in harmony with the supposition that the salt (I) exists in aqueous solution largely in the form of its enammonium tautomer, presumably $\underset{\llcorner\!\!\lrcorner}{CH_2CH_2CH}—C(—NH_3Cl)=CHCH_3$.

The reason for suggesting that the tautomerism,[15] if it exists, concerns the ethyl rather than the cyclopropyl group will be considered in a later communication.

Summary

Ketimines are saponified by water to give a ketone and ammonia; similarly, ketimmonium salts give a ketone and an ammonium salt. The measurement of the reaction velocity constants for the saponification of ethyl cyclopropyl ketimmonium chloride and for the phenyl cyclopropyl analog shows, contrary to a previous report, that the former compound is more reactive with water than the latter. More notable is the fact that the free ethyl cyclopropyl ketimine base is still more reactive with water than is its hydrochloride, an anomalous behavior which suggests that the dissolved salt may exist largely in the form of an enammonium tautomer. The work has also shown that the reaction velocity for the decomposition of a ketimmonium salt by water decreases as the hydrogen-ion concentration rises.

Subsequent papers will consider various aspects of ketimine stability.

TROY, NEW YORK RECEIVED SEPTEMBER 18, 1939

(13) N. B. Tweed, *Thesis*, Rensselaer Polytechnic Institute, 1932.

(14) Culbertson, *et al.*, *Proc. Iowa Acad. Sci.*, **39**, 177 (1932); *ibid.*, **41**, 170, 172 (1934).

(15) In order to get additional evidence for the idea, much effort was expended in the measurement of the hydrolysis constants of the bases corresponding to the salts (I) and (II), and also of the free ethyl cyclopropyl ketimine base. Since these measurements were made a number of years ago by a somewhat involved quinhydrone electrode method, which was subject to several unavoidable errors, the data will not be given until they can be checked by more straightforward methods now available. Nevertheless, the data, as collected, indicated that the base corresponding to the more stable phenyl salt (II) is stronger than that of the less stable ethyl analog (I). The same relationship was found by Stieglitz and his associates in the case of the imido esters.

Condensations by Sodium. XV. Reactions of Disodium Compounds with Ethylidene and Methylene Chlorides*

BY AVERY A. MORTON AND JOHN T. MASSENGALE

Amylidenedisodium has failed[1] to give branched chain hydrocarbons with monohalogen alkyls. However, reaction with ethylidene chloride is now shown to take place smoothly with formation of the expected heptene-2 (equation 1) in a yield of

$$C_4H_8CHNa_2 + Cl_2CHCH_3 \longrightarrow C_4H_9CH{=}CHCH_3 + 2NaCl \quad (1)$$

13%, or 80% of the maximum possible (17%) estimated from the butylmalonic acid usually obtained by carbonation. This compound is the first Wurtz product from disodium compounds reported in this work. Its isolation in the quantity noted is in agreement with the view that amylidenedisodium is present as an intermediate[2] from which butylmalonic acid is derived by carbonation.

Efforts to use this reaction for showing the existence of some benzylidenedisodium along with benzylsodium as a product of the exchange reaction between phenylsodium and toluene were qualitatively successful. Styrene from methylene chloride and methylstyrene from ethylidene chloride were both formed though the yield (not over 4%) did not exceed a quarter of that expected. It will be recalled[2] that a secondary reaction made estimation of this disodium intermediate by carbonation unreliable. Accordingly, an indirect method was used. Benzylsodium was first determined by measuring the amount of ethylbenzene produced with methyl iodide and with methyl sulfate. These values are in approximate agreement (46 and 43%, respectively) with each other and are considered a fair index of the quantity of benzylsodium since reactions of this organosodium compound have so far been among the most quantitative[3] with respect to the Wurtz product observed in this series. The difference between the total organosodium intermediates found by carbonation and the mono product approximated by the above method amounts to around 15%. Low yields of styrene may be due to difficulties in isolating the product as well as to poor reaction. Efforts to increase the styrene yield by heating benzylsodium with excess phenylsodium led to inactivation of the latter.

On the supposition that styrene might come by splitting out of hydrochloric acid from another likely intermediate (equation 2), beta-phenylethyl chloride, addition of the latter instead of methylene chloride was tried. No trace of styrene could be observed.

$$CH_2Cl_2 \xrightarrow{C_6H_5CH_2Na} \quad (2)$$

$$C_6H_5CH_2CH_2Cl \begin{cases} \xrightarrow{-HCl} C_6H_5CH{=}CH_2 \\ \xrightarrow[RNa]{} C_6H_5CH_2CH_2CH_2C_6H_5 \end{cases}$$

Chlorobenzene instead of amyl chloride was used as a source of phenylsodium in most of this work. The yield was as high as that which has been obtained with amyl chloride and benzene (78%)[4] but the resulting phenylsodium was less reactive with toluene so that the quantities of phenylacetic and phenylmalonic acids were below those produced by the former method. This result is probably due to the higher temperature (85 instead of 55°) necessary for exchange. Indeed, when the time at 85° was extended or the temperature raised to 110° the yield dropped appreciably. Indicative also of lower activity of this phenylsodium was the failure of methyl iodide to give ethylbenzene unless the exchange mixture were heated to 85° though this reagent uncovered evidence of metallation at room temperature in the case of the reactive phenylsodium from amyl chloride, benzene, and sodium.[2] The physical appearance of the two phenylsodiums was also different, that from chlorobenzene being a black powder which settled quickly when stirring was stopped so that an almost clear solution resulted. The green phenylsodium from amyl chloride, on the other hand, remained suspended for some time.

Attempts to use benzyl chloride and benzal chloride as sources of mono- and di-sodium compounds, respectively, were unsuccessful, either because the sodium compound formed was too reactive for isolation in the presence of incoming

benzyl chloride or because little or no reaction occurred with the metal. Behavior of the disodium compounds with other di-halogen compounds such as pentamethylene dibromide and benzal chloride also was tried but no evidence of the expected reaction was found.

Experimental

Heptene-2.—Amylidenedisodium was made in the usual manner[1] from 63.9 g. (0.6 mole) of amyl chloride and 37 g. (1.6 atoms) of sodium at 20–25° in a special cut of petroleum ether which boiled below 45°. It reacted vigorously when 23 g. (0.24 mole) of ethylidene chloride was added. Fractionation of the product yielded 2 g. of material boiling at 50–95° and 3.8 g. at 95–97°. The latter was strongly unsaturated when tested with bromine water and corresponded in boiling point with that recorded[5] for heptene-2 (97.8°); boiling point of dibromide 95–96° at 12 mm.; refractive index 1.4997. Recorded values were 96.2° at 12 mm. and 1.5000, respectively. The yield was 13% calculated on an amyl chloride basis. A higher boiling fraction, 110–115° at 120 mm. amounting to 5.2 g., was examined in hope that it might prove to be 6-ethylundecane but was found to have a molecular weight (Rast) of 226, and to be unsaturated to bromine.

Under similar conditions methylene chloride was added to amylidenedisodium which had been prepared in solvent ligroin carefully fractionated to remove material boiling below 85°. After decomposing in the usual manner a fraction unsaturated to bromine and boiling 61–66° corresponding to hexene-1 was obtained.

Phenylsodium from Chlorobenzene and Its Exchange with Toluene.—Chlorobenzene, 68 g. (0.6 mole), was added with stirring to 37 g. (1.6 atoms) of fine sodium sand which had been activated by addition of 5 ml. of *n*-amyl alcohol while suspended in petroleum ether. Reaction was very sluggish below 30° whereas amyl chloride reacts smoothly below 0°. After two and one-half hours required for addition of chlorobenzene, the mixture was stirred one hour longer before adding 135 g. of toluene and refluxing at 52° for two hours. Carbonation showed that this phenylsodium was relatively inactive, no exchange having occurred. The yield of benzoic acid was 53.5 g. (79%). Diphenyl, 2.7 g. (8%), also was recovered. Addition of methyl iodide in place of carbon dioxide likewise failed to show occurrence of any exchange, 35 ml. or 55% excess toluene being recovered.

When the above experiment was repeated, enough petroleum ether was distilled from the reaction mixture after addition of toluene to make the boiling temperature 85°. The mixture was maintained with stirring at this temperature for two hours before carbonation: yield of phenylacetic acid 21.6 g. (26%); of phenylmalonic acid 19.1 g. (35%). A similar experiment in which more petroleum ether was distilled from the mixture so that the exchange temperature with toluene was 106° produced 14.2 g. (17%) of phenylacetic and 21.2 g. (39%) of phenylmalonic acid. Separation of acids from this and a number of other experiments in which the exchange temperature was 106 to 115° was complicated by presence of an oily impurity which was removed only after repeated precipitations and extractions. In all cases yields were progressively lower with increasing temperatures of metallation.

Exchange of phenylsodium with toluene gave low yields when the organosodium compound was heated for some time before adding all of the toluene. Thus, phenylsodium prepared from 0.6 mole of chlorobenzene in 250 ml. of benzene was treated successively with 30-g. and 200-g. portions of toluene, each addition being followed by heating at 85° for one and one-half hours. Exchange was not complete, for on carbonation 2.6 g. (3.6%) of benzoic acid was found with 13.1 g. (16%) of phenylacetic acid and 13.8 g. (26%) of phenylmalonic acid. Addition of 215 ml. of toluene to a similar preparation of phenylsodium followed by heating at 85° for two hours yielded 2.2 g. (3%) of benzoic acid, 12.4 g. (22%) of phenylacetic acid, and 16.9 g. (31%) of phenylmalonic acid. It was necessary, however, to heat for some time to effect an exchange at 85°, for holding the temperature at 85° for five minutes (the experiment was identical in other respects with the one using petroleum ether as a solvent) yielded benzoic acid, 28 g. (38%), phenylacetic acid, 2.5 g. (3%) and phenylmalonic acid, 11.4 g. (20%).

Styrene.—Preparation of organosodium intermediates from toluene and phenylsodium was made at 85° as first described. A vigorous reaction ensued as methylene chloride, 16.9 g. (0.2 mole), was added as quickly as possible over a thirty- to forty-minute interval, the reaction temperature being kept at 35° while the kerosene bath temperature was maintained at −10° by addition of dry-ice. The mixture was stirred at 30° for one-half hour longer and then carbonated to ensure that all possible products had been obtained. After decomposing excess sodium by adding water (care must be taken that the first few portions of water have had time to react before more is added) directly to the reaction flask under an atmosphere of carbon dioxide, the organic layer was separated, washed twice with water, once with dilute acid, and three times again with water before distilling through a fifteen-plate column. By careful fractionation at a 15 to 1 reflux ratio over a period of two and one-half days, a fraction beginning at 78° and 160 mm., containing some amyl alcohol, and ending at 104° and 6 mm. (when diphenyl began to crystallize in the condenser), was obtained which gave, upon reaction with bromine in carbon tetrachlorde, 2.7 g. (3.3%) of styrene dibromide, m. p. 69–71°. The pure material is reported[6] melting at 73°.

Anal. Calcd.: Br, 60.6. Found: Br, 60.3. No acids were recovered by acidifying the water layer.

In an experiment with a larger quantity, 112.5 g. (1 mole) of chlorobenzene and 61 g. (2.6 atoms) of sodium sand there was obtained 5 ml. of the fraction which contained styrene at 90–92° and 27 mm., 6.4 g. (8%) of diphenyl at 129–132° at 11 mm., and 19 ml. of a fraction boiling 145–149° at 8 mm. corresponding to diphenylpropane.

To discover some of the factors affecting the yield of styrene, *i. e.*, of benzylidenedisodium, a series of runs was made. For each set of conditions, reactions with carbon dioxide, methyl iodide, and methylene chloride were successively tried. Results are listed in Table I with the theoretical amount of benzylidenedisodium possible cal-

(5) Soday and Boord, THIS JOURNAL, **55**, 3293 (1933).

culated as the difference between total acids and ethylbenzene. Where toluene was formed from unreacted phenylsodium and methyl iodide the amount was added to that of ethylbenzene in estimating the quantity of styrene possible. No diphenylethane was found among products of the reaction with methyl iodide.

TABLE I

ESTIMATION OF MONO- AND DI-SODIUM INTERMEDIATES PRESENT FROM REACTION OF PHENYLSODIUM WITH TOLUENE UNDER VARYING CONDITIONS

Products	Percentage yields obtained for condition a	b	c
Benzoic acid		19	24
Phenylacetic acid	26	14	7
Phenylmalonic acid	35	18	23
Total acids	61	51	54
Ethylbenzene	46	35	22
Toluene	..	13	15
Total monosodium, acid	46	48	37
Styrene { Theoretical	15	3	17
Styrene { Observed	3.3	1.4	2

[a] Phenylsodium prepared from chlorobenzene in petroleum ether and exchange carried out at 85° as described earlier in this paper. [b] Phenylsodium prepared from 0.6 mole of chlorobenzene in 250 ml. of benzene followed by addition of 30 g. of toluene and heating for two hours at 84°. [c] Same as in (*b*) except that 15 g. of toluene was added, the mixture heated for one and one-half hours at 82°, 15 g. additional toluene then added, and the mixture again heated for two hours at 83°. The purpose of conditions (*b*) and (*c*) was to test if a deficiency of toluene favored formation of benzylidenedisodium; the result actually revealed that phenylsodium had been inactivated by heat.

Methylstyrene.—Benzylidenedisodium was prepared from phenylsodium (chlorobenzene source) at 85° and treated with 23 g. of ethylidene chloride added gradually at 35° over a period of one hour. The product was then carbonated and decomposed with water. Acidifying the water layer gave no acids recoverable by ether extraction. On careful fractionation of the hydrocarbon layer a portion boiling from 85 to 95° at 70 mm. and amounting to 12 g. was found to be unsaturated to bromine water. The dibromide isolated amounted to 2.7 g. (3%), m. p. 63–64°; recorded[7] value 66.5°. Analysis for bromine in this sample showed a value high enough (56.7%, theory 57.5) to distinguish it from any other possible product.

Benzylsodium and Dimethyl Sulfate.—The organosodium intermediates were prepared from 112.5 g. (1 mole) of chlorobenzene and other reactants in proportion. After heating for two hours at 85° in order to metallate toluene, the mixture was cooled to 35° and treated with 70 g. (0.55 mole) of undiluted dimethyl sulfate over a two and a half hour period. Addition was discontinued as soon as heat ceased to be evolved. After decomposition the hydrocarbon layer was washed with sodium carbonate several times and then twice with water but on distillation some decomposition with evolution of sulfur dioxide began. Distillation was therefore halted until the mixture had been steam distilled. The distillate was then fractionated under a 10 to 1 reflux ratio through the fifteen-plate column whereupon 46 g. (43%) of ethylbenzene, b. p. 134–134.8°, was obtained. No fraction corresponding to isopropylbenzene was found. Above 200° sulfur dioxide fumes were evolved.

Reaction with Phenylethyl Chloride.—Benzylidenedisodium, with the accompanying benzylsodium, was made in the same manner employed for the styrene experiment except that 30.3 g. of chlorobenzene with a proportionately smaller amount of sodium was used. β-Phenylethyl chloride, 25 g. (0.18 mole), Eastman Kodak Co. grade, was added in place of methylene chloride. After decomposing and fractionating no dibromide could be isolated nor could even a test for unsaturation be detected in the fraction which should have contained styrene. Diphenylpropane was the only product obtained from this experiment.

Reaction with Benzal Chloride.—The mixture of benzyl sodium and benzylidenedisodium was treated dropwise with 29 g. (0.18 mole) of benzal chloride which had been distilled just before use. Fractionation of the hydrocarbon layer obtained after decomposing excess sodium gave at 6 mm. and a reflux ratio of 10 to 1: at 104–106°, 4.1 g. of diphenyl; at 106–129°, 1 g. of a liquid; and at 129–132°, 6.2 g. of a liquid which crystallized upon chilling and scratching, m. p. 46–48°. Several crystallizations from petroleum ether did not raise its melting point above 51–51.5°. No depression was observed with an authentic sample of diphenylethane.

Reactions of Benzyl and Benzal Chlorides with Sodium.—Benzyl chloride, 76 g. (0.6 mole), was added at 25° to 37 g. (1.6 atoms) of sodium sand which had been activated by addition of 5 ml. of amyl alcohol. Petroleum ether, 300 ml., was used as the solvent. There was an immediate reaction and the mixture became blue-black in color. No heat was evolved on carbonation and the product after decomposing in the usual manner had a strong odor of unreacted benzyl chloride. After distilling up to 200° at atmospheric pressure, the residue crystallized, giving 29.1 g. of diphenylethane. The yield was 51%, no allowance being made for unreacted benzyl chloride. The reaction was repeated using petroleum ether, 300 ml., and toluene, 50 ml., as the solvent in the hope that benzylsodium would be stable in this mixed solvent as it had once before[4] proved to be when amyl chloride had been used. Again no acids were found after carbonation. Some unreacted benzyl chloride was present, and the yield of dibenzyl was 20 g. (45%).

Benzal chloride, 48.3 g., was added to 37 g. of sodium sand in the same manner first tried with benzyl chloride above. No acids were found after carbonation. A considerable quantity of unreacted benzal chloride was present but the products in general were difficult to separate. A small amount of stilbene, m. p. 118–120°, was isolated.

Pentamethylene Dibromide with Benzylidene- and Amylidenedisodium.—Benzene, 300 ml., was added to phenylsodium from 0.6 mole of chlorobenzene and 1.6 atoms of sodium in 250 ml. of petroleum ether. After distilling until the temperature of the mixture reached 78°, 60 ml. of toluene was added, the mixture refluxed at 86° for two hours, cooled to 25°, and treated dropwise with 36 g. (0.16 mole) of pentamethylene bromide[8] over a one

(8) Von Braun, "Org. Syntheses," Coll. Vol. I, 1932, p. 419.

and a half hour period. Carbonation yielded no acids. The hydrocarbon layer was washed and fractionated at atmospheric pressure until nothing more would come over with the jacket temperature of the column at 186°. At 10 mm. pressure 11 ml. of material boiling from 98 to 112° and obviously containing some diphenyl, along with the hoped for cyclohexylbenzene, was obtained. This fraction was nitrated according to the procedure of Kursanoff,[9] in an attempt to obtain the 4-nitrocyclohexylbenzene, m. p. 57.5–58.5°. The only products obtained were apparently higher melting nitro derivatives of diphenyl for the crude material melted 71–95°, and after crystallization from dilute acetic acid at 90–98°. Sublimation did not change the value appreciably.

Unsatisfactory results were likewise obtained in the reaction of this dibromide with amylidenedisodium, the latter being made from 63.9 g. of amyl chloride with 37 g. of sodium in 300 ml. of petroleum ether in the usual manner. The dibromide, 36 g., was added dropwise. Carbonation produced no acids. Upon fractionation 9 ml. boiling 161–172° at atmospheric pressure was collected. It contained some decane as well as some of the expected *n*-butylcyclohexane. Hydrogen sulfide was evolved when the fraction was heated with sulfur but no evidence of *n*-butylbenzene could be obtained on applying Ipatieff's[10] procedure for making the diacetamino derivative.

Summary

Ethylidene chloride reacts with amylidenedisodium to form heptene-2. The yield is the same within the experimental error as that of butylmalonic acid obtained by carbonation.

Methylene chloride and ethylidene chloride react with benzylidenedisodium, yielding styrene and methylstyrene, respectively.

Styrene is not obtained from the reaction of β-phenylethyl chloride with benzylsodium.

Phenylsodium prepared from chlorobenzene is not as active in exchanges with toluene as is phenylsodium prepared from amylsodium.

Methyl iodide and dimethyl sulfate give approximately the same yields of ethylbenzene when added to the mixture of benzylsodium and benzylidenedisodium. In neither case is the branched chain hydrocarbon, isopropylbenzene, found among the products.

Condensations by Sodium. XVI. The Formation of Decane in the Wurtz Reaction

BY AVERY A. MORTON AND GRAHAM M. RICHARDSON

It is the purpose of this work to show that no Wurtz product, decane, is formed until after formation of organosodium compounds. In brief, free radicals, if formed prior to organosodium intermediates by reaction of amyl chloride and sodium, do not dimerize to yield decane. The method employed was the simple one of increasing the quantity of sodium and noting whether the yield of organosodium compounds approached 100% as that of decane fell to zero. Such an examination of the early stages of addition of amyl chloride to sodium showed (Fig. 1) that yields were essentially quantitative, as high as 95% total organosodium compounds (amylsodium and amylidenedisodium) being revealed by carbonation. This Wurtz reaction is therefore sharply divisible into two phases: first, the formation of organosodium compounds and, second, their reaction with alkyl chloride. Decane was exclusively a product of the second stage. Under certain conditions the yield of decane was as high as 90% with respect to the monosodium compound.

At one time or another presence of free radicals has been proposed for nearly every stage of the Wurtz reaction. One argument for their existence is the finding of products of disproportionation, in this instance, pentane and pentene. Because of the prevalence of the free radical view and the failure of alternative mechanisms to prove satisfactory, presence of amylidenedisodium (butylmalonic acid) was attributed[1] to occurrence of this active intermediate. Such a mechanism is in full accord with present notions of free radicals in solution and their behavior. Yet critical questions can be asked. Why, for example, should disproportionation occur when the free energies of the products unquestionably favor dimerization? Thus, in the case of ethyl reacting with itself to form ethylene and ethane or butane

(1) Morton and Hechenbleikner, THIS JOURNAL, **58**, 2599 (1936); Morton, Fallwell, and Palmer, *ibid.*, **60**, 1426 (1938).

the free energies[2] are +12,300, −10,700, and −6200, respectively. Data for trimethylethylene (+13,700), pentane (−8600), and decane (−2900) suggest that the same relations exist for the products in the reaction of amyl chloride and sodium. If heats of formation of bonds are considered, a greater amount of heat would be evolved for dimerization than for disproportionation. By applying Rice's[3] method of calculating the probable proportion of products, the amount of disproportionation should be trifling. It is indeed an interesting fact that alkyl disproportionation, universally considered as evidence for free radicals, should not occur according to this single aspect of thermodynamics.

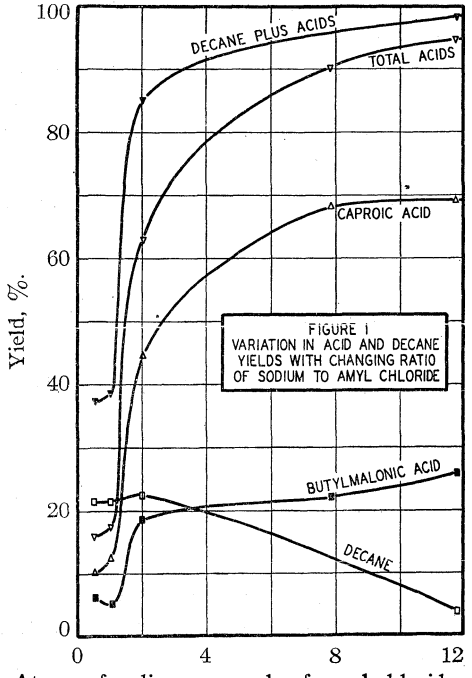

FIGURE 1
VARIATION IN ACID AND DECANE YIELDS WITH CHANGING RATIO OF SODIUM TO AMYL CHLORIDE

Fig. 1.—Variation in acid and decane yields with changing ratio of sodium to amyl chloride.

Furthermore, if free radicals are present in the first phase of reaction between amyl chloride and sodium and they react with sodium to form amylsodium or disproportionate to an -idene radical which in turn adds two atoms of sodium, one must concede that metallic sodium has acted as a nearly perfect trap for this radical or its disproportionated product. Yet how free can a free radical be which never escapes the influence of the surface of a metal on which it is formed and how can such a radical be distinguished from a radical in a complex, evidences of which are not entirely lacking in these reactions? Far more serious is the question of why disproportionation should be the sole product of reaction of a free radical with itself on the metal surface when free energies so overwhelmingly favor decane formation.

Our present opinion of the Wurtz reaction can be stated briefly. The Wurtz product, *i. e.*, the dimer, is reached by way of an intermediate organometallic compound. There is no need for any other special mechanism, although it is possible to superimpose on this view an ionic (organosodium compounds are salts) or a free radical mechanism. Owing to the vigor of the reactants and of the organosodium reagent, simultaneous side reactions and decompositions may occur to subordinate the Wurtz synthesis. Assumption of an intermediate free radical provides at present a convenient explanation for some of these products. This suggestion, while in general accord with current notions, requires further clarification before it can be unqualifiedly accepted. Certainly, at present, the evidence for such an intermediate is no better than that for a radical within a complex.

Experiments

General Conditions.—The general method described in previous papers was employed but owing to the purpose of the work special attention was paid to a number of factors having to do with increased yields. Sodium sand was made in pound lots in a special 1-liter flask[4] in which stirring was more effective. The particles were about one-fourth the size of those formerly obtained. The reactions themselves were carried out in similar flasks which before alteration had a capacity of 500 ml. The quantity of amyl alcohol needed to activate 30 g. of sodium metal was found to be 2 ml. by the following series of experiments. Amyl chloride, 20 ml., in 40 ml. of benzene was dropped onto 30 g. of sodium in a mixed solvent of 80 ml. of benzene and 25 ml. of petroleum ether under an atmosphere of nitrogen at 0 to −4° over a period of one hour. The mixture was then stirred for two hours at room temperature, more of the solvent mixture being added if necessary, before carbonation at 22–28°. Yields of total acids were 82, 88, 84, 76, and 73% when the amounts of alcohol used to activate the metal were 0, 2, 4, 6, and 8 ml., respectively. At room temperature amylsodium was converted to phenylsodium but amylidenedisodium was largely unaffected so that yields of different acids in this series were, respectively: for benzoic acid, 72, 83, 62, 71, and 64%

(4) Morton, *Ind. Eng. Chem., Anal. Ed.*, **11**, 170 (1939).

(14.6, 15.4, 12.7, 14.2 and 13 g.); for butylmalonic acid, 9.5, 5.0, 22.5, 5.0, and 8% (1.3, 0.7, 3, 0.7, and 1.0 g.). Total yields of all acids showed a definite drop when large quantities of alcohol were used but the respective amounts of benzoic and butylmalonic acid varied once (with 4 ml.) in an unpredictable manner. In general loss of monosodium compound was greater.

Purifying nitrogen by passing it over heated copper, through sulfuric acid, and then finally through a preliminary reaction mixture to ensure thorough scrubbing showed little, if any, difference from results obtained with no gas purification. Thus under conditions identical with those described in the preceding paragraph except that 4 ml. of amyl alcohol was used to activate the sodium, yields of 16.3 g. (81%) of benzoic acid and 0.8 g. (6%) of butylmalonic acid were obtained. The total yield of 87% was only slightly higher than the corresponding value of 84% reported above. The purified and dried nitrogen had been allowed to bubble slowly through the prereaction scrubber which contained double the quantity of amylsodium for a total time of twenty hours. After carbonating and decomposing the contents of this scrubber in the usual manner there was found 29.5 g. (73%) of benzoic acid and 1.2 g. (5%) of butylmalonic acid (total 78%). No nitrogen-containing compound could be observed among the products. In all other experiments reported in this paper no attempt was made to purify the commercial nitrogen being used as the inert atmosphere.

Effect of Varying the Quantity of Sodium.—Amyl chloride, 20 ml. (0.17 mole), dissolved in 40 ml. of petroleum ether was dropped onto varying amounts of sodium sand suspended in 120 ml. of petroleum ether. The amyl alcohol used to activate the sodium was in the proportion of 2 ml. of alcohol to 30 g. of metal. The temperature was maintained at −15 to −20° throughout the one hour needed for addition, the thirty minutes required for agitation, and the time for carbonation. Usually it was unnecessary to add more solvent to facilitate stirring. At this low temperature elimination of side reactions such as decomposition of amylsodium, or metallation of sodium caproate during carbonation was expected. With 2, 4, 7.6, 30 and 45 g. (0.5, 1, 2, 7.9 and 11.8 ratio of atoms of sodium to moles of amyl chloride) of sodium the yields of total acids were 16, 17, 63, 90 and 95%, respectively, distributed between caproic 10, 12, 44, 68, and 69% (1.1, 2.4, 8.5, 13.1, and 13.2 g.) and butylmalonic acid 6, 5, 19, 22, and 26% (0.4, 0.7, 2.4, 2.9, and 3.4 g.). Decane was determined by fractionation, 40 ml. of Nujol being added in order to have a high boiling residue in the flask. In a test run, 10 ml. out of 10 ml. of decane was recovered in this manner. Corresponding yields of decane in the above series were 21, 21, 22, —, 3.8% (1.4, 2.51, 2.62, —, 0.44 g.). The blank space represents failure to estimate decane accurately because the Nujol method had not been developed at that time. The remainder of the product was a little high boiling residue but largely pentane and pentene, determined by difference. Results are shown graphically in Fig. 1. Attention is called to the stability of amylsodium under these conditions which even in the presence of excess amyl chloride (experiments with 0.5 atom of sodium to a mole equivalent of amyl chloride) failed to react completely. From this experiment 45% (7.9 g.) of unreacted amyl chloride was recovered. From all other experiments no such halide fraction was found. Another interesting fact is that the ratio of percentage yields of butylmalonic to caproic acid did not vary greatly in this series, being 0.6, 0.4, 0.4, 0.3, 0.4, respectively. These data are in accord with the view that the disodium compound is not a secondary product of amylsodium.

Effect of Benzene and Petroleum Ether Mixtures.—This series of experiments was made in expectation that yields of organosodium compounds might be higher if the alkyl- were converted to the relatively inactive phenylsodium. The series showed, however, that amylsodium did not react with benzene below 0° and that the use of a mixed solvent had little effect on the yields of organometallic reagents. Results from typical experiments are shown in Table I.

TABLE I

EXPERIMENTS IN MIXTURES OF PETROLEUM ETHER AND BENZENE AS SOLVENTS

Constant factors: sodium 30 g. in a mixture of benzene and petroleum ether, amyl alcohol 4 ml., amyl chloride 20 ml. in 40 ml. of benzene; addition temp. −0 to −4°, addition time one and one-half hours, stirring temperature 27°, stirring time two hours, carbonation at room temp.

Benzene–petroleum ether mixture		Carbonation products				
		Benzoic		Butylmalonic		Total,
Benzene, ml.	Petroleum ether, ml.	G.	%	G.	%	%
80	50	11.5	57	3	23	79
80	25	12.7	62	3	22	84
80	10	12.4	61	3	22	83
80	5	10.0	49[a]	1.5	11	60
80	25	10.5	54[b]	3	24	78

[a] Owing to the small amount of petroleum ether present, the benzene crystallized from the solution and prevented uniform stirring. [b] Caproic rather than benzoic acid because the temperature of stirring and carbonation was 0 to −4°. Amyl alcohol, 2 ml., used for activation.

Attention is called to (a) the lower yields in this series as compared with the one (90%) just previous, possibly because of the higher temperature at which these runs were made, (b) the constancy of the values for butylmalonic acid which were approximately the same as that in petroleum ether alone (22%) at −15 to −20° and which remained practically unchanged in the last experiment when carbonation was carried out at 0 to −4°, (c) the comparative inactivity of amylidenedisodium which did not react with benzene under these conditions, although amylsodium was entirely changed.

Decane.—The following experiments were made in order to see whether the yield of decane could be made approximately quantitative with respect to the amylsodium. Amylsodium was prepared from 20 ml. of amyl chloride and 2 atom equivalents (8 g.) of sodium sand according to the method used in studying the effect of varying the quantity of sodium. After the customary half hour of stirring at −15° the mixture was warmed to 30° and an additional lot of 20 ml. of amyl chloride added over a period of thirty minutes. The mixture was stirred for a half hour longer, carbonated and decomposed.

Caproic acid, 0.24 g. (0.6%), and butylmalonic acid, 0.17 g., were obtained. On fractionation 6.2 g. of amyl chloride and 7.6 g. of decane were recovered. The decane amounted to 40% of the amyl chloride actually consumed. The yield when the same experiment was carried out at −15° amounted to only 21%.

In the same apparatus with the same quantities of material but with the sodium being added to a solution of amyl chloride at 30° rather than amyl chloride to sodium, the yield of decane was 10 g. (41%). This last experiment was prompted by the idea that excess amyl chloride might act as a trap for amylsodium and thereby show whether the initial phase of the reaction were yielding a larger amount of amylsodium than was being obtained by the usual method. The decane formed, however, did not exceed the amount of amylsodium (44%) revealed by carbonation experiments.

High-boiling Compounds.—In order to see whether part of the amylsodium had been consumed during carbonation to form triamylcarbinol or other oxygen-containing substances, the non-acid products from eleven runs in petroleum ether as a solvent were combined and fractionated. The quantity represented was a total of 285 g. of amyl chloride, 430 g. of sodium activated by 41 g. of amyl alcohol from which 143 g. (46%) of caproic acid, 57 g. (27%) of butylmalonic acid, had been recovered. After removing 1 ml. of low-boiling material, 8.7 ml. of *n*-amyl alcohol and 24 ml. of decane, the residue consisting of 17 g. (only 7% of the total amyl chloride) was fractionated at 2 ml. pressure through an 8-plate column of the Podbielniak type. Six cuts were made from 44 to 114° but carbon (85%) and hydrogen (15%) determinations showed that no oxygen was present. A final residue of 2.5 g. was fractionated at 1 mm. in the apparatus of Peakes[5] yielding 1 g. at 110–130°, 0.5 g. at 130–170° and 0.6 g. at 170–230°. This last fraction contained 3% of oxygen and was the only one found not to be entirely a hydrocarbon. All fractions showed a positive test for unsaturation with permanganate.

(5) Peakes, Jr., *Mikrochemie*, **18**, 100 (1935).

In the case of experiments in benzene, however, there was evidence of considerable oxygen-containing material. From thirteen separate experiments made in mixtures of petroleum ether and benzene involving a total of 280 ml. of amyl chloride, 420 g. of sodium and 58 ml. of amyl alcohol for activation, there was obtained a grand total of 164 g. (58%) of benzoic acid, 21 g. (6%) of butylmalonic acid and 11 g. (4%) of caproic acid, this last material coming from one run listed in Table I in which the temperature of carbonation was kept at 0 to −4°. The non-acidic portions from these experiments were combined and the benzene and petroleum ether removed by distillation. Triphenylcarbinol, 4.4 g. (0.7%), crystallized from the residue and was identified by its melting point and mixed melting point with an authentic sample. The remaining 35 g. of residue was stripped of about 12 g. of amyl alcohol and decane and then fractionated at reduced pressures. The oxygen content of this high-boiling material changed from an initial zero value to 3.9% for the last fraction. This oxygen was apparently not due to triphenylcarbinol since no further quantity could be separated from these portions.

Summary

No decane is formed prior to formation of amylsodium in the reaction between amyl chloride and sodium.

This Wurtz synthesis is divided into two distinct phases, that concerned with formation of the organometallic compound and that related to reaction of this intermediate with addition of alkyl chloride.

If free radicals are present in the early phase, their activity is limited to addition with sodium or to disproportionation and combination of the -idene product with two atoms of sodium to form another organometallic compound.

Condensations by Sodium. XVII. Comments on the Formation of Triphenylene

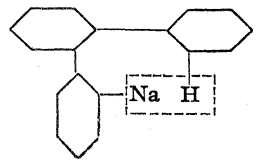
BY AVERY A. MORTON, JOHN T. MASSENGALE AND GRAHAM M. RICHARDSON

In an excellent paper by Bachmann and Clarke,[1] presence of around 2.0% of triphenylene among the products of the reaction of chlorobenzene and sodium was noted. Lately, Blum-Bergmann[2] has reported small quantities of the same compound from the reaction of phenylsodium and bromobenzene thus showing that this substance can arise from the second stage of a Wurtz synthesis. The importance of this material is that its formation is one of the major arguments for a free radical mechanism in Wurtz reactions, Bachmann and Clarke regarding its presence "among the reaction products as decisive in favor of the free radical explanation." In this paper we shall record the inadequacy of two other possible mechanisms not considered by the original investigators.

The first alternative is that *o*-phenylbiphenyl

(1) Bachmann and Clarke, THIS JOURNAL, **49**, 2089 (1927).
(2) Blum-Bergmann, *ibid.*, **60**, 1999 (1938).

could be metallated in the ortho position giving *o*-phenylbiphenylsodium, which then would split



out sodium hydride after the general method suggested for ethylsodium by Carothers[3] to form triphenylene. Under the conditions for isolating intermediate organometallic compounds employed in our work, triphenylene was shown to occur to a small extent from the reaction of chlorobenzene with sodium. Yet no evidence of metallation of *o*-phenylbiphenyl or of biphenyl itself by phenylsodium could be obtained. It is true that both of these hydrocarbons were metallated by amylsodium but no indication was observed that sodium hydride split from such a substance and formed triphenylene. Neither did the carrying out of a reaction between chlorobenzene and sodium in the presence of *o*-phenylbiphenyl produce any measurable conversion of that material into triphenylene.

The second proposition is that chlorobenzene could be metallated by phenylsodium giving chlorophenylsodium which could then condense with two similar molecules to give triphenylene. Substance is given to this idea by the work of Goldschmidt and Schön[4] suggesting that sodium and iodine might be present together in the cresol molecule, and by the work of Wittig[5] and of Gilman[6] in which lithium and bromine were likewise substituents together in methoxy containing compounds such as dimethoxybenzene and anisole. In the latter work indeed reference was made to a private communication from Wright that chlorobenzoic acid was obtained by carbonating the product of the reaction of chlorobenzene with sodium. Under conditions employed in our work, however, there is no evidence that a similar reaction occurred here. We have tested the action of both phenyl- and amylsodium on chlorobenzene under conditions which favor isolating such an intermediate product and find after carbonating no trace of chlorobenzoic acid.

Although the free radical mechanism is a convenient vehicle for expressing the manner in which triphenylene is formed, it does not necessarily follow that a similar mechanism has been demonstrated for occurrence of biphenyl, for the presence of such a small amount of triphenylene is equally explicable on the basis of its being the result of a side reaction wholly unrelated to the main one. In this connection it is worth noting that the free radical, phenyl, obtained by decomposition of phenylazotriphenylmethane by Wieland[7] showed no tendency to form biphenyl. The general comments relative to radicals (free or in a complex) and the role of organometallic compounds in Wurtz syntheses as mentioned in the paper just previous are worthy of consideration in this case also.

Experiments

Triphenylene and other Phenylated Polymers. (J. T. M.).—Formation of triphenylene under conditions employed in our work for isolating intermediate organometallic compounds was demonstrated by combining the high-boiling residues from nine separate experiments, in which chlorobenzene[8] (total of 550 g., 5.8 moles) had been added to sodium at room temperature to obtain a yield of approximately 75% of phenylsodium which was later used to metallate toluene. These high-boiling ends were distilled carefully through a fifteen-plate column. Out of 14.1 g. collected in three fractions from 135 to 155° at 2 mm., a total of 4.6 g. *o*-phenylbiphenyl, m. p. 52–53° (recorded[1] value 57°) was collected. A mixed melting point with an authentic sample (m. p. 55°) gave a value of 53–54°. The uncrystallizable oil from this fraction was adsorbed from a petroleum ether solution on 40–60 mesh activated alumina, giving several short indistinct bands at the top of the tube and one long band with deep blue fluorescence under the ultraviolet light. This last band was extracted with benzene yielding 0.9 g. of additional *o*-phenylbiphenyl, making a total of 1.5%.

From the fraction boiling from 155 to 165° there was isolated 0.3 g. of material melting at 144 to 146° which was not identified. The residue from the above distillation was distilled in a molecular still and the 4.8 g. of distillate was chromatographically adsorbed as described above. Several indistinct bands of a yellowish tint were in the top of the tube and one long band with a very bright blue fluorescence under the ultraviolet light in the lower portion. This material was also removed by benzene from which on evaporation fine needle-like crystals separated out of a viscous mother liquid. These were identified by their melting point of 192–194° (recorded[1] 199°, cor.) and by a mixed melting point (193–195°) with an authentic sample. The residual yellow liquid was dissolved in a mixture of petroleum ether and benzene and allowed to evaporate over a period of several days whereupon a mass of fine needle-like crystals and ten large diamond-shaped

(8) Morton and Massengale, THIS JOURNAL, **62**, 123 (1940).

crystals were deposited. The residual oil was sucked off by vacuum filtration and the crystals were washed quickly with a mixture of benzene and petroleum ether. The ten large crystals were then picked out with a pair of tweezers and brushed clean from the needles. Their weight was 0.1 g., melting point 115–117° (recorded[1] value for *o,o'*-diphenylbiphenyl is 118°) and mixed melting point with an authentic sample 117°.

Metallation of *o*-Phenylbiphenyl. (J. T. M.).—Phenylsodium was prepared from 64 g. (0.6 mole) of amyl chloride, 37 g. (2.7 atom equivalents) of sodium sand activated by 5 ml. of *n*-amyl alcohol in 600 ml. of benzene. Phenylbiphenyl, 10 g., was added and the solution stirred and refluxed at 73° for nineteen hours before cooling and carbonating. On distillation 81% of the phenylbiphenyl was recovered intact, together with smaller amounts contaminated with adjacent fractions. No trace of triphenylene could be detected in the final residue. The acid recovered proved to be entirely benzoic and amounted to 33 g. (46%).

The experiment was repeated and methyl iodide, 60 g. (0.42 mole) instead of carbon dioxide added to the supposedly metallated *o*-phenylbiphenyl since methyl iodide once before[9] proved to be a more sensitive reagent for testing occurrence of an exchange reaction. Toluene was the chief product and 91% of the 7.5 g. of *o*-phenylbiphenyl originally added was recovered pure. The remainder was present as contamination in adjacent fractions. No trace of triphenylene could be noted.

Amylsodium was prepared from 8 g. of amyl chloride and 2.7 equivalent atoms of sodium sand in 100 ml. of petroleum ether. *o*-Phenylbiphenyl, 11.3 g., was added, the mixture warmed for thirty minutes at 40° and then carbonated. A mixture of acids with a neutralization equivalent of 189 between that for a mono- (284) and a dicarboxylic acid (164) of the phenylbiphenyl compound was obtained after separating the benzoic acid. The unchanged hydrocarbon amounted to 80% and no trace of triphenylene was noted.

Phenylsodium was prepared from 30 g. of chlorobenzene and 6 g. of sodium sand in the presence of 7.5 g. of *o*-phenylbiphenyl in order to see whether the reaction in the presence of this hydrocarbon would provoke ring closure or if the hydrocarbon would be metallated. After four hours of stirring at 40° and carbonating the products, 30% of benzoic acid and 20% of diphenyl was obtained. Of the original hydrocarbon, 90% was recovered unchanged in one fraction. No triphenylene corresponding to the missing 10% could be noted.

Metallation of Diphenyl. (G. M. R.).—When amylsodium from 150 ml. of amyl chloride and 75 g. of sodium in petroleum ether were stirred for eighty-eight hours with 12 g. of biphenyl at room temperature, the mixture after carbonation showed definite evidence of the expected metallation. Caproic acid, 4.7 g. (3%) and ether soluble acids (13%) were recovered. From the brown gummy residue, after ether evaporation, a white crystalline acid, 0.7 g., with neutralization equivalent of 188 and melting point of 205° in the crude state was obtained. It appeared to be *p*-phenylbenzoic acid (224°). On purifying and converting to the methyl ester a melting point of 116–117° (recorded[10] value 117–118°) was obtained. More of this same material (0.7 g.) precipitated from a petroleum ether wash of the residue and 0.4 g. of still more impure material of similar properties was obtained on further extraction with petroleum ether. The residue consisting of 1.9 g. was extracted with ether, acetic acid and benzene and appeared to be a mixture of di- and tri-substituted acids but no definite product was isolated. The non-acid portion contained no biphenyl but after evaporation left 2.7 g. of a thick amber colored liquid which was distilled in a molecular still at temperatures ranging from 114 to 230°. From the three fractions thus collected no crystalline derivative such as might be expected from splitting out of sodium hydride from two molecules could be obtained.

Metallation of biphenyl by phenylsodium failed when a mixture of 8.8 g. of biphenyl in 100 ml. of benzene was added to amylsodium prepared from 38 g. of amyl chloride and 35 g. of sodium (activated by 2.5 ml. of amyl alcohol) in benzene at room temperature. After stirring at 27° for two hours and at 75° for one and one-half hours, the mixture was carbonated. No trace of acids of biphenyl could be noted, although 9.7 g. (26%) of benzoic acid was obtained. Curiously enough, 5.5 g. (22% or the usual amount) of butylmalonic acid was found, presence of biphenyl apparently being sufficient to prevent the exchange of amylidenedisodium with benzene even at 75°.

Attempted Metallation of Chlorobenzene. (J. T. M.).—The Beilstein[11] test was found to be unreliable as a test for halogen in benzoic acid since the purest samples could be made to give a green color. In order to test for very small traces of chlorobenzoic acid, 30 g. of pure benzoic acid and 0.1 g. of chlorobenzoic acid were treated with ethyl alcohol, benzene, and sulfuric acid as a catalyst, the water removed to effect complete esterification by means of a ternary mixture under a fractionating column of fifteen plates, the mineral acid separated by washing, and the ester then distilled. Chlorine could be detected readily in the last 1 ml. of distillate, either by the Beilstein test or by sodium fusion and subsequent testing with silver nitrate. In parallel experiments with benzoic acid, no chlorine could be observed. This method was applied to the combined benzoic acid residues from a number of preparations of phenylsodium from chlorobenzene and sodium but no evidence of chlorobenzoic acid could be found. Furthermore, a mixture of 11 g. of amyl chloride and 12 g. of chlorobenzene (0.1 mole of each) was dropped onto 0.5 atom of sodium in 200 ml. of petroleum ether. Addition and stirring time were one-half hour each. The temperature during these periods and during carbonation did not exceed 3° in order to make the conditions as favorable as possible for isolating chlorophenylsodium. The yield of benzoic acid was 1.9% based on the combined reactants and contained no detectable trace of chlorobenzoic acid when tested in the above manner. The hydrocarbon layers likewise gave no halogen tests in the fraction which boiled above the boiling point of chlorobenzene.

Phenylsodium was prepared from 43 g. of amyl chloride and 24 g. of sodium in benzene in the usual manner and treated dropwise with 68 g. of chlorobenzene over a period

(9) Morton and Fallwell, THIS JOURNAL, **60**, 1426 (1938).

(10) Meyer and Hofmann, *Monatsh.*, **38**, 353 (1917).

(11) Similarly the Beilstein test for chlorine was found (G. M. R.) to be worthless in the case of caproic acid.

of one hour and a half before carbonation. The mixture of acids obtained from this experiment gave no halogen test. Similarly amylsodium was prepared in petroleum ether and the mixture stirred for four hours at room temperature before carbonation. Tests for halogen in the acid and hydrocarbon fractions were negative.

Summary

o-Phenylbiphenyl and biphenyl are not metallated by phenylsodium but are by amylsodium.

Under the conditions in which organometallic compounds are isolated in this work no evidence of metallation of chlorobenzene could be detected.

Triphenylene is not formed under the conditions of this work either as a result of metallation of *o*-phenylbiphenyl or of chlorobenzene.

Condensations by Sodium. XVIII. A Study of the Possible Conversion of Amylsodium to Amylidenedisodium

BY AVERY A. MORTON AND GRAHAM M. RICHARDSON

In an earlier paper[1] primarily connected with formation of phthalic acid, curves related to exchange of amylsodium with benzene showed that with small amounts (5 ml.) of benzene a drop in yield of caproic acid appeared with an increase of butylmalonic acid. These results suggested conversion of amylsodium into amylidenedisodium at 42° and necessitated reëxamination of the subject. As a result of an extensive investigation we find: (a) that higher yields of butylmalonic acid are more apt to be obtained if the mixture of organosodium compounds is heated at 42° or stirred for a long time at room temperature but the results are very erratic and if such a change occurs it does not exceed 10%; (b) that at −15° where the experiments proved quite reproducible no hint of such a change has been observed even on long stirring; (c) that when benzene is used as a trap at room temperature amylidenedisodium is still formed. These results, together with the earlier work on this subject, confirm the original opinion[2] that the chief source of amylidenedisodium is not by way of amylsodium. Subject to the restriction on the nature of free radicals in these solutions as discussed in two papers just previous in this series, the view of a radical origin for this material appears the most reasonable.

Irrespective of whether conversion actually occurs, warming at 42° is reasonably successful as a general method of increasing the yield of butylmalonic acid. Higher temperatures (70–80°) have earlier[3] been shown to lead to decomposition. The erratic results (see Tables I and II) at 42° are probably due to thickening of the reaction mixture when warmed, a difficulty absent at −15°.

In hope that a nickel catalyst would labilize the hydrogen atom and promote the hoped for change, experiments were made in the presence of this metal. The results were unexpected in that no increase in butylmalonic acid was observed and that portion of the amylsodium which formerly had been converted to the disodium intermediate, was decomposed. Apparently a small amount only of the amylsodium is active, possibly because of particle size or because of a complex salt structure.

It might be argued from these facts that the original amylidenedisodium present before heating at 42° owed its origin also to a certain proportion of very active amylsodium. Against this notion some experiments in benzene can be cited. Amylsodium reacts readily with benzene at room temperature, thereby making it possible to use it as a trap. Amylidenedisodium reacts more slowly so that it is possible to find butylmalonic acid among the products of carbonation when addition of amyl chloride to sodium is made in benzene at room temperature. Indeed, when biphenyl was present (preceding paper) the disodium compound apparently was protected and the quantity of butylmalonic acid was essentially the same as when petroleum ether was the solvent. An especially active amylsodium, however, would be expected to be more active also toward benzene so that little or no disproportionation should occur. The same argument applies also to the

(3) Morton and Hechenbleikner, *ibid.*, **58**, 1697 (1936).

experiments under pressure of carbon dioxide reported[4] early in this series.

In the curve referred to at the beginning of this paper a second minimum (total acids) in addition to the first already discussed, was noted when a larger amount of benzene was added. This second point is now shown to be due in all probability to physical factors such as stirring. The reaction mixture becomes very thick during this exchange reaction and erratic results are therefore possible. As a result of a considerable number of experiments under greatly improved stirring, we find that it is possible to eliminate this second minimum entirely. Erratic results are still secured but under proper agitation the number is reduced materially. The reconstructed curve (Fig. 1) suggests that amyl- may be more closely related to phenyl-sodium and amylidenedisodium to phenylenedisodium than was at first suspected.

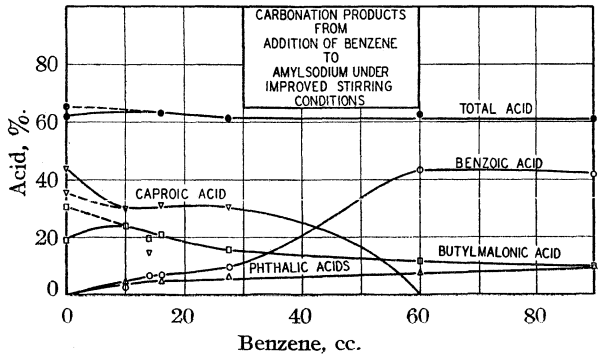

Fig. 1.—Carbonation products from addition of benzene to amylsodium under improved stirring conditions.

Much effort has been spent in order to effect 100% metallation of benzene by excess amylsodium in hope that the procedure would be useful in identification or analysis of benzene in certain petroleum fractions. The best results, however, did not reveal more than 50% of benzene converted to phenylsodium. In contrast to these results biphenyl is completely removed by amylsodium as shown in the paper just previous. This greater susceptibility toward metallation by amylsodium of biphenyl over benzene is particularly interesting since phenyl appears to have a greater affinity for sodium than the biphenyl radical.

Experiments

Effect of Warming Amylsodium.—The general conditions described in the two previous papers were applied to this work. Amyl chloride[5] was distilled before use and a fraction boiling at 107–108° was used. The quantities employed and the results obtained are listed in Tables I and II.

TABLE I

AMYLSODIUM PREPARED AT 18 TO 22°

Constant factors: amyl chloride 37.5 ml. diluted with 25 ml. of petroleum ether; sodium 17.5 g. activated with 2 ml. of *n*-amyl alcohol; petroleum ether 150 ml. at start of the reaction, more being added as the mixture thickened on heating; addition time one and one-half hours; carbonation at 22 to 28°.

No.	Hrs. stirring time at 27°	Hrs. stirring time at 42°	Yields of acids: Caproic G.	Caproic %	Butylmalonic G.	Butylmalonic %	Total, %
1	1	0	15.8	43	4.7	19	62
2	3	0	13.0	36	4.5	18	54
3	4	0	10.9	30	7.4	30	60
4	6	0	13.0	36	4.5	18	54
5	1	2	12.5	35	7.6	31	66
6	1	2	14.5	40	4.5	18	58
7	4	2	14.8	41	5.9	24	65

Attention is called to the first four experiments in which the time of stirring was gradually lengthened. In the four-hour period a yield of 30% of butylmalonic acid with a decreased yield of caproic acid was obtained. The inconsistency of this result is shown in experiment 4, in which such a change could not be effected even in six hours. Experiment 5 likewise gives a high yield of the dicarboxylic acid which was not duplicated in 6. Experiment 7 was intended to be a combination of the two best conditions noted before. Although the yield of the malonic acid in this case was disappointingly low, it nevertheless was the third highest in the whole series.

TABLE II

ADDITION OF AMYL CHLORIDE AT 0 TO −4°

Constant factors: amyl chloride 20 ml. diluted with 40 ml. of petroleum ether; sodium 30 g. activated by 2 ml. of *n*-amyl alcohol; petroleum ether 150 ml. at start of the reaction; addition time one hour; carbonated at 0 to −4°.

No.	Hrs. stirring time at 0–4°	Hrs. stirring time at 42°	Yields of acids: Caproic G.	Caproic %	Butylmalonic G.	Butylmalonic %	Total %
8	3.5	0	11.0	58	2.9	22	80
9[a]	0.5	0	10.8	56	2.5	20	76
10	.5	0	11.5	60	3.0	23	83
11	.5	1	11.5	60	3.4	26	86
12	.5	2	13.1	68	3.1	21	89
13	.5	2	10.9	57	2.4	18	75
14	.5	3	10.1	53	4.0	31	84
15	.5	8	9.8	51	3.6	27	78

[a] Special attention is called to the changes which occur in experiments 9 to 15, in which the time of heating at 42° gradually was extended to eight hours.

In one experiment only could the yield of butylmalonic acid be raised to 31% although the second highest yield was one in which long heating had been applied. The only suggestion of consistency in these results is that the two experiments which were heated for the longest time

(4) Morton and Hechenbleikner, THIS JOURNAL, **58**, 754 (1936).

(5) Amyl chloride was furnished by the courtesy of the Sharples Solvent Corporation.

had the highest yields of butylmalonic acid and the lowest yields of caproic acid.

In another experiment, using the same quantity of reagents given in Table II but carrying out the addition at −15 to −20°, the stirring time at that same temperature was varied from one-half hour to four hours. Carbonation at the same low temperature resulted in the same yields in both cases for butylmalonic acid, 2.9 g. or 22% but the yield of caproic acid fell during that period from 13 to 11 g. (68 to 59%).

Experiments with a Nickel Catalyst.—The conditions were the same as those employed in Table II except that nickel catalyst prepared from 4 g. of Raney nickel was employed under the conditions specified.

TABLE III

No.	Hrs. stirring time at 0 to −4°	Hrs. stirring time at 42°	Yields of acids: Caproic G.	Caproic %	Butylmalonic G.	Butylmalonic %	Total %
16	3.5[a]	0	11.5	60	3.0	23	83
17	0.5[a]	3	10.1	53	2.4	18	71
18	.5[b]	3	10.0	52	3.0	23	75

[a] Catalyst present during addition of amyl chloride. [b] Catalyst added after addition of amyl chloride.

Experiment 16 was almost an exact duplicate of experiment 8 in Table II and shows that nickel was without appreciable effect as long as the mixture was not heated. Experiment 17 is a duplicate of number 14 and shows that while caproic acid decreased the butylmalonic acid was not increased. Experiment 18 likewise shows the effect of nickel on amylsodium. Yields of caproic acid in 17 and 18 are as low as the two lowest in Table II.

Experiments in Benzene.—The results listed in Table IV show the formation of amylidenedisodium (butylmalonic acid) from amyl chloride and sodium in presence of solvent used as a trap for amylsodium. Addition temperature in all cases was at 18–22°. Carbonation temperature was at 22 to 28°. All results and special conditions are listed in the accompanying table with explanatory notes.

TABLE IV

No.	Yields of acids: Benzoic G.	Benzoic %	Butylmalonic G.	Butylmalonic %	Total %
19[a]	14.4	38	2.5	10	48
20[b]	30.0	40	3.3	7	47
21	27.9	37	4.9	10	47
22	9.7	26	5.5	22	48

[a] Experiment 19: amyl chloride 37.5 ml., sodium 53 g. activated by 7.5 ml. of amyl alcohol, 500 ml. creased flask as a reaction vessel. Addition time three hours, stirring at 27° for one hour. [b] Experiment 20: amyl chloride 75 ml., sodium 35 g., 1-l. three-necked flask as a reaction vessel, addition time two and one-half hours. Stirring time four hours at 27°. From among the products phthalic acid (iso- and tere- mixture) 3.2 g. or 6% was isolated also. In experiment 21, conditions were the same as in 20 except that a 1-l. creased flask was used as the reaction vessel. Experiment 22 is the one which contained biphenyl and is described in the paper immediately preceding. A trace of the phthalic acid was formed.

Exchange Reaction of Amylsodium with Benzene.—In these experiments a 500-ml. creased flask was used to effect better agitation. Amyl chloride, 37.5 ml., mixed with an equal quantity of petroleum ether was added dropwise over a one and one-half hour period to 35 g. of sodium sand activated with 5 ml. of alcohol, and suspended in 250 ml. of petroleum ether; addition temperature was 18 to 22°. After addition was complete the mixture was stirred at 25 to 30° for one hour. Benzene was then usually added and the mixture with or without benzene heated at 42° for two hours. Carbonation was at 22 to 28°. Quantities of benzene added in separate experiments were 10, 14, 16, 27.5, 60 and 90 ml. Corresponding yields of acids are caproic: 10.7, 5.4, 11.2, 11.0, 0 and 0.9 (30, 15, 31, 0, 0.7%); butylmalonic acid 5.9, 4.9, 5.1, 3.9, 2.9 and 2.5 g. (24, 20, 21, 16, 12 and 10%); benzoic acid, 1.1, 2.5, 2.5, 3.5, 16.4 and 15.8 g. (3, 7, 7, 9, 43 and 41%); phthalic acid 1.1, 0.7, 1.2, 1.6, 2.0 and 2.5 g. (4, 3, 5, 6, 8 and 10%). In the graph the values for zero benzene are from two separate observations in one of which (dotted line) the conversion did not occur.

Attempted Quantitative Metallation of Benzene.—In addition to the foregoing experiments, 5 ml. of benzene was put in the solvent before addition of amyl chloride and treated in the usual manner. Not more than 28% of this benzene was converted to benzoic and phthalic acids. In another case, 5 ml. of benzene was added after addition of amyl chloride was completed and the mixture then stirred at room temperature for seventy-two hours. In this way 50% of the benzene was converted to acids.

Summary

Amylidenedisodium frequently is obtained in somewhat higher yields if the mixture is warmed at 42° or is stirred for a very long time. Simultaneously lower yields of caproic acid are usually found. These results suggest that amylsodium is capable of being converted into amylidenedisodium but the change is an uncertain one and does not exceed 10% at the most.

Active nickel appears to decompose a portion of the amylsodium at 42°.

Under appropriate conditions butylmalonic acid is one of the carbonation products of the reaction of amyl chloride on sodium in benzene solution although amylsodium is completely removed by the solvent at room temperature.

Small quantities of benzene are not quantitatively metallated by amylsodium.

Further Evidence on the Mills–Nixon Effect

BY WARREN C. LOTHROP

In view of much recent evidence[1] indicating that in the case of hydrindene no quantitative stabilization of one Kekulé form exists as had been proposed,[2] it seemed well to describe some further confirmatory observations of our own. The successful diazo coupling of 5-hydroxy-6-methylhydrindene[3] gave evidence in agreement with the above, and Table I contains the results of these coupling tests on 0.1-g. samples with excess diazotized *p*-nitroaniline.

TABLE I

Case	Soln., cc.	*N* NaOH	Crude product, g.	% yield
1	10.5	0.119	0.072	35.9
2	11.0	.226	.046	23.0
3	12.0	.415	.029	14.5
4	14.0	.679	.017	8.5
5	16.0	.932	.009	4.5
6	20.0	1.24	.002	1.0
7	15.0	2.49	.001	0.5

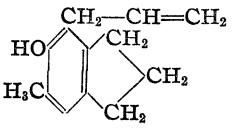
The apparent importance of the alkaline concentration to the coupling was investigated in further tests using buffered solutions and the theoretical quantities of a freshly prepared solution of *p*-nitrobenzenediazonium sulfate with the results given in Table II as the percentage yield of alkaline insoluble material. This seemed justifiable since the coupling products are the chief substances present which are insoluble in alkali and have all been reported and prepared by the same method. These figures indicate that the derivatives of hydrindene and tetralin are all inferior to β-naphthol in coupling ability and are more comparable with 2,4-dimethylphenol.

TABLE II

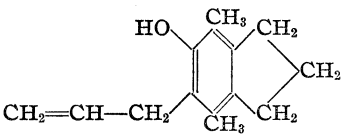
PER CENT. YIELD OF CRUDE COUPLING PRODUCT

Compound	*p*H 7.5	*p*H 11.3	10% NaOH
β-Naphthol	95.0	96.0	4.0
2,4-Dimethylphenol	71.5	52.5	5.8
5-Hydroxy-6-methylhydrindene (I)	69.0	68.7	0.5
5-Hydroxy-4,7-dimethylhydrindene (II)		69.5	5.7
6-Hydroxy-5,8-dimethyltetralin		55.5	7.0
1-Benzyl-2-hydroxynaphthalene	Alkali-soluble tars		
1,5-Diallyl-2,6-dihydroxynaphthalene	Alkali-soluble tars		

While this evidence seemed sufficient to classify hydrindene among the benzenoid compounds, samples of both I and II were converted into their allyl ethers and subjected to pyrolysis in sealed tubes, when both the ethers underwent the Claisen rearrangement to yield the corresponding substituted phenols (III) and (IV)



III



IV

These results are in complete agreement with all the evidence cited and with the similar case of fluorene.[4]

In conclusion the author wishes to express his appreciation to Professor L. F. Fieser for many helpful suggestions.

Experimental Part

The **preliminary coupling tests** (Table I) require no special description, but for the **buffered coupling tests** (Table II) the procedure was varied from the usual in that dioxane (5 to 10 cc.) was added to each 10-cc. portion of the buffer (containing 0.000675 mole of the substance to be tested) in order to achieve complete solution. The buffers were standard sodium and potassium phosphate mixtures, and the standardized diazonium solution was prepared[5] and standardized[6] as described in the literature.

5-Alloxy-6-methylhydrindene (allyl ether of I).—A mixture of 2.0 g. of 5-hydroxy-6-methylhydrindene (I), 2.2 g. of powdered anhydrous potassium carbonate and 1.8 g. of allyl bromide in 50 cc. of methyl ethyl ketone was refluxed for sixty-four hours and poured into water. The light brown oil which separated was warmed with 5% potassium hydroxide for one hour, recovered by ether extraction and distilled *in vacuo*, being thus obtained as a colorless oil (b. p. 95–97° at 3 mm.). The yield was 2.5 g. or 98%.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.92; H, 8.55. Found: C, 82.90; H, 8.88.

4-Allyl-5-hydroxy-6-methylhydrindene (III).—A mixture of 0.97 g. of the above allyl ether and 2.75 g. of dimethylaniline was heated in a sealed tube at 245° for

one hour. The pale brown solution was then poured into cold dilute hydrochloric acid. On standing the product solidified in faintly purple needles. It weighed 0.83 g. (86%) and was soluble in alkali. The material had a phenolic odor and showed a characteristic tendency to sublime, filling the tube in which it was stored with a dense mass of fine needles (m. p. 43–45°).

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.92; H, 8.55. Found: C, 82.86; H, 8.74.

5-Alloxy-4,7-dimethylhydrindene (allyl ether of II).—A mixture of 2.2 g. of 5-hydroxy-4,7-dimethylhydrindene (II) 2.2 g. of finely powdered anhydrous potassium carbonate and 1.8 g. of allyl bromide in 35 cc. of methyl ethyl ketone was refluxed for twenty-four hours. The product was a colorless oil distilling at 107–108° at 2 mm. The yield was nearly quantitative.

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.14; H, 8.95. Found: 3, 83.20; H, 8.70.

5 - Hydroxy - 6 - allyl - 4,7 - dimethylhydrindene (IV).—When a mixture of 1.34 g. of the above allyl ether and 3.00 g. of dimethylaniline was heated to 280° in a sealed tube and the amine was removed by dilute hydrochloric acid, the product was obtained in 75% yield as a pink solid. The color was removed by two crystallizations from petroleum ether but always returned on standing in contact with air. A sample stored in the ordinary way turned a bright violet in the course of two months while one kept in a sealed tube showed no color change. The melting point remained unaffected, however, at 66–67°.

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.14; H, 8.95. Found: C, 83.38; H, 8.94.

Summary

The diazo coupling of and the rearrangement of the allyl ethers of 5-hydroxy-6-methylhydrindene and 5-hydroxy-4,7-dimethylhydrindene have been investigated with results which concur with much other evidence that the Mills–Nixon effect is at the most qualitative in the case of hydrindene.

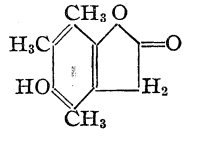
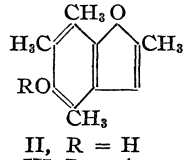
The Reaction between Quinones and Metallic Enolates. X. Trimethylquinone and the Enolates of β-Diketones[1]

BY LEE IRVIN SMITH AND E. W. KAISER[2]

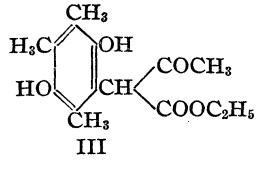
A few years ago, Smith and MacMullen[3] added the enolates of malonic ester and acetoacetic ester to trimethylquinone. From the malonic ester addition, one product, the isocoumaranone I, was obtained, while the addition of acetoacetic ester led to two substances, the isocoumaranone I, and the coumaron II. The formation of these products



I



II, R = H
IX, R = Ac



III

was interpreted as a primary 1,4-addition of the enolate to the quinone conjugated system which carried no substituent in the β-position, to give III (from acetoacetic ester), followed by the usual cleavages and ring closure.

Ionescu[4] studied the reaction between acetylacetone and *p*-benzoquinone. The reaction was interpreted as an initial 1,4-addition of the β-diketone (two molecules), leading first to IV (not isolated) which was then oxidized by excess quinone or by air to V (also not isolated). The latter

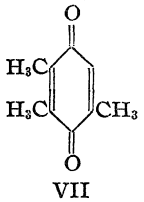
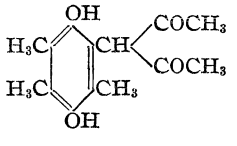
substance then underwent ring closure by elimination of water between the quinone oxygen atoms and a methyl group in each of the side chains, to give the final product, which was represented as VI. This substance VI is essentially a methylenequinone, and its formation from IV or V by ring closure involving a break in the carbon–oxygen bond of the quinone V or hydroquinone IV represents a rather unusual type of reaction.

In order to study this reaction, as well as to extend the general study of the addition of enolates to quinones, we have investigated the addition of the enolates of two β-diketones (acetylacetone and acetylisobutyrylmethane) to trimethylquinone VII. This quinone was chosen because it has but one open position, and previous work[3] had indicated that only one molecule of enolate would add to a quinone substituted in this manner. Moreover, since the first reaction products would be substances of the type of III, it seemed possible that this reaction might serve as a useful method for preparation of a variety of 5-hydroxycoumarons, which would be useful as sources of model compounds for use in investigations of certain phases of the chemistry of vitamin E.

When a dilute alcoholic solution of the quinone VII was added slowly to the enolate of acetylacetone, the product, formed in 72% yield, was the phenylacetyl acetone VIII. This substance reacted with phenylhydrazine, and was readily converted into the known coumarone II by action of hot concentrated hydrochloric acid.

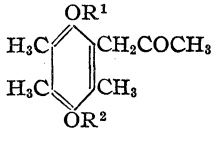


VII



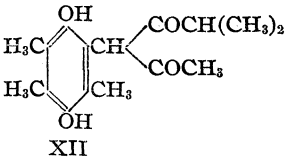
VIII

X, $R^1 = R^2 = Ac$
XI, monoxime of X
XIV, $R^1 = (CH_3)_2CHCO$; $R^2 = Ac$
XV, monoxime of XIV
XVII, $R^1 = Ac$; $R^2 = (CH_3)_2CHCO$
XVIII, $R^1 = Ac$; $R^2 = CH_2ClCO$

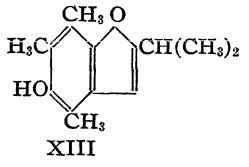


The action of acetic anhydride containing a trace of sulfuric acid upon the diketone VIII resulted in acetylation of both hydroxyl groups and the simultaneous loss of one of the acetyl groups from the β-diketone residue. The product X formed a monoxime XI, gave a negative phenol test (Folin), and was transformed by hot concentrated hydrochloric acid into the coumaron II. Attempts were made to hydrolyze the acetate X to the dihydroxy compound, using dilute sodium hydroxide, but this reagent also transformed X into the coumaron II, even at room temperature. Dilute hydrochloric acid under varying conditions either did not attack the acetate X, or else transformed it into the coumaron. From these results, and analogy with previous work,[3] there appears to be little doubt concerning structure VIII for the primary product of the reaction.

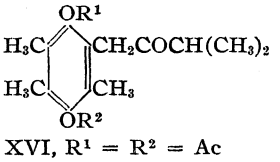
When the enolate of acetylisobutyrylmethane was added to the quinone VII, the product, formed in 81% yield, was the phenylated diketone XII. This substance reacted with phenyl-



XII



XIII



XVI, $R^1 = R^2 = Ac$

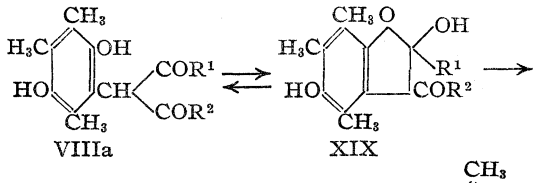
hydrazine, and was converted by action of hydrochloric acid into a mixture of coumarons, II and XIII, although the pure compounds were not separated from this mixture. Acetylation of XII with acetic anhydride containing a trace of sulfuric acid produced a mixture, from which a substance having the composition $C_{18}H_{24}O_5$ was isolated. This substance formed a monoxime XV, and in analogy with the acetylation of VIII, it was at first thought that the substance was the diacetoxybenzyl isopropyl ketone, XVI. However, when it was discovered that the action of hot hydrochloric acid upon $C_{18}H_{24}O_5$ produced the coumaron II, it became obvious that this compound could not possess the side chain of XVI, but must contain the acetone side chain of X, since XVI, on cyclization, would produce the coumaron XIII. Since $C_{18}H_{24}O_5$ gave a negative phenol test, and since it was isomeric with XVI, only two formulas for it were possible: XIV and XVII.

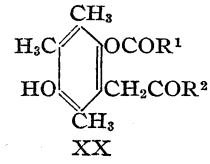
The choice between XIV and XVII was made as follows: the diketone VIII from acetylacetone was acylated with isobutyric anhydride. The product, XVII, formed in 56% yield, was a new substance also having the composition $C_{18}H_{24}O_5$. This substance also gave a negative phenol test. When VIII was acylated with chloroacetic anhy-

dride a product XVIII resulted which contained only one chloroacetyl group. It followed, therefore, that when substances of the type of VIII and XII were acetylated, the reaction involved a migration of one of the acyl groups from the diketone side chain to the *ortho* oxygen atom, and simultaneous acylation of the other hydroxyl group by the acylating agent used. On this basis, the first substance was assigned structure XIV, while its isomer, obtained from isobutyric anhydride and VIII, was assigned structure XVII. It followed also that the chloroacetyl derivative XVIII had an analogous structure; that is, an acetyl group of VIII migrated from the side chain to the *ortho*-oxygen atom, and simultaneously the other hydroxyl group was chloroacetylated.

That the reaction is a true intramolecular rearrangement is indicated by the yields of the products obtained in these acylations. If the reaction involved a complete rupture of an acyl group from the molecule, this acyl group would then be present in the reaction mixture as an acid, a simple anhydride, or a mixed anhydride, together with a large excess of the acylating agent used. Under these circumstances, *acetylation* of XII could give rise to no less than seven different compounds. Unless the isobutyryl group had a *much* greater acylating power than any of the other possible acyl groups, it could not have left the molecule entirely and then reëntered at some other position to give over 30% of XIV in the presence of a large excess of acetic anhydride. The fact that cleavage of the mixed β-diketone XII could occur in more than one way renders the probability of isolating XIV in good yield even less likely, assuming a mechanism which involved cleavage. Moreover, chloroacetic anhydride is much more reactive toward the hydroxyl group than is acetic anhydride, while isobutyric anhydride is the least reactive of the three in this respect.[5] Therefore, if in the acylation of VIII with either chloroacetic anhydride or isobutyric anhydride, the cleavage of an acetyl group had occurred to give acetic anhydride, competing reactions would have resulted in the formation of acylation products containing two chloroacetoxy groups in one case and two acetoxy groups in the other. Actually, however, the acylating agent used supplies only one acyl group; the other acetoxy group is derived from one of the acyl groups in the β-diketone side chain.

These results can be explained by assuming a primary ring closure between one carbonyl group of the β-diketone VIIIa and the *ortho* hydroxyl group to give a hemiacetal, XIX. This intermediate, being a potential β-diketone, can be cleaved to give the final product, a phenolic ester XX





This cleavage is analogous to the well-known decarboxylation of certain β-hydroxy acids which occurs on dehydration, and also to the cleavage of the addition products of certain β-diketones and Grignard reagents, observed by Kohler and Erickson.[6]

In these rearrangements, there is involved the shift of an acyl group from carbon to oxygen. Such rearrangements are very unusual, the reverse shift, from oxygen to carbon, being the common type. Nevertheless, a few examples of this sort have been recorded. Thus Kohler and Erickson[6] found that addition of one mole of phenylmagnesium bromide to diphenyl triketone XXI produced not the expected phenyldibenzoylcarbinol XXII but the benzoate of benzoin XXIII. Likewise, Blatt and Hawkins[7] reported that dibenzoylcarbinol XXIV, when vacuum distilled, rearranged to the benzoate of benzoylcarbinol XXV.

$C_6H_5COCOCOC_6H_5$ XXI

$(C_6H_5CO)_2C(OH)C_6H_5$ XXII

$C_6H_5COCH(C_6H_5)OCOC_6H_5$ XXIII

$C_6H_5COCHOHCOC_6H_5$ XXIV

$C_6H_5COCH_2OCOC_6H_5$ XXV

Attempts were made to add *n*-butyrylacetylmethane, benzoylacetone, and dibenzoylmethane to trimethylquinone, without success. Addition of the first of these diketones led to an oil, which could not be crystallized; addition of benzoylacetone produced only a very small amount of tan solid; while the only product obtained when dibenzoylmethane was used was unchanged diketone.

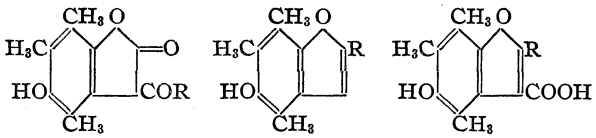
The method of Smith and MacMullen has been used by Bergel, Jacob, Todd and Work[8] for the preparation of coumaron and coumaran derivatives; from the product of addition of acetoacetic esters to trimethylquinone, these authors isolated three substances, the acyl isocoumaranone XXVI (main product), the coumaron XXVII, and the coumaron carboxylic acid XXVIII (R = $C_{15}H_{31}$ and $C_{17}H_{35}$).



XXVI XXVII XXVIII

Karrer, Escher and Rentschler[9] have also used the method; by addition of propionylacetic ester to the quinone they obtained the coumaron XXVIII (R = C_2H_5).

Repetition of the experiment of Smith and MacMullen[3] under slightly different conditions, has led to a good yield of the isocoumaranone XXVI (R = CH_3). This substance is a solid which melts at 126.5–128°; when steam distilled, it is transformed into the two products obtained by Smith and MacMullen, *viz.*, the isocoumaranone I and the coumaron II. Neither the intermediate III nor the coumaron acid (XXVIII, R = CH_3) was obtained, although these substances may have been formed in small amounts and lost in the purification of the main product, which required several crystallizations.

Experimental Part[10]

Acetylacetone and acetylisobutyrylmethane were prepared by the method of Sprague, Beckham and Adkins.[11] **Acetylacetone** was distilled several times through a Widmer column and the fraction boiling at 135–136°, obtained in 27% yield, was used. **Acetylisobutyrylmethane**, purified in a similar manner, boiled at 159–161° and was obtained in 20% yield.

Trimethylquinone (VII) was prepared by the method of Smith, Opie, Prichard and Wawzonek.[12]

(3,6 - Dihydroxy - 2,4,5 - trimethylphenyl) - acetylacetone, VIII.—Acetylacetone (3.8 g., 0.038 mole) was added to alcoholic sodium ethoxide (prepared from sodium, 0.75 g., 0.0326 mole, and dry ethanol, 12 cc.). The solution was cooled (0°) and stirred, and to it was added slowly (twelve hours) a solution of trimethylquinone (2.25 g., 0.015 mole) in dry ethanol (30 cc.). The resulting deep purple solution was stirred for an hour at room temperature, and then, with cooling (0°) and stirring, concd. hydrochloric acid was added dropwise until the color changed to light yellow. The acidified mixture was poured over cracked ice (300 g.) and the solid (2.7 g.) was removed and crystallized from benzene–petroleum ether (b. p. 90–100°). The product was white and melted at 129–130°.

Anal. Calcd. for $C_{14}H_{18}O_4$: C, 67.16; H, 7.21. Found: C, 67.47; H, 7.28.

Reaction with Phenylhydrazine.—The diketone VIII (0.32 g.) was dissolved in ethanol and water was added until the first trace of turbidity resulted. Phenylhydrazine (0.5 cc.) and acetic acid (1 drop) were added. A solid precipitated almost immediately. After standing overnight, this was removed and crystallized from ethanol. It weighed 0.43 g., and melted at 205–206° with decomposition. The structure was not investigated.

Anal. Found: C, 69.41; H, 6.94.

2,4,6,7-Tetramethyl-5-hydroxycoumaron (II).—The diketone VIII (0.5 g.) was refluxed with concd. hydrochloric acid (30 cc.) and ethanol (1 cc.) for three and one-half hours. Water (70 cc.) was added and the mixture was steam distilled. The product (0.3 g.) was isolated from the distillate and crystallized from dilute ethanol. It melted at 138–139°, alone or when mixed with an authentic specimen.[3]

2,4,6,7-Tetramethyl-5-acetoxycoumaron IX.—The coumaron II (0.5 g.) was acetylated in the usual way with acetic anhydride (2.1 cc.) and a drop of sulfuric acid. The product (0.46 g.) after crystallization from dilute ethanol, melted at 91–92°.

Anal. Calcd. for $C_{14}H_{16}O_3$: C, 72.39; H, 6.92. Found: C, 72.13; H, 7.12.

(3,6-Diacetoxy-2,4,5-trimethylphenyl)-acetone X.—The diketone VIII (1.04 g.) was acetylated with acetic anhydride (6.2 cc.) and a drop of sulfuric acid. The reaction was slightly exothermic and the diketone slowly dissolved. After standing at room temperature for an hour, the mixture was poured over ice (75 g.). The product (0.99 g., 81%) melted at 130–132°; after crystallization three times from petroleum ether (b. p. 90–100°), it melted at 135.5–136.0°. The material gave a negative Folin test and was insoluble in cold 10% sodium hydroxide. Attempts to remove the acetyl groups from this ketone invariably gave either unchanged material or the coumaron II. Dilute (0.12 *N*) hydrochloric acid was without action during eight hours at 65°; the action of more concentrated acid (1 *N*) at 100° for seven hours led to a mixture of starting material and II; while concentrated acid (12 *N*) gave only the coumaron. Likewise dilute sodium hydroxide gave only the coumaron.

Anal. Calcd. for $C_{16}H_{20}O_5$: C, 65.71; H, 6.91. Found: C, 65.91; H, 7.42.

Oxime XI.—The oxime (0.12 g.) was prepared from the ketone X (0.16 g.) in the usual way. The crude product melted at 160–162°; after several crystallizations from dilute ethanol, the monoxime melted at 172–175° with decomposition. The oxime dissolves immediately in 10% sodium hydroxide, giving a yellow solution.

Anal. Calcd. for $C_{16}H_{21}O_5N$: C, 62.48; H, 6.90; N, 4.56. Found: C, 63.02; H, 7.18; N, 4.55.

(3 - Isobutyroxy - 6 - acetoxy - 2,4,5 - trimethylphenyl)-acetone, XVII.—The diketone VIII (0.53 g., 0.0021 mole) was dropped into isobutyric anhydride (5.3 cc.) and sulfuric acid (2 drops) at room temperature. After two hours, all of the solid dissolved. After seven hours, the mixture was poured over ice (75 g.) and concd. ammonium hydroxide (8 cc.) was added. The solid was removed and washed thoroughly with water. It weighed 0.38 g. (56%) and melted at 117.5–123°. After crystallization from petroleum ether, the white solid melted at 127.5–128°. It gave a negative Folin phenol test.

Anal. Calcd. for $C_{18}H_{24}O_5$ (XVII): C, 67.46; H, 7.57; mol. wt., 320. Calcd. for $C_{22}H_{30}O_6$ (diisobutyrate of VIII): C, 67.66; H, 7.75; mol. wt., 390. Found: C, 67.55; H, 7.43; mol. wt. (Rast), 336, 302.

(3 - Chloroacetoxy - 6 - acetoxy - 2,4,5 - trimethylphenyl)-acetone, XVIII.—The diketone VIII (0.53 g., 0.0021 mole) was warmed (45–50°) with chloroacetic anhydride (6 g., 0.0033 mole) for an hour and fifteen minutes. The mixture was poured onto ice (75 g.) and allowed to stand for fifteen minutes. The oily solid was removed and washed several times with small portions of petroleum ether (b. p. 28–38°). It melted at 47–53° and was contaminated with much chloroacetic anhydride. The aqueous filtrate, on standing overnight, deposited 0.1 g. (17.5%) of a white solid (XVIII), which after several crystallizations from benzene–petroleum ether (b. p. 90–100°) melted at 162–163°. Although the yield of pure solid was poor, the actual yield of product was undoubtedly much higher. This substance gave a strongly positive Folin test, which, however, was of little consequence since chloroacetic anhydride itself gave a positive test.

Anal. Calcd. for $C_{16}H_{19}O_5Cl$: C, 58.79; H, 5.85. Found: C, 59.02; H, 6.29.

(3,6 - Dihydroxy - 2,4,5 - trimethylphenyl) - acetylisobutyrylmethane XII.—Acetylisobutyrylmethane (10 g., 0.078 mole) was added to alcoholic sodium ethoxide (prepared from sodium, 1.51 g., 0.066 mole, and dry ethanol, 14 cc.). The solution was cooled (0°) and stirred, and to it was added slowly (two hours) a solution of trimethylquinone (4.95 g., 0.033 mole) in dry ethanol (20 cc.). Stirring was continued for half an hour at room temperature after the addition, and then, with cooling (0°) and stirring, concd. hydrochloric acid was added dropwise until the deep violet color changed to yellow. The acidified mixture was poured onto ice (250 g.), the solid was removed and washed three times with petroleum ether (25 cc. each time, b. p. 40–70°) and once with water (25 cc.). The product XII weighed 7.43 g. (81%). After crystallization from dilute ethanol or benzene–petroleum ether (b. p. 90–100°) the substance formed colorless needles which melted at 131.5–132.5°.

Anal. Calcd. for $C_{16}H_{22}O_4$ (XII): C, 69.02; H, 7.97. Calcd. for $C_{12}H_{16}O_3$ (X, $R^1=R^2=H$): C, 69.30; H, 7.67. Found: C, 69.36; H, 7.98.

Reaction with Phenylhydrazine.—The diketone XII (0.32 g.) reacted with phenylhydrazine (0.5 cc.) and acetic acid (3 drops) in dilute alcohol, to give a product (0.3 g.) which melted at 167° with decomposition. The structure of this compound was not investigated.

(3 - Acetoxy - 6 - isobutyroxy - 2,4,5 - trimethylphenyl)-acetone XIV.—The diketone XII (1.64 g., 0.0059 mole) was dropped into acetic anhydride (12 cc.) containing a drop of sulfuric acid. The mixture became warm, and the solid dissolved. After standing for an hour, the solution was poured onto ice (75 g.). The solid was removed, washed with water, and dried. It weighed 1.44 g. After crystallization from petroleum ether (b. p. 90–100°), the solid weighed 0.52 g. and melted at 114–115.5°.

Anal. Calcd. for $C_{18}H_{24}O_5$: C, 67.46; H, 7.57. Found: C, 67.19; H, 7.27.

The filtrate on evaporation, left a mixture which melted at 100–115°.

When the ketone XIV (0.25 g.) was refluxed with concd. hydrochloric acid (17 cc.) for two and one-half hours, the product (0.13 g.) was the coumaron II, m. p. and mixed m. p., 137–138°.

Anal. Calcd. for $C_{12}H_{14}O_2$ (II): C, 75.75; H, 7.42. Calcd. for $C_{14}H_{18}O_2$ (XIII): C, 76.99; H, 8.33. Found: C, 75.57, 75.42; H, 7.81, 7.60.

Oxime XV.—The ketone XIV (0.24 g.) was converted to the oxime (0.1 g.) in the usual way. After crystallization from dilute ethanol, the product melted at 165–170° with decomposition. When mixed with the oxime XI, the substance melted at 150–160°.

Anal. Calcd. for $C_{18}H_{25}O_5N$: C, 64.41; H, 7.56; N, 4.18. Found: C, 64.50; H, 7.47; N, 4.51.

Cyclization of XII.—The diketone (0.53 g., 0.0019 mole) was refluxed for two and a half hours with concd. hydrochloric acid (25 cc.) and ethanol (1 cc.). The reaction mixture, after dilution with water, was steam distilled. The white solid (0.36 g.) which was removed from the distillate melted at 100–125°. This mixture probably consisted of the coumarons II and XIII, but the amount of material available was too small for fractional crystallization.

Addition of Other Diketones.—(a) Trimethylquinone (0.65 g.) was added to the sodium enolate of *n*-butyrylacetylmethane (from 1.3 cc. of diketone) in dry ethanol as described for the addition of acetylacetone. The only product was an oil which could not be crystallized. (b) The quinone (1.65 g.) in dry ethanol (10 cc.) was added to a suspension of sodium benzoylacetone (sodium, 0.58 g., diketone, 4.1 g., ethanol, 10 cc.) in the same manner. Only a few milligrams of a tan solid, m. p. 110–120°, was obtained. (c) The quinone (0.75 g.) in ethanol (10 cc.) was added to a suspension of the enolate of dibenzoylmethane (sodium, 0.21 g., diketone, 2.20 g., ethanol, 30 cc.) as described. The only product was dibenzoylmethane, m. p. and mixed m. p. 74–76°.

3 - Acetyl - 4,6,7 - trimethyl - 5 - hydroxyisocoumaranone (XXVI, R = CH_3).—Acetoacetic ester (5.7 g.) was added to a solution of sodium ethoxide prepared from sodium (0.97 g.) and dry ethanol (20 cc.). The quinone (3.1 g.) in ethanol (2 cc.) was gradually added and the deep purple solution was allowed to stand at room temperature for three and one-half hours. The reaction mixture was poured into ice (200 g.) and hydrochloric acid (20 cc.). The product appeared as an oil which soon crys-

tallized to a tan solid (4.5 g.) melting at 100–121°. Repeated crystallization from benzene–petroleum ether (b. p. 90–100°) gave white needles (2.58 g.) which melted at 126.5–128°.

Anal. Calcd. for $C_{13}H_{14}O_4$: C, 66.64; H, 6.03. Found: C, 66.48, 67.00; H, 5.88, 6.19.

The substance is relatively stable toward heat and inert solvents, but is unstable toward polar solvents. It is insoluble in sodium carbonate and in sodium bicarbonate solutions. No ether was formed using either methyl sulfate or diazomethane, nor could an oxime be obtained.

When the acetylisocoumaranone (0.4 g.) was steam distilled, coumaron II (0.07 g.), m. p. and mixed m. p. 137–138°, was isolated from the distillate and the isocoumaranone I (0.26 g.), m. p. 200.5–202.5°,[13] remained in the flask.

Summary

1. The sodium enolates of acetylacetone and isobutyrylacetylmethane react with trimethylquinone to give (3,6-dihydroxy-2,4,5-trimethylphenyl)-acetylacetone (VIII) and -acetylisobutyrylmethane (XII), respectively. No pure substances could be isolated from the product of the reaction between the quinone and the enolates of *n*-butyrylacetylmethane or benzoylacetone, and only unchanged diketone was isolated when the enolate of dibenzoylmethane was used.

2. Acylation of the diketones VIII and XII involves a rearrangement of one of the side chain acyl groups from carbon to the *ortho*-oxygen atom; simultaneously, the other hydroxyl group is acylated by the reagent used. A mechanism is suggested for this rearrangement.

3. An intermediate has been isolated from the reaction between trimethylquinone and sodium acetoacetic ester. This intermediate, when steam distilled, gives the final products obtained previously in a study of this reaction.

The Reaction between Quinones and Metallic Enolates. XI. Duroquinone and the Enolates of Cyanoacetic Ester and of β-Diketones[1]

BY LEE IRVIN SMITH AND E. W. KAISER[2]

The reaction between duroquinone and sodium malonic ester,[3] was extended to other tetrasubstituted quinones by Webster,[4] who used 2,3-dimethyl-1,4-naphthoquinone, and by Johnson,[5] who used trimethylbromoquinone. Tenenbaum[6] varied the enolate by using sodium acetoacetic ester, but in all these cases the reaction led to a substituted coumarin (III, IV), and evidence was supplied by Horner[7] that the quinone was first converted into a "pentad-enolate" (I) which then underwent a Michael reaction with the other enolate. The first product (II) was cyclized and oxidized, leading to the coumarin as the final product. In every case so far studied, the enolate used contained an ester group so that the ring closure, by elimination of an alcohol, took place easily, and it has been thought that this easy ring closure was in large part responsible for driving

the series of reactions to completion, since the first step presumably, and the second step certainly, are reversible. In order to explore still further the limits of this reaction, the enolates of cyanoacetic ester and of two β-diketones (acetylacetone

and dibenzoylmethane) have been studied with regard to their behavior toward duroquinone.

Sodium methyl cyanoacetate and duroquinone reacted in benzene to give the yellow cyanocoumarin V. In common with coumarins of the type of III and IV, this yellow coumarin V gave a colorless monoacetate, VI. The presence of the cyano group in the coumarin was shown by hydrolysis to the amide (VII). Although the cyano compound survived the action of hydrogen peroxide,[8] it was hydrolyzed to the amide in fair yield by warming with 80% sulfuric acid. This amide was resistant to further hydrolysis by sulfuric acid or phosphoric acid, consequently it was not possible to convert it to the acid VIII, a known substance. However, the acid VIII was readily converted into the amide VII via the acid chloride, and the two specimens of VII thus prepared were identical. Both specimens also gave the same acetate IX. Although this acetate IX was not a simple acetate and was probably a diacetate, the identity of the amides prepared by the two methods and the identity of the acetates prepared from these amides, serve amply to fix the structure of the coumarin V. This coumarin is therefore 3-cyano-5,7,8-trimethyl-6-hydroxycoumarin, and its formation from duroquinone and sodium cyanoacetic ester shows that this enolate, in common with all of the enolates containing a carbalkoxyl group, enters into a reaction with the quinone which involves the loss of the elements of alcohol as one of the steps.

Turning to the β-diketones, it is obvious that the reaction between the enolates of these substances and duroquinone, involving as an intermediate an analog X of II, cannot be completed by elimination of the elements of an alcohol. Elimination of the elements of an aldehyde RCHO to give the 2-acylcoumaran XI would not be very probable, but elimination of water from the enolate of X to give the 2-alkyl-3-acyl-Δ^2-chromene XII would be a possibility. Attempts were made to add the enolates of acetylacetone and dibenzoylmethane to duroquinone, under varying conditions, without success. No products were obtained under any of the experimental conditions tried and in most cases considerable unchanged duroquinone was recovered. The failure of the β-diketones to add to duroquinone is of significance in connection with the mechanism of the addition of enolates to this quinone, and lends support to the hypothesis that an easy ring closure is necessary in order that the sequence from I to III may be completed. This sequence involves a Michael reaction which is reversible[9]; if, therefore, in the intermediate X ring closure is difficult, reversal of the Michael reaction will result in the recovery of the starting materials, or products resulting from the action of alkali upon them. It therefore may be concluded from these results that elimination of the elements of water (or NaOH) from the enol of the diketone X is inherently more difficult than the elimination of the elements of alcohol (or RONa) from such a substance as II. Definite statements, however, must await the synthesis of substances such as X and a study of the action of alkali upon them; such experiments are under way.

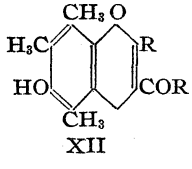
XI



XII

Experimental Part[10]

3-Cyano-5,7,8-trimethyl-6-hydroxycoumarin, V.—Methyl cyanoacetate (5.0 g., 0.05 mole) was converted into the enolate by refluxing it for an hour with powdered sodium (1.1 g., 0.05 mole) in dry benzene (50 cc., thiophene-free). A solution of duroquinone (6 g., 0.037 mole) in benzene (40 cc.) was added and the mixture was refluxed for seven days. The deep red solid was filtered off and washed thoroughly with benzene until the washings showed no yellow color. The solid was suspended in alcohol and iced hydrochloric acid (15 cc. acid, 15 g. ice) was added. The product weighed 2.38 g. and melted at 210–225°. After several crystallizations from acetic acid (with Norit the first time) the substance was obtained as a yellow solid which melted at 261.5–263°.

Anal. Calcd. for $C_{13}H_{11}O_3N$: C, 68.13; H, 4.80. Found: C, 68.17; H, 4.79.

3-Cyano-5,7,8-trimethyl-6-acetoxycoumarin, VI.—The coumarin (0.102 g.) was suspended in acetic anhydride (2 cc.) and a drop of sulfuric acid was added. The solid gradually dissolved and after standing for ten minutes at room temperature, the product began to crystallize out. More acetic anhydride (1 cc.) was added and the mixture was allowed to stand at room temperature for two hours. The suspension was poured onto a mixture of ice and am-

monium hydroxide (8 cc.) and the solid was removed. It weighed 0.11 g. and melted at 213–219°. After successive recrystallization from dry ethanol, acetic acid and dilute acetic acid, it was white and melted at 227–228°.

Anal. Calcd. for $C_{15}H_{13}O_4N$: C, 66.40; H, 4.84. Found: C, 66.46; H, 5.15.

3-Carbamido-5,7,8-trimethyl-6-hydroxycoumarin, VII. The cyanocoumarin V (0.2 g.) was heated on the steam-bath with sulfuric acid (13 cc., 81%) for three and one-half hours. The reddish-yellow solution was poured over cracked ice (75 g.) and the solid was removed and crystallized from acetic acid. The product weighed 0.129 g. (60%) and melted at 290–293° (metal block) with decomposition. Repeated crystallization from acetic acid gave a product which melted at 302° (block) with decomposition; the melting point of this sample, determined in a capillary in the usual manner, was 288–290° with decomposition.

Anal. Calcd. for $C_{13}H_{13}O_4N$: C, 63.15; H, 5.55. Found: C, 62.74; H, 5.50.

Acetyl Derivative, IX.—The amide VII (0.14 g.) was refluxed for forty-five minutes in acetic anhydride (4.5 cc.) containing a drop of sulfuric acid. The cooled solution was poured over cracked ice (50 cc.) and concd. ammonium hydroxide was added until the mixture was basic to litmus. The solid (0.15 g.) was removed and crystallized from acetic acid; it then melted at 243–244.5°.

Anal. Calcd. for $C_{15}H_{15}O_5N$ (monoacetyl): C, 62.28; H, 5.19. Calcd. for $C_{17}H_{17}O_6N$ (diacetyl): C, 61.63; H, 5.13. Found: C, 60.84, 61.17; H, 5.07, 5.53.

3-Carboxy-5,7,8-trimethyl-6-hydroxycoumarin, VIII.—The acid was prepared by hydrolysis of the ester III (0.36 g.)[3] with hydrochloric acid (6 *N*, 40 cc.) in acetone (20 cc.).[11] The crude product (0.29 g.), which melted at 255–256°, was used directly for conversion to the acid chloride.

Acid Chloride of VIII, and Amide, VII.—The acid VIII (0.15 g.) was refluxed for fifteen minutes with thionyl chloride (2 cc.). Excess thionyl chloride was removed under reduced pressure and the acid chloride (not purified) was converted to the amide by addition of ammonium hydroxide (2 cc.). The amide (0.14 g.) was removed and crystallized from acetic acid, when it melted at 288–290° with decomposition (capillary tube and liquid bath) alone or when mixed with a specimen prepared from duroquinone and cyanoacetic ester.

Acetyl Derivative, IX.—The above amide VII was acetylated as already described. The product weighed 0.14 g., and after crystallization first from acetic acid and then from dilute acetic acid, it melted at 241–242.5°, alone or when mixed with the acetyl amide derived from duroquinone and cyanoacetic ester.

Anal. Calcd. given above. Found: C, 60.87; H, 5.57.

Duroquinone and Acetylacetone.—Several attempts, using different conditions, were made to carry out this condensation, but all failed.

A. In Dry Benzene with Metallic Sodium.—Acetylacetone (7 g., 0.07 mole) was added to a suspension of powdered sodium (1.60 g., 0.07 mole) in dry benzene (50 cc., thiophene free). Duroquinone (5 g., 0.031 mole) dissolved in a few cc. of benzene was then added and the mixture was refluxed for four days. The initial very dark color changed to deep blue-green during this time. The solid (8.4 g.) was filtered off and thoroughly washed with benzene. Decomposition of this material with hydrochloric acid (2 *N*, 15 cc.) gave 2.7 g. of a reddish solid, which after crystallization from alcohol melted at 112–113° alone or when mixed with duroquinone. Extraction of the acid filtrate with benzene gave 1.6 g. of acetylacetone boiling at 135–140°. No other products could be isolated.

B. In Ethanol with Magnesium Ethoxide.[5]—Acetylacetone (2.0 g.) was added to a suspension of magnesium ethoxide (1.17 g.) in dry ethanol (15 cc.). Duroquinone (1 g.) was then added and the mixture was refluxed for forty-eight hours. Most of the alcohol was removed by distillation, and replaced by ether. The light tan solid which separated was removed and decomposed with dilute hydrochloric acid. An oil resulted which soon resinified to a very dark brown mass. No definite products could be isolated from this resinous material.

C. In Ethanol with Ammonia.—A solution of duroquinone (1 g.) and acetylacetone (2 g.) in dry ethanol (40 cc.) was saturated with dry ammonia. After standing overnight at room temperature, the clear red solution was acidified with hydrochloric acid and diluted with water. The only product obtained was duroquinone, m. p. and mixed m. p. 112–114°.

D. In Ethanol with Sodium Ethoxide.—To a solution of sodium ethoxide in dry ethanol (0.42 g. sodium, 15 cc. ethanol) acetylacetone (2.0 g.) was added. Duroquinone (1 g.) in dry ethanol (25 cc.) was added to the enolate solution and the mixture was refluxed for twenty-four hours. A deep red color developed as soon as the quinone was added, but decomposition of the reaction mixture with iced hydrochloric acid gave only a brick-red solid which melted at 115–150°. This solid was very soluble in alcohol, ether, acetic acid and other organic solvents and all attempts to obtain pure material from it failed. It was probably a mixture of duroquinone (m. p. 111–112°) and diduroquinone (m. p. 207°).

Summary

1. The enolate of methyl cyanoacetate condenses with duroquinone to give 3-cyano-5,7,8-trimethyl-6-hydroxycoumarin (V), the reaction taking the same course as that of other enolates containing a carbalkoxyl group.

2. The structure of the cyanocoumarin was proved by converting it to the amide and synthesizing the latter from the known 3-carboxy-5,7,8-trimethyl-6-hydroxycoumarin.

3. The cyanocoumarin could not be hydrolyzed to the acid; all attempts failed to carry the hydrolysis beyond the amide stage.

4. The enolates of acetylacetone could not be condensed with duroquinone. The possible bearing of this fact upon the mechanism of duroquinone–enolate reactions is discussed.

The Chemistry of Vitamin E. XX.[1] The Preparation of *o*-Xylohydroquinone

BY OLIVER H. EMERSON[2] AND LEE IRVIN SMITH

o-Xylenol is not available in quantity and is difficult to prepare. The preparation of *o*-xyloquinone and hydroquinone from it by the generally useful method previously described[3] is, therefore, impracticable. The present paper reports improvements in the previously described[4,5,6] synthesis of this quinone from *o*-xylene via the *o*-nitro compound and the amine. The yields obtained in the three steps are, respectively, 85, 75 and 33%, or an over-all yield of 21% of quinone from hydrocarbon. The corresponding over-all yield previously reported by this method is 12%.[4,5,6]

Procedure

3-Nitro-*o*-xylene.—*o*-Xylene (50 g.) is nitrated at −10 to 0° by stirring it vigorously and dropping into it slowly a mixture of sulfuric acid (100 g.) and nitric acid (50 g., d. 1.4). During the addition, the tip of the dropping funnel is shielded from spray by keeping it well up in the neck of the flask, out of the path of the droplets thrown by the stirrer. This prevents any contact of xylene with an excess of the nitrating mixture and thus avoids the formation of any dinitro compound.[5] The product is poured into water and washed with dilute sodium hydroxide. Any polynitro-*o*-xylene can be removed from the mono compound by steam distillation but is more efficiently eliminated by distillation in a vacuum from a Claisen flask, the fraction boiling at 115–130° at 15 mm. pressure being refractionated through a Fenske 1-meter column and the final fraction (61 g., 85.6%) boiling at 127–130° at 18 mm. pressure being taken as the pure 3-nitro compound. The residues, especially the first, should not be heated too strongly as they may decompose quite vigorously.[7]

3-Amino-*o*-xylene (II).—For the reduction of the nitro compound, the directions of Yokoyama[6] were followed, except that the amine finally was isolated as the sulfate, which is of advantage both for removal of small amounts of 4-amino-*o*-xylene whose sulfate is much more soluble, and in giving the amine in a good physical state for the subsequent oxidation. From 75 g. of the nitro compound there resulted about 60 g. of the amine. This was vigorously stirred into water (500 cc.) and sulfuric acid (30 g.) and the solution cooled overnight in a refrigerator. The amine sulfate weighed 62 g. (74%).[8]

***o*-Xyloquinone** (III).—The oxidation was based on the procedure of Yokoyama[6] but it is preferable to use the dry, powdered amine sulfate and dilute sulfuric acid rather than the free amine which forms coarse lumps when added to the strong sulfuric acid as recommended by Yokoyama. Dry, well powdered 3-amino-*o*-xylene sulfate (31 g.) was added to a solution of sulfuric acid (95 cc., 175 g.) in water (680 cc.) and the solution was placed in a refrigerator (5–10°) until cold. A solution of sodium dichromate dihydrate (22.5 g.) in water (60 cc.) was also cooled to 5–10°. During the course of an afternoon the dichromate was added to the amine solution in 4 or 5 portions, with vigorous shaking. The solutions were returned to the refrigerator between the additions, and the final solution was kept at 5–10° overnight. During the next day, more dichromate (50 g.) in water (150 cc.) was added in portions as before, and then the reaction mixture was kept in the refrigerator for thirty-six hours longer. The reaction mixture was filtered using a *large* Buchner funnel, and the filtrate was thoroughly extracted with ether (three times, 250 cc. of ether each time). The precipitate was thoroughly triturated with methanol (about 75 cc.),[9] filtered, and washed two or three times with small amounts of methanol. Ether (500 cc.) was added to the methanol filtrate; any precipitate was removed and washed with a little ether. All of the ethereal solutions and extractions were combined and shaken with water (400 cc.). Any precipitate at this point was removed, washed with ether and the ether washing was combined with the main solution. The aqueous layer was separated, and thoroughly extracted with ether. The united ether solutions and extracts were washed with small amounts of water, and the ether was distilled off. Since *o*-xyloquinone is thermolabile, care must be taken to keep a fair amount of ether in the distilling flask. Finally water was added, and the removal of the ether was completed by heating to 40–45°.

Ordinary steam distillation of the quinone is accompanied by great loss, but steam distillation under 100 mm. pressure proceeds quite well. A 500-cc. Kjeldahl flask with a side arm (12 mm. dia.) attached high up formed a very satisfactory still, and an Allihn condenser provided adequate cooling. The distillate was extracted with ether, the ether was evaporated carefully and the residue crystallized from petroleum ether (b. p. 30–60°). The quinone is quite soluble in this solvent, even in the cold, necessitating concentration of the mother liquors for second and third crops; yield 8.3 g. (33%); m. p. 56–57°.[6,10]

(1) Paper XIX, THIS JOURNAL, **61**, 3079 (1939).

(2) Honorary Fellow of the Graduate School, University of Minnesota, Spring Quarter, 1938–1939.

(3) Paper VII on Vitamin E, *J. Org. Chem.*, **4**, 318 (1939).

(4) Noelting and Forel, *Ber.*, **18**, 2670 (1885).

(5) Crossley and Renouf, *J. Chem. Soc.*, **95**, 207 (1909).

(6) Yokoyama, *Helv. Chim. Acta*, **12**, 771 (1929).

(7) The presence of small amounts of the 4-nitro isomer is of little consequence since the corresponding amine sulfate is much more soluble than the 3-amine sulfate (6 *vs.* 1.4% at 0°), Noelting and Pick, *Ber.*, **21**, 3153 (1888).

(8) Hydrochloric acid and tin or tin chloride should not be used for reduction of the nitro compound, because the product prepared in this way invariably contains considerable amounts of chloroxylidines which are very difficult to remove.

(9) A silver spatula or glass rod should be used at this point. Stainless steel appeared to catalyze the decomposition of the quinone to a red oil, while silver or glass had much less effect upon the quinone.

(10) Yokoyama, Ref. 6, reported 20% yield, m.p. 55°.

o-Xylohydroquinone.—The quinone (8.3 g.) was dissolved in acetic acid (50 cc.), water (25 cc.) was added, and the solution was refluxed with zinc (8.3 g., 20-mesh). The reduction proceeds rapidly and the solution is practically colorless in twenty minutes. Boiling water (50 cc.) is added to the hot solution, which is then immediately decanted from the zinc. The zinc is boiled with water (50 cc.) which is decanted into the main solution. On cooling, the solution deposits 7.90 g. (95%) of the hydroquinone, which melts at about 220° with complete decomposition.

Summary

1. This paper reports an improved preparation of *o*-xyloquinone and hydroquinone from *o*-xylene.

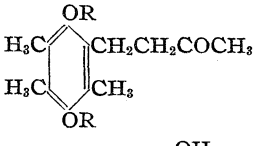
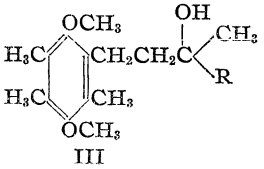
The Chemistry of Vitamin E. XXI.[1] Dealkylation of Hydroquinone Ethers Related to the Tocopherols

BY LEE IRVIN SMITH, HERBERT E. UNGNADE* AND WILLA B. IRWIN

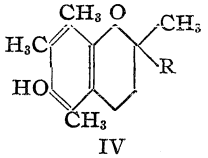
In a previous paper[2] a report has been made of the syntheses of certain compounds related to the tocopherols, using as starting materials 1-[3,6-dimethoxy-2,4,5-trimethylphenyl]-butanone-3 (I) and the closely related diacetate, II.



I, R = CH_3
II, R = Ac
IIa, R = H



III



IV
X R = CH_3

The substance I can be prepared readily from the dimethyl ether of pseudocumohydroquinone, via the chloromethyl derivative, which is used to alkylate acetoacetic ester. Hydrolysis of the substituted β-keto ester gives I, and the over-all yield in the synthesis is very good. The ketone I reacts well with Grignard reagents to give the carbinols III so that, by proper choice of Grignard reagent, a wide variety of these carbinols may be synthesized.

It was planned to convert the carbinols into the related chromans (IV) by demethylation followed by cyclization, but in the earlier work[2] no method could be found for cleaving the methoxyl groups without at the same time involving deep seated changes elsewhere in the molecule. While the acetate II underwent chloromethylation well, the chloromethyl derivative was difficult to handle and alkylation of acetoacetic ester with it gave only fair yields of the β-keto ester, from which, in turn, only a complicated mixture of products was obtained on hydrolysis. Thus, starting with either I or II, the synthesis of chromans IV appeared to involve such difficulties as to render the method of doubtful value.

While this work was in progress, a paper by John and Günther[3] appeared, in which was described the synthesis of ketone I starting with 3,4,6 - trimethyl - 2,5 - dimethoxybenzaldehyde.[4] The aldehyde was condensed with acetone to give 80% of the benzalacetone, which was then reduced to I. John and Günther found that I, when subjected to the action of hydrobromic acid, was simultaneously demethylated and reduced, giving the chroman IV (R = H). Addition of methylmagnesium iodide to I gave about 40% of III (R = CH_3), which was converted, by action of hydrobromic acid, into X. Addition of a dodecyl Grignard reagent was also carried out, although the results were not as satisfactory as those obtained using methylmagnesium iodide. Subsequently, John and Schmeil[5] by oxidation of the chroman IV (R = H) obtained the ketone IIa, and by addition of Grignard reagents to this ketone, the chromans IV, R = CH_3 and $C_{12}H_{25}$, were obtained.

It has now been found that the carbinol ether III (R = CH_3) can be cleaved by heating it at an elevated temperature with excess Grignard reagent.[6] Although the reaction does not pro-

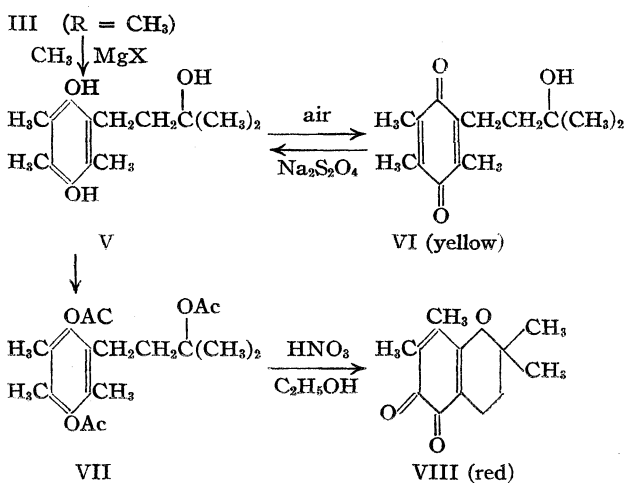
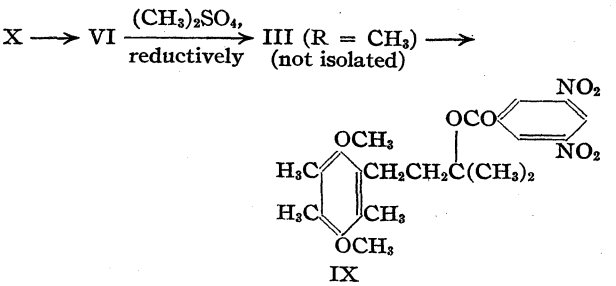
ceed to completion, it nevertheless affords another method of cleaving the methoxyl groups without affecting the rest of the molecule. Because of the incomplete reaction, it was not possible to isolate the products in a pure state, but sufficient evidence was available to follow the course of the reaction fairly accurately. The demethylation product appears to be the corresponding hydroquinone, V, since the ethereal solution, when shaken in air, turns to the yellow color of the quinone VI, and this color change can be reversed by shaking with sodium hydrosulfite. Neither of these substances could be isolated, since the presence of unchanged III in the reaction product prevents them from crystallizing. The reaction product was reductively acetylated, in the hope that the triacetate VII could be separated, but this likewise could not be crystallized. The product was therefore treated with nitric acid in ethanol[7]; the red color of the ortho quinone VIII[8] at once appeared. Since the carbinol ether III does not give the Furter and Meyer reaction, production of the very characteristic red color by nitric acid–ethanol after the carbinol III had been heated with the Grignard reagent indicated quite clearly that considerable demethylation had occurred.



The structure of the carbinol ether III (R = CH_3) was proved by converting it to a 3,5-dinitrobenzoate (IX), m. p. 147–148°. The same dinitrobenzoate was obtained from 2,2,5,7,8-tetramethyl-6-hydroxychroman (X) by oxidation, followed by reductive methylation of the quinone VI to the carbinol ether III (R = CH_3) and treatment of the latter with 3,5-dinitrobenzoyl chloride.



The identity of the dinitrobenzoates prepared by these two methods constitutes an additional proof of the structure of the chroman X, and it is also important as a model research for a direct structure proof of α-tocopherol, since the corresponding dimethoxy-3,5-dinitrobenzoate from α-tocopherol has already been prepared.[9]

Chromans such as IV and X have been prepared by the action of Grignard reagents upon hydrocoumarins, first by Robertson and his associates[10] and shortly thereafter in other laboratories.[11,12] Some doubt has been expressed, however, that the products of such reactions actually were chromans,[13] but the present results, together with those of John and his associates,[3,5] leave no doubt as to the course of these reactions; the products are certainly 2,2-dialkyl chromans.

Experimental Part

1 - (3,6 - Dimethoxy - 2,4,5 - trimethylphenyl) - 3-methylbutanol-3 (III, R = CH_3).—A solution of the ketone I (0.85 g.) in ether (25 cc.) was added to a solution of methylmagnesium iodide prepared from methyl iodide (1.419 g.), magnesium (0.243 g.) and ether (25 cc.). After stirring for an hour, the mixture was poured onto ice and sulfuric acid (30%) and extracted with ether. The ether extracts were washed with bicarbonate (10%), then with water, and dried over sodium sulfate. Evaporation of the solvent left 800 mg. of III, a colorless oil. It was not analyzed.

3,5-Dinitrobenzoate (IX).—The carbinol III (800 mg.) and 3,5-dinitrobenzoyl chloride (900 mg.) were allowed to stand in pure pyridine (15 cc.) for twenty-four hours. The solution was poured into iced sulfuric acid (30%) and extracted with ether. The extract was washed with bicarbonate (10%), and then with water. The residue obtained on evaporation of the solvent was crystallized from alcohol. It then melted at 147–148°; after several crystallizations it formed light yellow crystals which melted at 148–148.5°.

Anal. Calcd. for $C_{23}H_{28}O_8N_2$: C, 59.98; H, 6.10. Found: C, 59.78; H, 5.75.

Oxidation of 2,2,5,7,8-Pentamethyl-6-hydroxychroman (X).—A solution of the chroman (750 mg.) in methanol (30 cc.) was refluxed for an hour with silver acetate. The suspension was cooled and the sludge was removed and washed with a small amount of methanol. The combined filtrate and washings were diluted with water (100 cc.) and extracted with ether. The ether solution was washed with water and dried over calcium chloride. Evaporation of the solvent left the **quinone VI** (740 mg.) as a yellow oil. John, Dietzel and Emte[9] report that VI is a solid which melts at 62° but many preparations of VI in this Laboratory have given the substance only as an oil. This oil, when reductively acetylated, gave the known triacetate, m. p. 114–115°[9,14]; however, cleavage of the pure triacetate by methylmagnesium iodide according to the method of Doisy[15] followed by action of silver oxide upon the product also gave VI as an oil which could not be crystallized.

Carbinol III.—Reductive methylation of the quinone VI must be carried out with great care to avoid the destructive action of excess alkali upon the quinone. The general procedure of John, Dietzel and Emte[9] was used, modified so that there was never more than a momentary darkening of the reaction mixture due to free alkali. The above quinone (749 mg.) was taken up in methanol (15 cc.) and sodium hydrosulfite (700 mg.) was added. To this suspension sodium hydroxide (20%, 4 drops) was added, followed immediately by methyl sulfate (2 cc.). During the next forty-five minutes, base (12 cc.) and methyl sulfate (8 cc.) were added alternately and with intermittent refluxing, in such proportions that the solution never darkened. The final colorless solution was diluted with sodium hydroxide (3%, 100 cc.) and extracted with ether several times. The combined extracts were washed with dilute base, then with water, and dried over sodium sulfate. Removal of the solvent left a pale yellow oil (570 mg.).

3,5-Dinitrobenzoate, IX. A.—The crude carbinol III (210 mg.) was added to approximately an equivalent amount of standardized methylmagnesium iodide in ether (50 cc.). The volume of methane collected indicated roughly 0.67 mole of active hydrogen per mole of carbinol, and showed that reductive methylation of VI had not involved the aliphatic hydroxyl group too greatly. To the resulting suspension of the bromomagnesium derivative of III there was added 3,5-dinitrobenzoyl chloride (520 mg.) and the mixture was allowed to stand at room temperature for two days. It was poured into cold sulfuric acid (30%, 150 g.) and extracted with ether. The ether extracts were washed with water, saturated bicarbonate, and again with water. Evaporation of the solvent left an oily residue (360 mg.) which was taken up in a little ether and cooled. The light yellow solid was removed and washed twice with small amounts of cold ethanol. It weighed 50 mg. After crystallization from ethanol, the substance melted at 145–146°. When mixed with a specimen of IX (m. p. 147.5–148°) prepared from the dimethoxy ketone I, the substance melted at 145–147°.

B. The crude carbinol III (290 mg.) was dissolved in dry pyridine (5 cc.) and 3,5-dinitrobenzoyl chloride (550 mg.) was added. After standing at room temperature for four days, a small amount of white solid (m. p. 165–167°) was removed and the filtrate poured into cold sulfuric acid (30%, 150 g.). The product (300 mg.) was isolated and purified as described above. The solid weighed 100 mg. and melted at 143–144.5°. When mixed with the pure 3,5-dinitrobenzoate (m. p., 147.5–148°) the substance melted at 144–145.5°.

Cleavage of the Ether Carbinol, III (R = CH_3).—The ketone I (1.43 g.) in ether (30 cc.) was added to a Grignard solution prepared from methyl iodide (4.06 g.), magnesium (0.69 g.) and ether (50 cc.). After refluxing for an hour, the ether was distilled off and the residue was heated at 180° for forty-five minutes. After cooling, ice and sulfuric acid (30%) were added and the mixture was extracted with ether. A few cc. of the ethereal solution (practically colorless), when shaken in air, turned bright yellow (quinone VI). The whole of the ethereal solution was shaken with aqueous sodium hydrosulfite, and the *colorless* ethereal solution which resulted (hydroquinone V) was evaporated. The residue, a yellow oil, could not be crystallized. It was acetylated by refluxing it for thirty minutes with acetic anhydride (12 cc.), zinc (1 g.) and fused sodium acetate (3 g.). The mixture was poured into water and extracted with ether. The ether solution was washed with water, then with dilute sodium hydroxide, followed by water again. The solution was dried and the solvent was evaporated. This residue, a viscous oil (acetate VII), likewise could not be crystallized.

The acetate was dissolved in absolute ethanol (500 cc.) and nitric acid (100 cc.) and the solution was warmed on the steam-bath for thirty minutes. The deep red color characteristic of the Furter and Meyer reaction appeared at once (quinone VIII). The red quinone was removed by ether extraction, but evaporation of the solvent left a deep red oil which also could not be made to crystallize.

Summary

1. Carbinols such as III derived from 1-(3,6-dimethoxy-2,4,5-trimethylphenyl)-butanone-3 (I) by action of Grignard reagents, have been demethylated by heating with excess reagent.

2. The structure of the carbinol III (R = CH_3) has been proved by converting it to the same 3,5-dinitrobenzoate as that obtained from 2,2,5,7,8-pentamethyl-6-hydroxychroman (X) by a series of reactions involving oxidation to a quinone, reductive methylation of the quinone and conversion of the dimethoxy compound to the 3,5-dinitrobenzoate.

3. These reactions also prove the structure of the chroman X and show definitely that when Grignard reagents react with dihydrocoumarins, the products are 2,2-dialkylchromans.

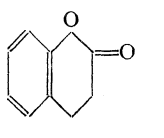
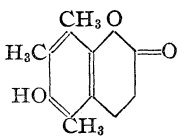
The Chemistry of Vitamin E. XXII. The Reaction between Grignard Reagents and Coumarins and Hydrocoumarins[1]

BY LEE IRVIN SMITH AND P. M. RUOFF[2]

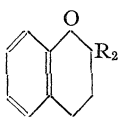
In paper XII of this series[3] a preliminary report has been given of the results obtained when certain Grignard reagents reacted with the dihydrocoumarins I and II. The products of these reactions were 2,2-dialkylchromans, III, and it was assumed that in all cases the intermediates were the ketones IVa (or IVb) and related carbinols V.



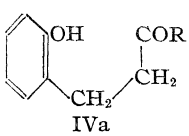
I



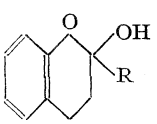
II



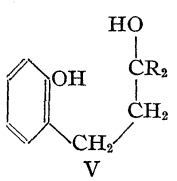
III



IVa



IVb

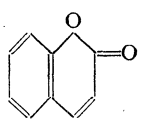


V

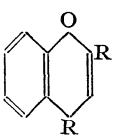
In one case, that in which R was ethyl, the carbinol V was isolated as a solid which melted at 71–72°; but in the other case studied (R = *n*-propyl) the carbinol appeared as an oil which was not characterized except by conversion to the chroman III (R = *n*-propyl).[4]

The reaction between hydrocoumarin (I) and Grignard reagents has now been extended and the series at present includes the products obtained from ethyl-, *n*-propyl- and *n*-butyl- Grignard reagents. In addition Claisen[5] prepared the carbinol V, R = CH_3, from methylmagnesium iodide and ethyl β-phenyl-propionate; he cyclized the carbinol to the chroman (III, R = CH_3) which he synthesized independently by condensation of phenol with isoprene.[6] Thus the series now includes all four of the chromans III (R = CH_3, C_2H_5, *n*-C_3H_7 and *n*-C_4H_9) as well as three of the carbinols V (R = CH_3, C_2H_5, *n*-C_4H_9). In view of this work, and the results reported in the previous paper,[1] it appears definitely established that the products obtained by action of Grignard reagents upon dihydrocoumarins consist of the carbinols V and the 2,2-dialkylchromans III derived from them. No ketones such as IVa or IVb have been isolated from these products although one such ketone recently has been synthesized in another way by John and Schmeil.[7] It is interesting that this ketone, 2,5-dihydroxy-3,4,6-trimethylbenzylacetone, shows properties which indicate that its structure may be analogous to IVb rather than to IVa.

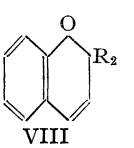
On the other hand, the action of Grignard reagents upon coumarins VI is much more complicated because of the presence of the conjugated double bond, and a variety of products, including



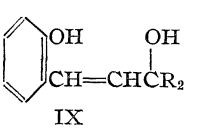
VI



VII



VIII



IX

pyrylium salts,[8] Δ²- and Δ³-chromenes (VII and VIII),[4,9] chromanols[10] as well as the unsaturated carbinols IX[9a,9b] have been reported. The evidence concerning the carbonols IX is conflicting, however, and from the work of Löwenbein[9b] it appears that Houben[9a] was in error in assigning structure IX to the product he obtained from coumarin and phenylmagnesium bromide. Nevertheless, formation of all the products so far reported can be accounted for on the basis of 1,2- or 1,4-addition of the reagent, or a combination of

1,4- and 1,2-addition, with cyclization possible at almost any point in the sequence of reactions.

It has now been found that the carbinols IX (R = CH_3 and C_2H_5) are readily obtained by addition of coumarin to aliphatic Grignard reagents under carefully controlled conditions. These unsaturated carbinols IX are readily reduced to the saturated carbinols V, identical with the products obtained from Grignard reagents and dihydrocoumarin. Thus the same product, V, results regardless of whether addition of the Grignard reagent precedes or follows reduction and this could be true only when the action of the reagent is confined to the carbonyl group. From these facts, it follows that these carbinols must be derived from coumarin and dihydrocoumarin by 1,2-addition of the reagent to the carbonyl group, and that the conjugated system in coumarin is not involved in the reaction when the procedure described below is used.

The unsaturated carbinols IX were cyclized by acids to chromenes, which, from the structure of the carbinols, must have the double bond in the 3,4-position (VIII). Elimination of water from the carbinols occurred quite readily; even distillation of the crude carbinol gave a product which separated into two layers, one of them aqueous. Cyclization, however, was not the only reaction which occurred when the carbinols were dehydrated for by-products, consisting of viscous, brown oils were always formed in considerable amounts. These by-products were probably formed by dehydration of the carbinols to dienes and polymerization of the latter. Steam distillation of the carbinols from a slightly acid suspension yielded colorless oils in the distillate, but this process was too slow to serve as a practical method for obtaining the chromenes. Cyclization of the carbinols IX by acids was always accompanied by the appearance of highly colored solutions; similar colors were developed when the magnesium complexes from the Grignard reaction were hydrolyzed. These colors indicated the presence of benzopyrylium salts, but no attempt was made to isolate them.[10a]

(10a) Since this manscript was submitted for publication, a paper by Shriner and Sharp, *J. Org. Chem.*, **4**, 575 (1939), appeared on the same subject. While Shriner and Sharp did not isolate the intermediate ketones, our results in general agree with theirs, and their reaction mechanism, which we regard as essentially correct, readily can be modified to provide for the formation of the ketones. Thus their compound XII could coördinate at the heterocyclic oxygen atom with a second molecule of the Grignard reagent and the resulting complex could rearrange to give either the chromene or the magnesium derivative of the ketone.

Experimental Part[11]

Diethyl-*o*-hydroxystyrylcarbinol IX (R = C_2H_5).—Coumarin (25 g., 0.17 mole) in ether (500 cc.) was added slowly (two hours) at room temperature to a Grignard solution prepared from ethyl bromide (40 g., 0.37 mole) and magnesium (8 g., 0.33 mole) in ether (250 cc.). Each drop of the coumarin solution produced in the reaction mixture a yellow precipitate which quickly dissolved; after about half of the coumarin was added, this transitory precipitate was white. The mixture was refluxed for an hour and the clear brownish-green and slightly fluorescent solution was allowed to stand overnight. It was then decomposed by slowly stirring it into sulfuric acid (10%, 200 cc.) and ice. After standing for an hour, the ether layer was removed and the aqueous layer was extracted (with ether) until it was colorless. The combined ether solutions were washed with water and dried over anhydrous sodium carbonate. Removal of the solvent left a yellow oil (32 g.) which partially solidified. The oily solid was spread on a porous plate and after the oil was absorbed, the solid was removed and crystallized twice from a mixture of equal parts of petroleum ether b. p. 30–60° and b. p. 60–68° using Norite the second time. Approximately 20 g. of white needles, melting at 67–68°, was obtained. The carbinol gave a deep red color with concd. sulfuric acid and an olive-green color with ferric chloride. It rapidly decolorized a dilute solution of bromine in carbon tetrachloride, and gave no reaction with phenylhydrazine. It was soluble in 10% sodium hydroxide.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.78. Found: C, 75.64; H, 8.89.

1-[*o*-Hydroxyphenyl]-3-ethyl-3-pentanol V (R = C_2H_5).—The above carbinol 2.0 g. in ethanol (50 cc.) was subjected at room temperature to the action of hydrogen under slight pressure in the presence of a platinum oxide catalyst (0.01 g.). Practically the theoretical volume of hydrogen was absorbed in two hours. After removal of the catalyst, the solvent was evaporated and the residue was crystallized from petroleum ether. The product (1.5 g.) was white and melted at 74–75° alone or when mixed with a specimen prepared from dihydrocoumarin and ethylmagnesium bromide.[3] When mixed with the unsaturated carbinol (m. p. 67–68°) the substance melted at 50–54°.

2,2-Diethyl-Δ^3-chromene, VIII (R = C_2H_5).—The unsaturated carbinol (4 g.) was refluxed in acetic acid (20 cc.) for an hour and the mixture was allowed to stand overnight. The solution was diluted with water and extracted with ether. The ether solution was extracted with sodium hydroxide (10%), then washed with water and dried over calcium chloride. Removal of the solvent left a clear amber oil (3.5 g.). Distilled from a small Claisen flask, this gave 2.5 g. of a clear colorless liquid boiling at 129–132° under 19 mm.; the residue (1 g.) in the flask was dark viscous non-volatile oil. Redistillation of the crude chromene gave a turbid distillate (2.0 g.) and to complete the cyclization this distillate was again refluxed in acetic acid and the product was isolated and purified as described above. Somewhat less than 1 g. of a colorless liquid, b. p. 125–126° under 14 mm., was obtained. The remainder

(11) Microanalyses by J. W. Opie and E. E. Renfrew.

of the product was a dark viscous oil. The chromene gave a bright red color with concd. sulfuric acid.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.98; H, 8.51. Found: C, 83.07; H, 8.65.

Dimethyl-*o*-hydroxystyrylcarbinol, IX (R = CH_3).—Coumarin was added to methylmagnesium iodide in the same molar quantities and by the same procedure as that described for preparation of the diethylcarbinol above. About a third of the reaction product was collected on a porous plate as a yellowish solid (10 g.). After crystallization from petroleum ether (as above) and decolorization with Norite, the substance was obtained as a white solid which melted at 53–55°. It gave the same color reaction with sulfuric acid and ferric chloride as those given by the ethyl compound; likewise it was soluble in 10% sodium hydroxide. Due to an accident, the analytical sample was destroyed.

2,2-Dimethyl-Δ^3-chromene, VIII (R = CH_3).—The porous plate used for absorbing the oil accompanying the above dimethylcarbinol was extracted with ether. The ether was removed and the residue was distilled under 19 mm. pressure. The chromene (2 g.) boiling at 102–103° resulted as a clear, colorless liquid.[12]

Cyclization of the solid carbinol (from above) as described for the ethyl compound gave only about 1 g. of the chromene. Consequently, the Grignard reaction was repeated, and the crude product (solid and oil) was distilled under 15 mm. At 90° an oil and water appeared in the distillate; as soon as water ceased to appear, the temperature gradually rose to 142°. Only a small amount of residue remained in the flask. The distillate solidified partially, showing unchanged carbinol. The entire distillate was dissolved in acetic acid (50 cc.), a drop of sulfuric acid was added and the mixture was refluxed for half an hour. The product was isolated and purified as described for the ethyl compound above. There resulted 6 g. of the pure chromene boiling at 96–97° under 15 mm. About half the material remained in the flask as a dark viscous oil. The methyl chromene, like the ethyl compound, gave a red color with sulfuric acid.

Anal. Calcd. for $C_{11}H_{12}O$: C, 82.50; H, 7.50. Found: C, 82.19; H, 7.86.

2,2-Di-*n*-butyl-Δ^3-chromene, VIII (R = *n*-C_4H_9).—Coumarin (22 g., 0.15 mole) in ether (450 cc.) was added to *n*-butylmagnesium bromide (7.3 g., 0.30 mole of magnesium, 45.2 g., 0.33 mole of butyl bromide) in ether (225 cc.). No attempt was made to isolate the small amount of solid (carbinol) which appeared in the product; instead, the crude product was distilled directly. The distillate (23 g., b. p. 161–163° under 15 mm.) contained some water, indicating dehydration of the carbinol. The ethereal solution of the distillate was extracted several times with sodium hydroxide (10%), then washed with water and dried over calcium chloride. The solvent was removed and the residue was distilled under 15 mm. The chromene (17–18 g.), a clear oil with a faint yellow cast, boiled at 164–165° and had $n^{27}D$ 1.5220. It gave a red color with sulfuric acid.

Anal. Calcd. for $C_{17}H_{24}O$: C, 83.53; H, 9.91. Found: C, 83.10; H, 9.76.

(12) See Ref. (9a); Houben gives the b. p. as 92–93° under 11 mm.

1-[*o*-Hydroxyphenyl]-3-*n*-butyl-3-heptanol V (R = *n*-C_4H_9).—Dihydrocoumarin (14.8 g., 0.1 mole) in ether (125 cc.) was slowly (1.5 hours) added to *n*-butylmagnesium bromide (butyl bromide, 28 g., 0.2 mole; magnesium, 4.8 g., 0.2 mole) in ether (200 cc.). The reaction mixture was allowed to stand at room temperature overnight and was then decomposed by pouring it into ice (300 g.) and sulfuric acid (20 cc.). The ether layer was removed, washed with dilute carbonate solution, then with water and was dried over anhydrous sodium carbonate. Removal of the solvent left an oil (25 g.) which soon solidified. After two crystallizations from petroleum ether (b. p. 30–68°) the substance was white and melted at 67–68.5°. It gave a strongly positive phenol test (Folin).

Anal. Calcd. for $C_{17}H_{28}O_2$: C, 77.27; H, 10.60. Found: C, 76.5; H, 10.0.

2,2-Di-*n*-butylchroman, III (R = *n*-C_4H_9).—The above carbinol (16.1 g.) was dissolved in acetic acid (100 cc.). Sulfuric acid (15 cc., 50%) was added. The solution turned red and an oil separated at the top. More acetic acid (50 cc.) was added to dissolve the oil, and the mixture was refluxed for an hour. The solution was diluted with water, and extracted with ether several times. The combined ether solutions were washed with dilute carbonate, then with water, and dried over anhydrous potassium carbonate. The solvent was removed and the residue (9 g.) was distilled. The distillate (5 g., b. p. 172–173° under 16 mm.) was slightly yellow and had a faint odor of butyl acetate. Considerable brown viscous oil remained in the flask. Much better results were obtained by refluxing the crude carbinol from a duplicate preparation with 25% sulfuric acid. Steam distillation of the mixture gave a colorless oil in the distillate but the process was very slow. The oil in the flask was taken up in ether, washed free of acid and dried. After the solvent was removed, the chroman was distilled from a Claisen flask. The distillate (12 g.) was a faintly yellow liquid which boiled at 165–168° under 8 mm., and it had $n^{27}D$ 1.5097.

Anal. Calcd. for $C_{17}H_{26}O$: C, 82.92; H, 10.57. Found: C, 82.70, 82.33; H, 10.10, 10.72.

Summary

1. *o*-Hydroxystyryldialkylcarbinols have been obtained by reaction between coumarin and Grignard reagents.

2. The structures of these carbinols have been proved by reducing the diethyl compound to the saturated carbinol and preparing the same substance from dihydrocoumarin and ethylmagnesium bromide.

3. The unsaturated carbinols have been cyclized to 2,2-dialkyl-Δ^3-chromenes, VIII but the chromenes are accompanied by large amounts of dark viscous oils, probably polymeric substances.

4. Previous work on the preparation of 2,2-dialkylchromans by action of Grignard reagents on dihydrocoumarins has been extended. At present the series of chromans III is complete

from R = CH_3 to R = n-C_4H_9; the series of saturated carbonols V includes those in which R = CH_3, C_2H_5 and n-C_4H_9; the series of unsaturated carbinols IX includes those in which R = CH_3 and C_2H_5; the series of chromenes VIII includes those in which R = CH_3, C_2H_5 and n-C_4H_9.

The Ultraviolet Absorption Spectra of Some Derivatives of 1,2-Benzanthracene

BY R. NORMAN JONES[1]

The ultraviolet absorption spectrum of 1,2-benzanthracene has been measured by Capper and Marsh,[2] by Clar[3] and by Mayneord and Roe.[4] Because of the carcinogenic activity of some of its simple alkyl and ace-derivatives, a large number of such compounds have been synthesized and their chemical and biological behavior investigated in several laboratories.[5,6,7] Since eleven such derivatives complementary to those previously studied were available in this Laboratory it seemed desirable to make a careful study of their absorption spectra.

Experimental Procedure

In this study a Bausch and Lomb Medium Quartz Spectrograph was used in conjunction with a Hilger Spekker Photometer and a hydrogen discharge tube designed by Dr. Hugh H. Darby.[8] Some difficulty was initially found in lining up the spectrograph with a photometer of different manufacture. This was overcome by mounting the photometer on a Hilger "Short Bar," the base support of which was replaced by a specially designed casting underslung from the projecting front platform of the spectrograph and accurately machined to fit the Short Bar. By means of set screws and lock nuts in the casting a lateral variation of about 10° on either side of the optical axis was possible to assist the correct alignment of the photometer and spectrograph. To obtain a sharp image it was found necessary to remove the quartz window from in front of the slit and bring the photometer to within 1 mm. of the slit cover.

The use of a hydrogen discharge tube as a source of continuous ultraviolet light is exceedingly convenient and much to be preferred to the tungsten steel spark. The Darby tube has the advantage over other designs of operating at 15 kilovolts, making it possible to interchange with the tungsten steel spark without alteration of the electrical supply circuit. It also requires no water cooling system. The Spekker photometer needs a point source of light and as the discharge in the hydrogen tube occurs along a 10 cm. capillary tube, the correct alignment of the tube with the photometer is difficult and it is necessary to mount the tube in a precision micrometer stand. Incorrect alignment is indicated by a difference in the intensities of the two spectra with no cells in the light path and the photometer drum set at zero. Once correctly aligned the tube has needed no further attention over a period of six months.

Eastman Process plates were used and developed for four minutes at 20–22° in Eastman high contrast developer (Formula D. 19). They were analyzed by visual spotting of the match points directly on the plate against a suitable uniformly illuminated background and the reading was facilitated by projection onto a ground glass screen.[9] The wave length scale was photographed onto the top and bottom of each plate and was calibrated against the spectrum of a copper spark.

All measurements were made in quartz cells of 1-cm. length with fused ends (Hilger Type H. 292). Absolute alcohol was used as solvent and solutions were prepared by progressive dilution of an initial sample weighed out on a microbalance. Measurements were made with a slit width of 0.12 mm. at 20–25°. The results are calculated in terms of $\log_{10} E_{molar}$ where $E_{molar} = \log_{10} I_0/I \cdot 1/cl$.

c = concentration of solute in moles per liter
l = cell length in cm.
$\log_{10} I_0/I$ = extinction coefficient read directly from the photometer drum

By suitable adjustment of the concentration it was possible to take the whole spectrum on four or five plates with thirty-one exposures on each, at the same time making certain that regions where fine structure was present were photographed under conditions of maximum sensitivity ($\log I_0/I > 1$).

Results

1,2-Benzanthracene.—Measurements on 1,2-benzanthracene itself were first made in order to compare the results obtained using this equipment with those of prior investigators. The first measurements of the absorption spectrum of 1,2-benzanthracene were made by Capper and Marsh,[2] whose curve agrees qualitatively in shape with that of the more recent investigators. The intensity

measurements in terms of log E are numerically about one log unit too great but the units in which E is calculated are not stated. Clar[3] obtained substantially the same curve with intensity measurements of the correct order of magnitude. In Table I are given the wave lengths and intensities of the maxima I obtained together with the values interpolated from the graph of Mayneord and Roe[4] and those of Capper and Marsh (the latter converted from oscillation frequencies to wave lengths).

TABLE I

POSITIONS AND INTENSITIES OF THE MAXIMA OF THE ULTRAVIOLET ABSORPTION SPECTRUM OF 1,2-BENZANTHRACENE

Band[a]	R. N. J.		Mayneord and Roe		Capper and Marsh
A	2540 Å.	(4.56)	2540 Å.	(4.62)	..
B	2655	(4.60)	2660	(4.65)	..
C	2765	(4.85)	2760	(5.00)	..
D	2870	(4.97)	2880	(5.10)	2875
E	2995	(3.99)	3000	(3.92)	2994
F	3125	(3.63)	3150	(3.65)	..
G	3275	(3.80)	3270	(3.82)	3275
H	3410	(3.87)	3400	(3.85)	3413
I	3580	(3.69)	3575	(3.70)	3593
I′	3655	(3.41)	...	..	3650

K	3845	(3.07)	3840	(2.95)	3840

[a] See Fig. 1.

It will be observed that agreement in both wave lengths and intensities of the maxima is very satisfactory except for the intensities of the two most strongly absorbing bands C and D for which the intensity measurements of Mayneord and Roe are appreciably high.

Monomethyl and Dimethyl Derivatives of 1,2-Benzanthracene.—The spectra and intensities measured for ten of the derivatives are given in Table II. All these give curves of the same general shape. The bands A, B, C, D and H are of approximately constant intensity throughout the series. Noticeable variations occur in the bands E, J, and K, E and J are missing entirely in the 9-methyl, 5,8-dimethyl and 9,10-dimethyl derivatives. The band K is missing also in the 10-methyl compound and is ill-defined in the 9-methyl compound. Variations are also to be observed in the degree of resolution of bands I and I′. Resolution into two separate bands is well-defined in the 1′-, 4-, 5-, 8- and 10-monomethyl compounds and in the 5,8-derivative but is absent in the others. It can just be resolved in the parent hydrocarbon. It does not seem possible to asso-

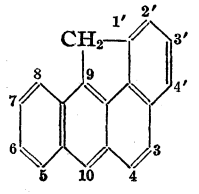
1',9-Methylene-1,2-benzanthracene. (I).—



(I)

Absorption measurements made on this compound show it to have a spectrum differing in many respects from that of the other derivatives (Fig. 2). The two bands C and D are here replaced by a system of one broad and two sharp maxima, all less intense. There is also more resolution in the longer wave region there being ten maxima resolved in the E–K range instead of eight. The act of bridge formation is not in itself sufficient cause for this change since cholanthrene and 20-methylcholanthrene show spectra of the normal type. Examination of Stuart models suggests that considerably more strain is present in the 1',9-methylene structure than in the 5,10-dimethylene bridge of cholanthrene and the changes produced in the spectrum may be associated with this condition.

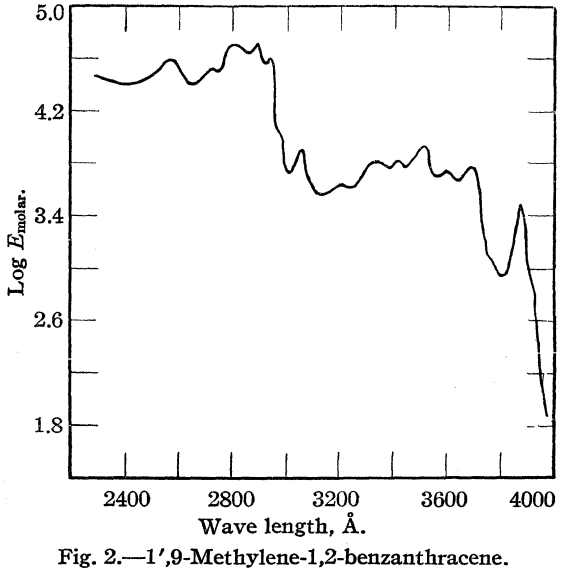


Fig. 2.—1',9-Methylene-1,2-benzanthracene.

Bathochromic Shifts Produced by Substitution.—The introduction of an alkyl group into an aromatic compound produces a shift of the absorption curve toward longer wave lengths (bathochromic shift). Klingstedt[10] found a shift of 820 cm.$^{-1}$ for toluene with respect to benzene and de Laszlo[11] observed shifts of 330 and 690 cm.$^{-1}$ for α- and β-methylnaphthalenes, respectively, in comparison with naphthalene.

An analysis of the alkyl 1,2-benzanthracenes shows that the shift produced differs very much according to the position of substitution. In making such an analysis the question arises as to what criterion should be taken in determining the relative shift. The displacement of each individual maximum may be measured (preferably on a frequency scale) and a mean value deduced but

such a method is open to criticism as the widths of the bands vary considerably and with them the degree of accuracy possible in determining the exact position of the maximum; furthermore, as the number of bands which can be resolved in all the compounds is not the same, such a mean would have little physical significance. Band D is the most intense and is quite narrow and obviously corresponds to some major electronic excitation of the molecule. In view of this steepness, the position of the maximum can be determined more accurately than that of the other bands and it was therefore decided to compare the position of the maximum of this band only in the various derivatives.

In Table IV, column 2 the positions of the maximum of band D of twenty derivatives of 1,2-benzanthracene are arranged in increasing order of bathochromic shift. The values of the compounds in italics are interpolated from the graphs of Mayneord and Roe.[4]

Bathochromic Shift and Carcinogenic Activity.—Many of the alkyl and ace-1,2-benzanthracenes are carcinogenically active and it is interesting to examine whether any relation can be found between the spectrum of these compounds and their physiological action. An attempt to discover such a relation implies that the carcinogenic activity can be assessed quantitatively or at least that the compounds can be arranged in order of increasing carcinogenic potency; much attention has been given to this subject in the laboratories of Fieser,[5] Shear[6] and Cook.[7] The carcinogenic activity is often expressed in terms of the latent period between the commencement of the administration and the development of tumors in mice. In the case of three compounds which have been very thoroughly investigated, *viz.*, 1,2,5,6-dibenzanthracene, 20-methylcholanthrene and 3,4-benzpyrene it has been shown that many factors enter into the determination of this latent period. These include the genetic history, age and sex of the mouse, and the dosage, manner and medium of administration of the hydrocarbon. Cook has usually administered the compound by skin painting producing a carcinoma, while Shear has largely employed subcutaneous injection to give a sarcoma of the connective tissue.

The carcinogenic activity of most of these alkyl 1,2-benzanthracenes has so far been examined only in a superficial manner; determinations of the latent period prior to tumor production have been made on only ten or twenty mice and not necessarily under comparable conditions of genetic strain, age, sex or dosage, etc. The data at present available are summarized in Table IV (Fieser[5]) and it will be observed that some correlation can be traced between the carcinogenic activity and

the bathochromic shift of band D. Considering first the monomethyl derivatives, of the twelve possible isomers eight have been examined and the carcinogenically inactive 1′- and 7-methyl compounds show a very small shift (5, 10 Å.) whereas the 10-methyl compound, the most active of this group, has the largest shift (45 Å.). The 9,10-dimethyl compound, which is highly active, particularly with regard to skin painting, and cholanthrene both show large shifts (95, 80 Å.) while 20-methylcholanthrene which acts very rapidly on both subcutaneous and cutaneous tissue has the maximum shift of 100 Å. The introduction of a second alkyl group into an alkylaromatic hydrocarbon causes a further shift of the spectrum to longer wave lengths, yet in the feebly carcinogenic 6,7-dimethyl compound the shift is small (10 Å.), less than that of many of the monomethyl derivatives. The relative carcinogenic activities of the 6,7- and 5,6-cyclopenteno derivatives are also in agreement with their spectral shifts.

The correlation, however, is not without exceptions. The 10-isopropyl compound is inactive yet the bathochromic shift is quite large. Here there is a second factor introduced in the lengthening of the side chain and it is known that even the extreme lengthening of an alkyl chain may produce little change in the absorption of an attached chromophore (*cf.* the spectra of acetic and palmitic acids[12]) while its effect on the physiological properties may be profound. The 8-methyl compound is a more significant exception. It has failed to produce tumors when the crystalline substance was repeatedly injected into twenty mice over a period of ten months (Shear[13]).

3,4-Benzpyrene is included in Table IV in parentheses since although the short wave region of the spectrum is like that of 1,2-benzanthracene the longer wave part is different. The spectrum of 1,2,5,6-dibenzanthracene is quite different and cannot be included in this analysis. Of the carcinogenically active hydrocarbons not closely related to 1,2-benzanthracene, the 3,4-benzphenanthrene group is the most interesting, particularly the 2-methyl compound, which is very potent when applied to the skin[14] but apparently inactive subcutaneously.[13] The absorption spectrum of 3,4-benzphenanthrene differs considerably from that of 1,2-benzanthracene.[4]

The magnitude of these spectral shifts corresponds to relatively small differences in the absorption energy involved. The general similarity in shape and constancy of intensity among all the curves show that the presence or absence of an alkyl group can have only a minor influence on the electronic activations of the molecule associated with light absorption in this near ultraviolet region of the spectrum. On the other hand, the observed displacements are considerably greater than the experimental errors of measurement. At present the mode of action of a carcinogen is obscure and the great differences in activity among compounds of closely similar structure show that the controlling factors may be exceedingly subtle. The small spectral shifts and variations in carcinogenic activity may be independent consequences of some such common structural influence.

Acknowledgment.—The author wishes to thank Professor L. F. Fieser for his encouragement and advice during the progress of this research, the Commonwealth Fund for fellowship support and Dr. Hugh H. Darby for many valuable suggestions regarding the setting up of the apparatus. Funds for the installation of the spectrograph were derived from a grant to Professor Fieser from the National Advisory Cancer Council.

Summary

The ultraviolet absorption spectra of 1,2-benzanthracene and of ten mono and dimethyl derivatives have been examined and found to be closely similar in shape and intensity. Considerable variation is observed in the bathochromic shift of the position of the maximum of the most intense band and this appears to show some correlation with the variation in the carcinogenic activity of the hydrocarbons.

The spectrum of 1′,9-methylene-1,2-benzanthracene differs markedly from that of the other derivatives and this is considered possibly to be due to steric strain in the molecule.

The spectrographic equipment recently installed in these laboratories is also described.

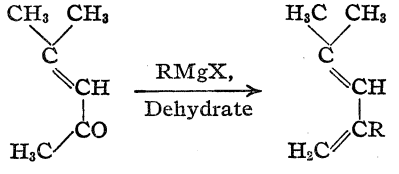
Diene Synthesis of 2,3-Dialkyl-1,4-naphthoquinones Related to Vitamin K

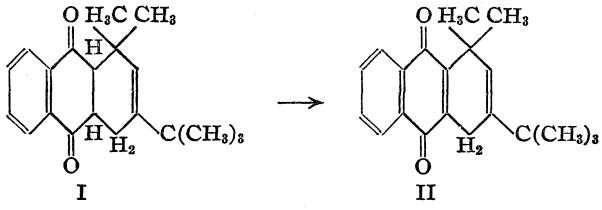
BY LOUIS F. FIESER AND CHARLOTTE W. WIEGHARD[1]

This research was undertaken with the idea of utilizing the reaction of α-naphthoquinone with dienes as a means of synthesizing compounds sharing with vitamins K_1 and K_2 the structural feature of a 1,4-naphthoquinone nucleus with alkyl substituents at the 2 and 3 positions. It soon became apparent from other observations in this Laboratory[2] that in the series of 2,3-dialkyl-1,4-naphthoquinones which have been assayed the antihemorrhagic activity of the first member (dimethyl) of the group is rather anomalous and that among the remaining compounds vitamin K activity begins to appear only when the alkyl side chains include a total of about ten carbon atoms. Preference was therefore given in the present work to the use of dienes of reasonably high molecular weight.

One scheme was to add a 1,1-dialkyl derivative of butadiene to α-naphthoquinone and convert the product to a 2,3-disubstituted naphthoquinone by isomerization and oxidation, for the presence of the *gem*-dialkyl group would counteract the normal tendency of the terminal ring to become aromatized with the formation of an anthraquinone. A satisfactory route to dienes of the desired type consists in the addition of a Grignard reagent to mesityl oxide and dehydration of the resulting carbinol.



The diene resulting from the use of the methyl Grignard reagent has already been added to α-naphthoquinone by Diels and Alder,[3] who converted the addition product as outlined above into 1,1,3-trimethyl-1,4-dihydroanthraquinone. On repeating their experiments a quinone was obtained of such widely different melting point as to suggest that a typographical error may have been made in their report. The substance was found by Dr. W. L. Sampson to be inactive in the chick assay at a dosage of 200 γ. A more promising case for present purposes consisted in the



introduction of a *t*-butyl group in the first step. The addition product I was obtained in a crystalline condition and easily isomerized and oxidized by treatment with alcoholic alkali and air and converted into the naphthoquinonoid substance II. A tertiary alkyl group has the advantage of preventing dehydration of the carbinol from occurring in more than one direction. This complication may have been involved in an experiment utilizing the carbinol[4] resulting from the reaction of mesityl oxide with ethylmagnesium bromide. The diene obtained on dehydration corresponded in boiling point with the material described by Abelmann[5] but gave no crystalline product when added to α-naphthoquinone.

A few attempts were made to employ 1,1,4,4-tetraalkylbutadienes in the synthesis without success. Suitable starting materials are available by the condensation of diethyl succinate with excess methyl[6] or ethyl[7] Grignard reagent and dehydration of the resulting glycols, as described for the first example by Faworsky.[8] The tetramethyl and tetraethyl compounds were both prepared but neither substance added readily to α-naphthoquinone and under forcing conditions extensive decomposition occurred.

A further scheme of synthesis is illustrated by the sequence of reactions starting with the addition of myrcene to α-naphthoquinone. The known addition product III[9] cannot be treated as above because of the ready conversion of the intermediate oxidation product into an anthraquinone under the conditions of its formation. The required partial dehydrogenation was accom-

plished successfully by conversion with acetic anhydride and pyridine into the diacetate IV, cleavage of this with methylmagnesium chloride, and oxidation of the liberated hydroquinone with silver oxide. 2-(∂-Methyl-γ-pentenyl)-1,4-dihydroanthraquinone (V) was thereby obtained in good yield as a crystalline yellow product.

Although 1,1-dimethyl-3-*t*-butyl-1,4-dihydroanthraquinone (II) and 2-(∂-methyl-γ-pentenyl)-1,4-dihydroanthraquinone (V) are comparable in molecular complexity with the antihemorrhagic 2-methyl-3-geranyl and 2-methyl-3-cinnamyl derivatives of α-naphthoquinone, neither substance showed vitamin K activity when assayed at 400 γ and 50 γ, respectively (W. L. Sampson).

Experimental Part[10]

1,1,3 - Trimethyl - 1,4 - dihydroanthraquinone.—**1,1,3-Trimethylbutadiene** was prepared essentially as described by Fellenberg.[11] From 50 g. of mesityl oxide and the reagent from 18 g. of magnesium and excess methyl chloride, refluxing in ether for one hour, there was obtained after two distillations 50 g. (86%) of the carbinol, b. p. 46° (14 mm.). This was dehydrated by distillation from 10 g. of potassium bisulfate at about 80–88°. The twice distilled diene boiled at 93°; yield, 27.5 g. (65%).

A mixture of 6 g. of the diene and 2 g. of α-naphthoquinone was refluxed for eight hours and the excess diene removed in vacuum. The residual yellow oil solidified on cooling, and two crystallizations from alcohol (Norite) gave 2 g. (62%) of colorless addition product, m. p. 119°, as reported by Diels and Alder.[3] This was dissolved in 10 cc. of hot alcohol and after adding one drop of 10% alcoholic potassium hydroxide, air was bubbled through the solution until the color changed from green to red to orange (ten minutes). The quinone separated in yellow plates and on recrystallization from alcohol formed yellow plates, m. p. 129–129.5°; yield 1.2 g. (60.5%). The melting point remained unchanged on recrystallization, and several preparations were made with the same results. Since Diels and Alder[3] report a very different m. p. (162°), the sample was analyzed. A cold alcoholic solution of the quinone acquires an intense greenish blue color on adding 10% alcoholic potassium hydroxide; the color fades slowly on standing, or rapidly on shaking with air, to a light orange.

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39. Found: C, 81.12; H, 6.58.

1,1 - Dimethyl - 3 - *t* - butyl - 1,4 - dihydroanthraquinone (II).—In the first step, conducted essentially as described by Stevens,[12] the reagent prepared under nitrogen from 18 g. of magnesium, 70 g. of *t*-butyl chloride, and 600 cc. of ether was added with stirring to 40 g. of mesityl oxide in 300 cc. of ether and after refluxing for one hour the complex was decomposed with dilute acetic acid. The ether layer was washed neutral, washed with sodium chloride solution, dried with sodium sulfate, and evaporated. In the first distillation of the carbinol a 36-g. fraction, b. p. 85–105° (40 mm.), was collected; redistillation gave 23.4 g. (37%) of material, b. p. 94–95° (40 mm.). This fraction was distilled from 5 g. of potassium bisulfate and the cloudy distillate dried over sodium sulfate and distilled. There was obtained 13.3 g. (64%) of **1,1-dimethyl-3-*t*-butylbutadiene,** b. p. 58–59° (32 mm.).

For preparation of the addition product 12 g. of the diene was first heated with 4 g. of α-naphthoquinone without solvent at 100–110° for twenty-four hours. Some product crystallized on cooling, but the reaction was evidently incomplete and some decomposition had occurred (dark melt), and consequently 10 cc. of dioxane was added and heating continued for twenty-four hours longer. After evaporation in vacuum the viscous brown residue was triturated with 3 cc. of alcohol and the dark crystalline product obtained was recrystallized three times from alcohol using Norite, when glistening, colorless needles of the **addition product I** were obtained. The substance melts at 142–143°; yield 1 g. (13%).

Anal. Calcd. for $C_{20}H_{24}O_2$: C, 81.04; H, 8.16. Found: C, 80.97; H, 8.09.

For isomerization and oxidation, 1 g. of the addition product was dissolved in 5 cc. of hot alcohol, a drop of 10% alcoholic potassium hydroxide was added, and air was bubbled through until the sequence of color changes reached an orange end-stage. The quinone crystallized on rubbing and the material, purified by two further crystallizations, formed yellow needles, m. p. 102–103°. The

(10) All melting points are corrected. Microanalyses by Lyon Southworth and Herbert S. Wight.

(11) Fellenberg, *Ber.*, **37**, 3578 (1904).

(12) Stevens, THIS JOURNAL, **57**, 1116 (1935).

yield of satisfactory material was 0.35 g. (35%). In the test with alcoholic potassium hydroxide in the cold, the quinone gives an intense blue changing slowly to yellow.

Anal. Calcd. for $C_{20}H_{22}O_2$: C, 81.59; H, 7.53. Found: C, 81.60; H, 7.62.

2 - (∂ - Methyl - γ - pentenyl) - 1,4 - dihydroanthraquinone (V).—The myrcene employed was obtained from a commercial terpene fraction of bay oil. About half of this distilled at 64–69° (20 mm., 1-m. column), and on redistillation of 250 cc. of this material the myrcene collected chiefly in a fraction boiling at 64.5–66° (20 mm.) and weighing 120 g. Semmler[13] reports the b. p. 67–68° at 20 mm. For identification a sample was converted into the maleic anhydride addition product, which corresponded in b. p. (188° at 8 mm.) and m. p. (34–35°) with the material described in the literature.[9,14]

The reaction between myrcene (30 cc.) and α-naphthoquinone (10 g.) was conducted by refluxing in dioxane (30 cc.) for twelve hours. After evaporation in vacuum the oily product was taken up in petroleum ether (b. p. 30–60°) and the solution was chilled and seeded with crystals obtained by cooling a dilute solution in petroleum ether to −70°. There was obtained 15.4 g. (83%) of cream colored crystalline product, m. p. 60–61°. Two crystallizations gave colorless crystals, m. p. 61–61.3°; yield 12 g. (64%). Arbusow and Abramow[9] found the m. p. 58–58.5°.

Anal. Calcd. for $C_{20}H_{22}O_2$: C, 81.59; H, 7.53. Found: C, 81.70; H, 7.66.

The **hydroquinone diacetate IV** was prepared by heating the addition product (12 g.) in acetic anhydride (20 cc.) and pyridine (4 cc.) for one hour on the steam-bath. The solution was cooled and stirred with dilute hydrochloric acid; with the hydrolysis of the excess anhydride the diacetate separated as a tan colored solid. This was taken into ether and the solution was washed free of acid, dried, and the solvent evaporated in vacuum. Three crystallizations from alcohol gave 13 g. (84%) of colorless needles having a fluorescent greenish tinge and melting at 121–122°.

Anal. Calcd. for $C_{24}H_{26}O_4$: C, 76.16; H, 6.93. Found: C, 76.34; H, 6.98.

For conversion to the quinone, 13 g. of the diacetate was added in ether solution to the Grignard reagent prepared from 12 g. of magnesium, 400 cc. of ether, and the required amount of methyl chloride. After refluxing for forty-five minutes the ether was largely displaced with benzene and refluxing was continued for one-half hour longer. The mixture was decomposed with ammonium chloride and hydrochloric acid and the yellow organic layer was washed, dried, and shaken for one-half hour with 3 g. of silver oxide and 20 g. of sodium sulfate. The filtered solution was evaporated, eventually under vacuum, leaving a residue of 7 g. (70%) of the quinone, m. p. 88–89°. Crystallized from alcohol, the substance formed glistening yellow plates, m. p. 89.8–90.8°. With alcoholic alkali the substance gives a red color changing rapidly on shaking with air to pale yellow.

Anal. Calcd. for $C_{20}H_{20}O_2$: C, 82.20; H, 6.89. Found: C, 82.25; H, 7.00.

Summary

As a route to 2,3-dialkyl-1,4-naphthoquinones of high molecular weight which might show vitamin K activity, a study has been made of the addition of suitable dienes to α-naphthoquinone and the partial dehydrogenation of the products. Two satisfactory syntheses were developed and applied to the preparation of C_{20}-quinones of the type desired. Neither of these substances shows activity.

Vitamin K-Active Derivatives of 2-Methyl-1,4-naphthohydroquinone

BY S. ANSBACHER, ERHARD FERNHOLZ AND M. A. DOLLIVER[1]

About six months ago we reported[2] that 2-methyl-1,4-naphthoquinone has a vitamin K potency of 1 unit[3] in about 0.5 γ. Simultaneously other investigators[4,5,6] published their work with this substance, and it is apparent that they then failed to observe the outstanding biological activity of this compound. However, the same authors,[7,8,9] and others[10,11] fully confirmed our results in more recent communications. Meanwhile we prepared and investigated several derivatives which are the object of the present report.

Experimental Part[12]

2 - Methyl - 1,4 - naphthohydroquinone - dipropionate.—A mixture of 10 g. of 2-methyl-1,4-naphthoquinone, 30 ml. of propionic acid, 100 ml. of propionic anhydride, 25 g. of zinc dust and 5 g. of fused sodium propionate was refluxed for thirty minutes in an oil-bath at 160–170°, then poured into water. An oily product separated and solidified on standing. It was removed by filtration and recrystallized from dilute methanol to a constant m. p. of 74–75°; yield 12 g. (72%).

Anal. Calcd. for $C_{17}H_{18}O_4$: C, 71.29; H, 6.34. Found: C, 71.48; H, 6.36.

The procedure followed for preparing the dipropionate is similar to the one used by Anderson and Newman[13] for the synthesis of the diacetate.

2 - Methyl - 1,4 - naphthohydroquinone - dibenzoate.—12.5 g. of 2-methyl-1,4-naphthohydroquinone was treated with 30 g. of benzoyl chloride in 60 g. of pyridine while cooling. After standing for one hour, the mixture was heated for thirty minutes at a bath temperature of 110–120° and poured into water. The resulting precipitate was collected by filtration and recrystallized from dilute acetone to a constant m. p. of 179°; yield 16.2 g. (59%).

Anal. Calcd. for $C_{25}H_{18}O_4$: C, 78.51; H, 4.97. Found: C, 78.71; H, 5.00.

A second crop of 9 g. (m. p. 174–176°) was obtained from the mother liquors, bringing the total yield to 25.2 g. (84%).

2 - Methyl - 1,4 - naphthohydroquinone - di - *n* - butyrate. Method A.—A mixture of 10 g. of 2-methyl-1,4-naphthoquinone, 30 ml. of butyric acid, 100 ml. of butyric anhydride, 5 g. of fused sodium butyrate, and 25 g. of zinc dust was refluxed for one hour in an oil-bath at 170–180°, then poured into water. As crystallization could not be induced, the oily product was extracted with ether, dried over anhydrous sodium sulfate and fractionated to give 12.5 g. of an oil distilling at 175–185° (1 mm.). The distillate solidified on cooling and stirring, and was recrystallized from dilute methanol to a constant m. p. of 52–53°; yield 10 g. (55%).

Anal. Calcd. for $C_{19}H_{22}O_4$: C, 72.57; H, 7.06. Found: C, 72.66; H, 7.31.

Method B. A mixture of 15 g. of *n*-butyryl chloride and 100 ml. of pyridine was added to 8.5 g. of 2-methyl-1,4-naphthohydroquinone and gently refluxed for one hour. After standing for one hour the mixture was poured into 800 ml. of water and the resulting oil extracted with ether. The ethereal solution was washed with 10% hydrochloric acid to remove pyridine, then freed from acid with water, and finally dried over anhydrous sodium sulfate. Fractionation gave 7.9 g. of an oil distilling at 190–195° (1.5 mm.). The distillate solidified on cooling and stirring. Recrystallization from dilute methanol yielded 3.5 g. of a compound melting at 52–53° and with no depression of melting point when mixed with the product resulting from method A.

2 - Methyl - 1,4 - naphthohydroquinone - di - isobutyrate.—Thirty grams of isobutyryl chloride in 75 ml. of pyridine was added to 19.5 g. of 2-methyl-1,4-naphthohydroquinone, the mixture allowed to stand for ninety minutes, then heated in an oil-bath at 120–135° for one hour, and finally poured into water. The solids thus obtained were removed by filtration, washed with water, and recrystallized from dilute methanol to a constant melting point of 73–74°; yield 24.6 g. (69%).

Anal. Calcd. for $C_{19}H_{22}O_4$: C, 72.57; H, 7.06. Found: C, 72.64; H, 7.02.

2 - Methyl - 1,4 - naphthohydroquinone - di - *n* - valerate.—Sixteen grams of 2-methyl-1,4-naphthohydroquinone was dissolved in 80 ml. of pyridine and treated dropwise while cooling and shaking with 30 g. of *n*-valeryl chloride. After standing for one hour the mixture was refluxed for one hour at a bath temperature of 120–130°, allowed to stand overnight and finally poured into water. The oily product was extracted with ether, the extract washed with water, 10% hydrochloric acid, and again with water. After being dried over anhydrous sodium sulfate, the ether was removed by distillation and the residual red oil was distilled three times under reduced pressure from a modified Claisen flask. The final product was a yellow oil distilling at 210° (1 mm.); yield 22 g. (70%).

Anal. Calcd. for $C_{21}H_{26}O_4$: C, 73.64; H, 7.66. Found: C, 73.43; H, 7.77.

After standing for some time, it crystallized and was recrystallized from dilute methanol to a constant melting point of 40–41°.

2 - Methyl - 1,4 - naphthohydroquinone - di - isovalerate.—Fifteen grams of 2-methyl-1,4-naphthohydroquinone was treated with 30 g. of isovaleryl chloride in 50 ml. of pyridine, then heated at a bath temperature of 130° for one hour. The mixture was poured into water and the resulting oil extracted with ether. The ethereal solution was washed with water, 10% hydrochloric acid, and again with water. After being dried over anhydrous sodium sulfate the ether was removed by evaporation and the residue was fractionated by three vacuum distillations from a modified Claisen flask. The final product was a yellow oil distilling at 185° (1 mm.); yield 14.2 g. (48%).

Anal. Calcd. for $C_{21}H_{26}O_4$: C, 73.64; H, 7.66. Found: C, 73.02; H, 7.44.

2-Methyl-1,4-dimethoxynaphthalene.—18.4 g. of 2-methyl-1,4-naphthohydroquinone was added to 53.6 g. of dimethyl sulfate in a flask equipped with a reflux condenser, mercury-seal stirrer, and a gas inlet tube. Nitrogen was passed through the apparatus while adding 1-ml. portions of a solution of 47.6 g. of potassium hydroxide in 100 ml. of water by way of the condenser. The mixture was then heated on the steam-bath for forty-five minutes, allowed to stand overnight, finally diluted to 500 ml. with water and extracted with ether. The extract was washed free from alkali with water, dried over anhydrous sodium sulfate and fractionated to yield 16.5 g. of an oily product distilling at 174–178° (18 mm.). The oil solidified on treatment with 50 ml. of 1 *N* sodium hydroxide and cooling. Recrystallization from petroleum ether gave a white crystalline product melting at 48–49°; yield 11.8 g. (55%).

Anal. Calcd. for $C_{13}H_{14}O_2$: C, 77.19; H, 6.98. Found: C, 77.09; H, 6.87.

The procedure followed for preparing the dimethyl ether

is essentially the one outlined by Giral.[14] However, the product obtained by this investigator had a b. p. of 175–178° (18 mm.) and a m. p. of 23–24°.

Bio-assays.—The rapid assay procedure, carried out to date on more than 15,000 chicks, was employed for determining the vitamin K unit of the various naphthohydroquinone derivatives summarized in Table I. The method has been described in detail[3] and found applicable to the testing of concentrates,[3,15,16] synthetic vitamins[15] and synthetic substitutes.[2,15,17,18] Certain minor, but nevertheless important, points seem to warrant emphasis, since they were overlooked by other investigators when attempting to make use of a rapid assay procedure.

TABLE I

VITAMIN K UNIT OF METHYLNAPHTHOHYDROQUINONE AND ITS DERIVATIVES

Compound, 2-Methyl-1,4-	1 unit equals, γ
Naphthohydroquinone	0.5
Naphthohydroquinonediacetate	1
Naphthohydroquinonedipropionate	1
Naphthohydroquinonedibenzoate	1
Naphthohydroquinone-di-*n*-butyrate	1.25
Naphthohydroquinone-di-isobutyrate	5
Naphthohydroquinone-di-*n*-valerate	1.25
Naphthohydroquinone-di-isovalerate	3
Dimethoxynaphthalene	5

The medium employed for administering the test substances was cod liver oil in most of our experiments. Other oils, such as peanut or corn oil, are likewise satisfactory vehicles. However, the amount of the menstruum plays a decisive role. In accordance with the definition of our unit,[3] we administer fat-soluble test substances always in 0.10 ml. of oil. If a product is soluble in water, its potency can be determined with aqueous solutions. The 2-methyl-1,4-naphthoquinone is soluble in water to the extent of about 100 γ/ml.; it shows a biological response indicative of 1 unit in about 0.5 γ, irrespective of whether it is dissolved in 0.10 ml. of cod liver oil or 1 ml. of water. Incidentally, such aqueous solutions can be administered intravenously.

If a vitamin K experiment is carried out properly, the chicks become deficient within two weeks, no spontaneous cures occur, the blood clotting time of all the animals remains prolonged, and hemorrhages develop as a result of which death occurs. If a bird shows hemorrhages but has a normal or only slightly prolonged coagulation time after the depletion period, it undoubtedly has had access to vitamin K. There are chicks which will be more resistant to vitamin K deficiency than others, as already pointed out for birds with enlarged thyroid glands.[3] Furthermore, many investigators have commented on the apparent resistance of animals hatched during the summer months, and we have found that exposure of day-old chicks to freezing temperatures for about six hours, as a preliminary step to the depletion period, is a contributing factor to a high incidence of vitamin K deficiency. A biological assay properly conducted will permit the determination not only of the minimum effective dose, but also of the duration of the curative effect, summarized for the naphthohydroquinone derivatives in Table I and Table II, respectively.*

TABLE II

DURATION OF THE CURATIVE EFFECT OF THE VARIOUS COMPOUNDS

Compd.	Amount, γ	Hours
2-Methyl-1,4-naphthoquinone	0.75	72
	.50 (1 unit)	48
	.25	24
2-Methyl-1,4-naphthohydroquinonediacetate	1.5	72
	1.0 (1 unit)	48
	0.75	24
2-Methyl-1,4-naphthohydroquinonedipropionate	1.5	72
	1.0 (1 unit)	48
	0.75	24
2-Methyl-1,4-naphthohydroquinone-di-*n*-butyrate	1.5	72
	1.25 (1 unit)	48
	1.0	24

Discussion

Since 2-methyl-1,4-naphthohydroquinone may be oxidized easily to methyl-1,4-naphthoquinone, the equal potency of the two compounds was to be expected and has been mentioned already by Thayer, *et al.*[8] The mechanism of the biological effect of vitamin K active naphthohydroquinone derivatives has not been explained; it appears possible that an oxidation–reduction phenomenon is involved and certain data apparently substantiate such a hypothesis. The diacetate, dipropionate and dibenzoate esters are identical as far as potency, speed of action and period of efficacy within the animal body are concerned. This fact could be interpreted to mean that esters are

(*) The detailed data of Tables I and II are included in the authors' reprints of this paper.

first saponified and then act in the form of methylnaphthohydroquinone. However, the potencies of the di-*n*-butyrate and di-*n*-valerate were found to be significantly greater than those of the corresponding iso-compounds with their inherent branched chains. This interesting observation may be explained by a difference in the rate of absorption, but it is also possible that these derivatives act as a whole and not in the form of a methylnaphthohydroquinone–methylnaphthoquinone equilibrium. Furthermore, the activity of the dimethyl ether is remarkably great, although in all probability this compound cannot be transformed to methylnaphthohydroquinone, considering the difficulty with which methyl ethers of phenols are split *in vitro*.

Our data confirm the results of Binkley, *et al.*,[19] namely: "In general, the activities of the diacetates of the 1,4-diols were about one-half that of the corresponding quinones." Most recently Doisy and his co-workers[20] stated, furthermore: "Only 1,4-naphthoquinones and compounds which upon oxidation in the organism might yield 1,4-naphthoquinones showed activity." In view of our observations above, particularly in conjunction with the vitamin K potency of phlorone, already reported,[18] it would seem that vitamin K activity is not confined solely to 1,4-naphthoquinones. Incidentally, anthraquinone appears to have a potency of one unit in about 2 mg.

Summary

The preparation of several esters and an ether of 2-methyl-1,4-naphthohydroquinone is described.

The various derivatives were found to have different vitamin K potencies.

A discussion of the relationship between structure and vitamin K activity is presented.

Sulfanilamide Compounds. II. Arylidine Derivatives of N^1-Substituted Sulfanilamides

BY H. G. KOLLOFF AND JAMES H. HUNTER

In 1936 Buttle, Gray and Stephenson[1] reported N^1-phenylsulfanilamide to be as active against streptococcal infections in mice as sulfanilamide and on the basis of our preliminary tests N^1-(4-nitro)-phenylsulfanilamide[2] shows considerable activity against both streptococcal and pneumococcal infections. Since 1938 N^1-(2-pyridyl)-sulfanilamide[3] (Sulfapyridine, M. and B. 693) has attained a foremost position in the ranks of antibacterial agents.

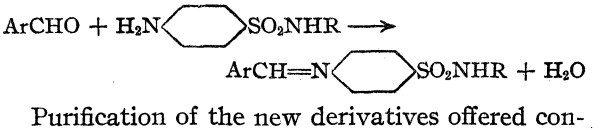
Goissedet, Despois, Galliot and Mayer[4] observed that some benzylidine sulfonamides were active and during the following year work along this line was continued by Gray, Buttle and Stephenson.[5]

The foregoing considerations suggested the preparation of a series of arylidine derivatives of the N^1-substituted sulfanilamides in order to ascertain in what respect their activity was generally affected by introducing an arylidine group.

For sake of comparison between structure and activity, the arylidine derivatives of the parent compound, sulfanilamide, have been included.

Sulfanilamide and sulfapyridine were obtained through commercial sources; N^1-phenylsulfanilamide was prepared according to Gelmo,[6] and for the preparation of N^1-(4-nitro)-phenylsulfanilamide the procedure of Webster and Powers[2] was successfully modified in that pyridine rather than dimethylaniline was used as a reaction medium.

The arylidine derivatives listed in Table I were prepared in 73% to practically quantitative yields by condensing the N^1-substituted sulfanilamides with the appropriate aldehyde in the absence of a solvent according to the equation



Purification of the new derivatives offered con-

siderable difficulty because of both their slight solubility and their instability. When possible, the products were crystallized from benzene and its homologs or from an acetone–petroleum ether mixture. In some cases the crude products were simply washed with suitable solvents for removal of unreacted starting materials.

These arylidine derivatives, particularly the benzylidine and 4-methoxybenzylidine derivatives, hydrolyze easily. Some underwent hydrolysis merely by crystallization from dilute alcohol; for this reason water was excluded from the crystallizing media. A few compounds, N^4-(4-methoxy)-benzylidine-N^1-phenylsulfanilamide, for instance, decomposed when crystallized from high-boiling solvents such as toluene or xylene.

We are indebted to Dr. F. A. Eberly and Mr. E. A. Gibson[7] for the biological data herein reported.

These preliminary studies indicate that in general introduction of an arylidine group results in a slight, but not particularly significant, decrease in both the antistreptococcal and antipneumococcal activity; the latter was diminished to a greater extent than the former. In every instance the toxicity was found to be lowered.

(7) A detailed report of the biological study of these and other derivatives will be published elsewhere.

Further biologic studies are being made on certain compounds of this series where preliminary indications warrant.

Work on similar arylidine derivatives is now in progress in these Laboratories.

Experimental

N^4-Arylidine-N^1-substituted Sulfanilamides.—The following procedure for the preparation of **N^4-(4-methoxy)-benzylidine-N^1-(4-nitro)-phenylsulfanilamide** is typical of that used in preparing the derivatives given in Table I. Seven and forty-eight hundredths grams (0.055 mole) of anisaldehyde (Eastman Kodak Company, "Practical") was added to 14.6 g. (0.05 mole) of N^1-(4-nitro)-phenylsulfanilamide[2] (m. p. 166.5–167.5°) contained in a 500-cc. round-bottom flask, and the latter immersed one-half its depth in an oil or metal bath at 140–150°. After about five minutes the mixture liquefied and the orange-colored melt was stirred mechanically for fifteen minutes, at which time it had partially resolidified. Stirring was discontinued and the mixture heated for an additional one and three-fourths hours. Lumps of material were occasionally crushed during the heating. The crude product was cooled and thoroughly washed with five 50-cc. portions of ether; yield, 20.1 g. (98% of the theoretical). Nine grams of the crude product was crystallized from 400 cc. of xylene using a little decolorizing charcoal; yield, 5.7 g., m. p. 211–211.5° (uncorr.).

Summary

A detailed procedure is given for a general method of preparing N^4-arylidine sulfanilamides;

the preparation of N^4-(4-methoxy)-benzylidine-N^1-(4-nitro)-phenylsulfanilamide is described as an example.

On the basis of preliminary biological studies, introduction of the arylidine group causes some diminution in activity, and a significant decrease in toxicity.

Sulfanilyl Derivatives of Pyridine and Quinoline Amines

BY ROBERT WINTERBOTTOM

Since the discovery by Whitby[1] of the therapeutic action of 2-sulfanilamidopyridine, numerous compounds of similar structure have been prepared. This paper describes the preparation of sulfanilamides containing a pyridine or a quinoline ring. The sulfanilyl derivatives of 5, 6, 7, and 8 aminoquinoline[2] were published by Bobranski while this research was in progress. Their physical properties correspond with those of the same compounds prepared in this Laboratory. Although there are many references in the literature to 2-sulfanilamidopyridine, its detailed method of synthesis has never appeared; for this reason its preparation has been included.

The aminoquinolines, with the exception of 3-aminoquinoline, were prepared from the corresponding nitroquinolines by catalytic reduction using Raney nickel. The yields were slightly better than those obtained by using iron and acetic acid.[3] Attempts to prepare 7-nitroquinoline by nitration of quinoline with lithium nitrate in acetic anhydride[4] failed to give appreciable yields. Diacetyl orthonitric acid was tried because of its peculiar orienting effects but was ineffective. 7-Nitroquinoline, prepared by the Skraup reaction using metanitraniline, upon catalytic reduction gave an aminoquinoline corresponding in physical properties to that prepared by Hamer.[5] It melted at 74–75.5° and not at 189° as described by earlier workers.[6] 3-Aminoquinoline was prepared from the corresponding bromo compound by treatment with aqueous ammonia at 200°.[7]

The sulfanilamides were prepared by condensing recrystallized acetylsulfanilyl chloride with the appropriate amine in pyridine solution. 5-N^4-Acetylsulfanilamido-2-acetylaminopyridine was prepared from 5-amino-2-acetylaminopyridine by Bauer's[8] method employing acetone. A sample of 2-acetylamino-5-aminopyridine was obtained through the courtesy of the Pyridium Corporation. The crude acetyl derivatives were recrystallized from ethanol or propanol. In cases where no suitable solvent could be found, the crude products were washed and dried before analysis, or prepared by acetylation of the free amine. In all cases, except that of 2-N^4-acetylsulfanilamidopyridine, removal of the acetyl group was effected by boiling for a half hour with 12% hydrochloric acid. This treatment causes rupture of the sulfonamide linkage when applied to 2-N^4-acetylsulfanilamidopyridine. When the hydrolysis was carried out in alcoholic hydrochloric acid solution, the sulfonamide link remained intact.

Experimental Part

7-Aminoquinoline.—7-Nitroquinoline (10 g., 0.058 mole), dissolved in 100 cc. of acetone, was reduced in a low pressure Parr hydrogenator in the presence of 0.6 g. (0.001 mole) of Raney nickel. Reduction was complete in one hour. The acetone was then allowed to evaporate. The product separated as an oil which soon solidified. Upon recrystallization from water, light yellow needles were obtained; yield: 8 g. (95%), m. p. 74–75.5°.

The same procedure was utilized for 5- and 8-aminoquinoline, using ethanol as the solvent. Recrystallization from ligroin and petroleum ether have yields of 75 and 69%, respectively.

2-Sulfanilamidopyridine.—Acetylsulfanilyl chloride (10 g.) and 2-aminopyridine (4 g.) were dissolved in 34 cc. of acetone containing 5 cc. of pyridine. Upon standing overnight 5 g. of almost pure product separated as a white deposit. The filtrate upon dilution with water gave an additional 4 g. For analysis it was recrystallized from acetone as small white needles. Removal of the acetyl group was effected by treating 1 g. of the crude acetyl compound with 10 cc. of ethanol and 2 cc. of concd. hydro-

8-N^4-Acetylsulfanilamidoquinoline[c,d]	193–194	$C_{17}H_{15}N_3O_3S$	12.31	12.02
8-Sulfanilamidoquinoline[c,d]	194–195	$C_{15}H_{13}N_3O_2S$	14.04	13.87

[a] Nomenclature according to Crossley, Northey and Hultquist, THIS JOURNAL, 60, 2217 (1938). [b] Dumas. [c] Previously prepared by Bobranski.[2] [d] Previously prepared by A. D. Choudhury, *et al.*, *J. Ind. Chem. Soc.*, 14, 733 (1937).

chloric acid. After refluxing for twenty minutes, the reaction mixture was diluted with water and made basic with ammonium hydroxide. It was recrystallized from ethanol; yield, 0.67 g. (75%).

5 - N^4 - Acetylsulfanilamido - 2 - acetylaminopyridine.—Using the same procedure as above, 3.0 g. of 5-amino-2-acetylaminopyridine and 4.0 g. of acetyl sulfanilyl chloride gave 6.0 g. (94%) of crude 5-N^4-acetylsulfanilamido-2-acetylaminopyridine. This was converted to 5-sulfanilamido-2-aminopyridine by the same procedure used below for 3-sulfanilamidoquinoline.

3-Sulfanilamidoquinoline.—3-Aminoquinoline (2.5 g.) and acetylsulfanilyl chloride (4.0 g.) were dissolved in 30 cc. of dry pyridine. After heating for two hours on the steam-bath, the reaction mixture was poured into 400 cc. of cold water. The product separated as a white crystalline mass weighing 5.4 g. when dry. For analysis a small amount was washed successively with water and ethanol and dried at 100°. One gram of the crude acetyl compound was boiled for a half hour with 25 cc. of 12% hydrochloric acid. Upon cooling and neutralizing with ammonium hydroxide, the sulfonamide was obtained; yield 0.8 g. (91%). It was recrystallized from ethanol.

Summary

An improved method of preparation of the 5, 7, and 8-aminoquinolines as well as the preparation of certain sulfanilamido derivatives of pyridine and quinoline amines is described.

The results obtained by Bobranski[2] are confirmed.

Amines Related to 2,5-Dimethoxyphenethylamine.[1] I

BY RICHARD BALTZLY AND JOHANNES S. BUCK

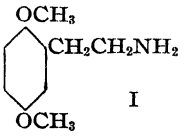
Preliminary pharmacological work has indicated that some amines containing the 2,5-dimethoxyphenyl group show activity comparable with that of similar phenolic amines, and also that they probably will be active orally. It therefore became important to prepare, for pharmacological examination, as complete a series as possible of amines (as hydrochlorides) containing the 2,5-dimethoxyphenethyl grouping, the optimal C–C–N side chain being present in all cases.

(1) This work is part of a joint research being carried out in collaboration with a pharmacological group at the above laboratories.

Six series of 2,5-dimethoxyphenethylamines were prepared, in each series the primary, secondary, tertiary and quaternary compounds being made. Included in the series are the analogs of practically all the known pharmacologically active amines containing the phenethyl group (that is, containing the C–C–N side chain).

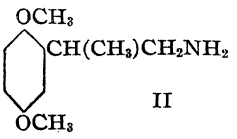
The present paper deals with the preparation and properties of the amines with no hydroxyl group in the side chain. One hydrochloride has been described previously.

The formulas of the primary amines are



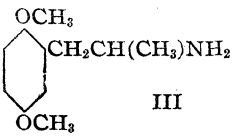
I

2,5-Dimethoxyphenethylamine



II

β-(2,5-Dimethoxyphenyl)-propylamine



III

β-(2,5-Dimethoxyphenyl)-isopropylamine

The syntheses of the first primary amine (I) and of the corresponding secondary amine have been described.[2] The starting material for the β-phenylpropylamine (II) was obtained by a Reformatzky reaction (2,5-dimethoxyacetophenone and ethyl bromoacetate). The remaining stages of the synthesis paralleled those of the first amine. The 2,5-dimethoxy-α-methylhydrocinnamic acid required for the third, β-phenylisopropylamine, was obtained by two methods, (a) by condensation of 2,5-dimethoxybenzaldehyde with ethyl α-bromopropionate, followed by reduction, and (b) by condensation of 2,5-dimethoxybenzaldehyde with diethyl malonate, followed by reduction, methylation, saponification and decarboxylation. Inaccessibility of the starting aldehyde deterred the authors from using the Claisen condensation with ethyl propionate, as this condensation in similar cases is wasteful and troublesome. The method of Bogert and Davidson[3] also was avoided, as in the authors' hands it gave discouraging results with dialkoxybenzaldehydes.

Secondary amines were obtained from the primary amines by the method of Decker.[2,4] The tertiary amines were prepared from the primary (or, better, secondary) amines by an adaptation of the Eschweiler reaction. Quaternary chlorides were obtained by the action of silver chloride on the methiodides of the tertiary amines.

Experimental

2,5-Dimethoxybenzaldehyde (gentisic aldehyde dimethyl ether) was prepared by the Gattermann method.[5] Amine hydrochlorides were all recrystallized, until pure, from absolute alcohol–ether mixture, sometimes with the addition of ethyl acetate. The solubilities of the hydrochlorides are all very similar, the compounds being readily soluble in water, alcohol, and methanol, and practically insoluble in less polar solvents. The melting points were determined on material dried for several hours at 100° *in vacuo*. All melting points are corrected.

2,5-Dimethoxyphenethylamine Hydrochloride.—The amine has been described previously.[2] The hydrochloride, made by the addition of absolute alcoholic hydrogen chloride to an ether solution of the amine, forms lustrous leaflets, melting at 139°.

Anal. Calcd. for $C_{10}H_{16}O_2NCl$: C, 55.15; H, 7.41. Found: C, 55.19; H, 7.37.

2,5-Dimethoxyphenethylmethylamine Hydrochloride.—This has been described previously.[2]

2,5-Dimethoxyphenethyldimethylamine Hydrochloride.—The above primary amine was converted into the tertiary amine by a modified Eschweiler reaction.[6,7,8] Nine grams of primary amine, 40 cc. of 36% formaldehyde solution and 0.1 cc. formic acid were heated for three hours at 125° in a sealed tube. The tertiary amine, b. p. 159° (23 mm.), was isolated in good yield and converted into the hydrochloride by adding alcoholic hydrogen chloride to the ether solution. The hydrochloride forms small, colorless plates, melting at 148°, and is rather hygroscopic.

Anal. Calcd. for $C_{12}H_{20}O_2NCl$: C, 58.63; H, 8.21. Found: C, 58.79; H, 8.25.

2,5-Dimethoxyphenethyltrimethylammonium Chloride.—The foregoing tertiary amine was converted, in ether solution, into the methiodide, which was filtered off, dissolved in water, and allowed to stand with silver chloride. After filtration, evaporation *in vacuo* and recrystallization, the chloride forms very hygroscopic lustrous plates, melting at 184–185°.

Anal. Calcd. for $C_{13}H_{22}O_2NCl$: C, 60.06; H, 8.54. Found: C, 60.28; H, 8.79.

2,5-Dimethoxy-β-methylcinnamic Acid.—2,5-Dimethoxyacetophenone and ethyl bromoacetate were condensed by the Reformatzky method, using a zinc–copper alloy. The resulting β-hydroxybutyric ester was dehydrated by phosphorus oxychloride to the β-methylcinnamic ester,[9,10] which was distilled, b. p. 140–143° (1.0 mm.). Saponification yielded the acid which crystallized from aqueous alcohol in slender prisms, melting at 113.5°.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.83; H, 6.35. Found: C, 64.82; H, 6.69.

β-(2,5-Dimethoxyphenyl)-butyric Acid.—The ester described above was reduced (platinum oxide and hydrogen) and then saponified. The resulting acid forms irregular crystals from ether–petroleum ether, melting at 79°.

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 64.27; H, 7.20. Found: C, 64.62; H, 7.40.

β-(2,5-Dimethoxyphenyl)-butyramide.—The foregoing acid was heated in a stream of ammonia, at 220–230°, for two hours. Recrystallized from benzene the amide forms columnar prisms melting at 121°.

β - (2,5 - Dimethoxyphenyl) - propylamine Hydrochloride.—The amine was obtained from the amide, in 45% yield, by the usual Hofmann procedure, using sodium hypochlorite. It boiled at 114° (1.0 mm.) and was converted into the hydrochloride by adding alcoholic hydrogen chloride to the ether solution. After recrystallization the hydrochlorite forms fine, colorless, felted needles melting at 149–150°.

Anal. Calcd. for $C_{11}H_{18}O_2NCl$: C, 56.99; H, 7.83. Found: C, 57.11; H, 8.03.

β - (2,5 - Dimethoxyphenyl) - propylmethylamine Hydrochloride.—The above primary amine was converted into the hydriodide of the secondary amine (m. p. 131°) by the Decker method (v. s.). The base, liberated from the hydriodide, was converted directly into the hydrochloride, which crystallizes in fine, colorless needles, melting at 146°.

Anal. Calcd. for $C_{12}H_{20}O_2NCl$: C, 58.63; H, 8.21. Found: C, 58.82; H, 8.07.

β - (2,5 - Dimethoxyphenyl) - propyldimethylamine Hydrochloride.—The tertiary amine may be prepared from the primary amine (or, better, from the secondary amine) by the Eschweiler methylation (v. s.). The amine was purified as the hydrochloride, which forms slender prisms, melting at 182–183°.

Anal. Calcd. for $C_{13}H_{22}O_2NCl$: C, 60.06; H, 8.54. Found: C, 60.33; H, 8.60.

β - (2,5 - Dimethoxyphenyl) - propyltrimethylammonium Chloride.—β - (2,5 - Dimethoxyphenyl) - propyldimethylamine (above) was treated with methyl iodide in ether solution to give the quaternary iodide (*i. e.*, the methiodide). Silver chloride converted the iodide (m. p. 139°) into the required chloride, which crystallizes in hygroscopic slender prisms. It forms a stable monohydrate, melting at 92°. After thorough drying, the chloride melts at 159–161° with discoloration.

Anal. Calcd. for $C_{14}H_{24}O_2NCl$: C, 61.37; H, 8.84. Found: C, 61.48; H, 9.18.

Diethyl 2,5-Dimethoxybenzalmalonate.—Diethyl malonate was condensed with 2,5-dimethoxybenzaldehyde in the presence of piperidine.[11] Saponification of a portion yielded an acid crystallizing in faint yellow leaflets from alcohol–benzene mixture. The acid melts at 183° (dec.). Kauffmann and Burr[5] prepared this acid by another method and gave the m. p. as 188° (dec.).

Anal. Calcd. for $C_{12}H_{12}O_6$: C, 57.12; H, 4.80. Found: C, 57.10; H, 5.13.

Diethyl 2,5-Dimethoxybenzylmalonate.—Catalytic reduction of the preceding ester yielded a nearly colorless oil, which was identified by saponifying a portion. The acid obtained, recrystallized from benzene, gave rhombic prisms melting at 156.5° (dec.).

Anal. Calcd. for $C_{12}H_{14}O_6$: C, 56.68; H, 5.55. Found: C, 57.03; H. 5.43.

2,5-Dimethoxybenzylmethylmalonic Acid.—The foregoing ester was methylated in the usual way (methyl iodide and sodium ethylate) and the product saponified. The resulting acid after crystallization from hexane forms fine, colorless crystals, melting at 143° (dec.).

Anal. Calcd. for $C_{13}H_{16}O_6$: C, 58.19; H, 6.02. Found: C, 58.35; H, 5.87.

α-Methyl-2,5-dimethoxyhydrocinnamic Acid.—This was obtained by heating the corresponding malonic acid (above) at 150°. After crystallization from ether–hexane mixture it forms a cream-colored powder melting at 59.5°.

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 64.27; H, 7.20. Found: C, 64.39; H, 7.14.

α-Methyl-2,5-dimethoxyhydrocinnamide.—The amide was obtained by heating the corresponding hydrocinnamic acid (above) in a stream of ammonia at 220–230° for two hours. Recrystallized from benzene it forms a finely crystalline powder melting at 99°.

Anal. Calcd. for $C_{12}H_{17}O_3N$: C, 64.54; H, 7.68. Found: C, 64.58; H, 7.91.

The same amide was prepared, in poor yield by condensing ethyl bromopropionate with 2,5-dimethoxybenzaldehyde (Reformatzky method with ordinary zinc), dehydrating the resulting ester with phosphorus oxychloride, reducing the unsaturated ester catalytically, and then saponifying, and, finally, amidating the acid produced. The dehydration with phosphorus oxychloride or the subsequent distillation resulted in extensive polymerization, the yield of unsaturated ester being only about 20%.

β-(2,5-Dimethoxyphenyl)-isopropylamine Hydrochloride.—The Hofmann reaction on the foregoing amide was carried out as usual except that the amide was added dissolved in dioxane to the hypochlorite solution.[12] The yield of distilled amine (b. p. 137–140° (3 mm.)) was 70%. The hydrochloride, prepared in the usual way (v. s.), crystallizes in fine prisms melting at 117.5°.

Anal. Calcd. for $C_{11}H_{18}O_2NCl$: C, 56.99; H, 7.83. Found: C, 57.25; H, 7.89.

The same hydrochloride was also prepared, in very poor yield, by the catalytic reduction, in strongly acid alcohol, of 2,5-dimethoxynitropropenylbenzene.[13] The compound was isolated via the hydriodide, which forms prismatic needles, m. p. 138°.

Anal. Calcd. for $C_{11}H_{18}O_2NI$: C, 40.86; H, 5.62. Found: C, 40.94; H, 5.94.

β - (2,5 - Dimethoxyphenyl) - isopropylmethylamine Hydrochloride.—The primary amine (v. s.) was readily converted into the secondary amine by the Decker method.[6] The hydrochloride crystallizes in needle prisms, melting at 98.5°.

Anal. Calcd. for $C_{12}H_{20}O_2NCl$: C, 58.63; H, 8.21. Found: C, 58.52; H, 8.46.

β - (2,5 - Dimethoxyphenyl) - isopropyldimethylamine Hydrochloride.—The tertiary amine, b. p. 118–121° (0.5 mm.), was obtained by the Eschweiler methylation (v. s.) of the primary amine. The hydrochloride forms needles melting at 138–139°.

(12) The use of dioxane to dissolve amides (using about one-third of the volume of the hypochlorite solution) greatly improves matters in cases where the amide is of low solubility. Cf. Woodruff and Conger, THIS JOURNAL, **60**, 465 (1938).

(13) Kauffmann, *Ber.*, **50**, 630 (1917).

Anal. Calcd. for $C_{13}H_{22}O_2NCl$: C, 60.06; H, 8.54. Found: C, 60.17; H, 8.39.

β - (2,5 - Dimethoxyphenyl) - isopropyltrimethylammonium Chloride.—The preceding tertiary amine was converted, in ether solution, into the methiodide (m. p. 142°), which on treatment with silver chloride gave the quaternary chloride. After crystallization, the chloride forms very hygroscopic, tiny, colorless prisms. After thorough drying (finally at 120° *in vacuo*) it melts at 203°.

Anal. Calcd. for $C_{14}H_{24}O_2NCl$: C, 61.37; H, 8.84. Found: C, 61.63; H, 8.81.

The authors wish to thank Mr. W. S. Ide for the many micro-analyses carried out during this work, and Dr. C. W. Ferry for the preparation of considerable amounts of 2,5-dimethoxybenzaldehyde.

Summary

As part of a series of 2,5-dimethoxyphenylalkyl- and alkanolamines, 2,5-dimethoxyphenethylamine hydrochloride, β-(2,5-dimethoxyphenyl)-propylamine hydrochloride and β-(2,5-dimethoxyphenyl)-isopropylamine hydrochloride, together with the corresponding secondary and tertiary amine hydrochlorides and the quaternary chlorides, have been prepared.

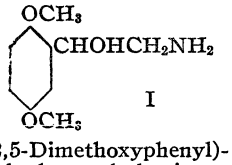
TUCKAHOE, NEW YORK RECEIVED OCTOBER 20, 1939

[CONTRIBUTION FROM THE BURROUGHS WELLCOME & CO. U. S. A. EXPERIMENTAL RESEARCH LABORATORIES]

Amines Related to 2,5-Dimethoxyphenethylamine.[1] II

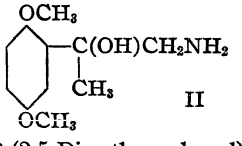
BY RICHARD BALTZLY AND JOHANNES S. BUCK

The work described below is a continuation and completion of that described in Part I.[2] The amines have the same structure as in the previous work but possess, in addition, a β-hydroxy group. As before, the primary, secondary, tertiary and quaternary compounds were made. The primary amines have the formulas



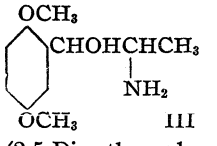
I

β-(2,5-Dimethoxyphenyl)-β-hydroxyethylamine



II

β-(2,5-Dimethoxyphenyl)-β-hydroxypropylamine



III

β-(2,5-Dimethoxyphenyl)-β-hydroxyisopropylamine

Secondary amines are denoted by "a," tertiary by "b," and quaternary salts by "c." The primary and secondary hydroxyethylamines and hydroxypropylamines (I, Ia, II, IIa) were prepared by the following series of reactions:

(R = 2,5-dimethoxyphenyl, Bz = benzyl)

$$RCOCH_3 \xrightarrow{Br_2} RCOCH_2Br \xrightarrow{(CH_2)_6N_4} RCOCH_2NH_2 \xrightarrow{PtO_2 + H_2} RCHOHCH_2NH_2 \quad (I)$$

$$RCHO \xrightarrow{CH_2BrCOOC_2H_5} RCHOHCH_2COOC_2H_5 \xrightarrow{NH_2NH_2} RCHOHCH_2CON_2H_3 \xrightarrow{HNO_2}$$

$$[RCHOHCH_2CON_3] \longrightarrow RCH(O{-}CO{-}NH)CH_2 \xrightarrow{HCl} RCHOHCH_2NH_2 \quad (I)$$

$$RCOCH_2Br(v.s.) \xrightarrow{BzNHCH_3} RCOCH_2NCH_3Bz \xrightarrow{PtO_2 + H_2} RCHOHCH_2NHCH_3 \quad (Ia)$$

$$RCOCH_3 \xrightarrow{CH_2BrCOOC_2H_5} RC(OH)(CH_3)CH_2COOC_2H_5 \xrightarrow{NH_2NH_2} RC(OH)(CH_3)CH_2CON_2H_3 \xrightarrow{HNO_2}$$

$$[RC(OH)(CH_3)CON_3] \longrightarrow RC(CH_3)(O{-}CO{-}NH)CH_2 \xrightarrow{HCl} RC(OH)(CH_3)CH_2NH_2 \quad (II)$$

$$RCOCH_2NCH_3Bz(v.s.) \xrightarrow{CH_3MgI} RC(OH)(CH_3)CH_2NCH_3Bz \xrightarrow{PtO_2 + H_2} RC(OH)(CH_3)CH_2NHCH_3 \quad (IIa)$$

The corresponding tertiary amines and quaternary salts were prepared as follows:

(1) This work is part of a joint research being carried out in collaboration with a pharmacological group at the above laboratories.

(2) Baltzly and Buck, THIS JOURNAL, 62, 161 (1940).

$$NCCH_2N(CH_3)_2 \xrightarrow{RMgBr} RCOCH_2N(CH_3)_2 \xrightarrow{PtO_2 + H_2} RCHOHCH_2N(CH_3)_2\ (Ib) \xrightarrow{CH_3I}$$

$$RCHOHCH_2N(CH_3)_3I \xrightarrow{AgCl} RCHOHCH_2N(CH_3)_3Cl \quad (Ic)$$

$$RCOCH_2N(CH_3)_2(v.s.) \xrightarrow{CH_3MgI} RC(OH)(CH_3)CH_2N(CH_3)_2\ (IIb) \xrightarrow{CH_3I}$$

$$RC(OH)(CH_3)CH_2N(CH_3)_3I \xrightarrow{AgCl} RC(OH)(CH_3)CH_2N(CH_3)_3Cl \quad (IIc)$$

The primary amine of the third (hydroxyisopropylamine) series (III) was prepared by Hartung's[3] method, by the reduction of α-isonitroso-2,5-dimethoxypropiophenone. The secondary amine (IIIa) and the tertiary amine (IIIb) were prepared, by a method similar to that of Hyde, Browning and Adams,[4] from α-bromo-2,5-dimethoxypropiophenone. From the tertiary amine, the quaternary chloride was prepared, via the methiodide.

It is assumed, pending further investigation, that the hydroxyisopropylamine group (III, IIIa, IIIb, IIIc) has the ephedrine, rather than the ψ-ephedrine, configuration. The relatively high melting points and the methods of preparation support this view.

Experimental

β-(2,5-Dimethoxyphenyl)-hydracrylic Hydrazide.—2,5-Dimethoxybenzaldehyde and ethyl bromoacetate were condensed by the Reformatzky method[2,5,6] to give ethyl β-(2,5-dimethoxyphenyl)-hydracrylate. This ester, obtained in 80% yield, is a viscous yellow oil, b. p. 164–167° (1.0 mm.). The ester was converted into the hydrazide, which, crystallized from alcohol–benzene mixture, formed glossy needles melting at 161.5°.

Anal. Calcd. for $C_{11}H_{16}O_4N_2$: C, 54.97; H, 6.72. Found: C, 55.19; H, 6.80.

5-(2,5-Dimethoxyphenyl)-oxazolidone-2.—Prepared by the Curtius[7] rearrangement from the hydrazide (v. s.) this crystallizes from benzene in colorless needles, m. p. 107°.

Anal. Calcd. for $C_{11}H_{13}O_4N$: C, 59.17; H, 5.87. Found: C, 59.38; H, 5.80.

β-(2,5-Dimethoxyphenyl)-β-hydroxyethylamine Hydrochloride (I).—Cleavage of the preceding oxazolidone[7] by cold concd. hydrochloric acid gave the desired amine hydrochloride. It forms fine colorless needles melting at 158.5°, and is very soluble in water, readily soluble in hot alcohol, moderately soluble in cold alcohol, sparingly soluble in ethyl acetate, and practically insoluble in non-polar solvents. Similar solubilities are shown by the other hydroxyamine hydrochlorides of this series, which may be crystallized conveniently from absolute alcohol solution by the addition of ether or ethyl acetate or both.

Anal. Calcd. for $C_{10}H_{16}O_3NCl$: C, 51.37; H, 6.91. Found: C, 51.24; H, 6.92.

(3) Hartung, U. S. Patent 1,989,093.

(4) Hyde, Browning and Adams, THIS JOURNAL, **50**, 2287 (1928).

(5) Cf. Lindenbaum, *Ber.*, **50**, 1270 (1917).

(6) Cf. Woodruff and Pierson, THIS JOURNAL, **60**, 1075 (1938).

(7) Cf. Schroeter, German Patent 220,852.

This amine also may be prepared by the reduction of 2,5-dimethoxyphenacylamine hydrobromide, prepared from 2,5-dimethoxyphenacyl bromide and hexamethylenetetramine by the procedure of Mannich and Hahn.[8] Hydrobromic acid was used for the hydrolysis so as to obtain a homogeneous hydrohalide. The amino ketone hydrobromide so prepared forms yellowish prisms, melting at 195° (dec.).

Anal. Calcd. for $C_{10}H_{14}O_3NBr$: C, 43.46; H, 5.11. Found: C, 43.60; H, 5.31.

2,5-Dimethoxyphenacylmethylbenzylamine.—2,5-Dimethoxyphenacyl bromide was added as a solid to twice its equivalent amount of methylbenzylamine[9] in absolute ether, with occasional shaking. After standing overnight, the methylbenzylamine hydrobromide formed was filtered off and the amino ketone precipitated as hydrochloride by the addition of absolute alcoholic hydrogen chloride. The hydrochloride forms a light yellow oil which soon crystallizes. On recrystallization (absolute alcohol–ether) it forms nearly colorless prisms melting at 167.5°.

Anal. Calcd. for $C_{18}H_{22}O_3NCl$: C, 64.38; H, 6.61. Found: C, 64.36; H, 6.73.

β-(2,5-Dimethoxyphenyl)-β-hydroxyethylmethylamine Hydrochloride (Ia).—The foregoing amino ketone hydrochloride is readily reduced (PtO_2 and hydrogen) in alcohol solution, yielding the desired amine hydrochloride, the benzyl group being eliminated as toluene.[10] The hydrochloride crystallizes in fine, felted needles, melting at 151.5°.

Anal. Calcd. for $C_{11}H_{18}O_3NCl$: C, 53.31; H, 7.33. Found: C, 53.62; H, 7.43.

β-(2,5-Dimethoxyphenyl)-β-hydroxypropylmethylamine Hydrochloride (IIa).—2,5-Dimethoxyphenacylmethylbenzylamine (v. s.), liberated from the hydrochloride, was dried, in ethereal solution, over potassium carbonate. The ether solution was added to an excess of methylmagnesium iodide. The reaction mixture was worked up as usual and the base liberated by ammonia, extracted with ether, the ether dried over potassium carbonate, and the hydrochloride precipitated by adding alcoholic carbonate chloride. The hydrochloride formed an uncrystallizable yellow sirup, probably due to a certain amount of dehydration. The sirup was reduced catalytically (reaction rather slow) and the desired amine hydrochloride isolated from the solution. It forms silky needles, melting at 158–159°.

(8) Mannich and Hahn, *Ber.*, **44**, 1542 (1911).

(9) Prepared by catalytic reduction of benzylidenemethylamine. Zaunschirm, *Ann.*, **245**, 279 (1888); *cf.* Emde, *Arch. Pharm.*, **247**, 351 (1909).

(10) The reductive removal of the N-benzyl group (mentioned in British Patent 318,488) is a very useful and convenient reaction, especially when, as in the present case, the method of Hyde, Browning and Adams (*loc. cit.*) proves unmanageable. The same process might profitably be used for the secondary amine (IIIa). Reductive removal of O-benzyl groups is a familiar procedure.

Anal. Calcd. for $C_{12}H_{20}O_3NCl$: C, 55.05; H, 7.71. Found: C, 55.11; H, 7.94.

β - Methyl - β - (2,5 - dimethoxyphenyl) - hydracrylic Acid.—2,5-Dimethoxyacetophenone was condensed with ethyl bromoacetate (zinc–copper alloy); after the usual washings, saponification and acidification gave the hydroxy acid, which crystallizes from benzene–petroleum ether in platelets, melting at 121–122°.

Anal. Calcd. for $C_{12}H_{16}O_5$: C, 59.98; H, 6.72. Found: C, 60.17; H, 6.77.

β - Methyl - β - (2,5 - dimethoxyphenyl) - hydracrylic Hydrazide.—The preparation of this hydrazide gave considerable trouble, due to the tendency of the compounds in this series to dehydrate when distilled or subjected to acids. Finally it was found that a 27% yield of hydrazide (reckoned on the starting ketone) could be obtained by treating the crude washed, but not distilled, ester from the Reformatzky reaction with hydrazine hydrate in alcohol. Nothing isolable was obtained when the ester was distilled or prepared from the acid. After considerable purification, the hydrazide was obtained as needles, m. p. 112°.

Anal. Calcd. for $C_{12}H_{18}O_4N_2$: C, 56.66; H, 7.14. Found: C, 56.83; H, 7.24.

5 - Methyl - 5 - (2,5 - dimethoxyphenyl) - oxazolidone-2.—The oxazolidone was obtained in excellent yield from the hydrazide, by the Curtius rearrangement.[7] It crystallizes from benzene in colorless prisms, melting at 159°.

Anal. Calcd. for $C_{12}H_{15}O_4N$: C, 60.74; H, 6.38. Found: C, 60.91; H, 6.66.

β - (2,5 - Dimethoxyphenyl) - β - hydroxypropylamine Hydrochloride (II).—The preceding oxazolidone was dissolved in concd. hydrochloric acid. After the evolution of carbon dioxide had ceased, excess acid was removed under reduced pressure at around room temperature. The yield of the amine salt is practically quantitative, but if higher temperatures are used other products make their appearance. The hydroxyamine salt, after recrystallization, forms flat-sided prisms, melting at 174°.

Anal. Calcd. for $C_{11}H_{18}O_3NCl$: C, 53.31; H, 7.33. Found: C, 53.57; H, 7.39.

2,5 - Dimethoxyphenacyldimethylamine.—Bromohydroquinone dimethyl ether[11] was converted into the Grignard reagent and dimethylaminoacetonitrile[12] added. The reaction mixture was decomposed with acid, the ether layer separated, and the base liberated by ammonia. After extraction with ether, the extract was washed, dried, and treated with alcoholic hydrogen chloride. The hydrochloride so obtained, after recrystallization, forms nearly colorless prisms, m. p. 171° (dec.).

Anal. Calcd. for $C_{12}H_{18}O_3NCl$: C, 55.48; H, 6.99. Found: C, 55.76; H, 7.17.

β - (2,5 - Dimethoxyphenyl) - β - hydroxyethyldimethylamine Hydrochloride (Ib).—This hydrochloride is readily obtained by the reduction (PtO_2 and hydrogen), in alcohol solution, of the above amino ketone hydrochloride. When recrystallized, it forms fine, colorless, needle-like prisms melting at 155°.

(11) Noelting and Werner, *Ber.*, **23**, 3246 (1890).

(12) Von Braun, *ibid.*, **40**, 3933 (1907).

Anal. Calcd. for $C_{12}H_{20}O_3NCl$: C, 55.05; H, 7.71. Found: C, 55.28; H, 7.98.

β - (2,5 - Dimethoxyphenyl) - β - hydroxyethyltrimethylammonium Chloride (Ic).—The methiodide of the foregoing tertiary amine was prepared in the usual way, and converted into the chloride by silver chloride. It forms slender prisms, melting at 185–186°.

Anal. Calcd. for $C_{13}H_{22}O_3NCl$: C, 56.60; H, 8.05. Found: C, 56.33; H, 7.99.

β - (2,5 - Dimethoxyphenyl) - β - hydroxypropyldimethylamine Hydrochloride (IIb).—This tertiary amine was prepared by the action of methylmagnesium iodide on 2,5-dimethoxyphenacyldimethylamine (v. s.) and was converted into the hydrochloride by alcoholic hydrogen chloride. It forms stout, almost colorless rhombs, melting at 176.5°.

Anal. Calcd. for $C_{13}H_{22}O_3NCl$: C, 56.60; H, 8.05. Found: C, 56.58; H, 7.76.

β - (2,5 - Dimethoxyphenyl) - β - hydroxypropyltrimethylammonium Chloride (IIc).—The quaternary salt was prepared from the preceding tertiary amine via the methiodide and silver chloride. After recrystallization it forms stout, colorless prisms, melting at 213.5°.

Anal. Calcd. for $C_{14}H_{24}O_3NCl$: C, 57.99; H, 8.33. Found: C, 58.06; H, 8.63.

α - Isonitroso - 2,5 - dimethoxypropiophenone.—2,5-Dimethoxypropiophenone[13] was converted into the isonitroso compound by Hartung's[3] method. After recrystallization from benzene–heptane mixture, the compound forms pale yellow leaflets, melting at 97–98°.

Anal. Calcd. for $C_{11}H_{13}O_4N$: C, 59.17; H, 5.87. Found: C, 59.25; H, 5.86.

β - (2,5 - Dimethoxyphenyl) - β - hydroxyisopropylamine Hydrochloride (III).—The above isonitroso compound was readily reduced by palladized charcoal in absolute alcohol containing hydrogen chloride. The product crystallizes in columnar prisms, melting at 175–176° (dec.).

Anal. Calcd. for $C_{11}H_{18}O_3NCl$: C, 53.31; H, 7.33. Found: C, 53.42; H, 7.34.

2,5 - Dimethoxy - α - methylaminopropiophenone.—2,5-Dimethoxy-α-bromopropiophenone was prepared by bromination of 2,5-dimethoxypropiophenone in chloroform solution (*cf.* 5). The bromo ketone was added to a large excess of methylamine in absolute ether. After standing overnight at 0°, the precipitated methylamine hydrobromide was filtered off, and the filtrate evaporated to dryness under reduced pressure, at room temperature or below. The residue was dissolved in ether and absolute alcoholic hydrogen chloride added. The hydrochloride still contains some methylamine salts, which are removed by repeated recrystallization. The pure amino ketone hydrochloride forms colorless prisms melting at 172–173° (dec.).

Anal. Calcd. for $C_{12}H_{18}O_3NCl$: C, 55.48; H, 6.99. Found: C, 55.48; H, 7.22.

β - (2,5 - Dimethoxyphenyl) - β - hydroxyisopropylmethylamine Hydrochloride (IIIa).—Catalytic reduction of the foregoing amino ketone hydrochloride yielded the

(13) Johnson and Hodge, THIS JOURNAL, **35**, 1014 (1913).

desired hydroxyamine hydrochloride, which crystallizes in fine, colorless needles, m. p. 170°.

Anal. Calcd. for $C_{12}H_{20}O_3NCl$: C, 55.05; H, 7.71. Found: C, 55.33; H, 7.91.

2,5 - Dimethoxy - α - dimethylaminopropiophenone.—The method of Hyde, Browning and Adams[4] gave very good results in this case. It was necessary, in order to remove dimethylamine completely, to wash the ether solution of the base with water. The tertiary amino ketones of this type are reasonably stable. The hydrochloride crystallizes in slender, practically colorless prisms, melting at 154–156° (dec.).

Anal. Calcd. for $C_{13}H_{20}O_3NCl$: C, 57.00; H, 7.37. Found: C, 56.89; H, 7.57.

β - (2,5 - Dimethoxyphenyl) - β - hydroxyisopropyldimethylamine Hydrochloride (IIIb).—Catalytic reduction of the preceding α-dimethylaminopropiophenone gave the desired compound. The hydrochloride crystallizes in fine, colorless needles, melting at 198° (dec.).

Anal. Calcd. for $C_{13}H_{22}O_3NCl$: C, 56.60; H, 8.05. Found: C, 56.52; H, 8.25.

β - (2,5 - Dimethoxyphenyl) - β - hydroxyisopropyltrimethylammonium Chloride (IIIc).—The methiodide, prepared from the above tertiary base, was converted into the chloride by the silver chloride method. After recrystallization, the chloride forms fine, colorless, felted needles, melting at 221–223° (dec.).

Anal. Calcd. for $C_{14}H_{24}O_3NCl$: C, 57.99; H, 8.33. Found: C, 58.08; H, 8.62.

Melting points are all corrected. Those for the hydrochlorides were determined on material dried *in vacuo* at 100° for several hours. The authors wish to make the same acknowledgments to Mr. W. S. Ide and Dr. C. W. Ferry as were made in Part I.

Summary

The projected series of 2,5-dimethoxyphenylalkyl- and alkanolamines has been completed by the preparation of the alkanolamines, β-(2,5-dimethoxyphenyl)-β-hydroxyethylamine hydrochloride, β-(2,5-dimethoxyphenyl)-β-hydroxypropylamine hydrochloride, and β-(2,5-dimethoxyphenyl)-β-hydroxyisopropylamine hydrochloride, together with the corresponding secondary and tertiary amine hydrochlorides and the quaternary chlorides.

A Modified Bart Reaction

BY G. O. DOAK

Indirect methods for preparing sulfonic and sulfamido substituted arsonic acids are tedious and give low yields. Although Oneto[1] recently has succeeded in preparing *p*-sulfophenyl- and *p*-sulfamidophenylarsonic acids by means of the Bart reaction, in this Laboratory this method failed with the corresponding *m*- and *o*- compounds. The alcoholic Bart reaction described by Scheller[2] has received but scant attention in the literature.[3a,b] When this modification proved successful in this Laboratory with both *p*- and *m*-sulfamidophenylarsonic acids, it was extended to include other arsonic acids, difficult to prepare by the customary Bart procedure. It was found that while anilines substituted in the ring by nitro, carboxy, or sulfamido groups gave excellent results, the reaction failed with 2,6- and 3,5-dimethylanilines. It also failed with metanilic acid. When applicable, the method gave higher yields, was less time consuming, and gave a product more easily purified than the customary Bart procedure.

Experimental Part

The amine, 0.1 mole in 250 cc. absolute alcohol with 10 g. of sulfuric acid and 28 g. arsenous chloride cooled to 0°, was diazotized with a saturated aqueous solution of the calculated amount of sodium nitrite, using starch–iodide paper to protect the end-point. Then, and not before, 1 g. of cuprous bromide[4] was added, the mixture thoroughly stirred, warmed to 60° until no more nitrogen was evolved, and then distilled with steam. The separated arsonic acid was recrystallized.

***p*-Sulfamidophenylarsonic Acid.**—This compound was obtained in 57% yield from sulfanilamide, crystallizing from water in small needles.

Anal. Calcd. for $C_6H_8NO_5SAs$: As, 26.7. Found: As, 26.8.

***m*-Sulfamidophenylarsonic Acid.**—*m*-Aminobenzenesulfonamide, 0.2 mole, gave 32.7 g. (58% yield) of *m*-sulfamidophenylarsonic acid, which crystallized from water in warty aggregates. When placed in a bath at 215° and the temperature slowly raised, it melted at 218–219°, but

(1) Oneto, THIS JOURNAL, 60, 2058 (1938); 61, 2105 (1939).

(2) Scheller, French Patent 624,028, *Chem. Zentr.*, 98, II, 229 (1927).

(3) (a) Steinkopf, *J. prakt. Chem.*, 128, 63 (1930); (b) Cherline and Iscoubovitch, *Bull. soc. chim.*, [5] 1, 1367 (1934).

(4) Cuprous bromide was found to give slightly better yields than the cuprous chloride as recommended by Scheller.

resolidified, probably to the anhydride, which charred without melting. It was extremely resistant to hydrolysis. After heating in a pressure bottle with concentrated hydrochloric acid at 100°, the compound was recovered unchanged, and it was only partially hydrolyzed with cold concentrated sulfuric acid after twenty-four hours.

Anal. Calcd. for $C_6H_8NO_5SAs$: As, 26.7. Found: As, 26.3.

m-**Nitrophenylarsonic Acid.**—*m*-Nitroaniline, 138 g. (1 mole) gave 133.5 g. (54% yield) of *m*-nitrophenylarsonic acid, after one recrystallization from water.

3-Nitro-4-methylphenylarsonic Acid.—2-Nitro-4-aminotoluene gave a 40% yield of 3-nitro-4-methylphenylarsonic acid by the modified method.

m-**Carboxyphenylarsonic Acid.**—*m*-Aminobenzoic acid gave a 76% yield by the modified procedure.

Analyses of these last three substances for arsonic acid gave percentages of arsenic in close agreement with the theoretical requirements.

Attempted Preparation of *m*-Sulfophenylarsonic Acid.—When metanilic acid was subjected to the modified Bart reaction, no crystals separated from the aqueous solution. An attempt to isolate the compound by means of the barium salt yielded only *m*-phenolsulfonic acid. Similarly, 2,6-dimethyl- and 3,5-dimethylanilines gave only the corresponding xylenols when subjected to the modified Bart reaction. In the case of the 2,6- compound, this failure cannot be due to any steric factor, since 2,6-dimethylphenylarsonic acid was prepared in a 30% yield by the usual Bart procedure.

The advantage of the modified Bart procedure may be shown by the following percentage yield figures, the first figure in each case corresponding to the ordinary procedure and the second figure to the modified one: *p*-sulfamido,[1] 25, 57; *m*-sulfamido, 0, 58; *m*-nitro,[5a] 28, 54; 3-nitro-4-methyl,[5b] 15.5, 40; *m*-carboxy,[5a] 36.6, 76.

Summary

The method of Scheller for the preparation of arsonic acids by an alcoholic Bart reaction has been tried with a series of aromatic amines. With sulfamido-, carboxy-, or nitro-substituted amines the reaction gave larger yields of the arsonic acid than the usual Bart procedure, but with two dimethylanilines and metanilic acid, the modification did not prove applicable.

BALTIMORE, MARYLAND RECEIVED SEPTEMBER 25, 1939

[CONTRIBUTION FROM THE SYPHILIS DIVISION OF THE DEPARTMENT OF MEDICINE, JOHNS HOPKINS MEDICAL SCHOOL BALTIMORE, MARYLAND, AND THE UNITED STATES PUBLIC HEALTH SERVICE, WASHINGTON, D. C.]

The Preparation of Phenylarsenoxides in Relation to a Projected Study of their Chemotherapeutic Activity. I. Monosubstituted Derivatives

BY G. O. DOAK, HARRY EAGLE, AND H. G. STEINMAN

There is now a considerable body of evidence to show that the chemotherapeutic action of arsonic acids and arseno compounds is due to their conversion *in vivo* to the corresponding arsenoxide. Thus, Voegtlin and Smith[1] concluded that both the arsonic acids and the arseno compounds are not in themselves trypanocidal but become active only after conversion to the arsenoxides in the animal body. Further, Tatum and Cooper[2] have shown that "Mapharsen," 3-amino-4-hydroxyphenylarsenoxide, while much more toxic, actually possesses a higher therapeutic index than neoarsphenamine. More recently, Eagle[3] has shown that although the arsphenamines are directly treponemicidal *in vitro*, that activity is primarily due to their rapid oxidation in solution by molecular oxygen, and is either absent or minimal if the experiment is carried out under nitrogen.

While considerable work has been done in attempting to correlate the chemical structure and chemotherapeutic activity of arsonic acids and arseno compounds, the arsenoxides themselves have received much less attention. The present investigation was therefore undertaken in an attempt to correlate the chemical structure of the arsenoxides with their treponemicidal activity, using as the test organism *Treponema pallidum*, the causative agent of syphilis. Although the majority of investigators have hitherto used trypanosomes in testing arsenicals, compounds active against one species of trypanosome will not necessarily be active against *T. pallidum*,[4] or even against another species of trypanosome.[5] The chemical preparation and properties of the arsenoxides will be presented here; data relating to their treponemicidal activity, toxicity, and potential therapeutic utility will be published elsewhere.

The initial series consisted of the parent com-

(5) Kuhs and Tatum, *J. Pharmacol.*, **61**, 451 (1937).

pound, phenylarsenoxide, the *o*-, *m*-, and *p*-monosubstituted methyl, carboxy, chloro, nitro, amino, and hydroxy derivatives, the *o*- and *p*-sulfophenyl arsenoxides, and *o*-iodophenyl-arsenoxide. For twelve of these compounds, work done in this Laboratory has merely confirmed previous descriptions in the literature. The *m*-chloro, *m*-amino, *m*-hydroxy, *o*-sulfo, and *o*-iodo compounds have not been previously reported. We have also obtained additional data on the three nitro arsenoxides, and slightly different results from those reported in the literature with the *o*-hydroxy and *o*-chloro compounds. The arsenoxides were prepared by reduction of the known arsonic acids in hydrochloric acid solution with sulfur dioxide and potassium iodide, followed by hydrolysis of the resulting dichloroarsine with ammonia or sodium bicarbonate. In the case of the sulfonic acids, hydrobromic acid was used in order to obtain the less soluble dibromoarsines.

There was a marked tendency for the arsenoxides to separate as sirups, particularly in the case of the meta compounds. In certain cases, these could be crystallized by the method suggested by Blicke and Smith,[6] but in other cases even this method failed to yield a crystalline compound. Except in a few cases, the arsenoxides did not melt, but charred above 250°, or softened without giving a definite melting point.

o-, *m*-, and *p*-nitrophenylarsonic acids reduced by sulfur dioxide in the usual manner gave the corresponding dichloroarsines, which yield the arsenous acids on hydrolysis with alkali.[7,8,9] It has been suggested that the presence of the nitro group prevents loss of water from the arsenous acid to form the arsenoxide. We found, however, that the *o*- and *p*-nitro compounds yielded the arsenoxides when reduced in suspension in dilute hydrochloric acid. The meta compound, however, gave only the arsenous acid. *o*-Nitro-phenylarsenoxide (or the arsenous acid) showed a curious anomaly in its pharmacological behavior, in that it dissolved in alkali to form a deep brown solution which no longer showed either the toxicity or activity of the typical arsenoxides. Unlike other arsenoxides, it could not be reprecipitated from such solutions with acid. When the alkaline solution was poured into a large excess of acetone, an oil formed which crystallized after standing for several days at −25°. Although these crystals analyzed for the composition $(NO_2C_6H_4As(ONa)_2 \cdot 2H_2O$, it seems unlikely that this is the correct formula, for when buffered with bicarbonate, the compound could not be titrated with iodine. By exposing *o*-nitrophenylarsenoxide to sunlight, Karrer[10] obtained a brown compound which he believed to be the *o*-nitrosoarsonic acid, formed by migration of one oxygen atom from the nitrogen to the arsenic. The compound we obtained, unlike Karrer's compound, did not give an insoluble magnesium salt under any conditions. It is accordingly unlikely that it is an arsonic acid. The remarkable color change on dissolving the arsenoxide in alkali suggests quinoid formation.

Experimental Part

p-Nitrophenylarsenoxide.—*p*-Nitrophenylarsonic acid was precipitated in a finely divided state by the addition of dilute hydrochloric acid to a 10% aqueous solution of the sodium salt. When reduced with sulfur dioxide and potassium iodide, the arsenoxide was obtained as a white solid, in contrast to the yellow *p*-nitrophenylarsenous acid.

Anal. Calcd. for $C_6H_4NO_3As$: As, 35.2; N, 6.6. Found; As, 35.1; N, 6.7.

o-Nitrophenylarsenoxide.—The reduction of 10 g. of sodium *o*-nitrophenylarsonate in a similar manner gave *o*-nitrophenylarsenoxide as a light yellow powder.

Anal. Calcd. for $C_6H_4NO_3As$: As, 35.2; N, 6.6. Found: As, 35.1; N, 6.2.

The **disodium salt**, which may have a quinoid structure, was prepared by the addition of acetone to an alkaline solution of the arsenoxide. The oily precipitate crystallized after several days at −25°. These crystals tended to become oily on exposure to air, and it was difficult to wash free from alkali.

Anal. Calcd. for $C_6H_4NO_4Na_2As \cdot 2H_2O$: As, 24.2; Na, 14.8; water, 11.6. Found: As, 23.5; Na, 15.2; loss at 100°, 10.3.

The reduction of *m*-nitrophenylarsonic acid by the same method gave only *m*-nitrophenylarsenous acid,[9] which did not lose water at 100°.

Anal. Calcd. for $C_6H_6NO_4As$: As, 32.4; N, 6.1. Found: As, 32.7, N, 6.1.

m-Aminophenylarsenoxide.—The reduction of 10 g. of *m*-aminophenylarsonic acid in concentrated hydrochloric acid gave the dichloroarsine hydrochloride as a white crystalline solid. On the addition of ammonia, this gave the oxide as an amorphous solid, which was purified by dissolving in dilute hydrochloric acid and again precipitating with ammonia. Although the compound could be crystallized from alkaline solution by the addition of saturated salt solution, it was difficult to wash the crystals free from salt because of their solubility. It is soluble in acids, alkali, water, excess ammonium hydroxide, and organic solvents. It softened at 62° (cor.) without giving a definite melting point.

(10) Karrer, *ibid.*, **47**, 1783 (1914).

Anal. Calcd. for C_6H_6ONAs: As, 40.9. Found: As, 40.8.

***m*-Hydroxyphenylarsenoxide.**—The *m*-dichloroarsine, obtained as a yellow oil, was dissolved in ether and neutralized with sodium carbonate solution. The ether layer was dried with anhydrous sodium sulfate and evaporated. The sirupy arsenoxide thus obtained contained two moles of water which were lost only after heating at 150° for twelve hours. The resulting compound was a brittle, pulverulent mass.

Anal. Calcd. for $C_6H_5O_2As \cdot 2H_2O$: As, 34.0. Found: As, 34.2. Calcd. for $C_6H_5O_2As$: As, 40.7. Found: As, 40.9.

***o*-Hydroxyphenylarsenoxide.**—This compound, previously described by Kalb[8] as the anhydride, was obtained as the crystalline arsenoxide when the dichloroarsine was treated with ammonia. It melted at 182–184° (cor.) and gave no coloration with ferric chloride. If a drop of hydrogen peroxide was added to a solution of the oxide containing ferric chloride, a deep wine color was produced, characteristic of *o*-hydroxyphenylarsonic acid.

Anal. Calcd. for $C_6H_5O_2As$: As, 40.7. Calcd. for $C_{12}H_8O_3As_2$: As, 42.8. Found: As, 40.5.

***m*-Chlorophenylarsenoxide.**—The dichloroarsine, obtained as a yellow oil, gave the oxide as a sirup on treatment with sodium bicarbonate solution. It could not be crystallized by the method of Blicke and Smith. When dissolved in alcohol and poured into ice water, the oxide separated as a white powder which again became sirupy on removal of the water.

Anal. Calcd. for C_6H_4OClAs: As, 37.0. Found: As, 36.6.

***o*-Chlorophenylarsenoxide.**—This compound, recently described by Hiratuka,[11] who gives a melting point of 140–150°, was obtained by reduction of the arsonic acid in methyl alcohol and precipitation of the dichloroarsine with water. Subsequent treatment with ammonia gave the oxide as an amorphous solid, purified by dissolving in sodium hydroxide solution and reprecipitating with dilute hydrochloric acid. The resulting compound was a white powder. It softened at 208° (cor.) without giving a definite melting point.

(11) Hiratuka, *J. Chem. Soc. Japan.*, **58**, 1051 (1937); *C. A.*, **33**, 157 (1939).

Anal. Calcd. for C_6H_4OClAs: As, 37.0. Found: As, 36.8.

Sodium Salt of *o*-Sulfophenylarsonic Acid.—*o*-Sulfophenylarsonic acid was isolated by Barber[12] as the barium salt in 90–95% yield by treating *o*-iodophenylarsonic acid with sodium sulfite and precipitating the barium salt with barium chloride. We have prepared the disodium salt in 95% yield by refluxing the iodoarsonic acid with sodium sulfite, making the resulting solution just acid to litmus, and precipitating with alcohol. The compound was recrystallized by dissolving in water and again precipitating with alcohol.

Anal. Calcd. for $C_6H_5O_6SAsNa_2 \cdot H_2O$: As, 21.3; Na, 13.4; water, 5.2. Found: As, 21.5; Na, 12.7; loss at 100°, 5.1.

Sodium Salt of *o*-Sulfophenylarsenoxide.—The disodium salt described in the preceding paragraph, 10 g. in hydrobromic acid solution, was reduced, and the solution evaporated to 30 cc., when the dibromoarsine crystallized from the solution. After recrystallization, this was treated with sodium hydroxide, made acid to litmus with hydrochloric acid, and evaporated to dryness. The arsenoxide was separated from the sodium bromide by successive extractions with absolute alcohol.

Anal. Calcd. for $C_6H_4O_4SAsNa$: As, 27.7. Found: As, 27.9.

***o*-Iodophenylarsenoxide.**—*o*-Iodophenylarsonic acid reduced in the usual manner and treated with sodium hydroxide gave *o*-iodophenylarsenoxide as a white powder. It softens at 263° and melts at 267°.

Anal. Calcd. for C_6H_4OIAs: As, 25.5. Found: As, 25.3.

Summary

A series of monosubstituted phenylarsenoxides has been prepared with a view to studying their action against *Treponema pallidum*. Five new compounds have been described, and additional data have been obtained on some of the known arsenoxides.

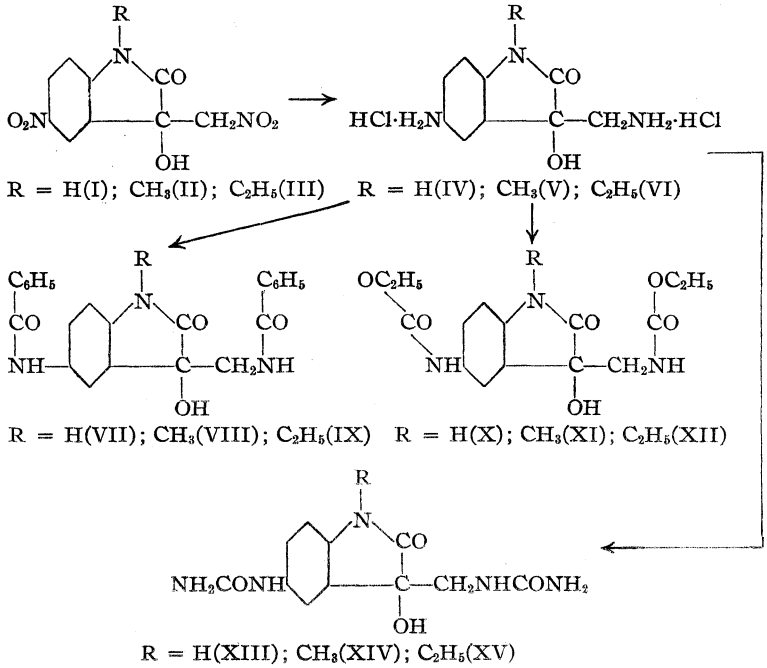
Ethanolamines of the Oxindole Series

BY RAYMOND B. CRAWFORD[1] AND H. G. LINDWALL

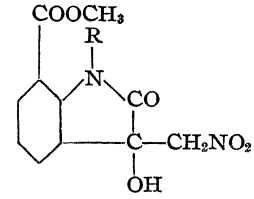
It has been reported previously[2] that isatin and N-alkylated isatins will condense with nitromethane to yield products of the type 3-hydroxy-3-nitromethyl-oxindole; these products, upon reduction, yield the respective 3-hydroxy-3-aminomethyl-oxindoles. That work has now been extended in order to obtain similar compounds containing salt-forming groups in the benzenoid ring of the oxindole structure.

CHART I



Isatin, 1-methylisatin, and 1-ethylisatin were nitrated in the 5-position by the method of Calvery, Noller and Adams.[3] The resulting nitroisatins were then condensed with nitromethane using diethylamine as the catalyst.[2] All three of these condensation products were reduced to the corresponding di-amino compounds readily, by the action of tin and hydrochloric acid (see Chart I). These di-amino compounds upon treatment with benzoyl chloride, ethyl chloroformate, and potassium cyanate, formed, respectively, the corresponding di-benzoyl, diurethan, and di-urea derivatives.

A similar study of derivatives of 7-carboxy-isatin was made. The 7-carboxy-isatin has been prepared by Sandmeyer[4] and by Rupe and Guggenbuhl[5] from anthranilic acid by the chloral hydrate and hydroxylamine method. Since Waldmann[6] has shown that a purer product can be obtained by using methyl anthranilate as the starting material, his procedure was followed in preparing the 7-carboxy-isatin and the 1-methyl- and 1-ethyl-analogs. The 7-carboxy-isatins thus obtained were then esterified and the esters were used in the condensation reactions with nitromethane. In this way the following compounds were obtained



R = H(XVI); CH_3(XVII); C_2H_5(XVIII)

Of these condensation products, compound XVI was subjected to treatment with tin and concentrated hydrochloric acid, and yielded 3-hydroxy-3-aminomethyl-7-carboxy-oxindole hydrochloride (XIX). Compound XIX formed benzoyl (XX), urethan (XXI), and urea (XXII) derivatives.

Several of the products will be tested for physiological activity.

Experimental Part

Compounds I, II, and III.—5-Nitro-isatin (or 1-methyl-5-nitro-isatin or 1-ethyl-5-nitro-isatin) (15 g.) was suspended in absolute ethyl alcohol (15 cc.) containing 10 g. of nitromethane, and the mixture was cooled to −15°. Then diethylamine (15 drops) was added with stirring. After standing at −15° for two hours, 1 cc. of glacial acetic acid was added and the solvent was partially removed

under vacuum at 30°, the product separated and recrystallized from ethyl alcohol (I), or (II and III) from glacial acetic acid.

Compounds IV, V, and VI from I, II, and III, respectively.—Compound I (or II or III) (25.3 g.) was suspended in 100 cc. of concentrated hydrochloric acid and mossy tin (41.6 g.) was added slowly, keeping the temperature below 60°. In one-half hour all of the nitro compound had gone into solution. Then 50 cc. of concentrated hydrochloric acid and 41.6 g. of mossy tin were added and the mixture was boiled for twenty hours. The unused tin was then filtered off, the solution was diluted to 1600 cc. with water, and tin was removed as the sulfide. The product was obtained by evaporation to dryness on the steam-bath. Purification of IV was by dissolving in water and saturating with hydrogen chloride; of VI by crystallization from alcohol; V could not be recrystallized.

The Benzoyl Derivatives of IV, V, and VI (VII, VIII, and IX).—Compound IV (or V or VI) (0.5 g.) was dissolved in 10 cc. of water and 1 g. of sodium carbonate and 1.5 g. of benzoyl chloride were added. The product separated after standing two hours at room temperature; recrystallized from ethyl alcohol.

The Urethan Derivatives of IV, V, and VI (X, XI, and XII).—Compound IV (or V or VI) (0.5 g.) was dissolved in 10 cc. of water and 1 g. of sodium carbonate and 0.7 g. of ethyl chloroformate were added. The products were crystallized from ethyl alcohol.

The Urea Derivatives of IV, V, and VI (XIII, XIV and XV).—Compound IV (or V or VI) (1.0 g.) was dissolved in 7 cc. of water and 1 g. of potassium cyanate dissolved in 3 cc. of water was added. The crystalline product separated after twelve hours standing in ice; in each case the product was recrystallized from water after treatment with bone coal.

Compounds XVI, XVII and XVIII.—Nitromethane (9 g.) and 7-carbomethoxy-isatin (12 g.) were placed in 12 cc. of absolute ethyl alcohol and the mixture was cooled to −15°. Diethylamine (15 drops) was added with stirring. The mixture was held at −15° for one hour, and part of the solvent was then removed to cause fairly complete separation of XVI. Compounds XVII and XVIII were prepared, respectively, by substituting 1-methyl-7-carbomethoxy-isatin and 1-ethyl-7-carbomethoxy-isatin in this procedure.

Compound XIX (from XVI).—Compound XVI (9.5 g.) was suspended in 50 cc. of concentrated hydrochloric acid and mossy tin (17 g.) was added slowly, keeping the temperature below 60°. After boiling the mixture for two hours it was diluted with water and tin was removed as the sulfide. The solution was evaporated until a solid separated; it was recrystallized from ethyl alcohol. Treatment of XIX with benzoyl chloride yielded **compound XX**; with ethyl chloroformate, **compound XXI**; with potassium cyanate, **compound XXII.**

Summary

Oxindole and N-alkylated-oxindole derivatives have been prepared in which the 3-position holds the hydroxyl and the aminomethyl groups, and the 5- or 7-position is occupied, respectively, by the amino or carboxyl group. For certain of these products benzoyl, urethan, and urea derivatives are described.

Sulfides and Sulfones of Pyridine and Quinoline

BY A. R. SURREY AND H. G. LINDWALL

The similarity of therapeutic effect to sulfanilamide of the dinitro- and diaminodiphenyl sulfides and sulfones,[1,2,3] suggested the preparation of like compounds in the pyridine and quinoline series.

The chemotherapy of these diphenyl compounds[4,5] showed that while some of them possess greater activity than sulfanilamide, in general they have a greater toxicity. The introduction of the pyridine ring in sulfanilamide not only enhances the activity but also adds desirable features absent from sulfanilamide. Encouraging results were obtained with certain other pyridine compounds[6] including the dihydrobromide of 2,2′-dipyridyl sulfide. Recently, sulfonamides of some aminoquinolines have been synthesized.[7] It therefore seemed desirable to prepare pyridine and quinoline analogs of the dinitro and diamino diphenyl sulfides and sulfones.

5,5′-Dinitro 2,2′-dipyridyl sulfide (I) has been prepared by the action of sodium sulfide on 2-chloro-5-nitropyridine. This is essentially the method used by Nietzki and Bothof[8] for the preparation of the diphenyl analog. The diquinolyl sulfides (IV) and (V) (see Table I) were prepared in the same way starting with 5-chloro-8-nitro-

[a] Begins to decompose at 245°, completely black at 260°.

quinoline and 8-chloro-5-nitroquinoline, respectively. The latter were made from the corresponding chloroquinolines by nitration. The dinitrodipyridylsulfone (VI) was prepared by oxidation of (I) with potassium dichromate. 5,5′-Dinitro-8,8′-diquinolylsulfone (IX) was formed from (V) by oxidation with chromic acid.

Reduction of the dinitrodipyridyl compounds (I and VI), to yield the corresponding amino compounds (II and VII), was carried out using stannous chloride. Two forms of 5,5′-diamino-2,2′-dipyridyl sulfide were obtained, one melting at 80–81°, the other at 130–131.5°. By heating the lower melting compound in the oven at 90° the higher melting variety was obtained. Both gave the same diacetylamino derivative (III). A calculated amount of stannous chloride was used in the reduction of (VI) to give 5,5′-diamino-2,2′-dipyridylsulfone (VII). An excess of stannous chloride reduced the sulfone group to give (II).

Certain of these compounds will be tested to determine their therapeutic effect.

Experimental Part

I, IV and V.—To a nearly saturated solution of 2-chloro-5-nitropyridine (or 5-chloro-8-nitroquinoline or 8-chloro-5-nitroquinoline) in hot alcohol was added a slight excess of a saturated aqueous solution of sodium sulfide. In each case the reaction mixture turned red and heat was evolved. After the initial reaction had subsided, the solution was refluxed for four hours on the steam-bath. The product which separated was filtered and washed with alcohol; yield: (I) 73%, yellow needles from alcohol; (IV) 90%, small yellow needles from acetone and water; (V) 85%, small orange crystals from pyridine.

5,5′-Dinitro-2,2′-dipyridylsulfone (VI).—A solution of 6 g. of potassium dichromate in 80 cc. of water was added with shaking to a solution of 4.5 g. of I in 80 cc. of water and 60 cc. of concd. sulfuric acid. In a short time a fine white precipitate began to separate. After all the dichromate solution had been added, the reaction mixture was allowed to stand for a few minutes and then diluted with four times its volume of water. The precipitate was filtered and washed with water until a clear filtrate was obtained, and then dried; yield, 4.5 g. (90%). The material crystallized from propyl alcohol in small white needles.

II and VII.—Compound I (or VI) (3 g.) was added slowly with cooling to a solution of 24 g. (or 14 g.) of stannous chloride in 30 cc. (or 17 cc.) of concd. hydrochloric acid. The solution was then heated on the steam-bath for one hour. The clear solution was allowed to cool and the tin salt which separated was filtered. To a solution of the tin salt in a small amount of water, 40% sodium hydroxide was added until the solution was strongly alkaline. The brown oil which separated was cooled until it solidified and then was filtered. The crude amine was dissolved in hot water and treated with bone black: yield, (II) 68%; (VII) 67%. Both were obtained as white needles after repeated recrystallizations from water.

5,5′-Diacetylamino-2,2′-dipyridyl Sulfide (III).—Compound II (0.5 g.) was added to 10 cc. of acetic anhydride. Heat was evolved and the diacetylamino compound (III) separated as a fine white powder. The product was purified by dissolving in alcohol, treating with bone black and allowing most of the alcohol to evaporate; yield, almost quantitative.

5,5′-Diacetylamino-2,2′-dipyridylsulfone (VIII).—Compound VII (0.5 g.) was added to 10 cc. of acetic anhydride. The solution was warmed until all of the amine went into solution. On cooling, light yellow needles separated out. The material was purified by recrystallizing from water.

5,5′-Dinitro-8,8′-diquinolylsulfone (IX).—Chromic acid (1.0 g.) was added to a solution of 1.0 g. of V in 30 cc. of glacial acetic acid. After the initial vigorous reaction, which was induced by warming, the solution was refluxed for fifteen minutes and then poured into ice. A yellow precipitate separated; yield, 0.6 g. (54%); small yellow needles from acetone.

Summary

Methods are described for the preparation of the 5,5′-dinitro, the 5,5′-diamino, the 5,5′-diacetylamino-2,2′-dipyridyl sulfides, and their respective sulfones, as well as the 5,5′-dinitro-8,8′-diquinolyl sulfide and its sulfone, and the 8,8′-dinitro-5,5′-diquinolyl sulfide.

A Quantitative Test for Biotin and Observations Regarding its Occurrence and Properties

BY ESMOND E. SNELL, ROBERT E. EAKIN AND ROGER J. WILLIAMS

In the course of studies on biotic acid[1] we found that vitamin B_6 serves as a yeast nutrilite[2] and were led to introduce the pure vitamin into our basal culture medium. (The effect of vitamin B_6 on yeast was independently discovered elsewhere at the same time.[3]) In this modified basal medium, yeast became much more sensitive to addenda of small amounts of liver preparations. Shortly after this, through the kindness of Professor Kögl, we were furnished with a sample of biotin, and a few tests demonstrated that in this medium the yeast was responding specifically to biotin.

Some of the observations reported herein were made before we were aware that biotin was the physiologically active substance involved.

Experimental Procedure

The yeast used in this test was isolated in pure culture from a cake (pound goods) of Fleischmann yeast, and was carried thereafter on molasses–agar slants as previously described.[4] Several cultures isolated from this source were found interchangeable for this purpose. The basal medium contains: C. P. sucrose 20 g., $(NH_4)_2SO_4$ 3 g., KH_2PO_4 2 g., $MgSO_4 \cdot 7H_2O$ 0.25 g., $CaCl_2 \cdot 2H_2O$ 0.25 g., H_3BO_3 1 mg., $ZnSO_4$ 1 mg., $MnCl_2$ 1 mg., $TlCl_3$ 1 mg., $FeCl_3$ 0.5 mg., $CuSO_4 \cdot 5H_2O$ 0.1 mg., KI 0.1 mg., *l*-aspartic acid 0.1 g., inositol 5 mg., β-alanine 0.5 mg., thiamin 20 γ and vitamin B_6 20 γ, all added to one liter of distilled water.

Addenda to the basal medium are dissolved in 2 ml. of water in 50-ml. Erlenmeyer flasks and sterilized by steaming for five minutes. After cooling, 10 ml. of the (previously sterilized) basal medium containing 0.02 mg. of suspended yeast is pipetted into each flask which is set unstoppered and without agitation in an incubator at 30° for the growth period of approximately sixteen hours. Very clean glassware is essential for proper results.

At the end of the growth period the yeast suspension is diluted with 10 ml. of saturated aqueous chlor thymol and shaken mechanically for three to five minutes. The amount of yeast present is determined by use of a thermocouple-galvanometer set-up.[5] The same instrument is used to gage the seeding in the basal medium at the start, the concentration being determined indirectly from a heavy suspension from which the proper aliquot is taken. We have found it convenient to use a box type galvanometer with lamp and scale enclosed, and to adjust so that it reads zero when basal medium alone is interposed between the light and the thermocouple, and 100 when an opaque object is interposed. This instrument is superior for this purpose to available photoelectric colorimeters.

Blank cultures (no addenda) and cultures containing known amounts of biotin (0.000025 to 0.00025 γ) are run simultaneously with the unknowns, and the amounts of biotin in the unknown sample are read off the standard curve, in which galvanometer readings are plotted against the known amounts of biotin (either pure or in a standardized extract) added.

Experimental Results

In Fig. 1 are plotted the results of parallel tests of a crude liver preparation and a biotin solution. The two curves are parallel through a wide range. At relatively high concentrations both curves flatten out and do not diverge strikingly. This parallelism means that when the test is applied to such an extract, values obtained at different dosage levels agree, which is true of extracts generally, as is illustrated by data presented below (Table II). This strongly indicates that the test is specific.

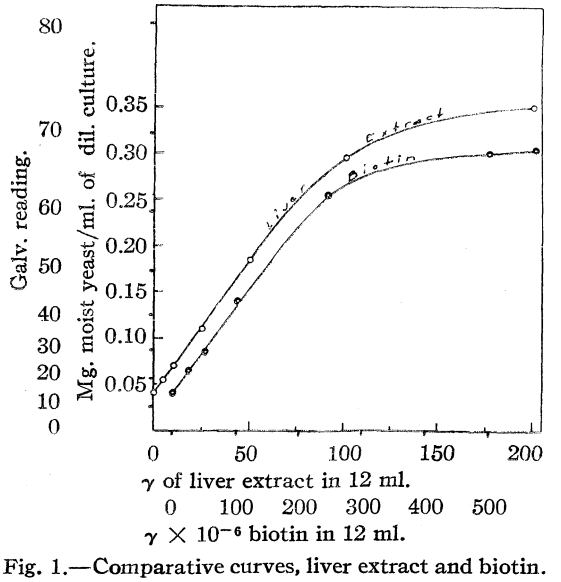

Fig. 1.—Comparative curves, liver extract and biotin.

Under our test conditions biotin gives a response at an exceedingly low dosage. Kögl,[6] speaking of biotin, says "it can be detected in the yeast test even at a dilution of 1 in 4×10^{11}." From Fig. 1 it is seen that in our test a concentra-

tion of 1 in 5×10^{11} increased the galvanometer reading from 16 to 22. This is considerably greater than the least detectable amount. The advantage of a small dosage in a test of this kind is evident. To get a *measurable* response, less than 0.1 mg. of extracted material (5 γ or more in the case of autolyzed liver extracts) must be added to a 12-ml. culture. The chance of introducing other physiologically active substances which might interfere with the test is thus minimized, and the specificity of the test is ensured.

The active substance concerned in our test has the known properties of biotin. Its activity is not destroyed by heating with normal alkali at 100°, and it withstands refluxing with acidic methanol (*cf.* Table III). The latter procedure brings about esterification but the ester is physiologically active.[7] Biotic acid is destroyed by this treatment. All of the well recognized yeast nutrilites are placed in the basal medium (in this medium β-alanine completely replaces pantothenic acid) and so far as we are aware no known or postulated substance can replace biotin in this test.

Vitamin B_6 must be present in the medium before any significant effect of biotin can be demonstrated. This is illustrated in Table I. The

TABLE I

EFFECT OF BIOTIN IN PRESENCE AND ABSENCE OF VITAMIN B_6

Addition to medium per flask, γ	Galvanometer readings on basal medium: Without vitamin B_6	Containing vitamin B_6
0.0	36.0	30.3
.00003 biotin	38.8	38.8
.00007 biotin	40.0	50.2
.00015 biotin	39.8	58.0
.00300 biotin	38.1	69.1
5.0 liver preparation	39.0	39.2
10.0 liver preparation	38.6	49.4
20.0 liver preparation	36.0	57.0
40.0 liver preparation	31.8	66.0
100.0 liver preparation	25.0	70.0

situation here is somewhat analogous to that with rats, where the presence of vitamin B_6 is necessary before the "filtrate factors" show their full effect.[8,9,10]

The test of Kögl involving a growth response from heavy seeding of "Rasse M" yeast seems not to be as specific as the one we have described. It has been indicated[7] that a crude extract in high dosage gives a 600% increase under his growth conditions, whereas pure biotin causes only a 300% increase. From the published assays[11] it is not clear whether the specificity of the test can be ensured by holding the dosages down to low levels, since assay values at different dosage levels are not given.

In the test investigated by Robbins and Schmidt[12] involving the organism *Ashbya gossypii*, no claim for specificity is made and the authors state that their results are "suggestive only." At different dosage levels the materials did not show the same relative potency, indicating that toxic and/or stimulating principles were influencing the results.

Data on Assays.—For further information regarding the quantitative distribution of biotin, assays on the materials listed below were carried out. Clear water extracts were obtained by autoclaving the material (finely ground if necessary) for ten minutes at 15 lb. (1 atm.) pressure with a large volume of water. If necessary the extract obtained was clarified by filtering with filter-cel. Casein samples were hydrolyzed with sulfuric acid and the $SO_4^=$ ion removed with Ba^{++} for assay. Examples are given in Table II showing comparative results at different dosage levels. In Table III single values are given for the sake of brevity. Liberation of biotin by autolysis of liver tissue is

clearly demonstrated and indicates that biotin is bound up with liver proteins or other colloids, an observation apparently not previously made. In the assays of Kögl and Hasselt on animal tissues,[11] livers appeared to be mediocre biotin sources. Had autolysis been carried out, results would doubtless have been different. Whether other tissues yield more biotin on autolysis is not known. Egg yolk extracts are not increased in biotin content by "autolysis."

In this connection it is interesting to note that casein contains considerable amounts of biotin; purification greatly decreases the amount present.[13]

Manure (and also urine) is a relatively rich source of biotin, but according to our tests it is not as rich as indicated by the tests of Robbins and Schmidt,[12] who judged the extract to be nearly 300 times as rich (on a dry weight basis) as egg yolk.

In view of its properties, occurrence and high physiological activity, the "growth substance" described in 1935[14] may have been biotin. The test organism used in its study became less and less sensitive on subculture and finally was lost. This "growth substance" was removed from casein and other proteins with difficulty.

The absolute values for the biotin content of materials given in Tables II and III are based upon the preparation which Professor Kögl kindly sent us and upon a limited number of samples and should not be accepted as final. If this standard preparation deteriorated during shipment or before use, then values given would be too high. Relative values would not, of course, be affected.

Destruction by Nitrous Acid.—Before we were aware that the active principle in liver extract was biotin, tests revealed that it was destroyed rapidly by nitrous acid.

Following the method of Dunn and Schmidt,[15] we investigated the rate at which the active principle in a liver autolysate was inactivated by standing at 23° in the presence of a given concentration of glacial acetic acid and sodium nitrite. Aliquots were removed and diluted to stop the reaction at time intervals noted in Table IV. Results are compared with those obtained by Dunn and Schmidt[15] for the rate of reaction of α, β and γ amino groups. Only 94% of the activity of the liver could be destroyed by this treatment; the residual activity may arise from the hydroxyl compound which presumably is formed. Assuming this to be true, and recalculating on this basis, it readily is seen that inactivation occurs at a rate most characteristic of α-amino acids. The destructive action of nitrous acid was later confirmed on a small sample of Kögl's biotin. Biotin may therefore be an α-amino acid. Its liberation from tissues by autolysis, the biological activity of its methyl ester and inactivity of its acetyl derivative[7] coupled with its destruction by nitrous acid, all point toward the significance of this amino group in determining its physiological activity.

TABLE IV

EFFECT OF NITROUS ACID ON BIOTIN ACTIVITY OF A LIVER CONCENTRATE AND ON AMINO ACIDS AT 23°

Summary

A sensitive and accurate assay for biotin is described which involves the growth of a strain of *Saccharomyces cerevisiae* from a small seeding. Under the test conditions the response of this organism to biotin is quantitative within a concentration range from 0.00002 to about 0.001 γ of biotin. Assay results on crude extracts agree well at different levels within this range, and the curves obtained are very similar to those obtained with pure biotin. Assay results on a number of natural materials are given.

The effectiveness of biotin under these conditions depends to a large extent on the presence of vitamin B_6 (and of β-alanine) in the medium. Biotin in liver concentrates is destroyed by nitrous acid at a rate which indicates that it may be an α-amino acid.

Catalytic Hydration of Acetylene and of Some Alkylacetylenes[1]

BY RAYMOND E. SCHAAD AND VLADIMIR N. IPATIEFF

Previously sulfuric acid, sulfuric acid with mercury salts, and the latter composite in the presence of organic solvents have been used as catalysts in the hydration of acetylene and of alkylacetylenes to acetaldehyde and ketones, respectively, as reviewed and described by Thomas, Campbell and Hennion.[2] For the hydration of acetylene several patents claim a similar use of phosphoric acid and mercury salts,[3] and of phosphoric acid on charcoal with[4] and without[5,6] added metals.

In the present work solid phosphoric acid polymerization catalyst[7,8,9] was found to catalyze hydration of butyne-1 rather than its polymerization, the water required for the hydration being removed from the catalyst which was thereby decreased in activity. Continuous hydrations of this and of other alkynes, including acetylene, propyne, pentyne-1, pentyne-2, hexyne-1, and heptyne-1, were effected without rapid decrease in catalyst activity by simultaneous passage of the hydrocarbon and steam through a heated tube containing the granular solid catalyst.

Acetaldehyde formed when steam and acetylene or mixtures of steam with acetylene and ethylene or nitrogen were passed through a tube containing solid phosphoric acid catalyst at 260–300° and atmospheric pressure. Some higher boiling products also formed apparently by condensation of acetaldehyde in the presence of the catalyst.

The different alkylacetylenes tried, both monoalkyl and dialkyl derivatives, underwent hydration to ketones in the presence of solid phosphoric acid catalyst at 204° and atmospheric pressure. Butyne-1 was hydrated also at 150°. Condensation of some of the ketone to oils of relatively high boiling point and refractive index accompanied its formation. By this hydration reaction propyne yielded acetone, butyne-1 formed 2-butanone, pentyne-1 and pentyne-2 each gave 2-pentanone, hexyne-1 produced 2-hexanone and heptyne-1 yielded 4-heptanone. The latter result indicates isomerization possibly involving migration of the triple bond along the carbon chain of heptyne-1 before hydration occurred producing 4-heptanone.

Experimental Part

Sources of Acetylene Hydrocarbons.—Acetylene from a commercial cylinder was purified from acetone vapors by passing through three scrubbers containing 96% sulfuric acid and then through a soda lime tower before use in the hydration experiments. Propyne was prepared following Hennion[10] and butyne-1 was produced according to the

method published by Hurd and Meinert.[11] The pentyne-1, pentyne-2, hexyne-1, and heptyne-1 were purchased from the University of Notre Dame.

Apparatus and Procedure.—When hydrating a liquid alkylacetylene, water and the acetylene hydrocarbon were dropped simultaneously at constant rates from burets into the upper end of a vertical Pyrex tube (10 mm. inside diam. × 90 cm.) containing the solid phosphoric acid catalyst (7.0 or 14.0 g. of 6-10 mesh particles) and surrounded by an insulated, electrically heated, aluminum bronze block furnace (60 cm. long) provided with a thermoregulator which maintained the temperature constant to within ±2°. The exit end of the catalyst tube was attached by a ground glass joint to an ice-cooled Pyrex receiver connected through a calcium chloride drying tube to a trap cooled by solid carbon dioxide and acetone.

When the alkylacetylene used was gaseous, it was passed from a weighed aluminum bomb through a calibrated flowmeter and thence to the top of the catalyst tube, the rest of the apparatus and procedure being the same as described. In the experiments on acetylene purified by sulfuric acid the amount of this gas entering and leaving the catalyst chamber (of 100 g. catalyst capacity) was measured by means of wet-test meters through which acetylene had been passed previously to saturate the water contained in them.

The trap cooled by solid carbon dioxide remained empty during the experiments on liquid alkylacetylenes, it collected small amounts of unreacted hydrocarbon in the experiments with gaseous alkylacetylenes and collected the main part of the acetaldehyde as an aqueous solution in the runs on the hydration of acetylene. In experiments on the alkylacetylene, the reaction products and water were collected mainly in the ice-cooled receiver from which the aqueous layer was removed by a pipet, and the main ketone layer and that obtained by salting-out the aqueous layer with potassium carbonate were combined, dried over anhydrous sodium sulfate or potassium carbonate and later distilled. These ketone fractions were characterized by their physical properties and by preparation of semicarbazones and 2,4-dinitrophenylhydrazones.

Distillation of the aqueous aldehyde solution, produced from acetylene, separated acetaldehyde with 20–22° boiling point from the excess of water used in the experiment, the higher boiling oily condensation products having been separated previously from the heavier lower layer of aqueous acetaldehyde solution.

Reaction between Acetylene and Water.—Formation of acetaldehyde from mixtures of approximately equal molecular proportions of acetylene and water began at about 260° under atmospheric pressure in the presence of solid phosphoric acid catalyst. At 300° hydration was more rapid in the equimolecular mixture and at the beginning of the experiment as much as 70% of the entering acetylene reacted. Of the acetylene consumed at the beginning of the reaction, about one-third yielded acetaldehyde and one-half produced higher boiling materials which apparently consisted of acetaldehyde condensation products containing crotonaldehyde and relatively high boiling aromatic hydrocarbons.

After the catalyst was in use for twenty-one hours and the absorption of acetylene had decreased to approximately 30% per pass, the cata yst was reactivated by heating in dry air at 500° for sixteen hours, followed by steaming at 260° for sixteen hours. Following this treatment the test was continued with 70% initial absorption of acetylene which dropped to 30% at the end of twenty-three hours and continued at that value for twenty-two hours more. The acetaldehyde yield reached 56% of the theoretical on the basis of the acetylene consumed with 9% accompanying condensation during this twenty-two hour period in which a reaction mixture consisting of two moles of water to one mole of acetylene was contacted with the reactivated catalyst. In all these acetylene hydration experiments the reaction mixture was in contact with the catalyst for an average time of 4.3 to 5.5 seconds.

Acetaldehyde from Acetylene–Ethylene and Acetylene–Nitrogen Mixtures.—Acetylene mixed with approximately an equal molecular proportion each of steam and ethylene, and with one proportion of steam and one-half proportion of nitrogen, also underwent hydration to acetaldehyde in the presence of solid phosphoric acid catalyst. Ethylene was not consumed, but apparently acted only as a diluent as was the case with nitrogen. These tests were made at an average contact time in the range of 5.0 to 5.7 seconds on both fresh, reactivated, and used catalysts. On the basis of the acetylene consumed, fresh catalyst gave the lowest yield of acetaldehyde and the highest production of oily condensation products; while used catalyst gave more acetaldehyde and less condensation products.

Hydration of Alkylacetylenes.—Propyne, butyne-1, pentyne-1 and -2, hexyne-1, and heptyne-1 underwent hydration in the presence of solid phosphoric acid catalyst and steam at 204° under atmospheric pressure and yielded acetone, 2-butanone, 2-pentanone, 2-hexanone, and 4-heptanone, respectively, as shown in Table I.

In addition to ketone formation by hydration of the different alkylacetylenes, there was also a production of small amounts of oils with relatively

(11) Hurd and Meinert, THIS JOURNAL, 52, 4544 (1930); 53, 289 (1931).

high boiling points and refractive indices. These were probably ketone condensation products but no attempt was made to identify them because of the small quantities available.

There were also indications that isomerization of alkylacetylenes involving migration of the triple bond occurred in contact with the catalyst. Thus the liquid products recovered from an experiment on butyne-1 (b. p. + 8°) contained a small quantity of material which may have been butyne-2 as it boiled at 25–30°, was insoluble in water, gave no reaction with semicarbazide hydrochloride, and turned red on contact with sulfuric acid, as is characteristic of butyne-2.

The materials available were insufficient to show whether pentyne-1 and pentyne-2 isomerized into each other. It is probable that each of these may hydrate to the same ketone without isomerization.

The fact that heptyne-1 hydrated to 4-heptanone is evidence that isomerization of this alkylacetylene occurred before hydration.

The authors are indebted to Mr. G. L. Hervert for assistance in conducting the hydration experiments.

Summary

Catalytic hydration of acetylene and of six alkylacetylenes has been accomplished readily by passing a mixture of the hydrocarbon and steam over a solid phosphoric acid-containing catalyst under atmospheric pressure at 260–300° for acetylene and at 150–204° for the alkylacetylenes.

Crystallite Growth during Carbonization

BY H. E. BLAYDEN, H. L. RILEY AND A. TAYLOR

The following is a description and discussion of further results obtained in a detailed X-ray and chemical study of the changes which occur in the solid phase during the carbonization of various carbonaceous materials. We already have described[1] the results of our study of the carbonization in the temperature range 400–1300° of cellulose and of a Northumberland coal. This work now has been extended in the case of cellulose to 2000° and also to the carbonization of two South Wales anthracites, an American anthracite, lignin and an Irish peat. Although the investigations are still incomplete and because of this their presentation must in some ways be tentative, the results already obtained appear to be of sufficient interest to justify publication at this stage. The demand for new knowledge of this kind need not be emphasized, for the fuller understanding of the molecular mechanism of the combustion and the reactivity of solid carbonaceous fuels demands more complete and fundamental information of their ultimate structure and of the effect of temperature, in the presence and absence of catalysts, upon this structure.

The Hull–Debye–Scherrer method of X-ray analysis has provided a means of obtaining this more detailed information. From the broadening of the diffraction lines in the X-ray powder photographs of the so-called "amorphous" carbons compared with the lines in the X-ray spectrum of macrocrystalline graphite, it is possible to calculate the average dimensions of the crystallites present (assumed to be cylindrical). This method already has been employed for this purpose by Koch-Holm,[2] Lowry and Bozorth,[3] U. Hofmann and co-workers,[4] Berl,[5] Corriez[6] and others. The magnitude of the results reported is affected by the particular method of computation used and to some extent also by the X-ray technique employed. This should be borne in mind when comparing the results of different investigators. The method and technique employed by us, which have already been described in detail,[1] are believed to be in closest keeping with the most recent developments of X-ray crystallographic analysis. Although, in the present state of our knowledge, it is not possible to claim any high order of fundamental accuracy, it is probable

that the results are relatively correct to within 10%.

The general picture of crystallite growth during carbonization which it is possible to form from our own observations and the work of other investigators, particularly U. Hofmann, is as follows. Crystallite growth as a result of processes occurring in the condensed phase with rise of temperature can be divided into three stages. *Stage 1:* from ordinary temperatures to approximately 700°.—In this temperature range the process is essentially one of aromatic condensation or aromatization, the main feature of the growth being the lateral extension of the hexagon layer planes of the graphite crystallites with little or no growth of the crystallites at right angles to the layer planes (*c* direction). That aromatization starts at relatively low temperatures when entirely non-aromatic substances are used has been demonstrated by Smith and Howard.[7] The experiments of Juettner[8] on the formation of mellitic acid from carbon show in a striking way the fundamental significance of 700° in relation to carbonization. *Stage 2:* from 700° to the temperature at which thermal recrystallization commences.—In this temperature range the *c* dimension remains constant and the *a* dimension (average diameter of cylindrical crystallites) increases slowly with rise in temperature. The most obvious explanation of this continued lateral growth of the layer planes appeared to be that the volatile matter still remaining in the carbon at 700° provided the carbon atoms for further aromatization. The results reported in the present paper, however, throw some doubt upon the validity of this

(7) Smith and Howard, THIS JOURNAL, 59, 234 (1937).
(8) Juettner, *ibid.*, 59, 1472 (1937).

simple explanation, for when the carbonization is carried to temperatures at which the residue is practically 100% carbon, the linear (*a*) dimensions of the crystallites continue to increase with temperature at the same rate as at lower temperatures. *Stage 3:* from the point at which thermal recrystallization commences upward.—During carbonization, at a more or less definite temperature, the *c* dimension, *i. e.*, the average number of layer planes in the crystallites, begins to increase rapidly. This type of growth which begins in certain cases sharply may be referred to conveniently as "thermal recrystallization," for it undoubtedly involves crystallites growing at the expense of their neighbors. Probably this type of growth is susceptible to "catalytic" influences perhaps due to inorganic substances present. In certain cases it begins at surprisingly low temperatures.

For purposes of comparison we propose to refer to the type of growth shown in the carbonization of cellulose as "normal," *viz.: Stage 1*, more or less rapid increase of the *a* dimension, *c* dimension constant; *Stage 2*, an equal or less rapid increase in the *a* dimension, *c* dimension constant; *Stage 3*, a relatively sharp onset of rapid growth in the *c* direction at a relatively high temperature. We have reason to believe that when growth departs from this "normal" type, extraneous factors are present and in seeking to elucidate these, it is possible that new and fundamental light will be thrown upon the process of crystallite growth and the structure of carbon.

The results obtained in the case of two South Wales anthracites, an American anthracite from the Pennsylvania southern coal field, a lignin prepared from soft wood and an Irish peat, are summarized in Fig. 1 (*a* dimensions) and Fig. 2 (*c* dimensions). The results obtained with cellulose previously reported[1] together with results obtained at higher temperatures, have been included for comparison purposes. Details of the X-ray and analytical results are given in Tables I–V.

Anthracites.—Ten-gram samples of the anthracites, graded between 60 and 100 I. M. M. sieves were carbonized in an atmosphere of nitrogen at 5°/min. up to the required temperature, the product being maintained at the final temperature for ten minutes and allowed to cool in nitrogen. This procedure was adopted for the preparation of cokes up to 1300°. A specially constructed carbon tube resistance furnace which operated in vacuum was employed for the preparation of the cokes at temperatures above 1300°. The rate of heating in this furnace could not be controlled so precisely as in the low temperature furnace as it was necessary occasionally to slow down the rate of heating in order to prevent the powdered charge being blown out of the tube due to the too rapid evolution of gas in the vacuum. The carbons heated to high temperatures in the carbon tube vacuum furnace were given a preliminary carbonization in nitrogen up to 1000° in the wire resistance tube furnace. In order to prevent the appearance of lines due to ash on the X-ray photograph the samples were thoroughly extracted after carbonization by boiling with 20% hydrochloric acid followed by two evaporations with hydrofluoric acid, then by another treatment with hydrochloric acid. This was usually sufficient to reduce the amounts of crystalline ash constituents to such an extent that no trace of ash lines was visible on the powder photographs. The coals and cokes after this treatment contained appreciable amounts of very firmly adsorbed hydrochloric acid (*vide infra*). To remove this it was necessary to heat the sample in vacuum to 110°. Duplicate chemical analyses were made and powder photographs taken from which crystallite dimensions were computed by the method already described.

The *a* dimension-carbonizing temperature curves obtained with these anthracites are interesting in several respects. In stage 1, the anthracite curves are consistently higher than the bituminous coal curve already reported. It is noteworthy that the American anthracite itself (95.92% C) and the cokes prepared from it up to 700° all give *a* dimensions greater than the corresponding samples prepared from the two Welsh anthracites (92.50 and 93.64% C). These results are in accord with the views of Bone and coworkers and others upon the relationship between coal rank and the development of "benzenoid" characteristics. Another interesting feature which could perhaps have been anticipated from the experiments of Juettner[8] is that the crystallite *a* dimensions for the two Welsh anthracite 700° cokes (18.0 and 17.6 Å.) and the *a* dimension of a corresponding bituminous coal coke crystallite

(18.2 Å.) are approximately the same while the American anthracite 700° coke gives a value only slightly greater (20.0 Å.). It is also perhaps significant that in stage 2, the growth curves of all four coals are approximately concurrent.

As far as our knowledge goes at present it would appear that the extent to which the lateral growth of a crystallite can occur in the earlier stages of carbonization must be governed primarily by two factors, *viz.* (1) the number of graphite nuclei present in the parent material or formed during carbonization, around which aromatic condensation occurs, and (2) the chemical nature of the carbonaceous material, *e. g.*, substances containing much oxygen would be expected, when carbonized, to give off a larger proportion of volatile matter and, other things being equal, to form smaller crystallites. The remarkable similarity of the *a* dimension of the 700° coke crystallites prepared from quite diverse substances suggests that other and possibly more fundamental factors control crystallite growth in stage 1.

The *c* dimension growth curve (Fig. 2) shows a very different state of affairs from that obtaining with the cellulose, lignin and Northumberland coal. Whereas with the latter the *c* dimension remains constant over a considerable range of carbonizing temperature this is not so with the anthracites. The Welsh anthracite crystallites contain on the average 6 layer planes and the American anthracite 5.6. At a carbonizing temperature of 400° the *c* dimension begins to decrease and at 900° reaches a value corresponding to an average of approximately 4.5 layer planes. As the temperature is further increased the crystallites show a pronounced growth in the *c* direction. This phenomenon is not quite so pronounced with the American as with the Welsh anthracites.

It already has been pointed out[1] that the *c* spacing is an inverse function of the *c* dimension. This fact provides an interesting and independent check of the crystallite size determinations. In Fig. 3, *c* dimension has been plotted against *c* spacing for a large number of crystallites and it will be seen that the anthracite results fall on a smooth curve drawn through these points.

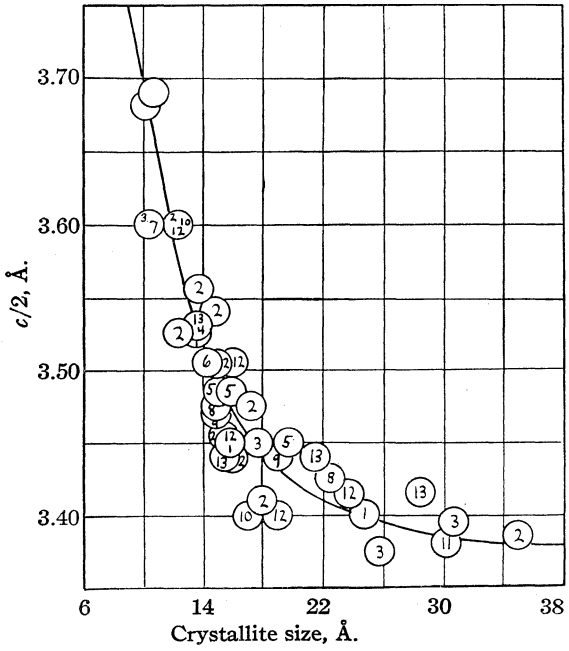

Fig. 3.—Variation of interplanar distances with crystallite size in *c* direction: 1, cellulose carbons; 2, S. W. anthracite C527; 3, peat; 4, coke C518; 5, coke C383; 6, lignin; 7, wood; 8, coke C526; 9, coke C528; 10, coke C458; 11, pentadiene carbon; 12, S. W. anthracite C607; 13, American anthracite C618.

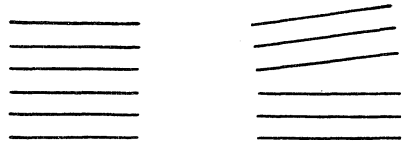
It is apparent from Fig. 1 that the lateral growth of the layer planes as the temperature increases is much too small to account for the decrease of the *c* dimension by the lateral growth of certain

of the layer planes at the expense of others. The most probable explanation appears to be that rise of temperature causes disruption of the original anthracite crystallites in the manner shown in Fig. 4. It is possible that this phenomenon is connected with the decrepitation which occurs when many anthracites are heated rapidly, for if the above explanation is correct then rise of temperature will be accompanied by a disruption of the crystallites and a consequent anisotropic expansion along the *c*-axis which would be sufficient to cause decrepitation.



(a) Original anthracite layer planes.

(b) Probable disorder introduced into the anthracite crystallite by heating to 500–900°.

Fig. 4.

The question naturally arises as to why this crystallite disruption occurs with the anthracites studied and not with the Northumberland coal and several other bituminous coals upon which preliminary tests have been made. Although a much greater number of coals must be examined before this question can be answered, the following points are worthy of consideration. Theoretical considerations have been advanced[9] which indicate the possibility of bonding hydrogen atoms or ions between the layer planes of the graphite crystal lattice. Anthracite has been reported to have an adsorptive power greater than coals of lower rank for both carbon dioxide[10] and methane.[11] These facts suggest that the disruption of the anthracite crystallites on heating, may be connected with the desorption of interstitially adsorbed gas, probably hydrogen. The fact that gas evolution and crystallite disruption commence at approximately the same temperature supports this hypothesis.

Lignin.—The lignin used was prepared from soft wood sawdust by Klason's method[12] and cokes were made from it in the manner already described. It will be seen from Fig. 1 that in stage 1 the lignin coke crystallites show an *a* dimension growth curve very similar to that of the anthracites. This is probably a reflection of the fact that the lignin itself contains highly condensed aromatic molecules[13] arranged in a lattice which must in many respects be similar to that of a graphite crystallite.[14]

TABLE IV

EXAMINATION OF LIGNIN

Analysis of lignin: ash, 0.59 (dry basis); C, 65.70; H, 4.57 (dry, ash-free basis).

Carbonization temp., °C.	Analysis (dry, ash-free basis) C, %	H, %	Crystallite size, Å. *a*-axis	*c*-axis	Interatomic dist., Å.	Interlayer plane dist., Å.
400	76.01	3.38	14.3	10.3	1.38	3.60
700	91.72	1.73	16.6	11.8	1.38	3.69
1000	96.62	0.57	20.4	10.4	1.37	3.69
1300	98.90	.20	22.6	11.2	1.37	3.75
2000	..	..	27.9	14.3	1.40	3.51

In other respects the lignin crystallite growth curves can be considered normal. The preparation of lignin involved the extraction of wood with strong mineral acid which removed not only the cellulose but also the major part of the inorganic constituents. The cokes were thus prepared from a material relatively low in ash. This is probably connected with the fact that thermal recrystallization as evidenced by the rapid increase of the *c* dimension only sets in at relatively high temperatures (*vide infra*).

Peat.—The Irish peat employed was from Turraun, and its properties already have been described in detail.[15] Owing to its ash content and the difficulty of eliminating this from the cokes prepared at low temperatures by acid extraction, it has not yet been possible to prepare X-ray photographs, for stage 1 of the growth curves, sufficiently free from ash lines to permit of their use in crystallite size determinations. The results recorded are from 700° upward. The growth curves are entirely anomalous. The growth of the *a* dimension between 700 and 1300° is considerably greater than that recorded for the other materials studied. More surprising is the rapid growth of the *c* dimension which occurs between 700 and 1000°. This is not an isolated result. Preliminary experiments have shown that

(15) D. S. I. R., Fuel Research Board, Technical Paper No. 4.

other Irish peats behave similarly. Two explanations of this phenomenon suggest themselves. The anomalous growth may be due to either (a) something inherent in the organic structure of the peat material or (b) a catalytic effect. (a) appears unlikely for the following reasons: (1) the anomalous growth in the *c* direction is not shown by cellulose, lignin or a sample of soft wood; (2) the X-ray photographs of the cokes give no indication that their organic structures are fundamentally different from those of other carbonaceous materials; (3) the anomalous growth is not prevented by carbonizing in high vacuum instead of nitrogen. The evidence in favor of (b) is as follows: (1) the ash content of the peat is higher than that of the other carbonaceous materials employed; (2) the ash is probably intimately associated with the organic matter, for acid extraction fails to remove it completely; (3) the carbonaceous material remaining after extraction of the original peat with boiling concentrated or dilute (2%) hydrochloric acid behaves normally and does not show the rapid growth in the *c* direction at low temperatures. Such treatment might, however, besides extracting ash, also bring about an alteration in the nature of the organic matter present; (4) attempts to promote growth in the *c* direction at low temperatures by the pretreatment of ash-free cellulose with iron and alkali salts so far have been unsuccessful. At higher temperatures (1600°), inorganic additions have a very pronounced effect, promoting very rapid growth.[16] Details of these experiments will be published at a later date.

TABLE V

EXAMINATION OF IRISH PEAT C445

Analysis of Irish peat: ash, 3.5 (dry basis); C, 57.22; H, 5.27 (dry, ash-free basis).

Carbonization temp., °C.	Analysis (dry, ash-free basis) C, %	H, %	Crystallite size, Å. *a*-axis	*c*-axis	Interatomic dist., Å.	Interlayer plane dist., Å.
400	76.35	3.92	..	..	..	..
700	90.12	1.76	17.0	10.3	1.38	3.60
800	91.80	1.20	17.8	11.5	1.38	3.58
900	93.88	0.68	20.0	16.7	1.39	3.45
1000	95.70	.56	22.4	25.2	1.39	3.36
1300	97.94	.27	27.4	25.8	1.39	3.38
2200	99.4	..	32.8	30.8	1.38	3.39

Although at present it is not possible to put forward a definite explanation of this phenomenon, these results suggest the possibility of rendering the carbon atoms in the graphite crystallites highly mobile at relatively low temperatures with a consequent enhancement of their reactivity.[17]

The pronounced falling off in the rate of growth in the *c* direction at 1000° may be due either to (a) the elimination of the catalyst by volatilization or (b) change in the degree of contact of individual crystallites, brought about by the pronounced growth which already has occurred.[18]

Crystallite Growth at High Temperatures.—With temperatures up to 1300°, a carbonization rate of 5° per minute and heating for ten minutes at the final temperature provides sufficient time for maximum growth. No appreciable further growth was detected when cellulose cokes were heated for an additional period of five hours at the maximum temperature. The nature of the growth occurring at temperatures greater than 1600° may be of a different character from that occurring at lower temperatures. The results obtained with cellulose show that after carbonizing at 5° per minute the retention of the specimen at the final temperature for several hours brings about considerable further crystallite growth.

The form of the *c* dimension curves of the anthracites, which were carbonized in the presence of their ash, compared with the corresponding curves for cellulose and lignin both of which were subjected to a preliminary acid extraction, suggests that the inorganic constituents must play an important role in the growth process at high temperatures.

The Adsorption of Hydrochloric Acid by Coals and Cokes.—The anomalous nature of the ultimate analyses of the cokes prepared from the anthracites after extraction with hydrochloric and hydrofluoric acids led us to investigate the adsorption of hydrochloric acid by these substances. It was discovered that both the coals and the cokes adsorb considerable quantities of hydrochloric acid which is not eliminated by several hours of heating in vacuum at 110°. That this adsorbed hydrochloric acid replaces some of the inherent water in the air dried coals is shown by the following results.

	%
(a) Increase in weight of anthracite after extraction with hydrochloric acid	2.11 (dry coal basis)
(b) Chlorine content of anthracite after extraction with hydrochloric and hydrofluoric acids	2.28 (dry coal basis)

(16) *Cf.*, however, statements of Arsem, *Trans. Am. Electrochem. Soc.*, **20**, 105 (1911).

(17) *Cf.* investigations of Hedvall, *Z. Elektrochem.*, **45**, 83 (1939).

(18) Wesselowsky and Pertzov, *Z. anorg. Chem.*, **216**, 228 (1934).

	%
(c) Moisture content of the air dried anthracite before extraction with hydrochloric acid	2.5
(d) Moisture content of the air dried anthracite after extraction with hydrochloric acid	0.5

The hydrochloric acid contents of a series of cokes after extraction with this acid and subsequent drying at 110° are shown in Table VI.

TABLE VI

ADSORPTION OF HYDROCHLORIC ACID

Carbonization temp., °C.	HCl adsorbed, % of dry substance			
	Anthracites C527	C607	Lignin	Irish peat
400	0.83	1.50	0.43	2.38
500	1.07	..	..	..
600	0.72	..	..	..
700	.59	1.60	.74	3.18
800	.51	1.45	..	1.96
900	.72	1.51	..	0.91
1000	.09	0.71	.04	.92
1100	..	.49	..	..
1150	.19	..	..	..
1200	..	.06	..	..
1300	..	..	Trace	1.18

It will be seen (Table VI) that the amount of adsorbed hydrochloric acid passes through a maximum with the 700° coke, which is significant in view of the results of other investigations on adsorptive power.[7]

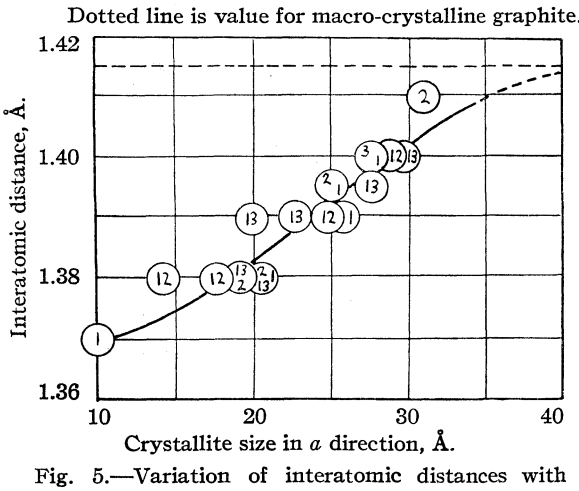

Fig. 5.—Variation of interatomic distances with crystallite size in *a* direction: 1, cellulose carbons; 2, S. W. anthracite C527; 3, peat; 4, coke C518; 5, coke C383; 6, lignin; 7, wood; 8, coke C526; 9, coke C528; 10, coke C458; 11, pentadiene carbon; 12, S. W. anthracite C607; 13, American anthracite C618.

Variation of C–C Spacing with Crystallite Size.—It already has been pointed out that the *c* spacing is an inverse function of the number of layer planes in the crystallite. The C–C spacing in the layer planes also shows an interesting variation with crystallite size. The C–C spacing in the layer planes of macrocrystalline graphite is 1.415 Å., while in the microcrystalline carbons already studied it is approximately 1.37–1.38 Å. The measurements recorded in this paper indicate that the latter value increases as the crystallites grow. Figure 5 shows the C–C spacing plotted against the *a* dimension of the layer plane.

Conclusion.—It is apparent from the above results that investigations of this kind are likely to throw considerable light upon the ultimate nature of coals and "amorphous" carbons and upon the changes which these substances undergo on heating. The investigation already has revealed a number of quite unexpected results and it would therefore at this stage be unwise to theorize as there is still a host of very diverse carbonaceous materials, both synthetic and natural, to be studied.

The authors are indebted to the Northern Coke Research Committee for permission to publish this paper, to Dr. F. S. Sinnatt (Director, Fuel Research Board, D. S. I. R.) and the Amalgamated Anthracite Co., Wales, for samples of peat and anthracite, respectively, and to Dr. A. C. Fieldner (U. S. Bureau of Mines) and the Lehigh Navigation Coal Co., Pa., for samples of the American Anthracite. They also record their thanks to Messrs. J. Gibson, B. Sc. and J. Almond for assistance with the analyses.

Summary

The investigations of crystallite growth during carbonization in the temperature range 400–1300°[1] have now been extended to include one American and two Welsh anthracites, lignin and an Irish peat, and carbonization temperatures up to 2200°. The anthracites and the peat all show interesting anomalies in their crystallite growth curves. The anthracite crystallites show a decrease in the *c* dimension as the carbonization temperature is increased from 400 to 900°. This has been interpreted as due to disruption of the crystallites. The peat coke crystallites show a very rapid growth in the *c* direction between 700 and 1000° which is probably due to a catalytic effect.

The significance of the results obtained is discussed in detail.

Thermodynamic Properties of the Hexyl Alcohols. III. 2-Methylpentanol-3 and 3-Methylpentanol-3

BY FRANK HOVORKA, HERMAN P. LANKELMA AND ABRAHAM E. AXELROD

This paper represents the third[1,2] of a series of investigations being carried out in this Laboratory dealing with the relation between the physical properties and chemical constitution of the hexyl alcohols, and concerns the vapor pressure, viscosity, surface tension, density and refractive index of 2-methylpentanol-3 and 3-methylpentanol-3.

Experimental

Preparation of Materials.—2-Methylpentanol-3 was prepared from ethyl bromide and isobutyraldehyde by the Grignard synthesis.[3] 3-Methylpentanol-3 was obtained from the Eastman Kodak Co. and further purified.

Purification.—The fractionating columns employed for the initial and final distillations have been described previously.

"Drierite"[4] was used as the drying agent for both alcohols. The alcohols were allowed to stand over the "Drierite" for two weeks, filtered, and then fractionally distilled.

The alcohols were considered pure when the final boiling point range did not exceed 0.02°.

Apparatus and Procedure for Determining Physical Constants.—The apparatus and the procedures used in this research are those described by Hovorka, Lankelma and Stanford.[2]

All of the instruments used in the surface tension, density, and viscosity measurements were recalibrated before determinations were made.

Discussion of Results

Vapor Pressure.—The vapor pressure data are tabulated in Table I, column 5.

The summary of the values calculated from the vapor pressure data is given in Table II. The constants of the Rankine equation are designated as A, B, and C. The vapor pressures calculated from the Rankine equation agree quite closely with the observed values.

The values of the Trouton constant are considerably higher than the normal value of 21 and indicate varying degrees of association. These high values correspond with those found by Hovorka, *et al.*,[1,2] for the hexanols thus far reported.

Viscosity.—The viscosity data are collected in Table I, column III. The relationship between chemical structure and viscosity is an obscure one since the curves of viscosity *vs.* temperature possess different slopes and even tend to cross each other. This fact has been noted previously. It is significant to observe, however, that the temperature *vs.* viscosity curves for the two hexanols under observation tend to approach the same value at 60° and that from 60 to 130°, the two hexanols have practically the same viscosity values. This behavior may be interpreted by assuming that the molecular aggregation of the alcohols is the same in the temperature interval 60–130°.

Stewart[5] has shown that there are two types of association found among alcohols. According to his theory, both of the hexanols under investigation are associated side by side, the spacing corresponding to one molecular length. Assuming that association takes place through the hydroxyl group, the shielding effect upon the association forces should be approximately the same in both cases. This observation is borne out by the fact that the slopes of the viscosity *vs.* temperature and the density *vs.* temperature curves are practically the same in the temperature interval 60–130°, thus pointing to the fact that the breakdown of these association complexes with temperature is approximately the same for both hexanols.

Plots of Raman's equation[6] and Andrade's[7] equation for 2-methylpentanol-3 yielded perfectly symmetrical curves instead of the straight lines which are to be expected if the equations held. In the case of 3-methylpentanol-3, the plot of the Andrade equation showed a decided break in the higher temperature range. A similar break occurs in the same temperature range when the specific volumes of 3-methylpentanol-3 are plotted against temperature. The constants

TABLE II

SUMMARY OF VALUES CALCULATED FROM VAPOR PRESSURE DATA

Substance	A	B	C	Max. devn. +	Max. devn. −	Av. devn.	Heat of vapn.[a]
2-Methylpentanol-3	−5078.0	−16.9262	59.6217	0.28	1.4	−0.40	10,624
3-Methylpentanol-3	−2013.4	− 1.0840	5.1802	1.15	2.14	− .03	10,057

	Boiling point, °C.[b]	Trouton's constant
2-Methylpentanol-3	126.68° ± 0.02	26.6
3-Methylpentanol-3	120.91° ± .02	25.5

[a] These are average values calculated from the slope of the curve obtained by plotting log P against $1/T$. [b] Boiling point values were obtained by interpolation from the vapor pressure curves.

of the Andrade equation were evaluated by the method of least squares and the viscosities calculated. The constants and the deviations of the calculated from the observed viscosities are given in Table III. The symmetrical nature of these deviations is very evident. The above observations are in accordance with those previously found.

TABLE III

CONSTANTS FOR THE EQUATION $nv^{1/3} = Ae^{c/VT}$

	$A \times 10^{-6}$	C	Maximum deviation +	Maximum deviation −
2-Methylpentanol-3	17.34	2804	15.2	25.6
3-Methylpentanol-3	36.12	2493	13.3	14.6

Bingham and co-workers[8,9] have proposed various methods for the calculation of the degree of association of liquids which are based upon the premise that fluidities are additive and that, accordingly, liquids should be compared at temperatures of equal fluidity. The association

(8) Bingham and Spooner, *J. Rheol.*, **3**, 228 (1932).
(9) Bingham and Darral, *ibid.*, **1-2**, 174 (1929-31).

factors of 2-methylpentanol-3 and 3-methylpentanol-3 have been calculated from Bingham's "atomic constants" and are given in Table IV.

Refractive Index.—Using the values given by Eisenlohr[10] for the atomic refractive constants of carbon, hydrogen and oxygen, we have calculated the molecular refractive power of 2-methylpentanol-3 and 3-methylpentanol-3. These values are compared in Table V with those calculated from the Lorenz–Lorentz formula.

TABLE IV

CALCULATION OF ASSOCIATION FROM FLUIDITY

200 rhes			300 rhes		
Calcd. temp., °A.	Obsd. temp., °A.	X	Calcd. temp., °A.	Obsd. temp., °A.	X
2-Methylpentanol-3					
271.1	367.0	1.36	305.5	393.0	1.28
3-Methylpentanol-3					
271.1	369	1.37	305.5	396.0	1.29

TABLE V

MOLECULAR REFRACTIVE POWER

	Lorenz–Lorentz equation	Summation of atomic constants
3-Methylpentanol-3	30.74	31.44
2-Methylpentanol-3	31.15	31.44

Surface Tension.—The surface tension data are collected in Table I, column 2.

The values of the Eötvös constant, parachor, and total surface energy were calculated over the entire temperature range and are tabulated in Table I. The general trend of these values is the same as that found by Hovorka, Lankelma and Stanford.[2] In all cases the values are those of associated substances.

(10) F. Eisenlohr, *Z. physik. Chem.*, **75**, 585 (1911).

If, according to Sidgwick, the parachor is to be used as a criterion for the degree of association, it is seen that 3-methylpentanol-3 is slightly more associated than 2-methylpentanol-3 at the lower temperature, and that both hexanols are more associated than those previously studied.

The critical constants have been calculated from the Ramsay–Shields equation and are given in Table VI. A large decrease in the values with increase in temperature is readily apparent.

TABLE VI

CRITICAL TEMPERATURES

Alcohol	T	°C.	T	°C.
2-Methylpentanol-3	364.7	(25–35)[a]	296.6	(115–125)
3-Methylpentanol-3	402.4	(25–35)	283.4	(105–115)

[a] The values in parentheses show the two temperatures used to calculate the critical temperatures in question.

Summary

1. The preparation and purification of two hexyl alcohols, 2-methylpentanol-3 and 3-methylpentanol-3, have been described.

2. The surface tension, density, viscosity and vapor pressure have been determined over the temperature range from 5° to the boiling point. The refractive index has been determined from 15 to 45°.

3. The average heat of vaporization and the constants for Rankine's equation have been calculated from vapor pressure data.

4. The parachor, Eötvös constant, total surface energy, and critical constants have been calculated from surface tension data.

The Determination of Organic Peroxides

BY HERMAN A. LIEBHAFSKY AND WILLIAM H. SHARKEY

Because of possible explosion hazards,[1] and for other reasons, a rapid, accurate method for determining organic peroxides was needed in connection with a synthesis involving the distillation of large amounts of *n*-butyl ether. A modification of iodometric methods already in the literature[2] seemed most likely to meet the following requirements: (1) a reaction system homogeneous even during the titration; (2) a negligible blank; (3) liberation of iodine complete in less than ten minutes; (4) accuracy to within two drops of 0.01 *N* solution.

Simple experiments showed that homogeneity and rapid iodine liberation both can be obtained in glacial acetic acid. Separation into two phases, which occurs more readily with *n*-butyl than with ethyl ether, is avoided at room temperature if less than 8 cc. of water is added to 5 cc. of *n*-butyl ether dissolved in 25 cc. of the acid. The blank, however, is a more serious problem, especially since there is no guarantee that the reaction between oxygen and iodide (the "oxygen error"), which gives rise to the blank, will proceed independently of the reaction between peroxide and iodide. Numerous trials, which cannot be described in detail, showed the blank to be unreproducible but always too high when oxygen was present, even though light was rigorously excluded between mixing and titration. It was found that the blank could be eliminated satisfactorily by adding about 1.5 g. of sodium bicarbonate to the reaction mixture; the carbon dioxide produced is effective not only because it is heavier than air, but also because it is liberated within the reaction mixture, which it thus frees of oxygen.

The logical order of mixing is acetic acid, sodium bicarbonate, potassium iodide solution. With this sequence no appreciable iodine need be formed provided the acetic acid contains enough water to ensure vigorous effervescence before the iodide solution is added. Unfortunately, this amount of water retards the reaction between peroxide and iodide more than is desirable and leads to a rapid exhaustion of the bicarbonate. The reaction mixture was accordingly prepared as follows. To 25 cc. of glacial acetic acid and approximately 1.5 g. of sodium bicarbonate in a glass-stoppered flask, 1 cc. of potassium iodide solution (0.4 g./cc.) is added. The mixture usually becomes faintly yellow. 0.01 *N* thiosulfate is now added, two drops at a time, with gentle swirling, until the color is that of the end-point. (It is safer to take the end-point as the faintest yellow perceptible to the eye; starch is an unsatisfactory indicator in this system.) Because the reaction between sodium thiosulfate and iodine does not seem to be instantaneous in this medium, there is danger of adding too much thiosulfate unless ten seconds or so intervene between successive additions. When no further deepening of the iodine color occurs, the sample for the peroxide determination (in our case usually 5 cc. of *n*-butyl ether) is added, the flask is stoppered and placed in a dark cabinet for five minutes, and the iodine titrated thereafter with standard 0.01 *N* sodium thiosulfate solution. The flask is subsequently replaced in the cabinet for a similar time; if no further iodine formation occurs, the titration is satisfactory. This analytical method, which already has proved useful for the determination of other peroxides, was tested specifically on hydrogen peroxide dissolved in glacial acetic acid, on benzoyl peroxide in the same solvent, and on the peroxides in *n*-butyl ether. In the two former cases, the volume of thiosulfate solution was within approximately 0.1 cc. of that known to be equivalent to the amounts of the

(2) (a) Rowe and Phelps, THIS JOURNAL, **46**, 2078 (1924); (b) Marks and Morrell, *Analyst*, **54**, 503 (1929); (c) Van Winkle and Christiansen, *J. Am. Pharm. Assoc.*, **18**, 1247 (1929); (d) Wheeler, *Oil and Soap*, **9**, 89 (1932); (e) Green and Schoetzow, *J. Am. Pharm. Assoc.*, **22**, 412 (1933); (f) French, Olcott, and Mattill, *Ind. Eng. Chem.*, **27**, 724 (1935). None of these methods meets all the requirements listed above.

A few experiments with cadmium iodide added to our reaction mixtures showed that its use detracted from our method. It appears to have been introduced (*cf.* (g) "U. S. Pharmacopoeia," 9th ed., 1916; and refs. 2a, 2c, and 2e) to minimize iodine liberation by oxygen in the qualitative test for peroxides in pharmaceutical ether, and then retained in the corresponding quantitative methods. It acts, through complex ion formation, to reduce the iodide concentration, but it is not very effective in dilute solution [Bates and Vosburgh, THIS JOURNAL, **60**, 137 (1938)]. However useful it may be in qualitative tests, its value in quantitative determinations is doubtful since a lower iodide concentration means a longer time for complete reduction of the peroxide, other things being equal. Certainly it appears to have no place in a method where the blank is negligible.

peroxides used; in the latter case, the analysis was considered satisfactory because samples permitted to stand for different times gave concordant results.

With this analytical method available, the observations of Table I were made on peroxide formation in *n*-butyl ether.

TABLE I

No.	Description of the ether	$10^3 \times$ peroxide normality
1	Stood in laboratory for several days	2.1
2	Exposed no. 1 to 2537 Å. (not monochromatic) for 30 min.	7.1
3	Exposed no. 1 to 3650 Å. (not monochromatic) for 30 min.	7.1
4	Left no. 3 near window for 1 day	8.5
5	No. 1 several days later	3.3
6	Refluxed no. 5 for 15 min.	0.9
7	Refluxed no. 6 for 15 min. longer	0.5
8	Fresh supply of ether	4.6
9	Bubbled oxygen for 15 min. through boiling no. 8 ether	24.6
10[a]	Bubbled oxygen for 45 min. longer through boiling no. 9 ether	66

[a] Intermediate values omitted. For an unknown reason, one of these was lower than the preceding value. This anomaly could not be reproduced.

The indications are that (1) exposure to ultraviolet radiation increases the peroxide concentration; (2) daylight is also effective; (3) refluxing destroys the peroxides; (4) bubbling oxygen through the boiling ether rapidly produces them. For the 5-cc. samples used, the average titration error (*ca.* 0.1 cc. of 0.01 *N* solution) corresponds to a peroxide concentration of $0.2(10^{-3})$ *N*.

Rates of Reactions.—During work on the analytical method, several observations on rates of reactions in glacial acetic acid containing water in varying amounts were made. These observations were confirmed in simple experiments, the results of which are given here in the hope that someone will find them sufficiently interesting to extend the investigations.

Owing to serious overstepping of the end-point, the titration of thiosulfate and iodine solutions in glacial acetic acid as a medium often gave erratic results when the amount of water in solution was small. The following experiment illustrates the difficulty involved: 100 cc. of glacial acetic acid and 1 cc. of 0.01 *N* sodium thiosulfate are thoroughly mixed, 0.6 cc. of 0.008 *N* tri-iodide solution is then added, and the solution shaken. Its color begins to disappear immediately, but the rate of disappearance decreases markedly with time. After several minutes, the solution is still colored; but it becomes colorless immediately upon being shaken with 10 cc. of water. If 10 cc. of water is added initially to the 100 cc. of acid, no appreciable persistence of color is observed. An experiment employing a photoelectric spectrophotometer confirmed these visual observations. The simplest, though by no means the only, explanation is that sodium thiosulfate and iodine do not react instantaneously in glacial acetic acid.

A crude measure of the rates at which various peroxides are reduced by iodide in glacial acetic acid was obtained in experiments carried out as follows. The peroxide solution was blown into the reaction mixture prepared as for the peroxide analysis, the initial time being observed on a suitable timer. A number of seconds later, when appreciable iodine formation had occurred, 0.01 *N* thiosulfate solution was added rapidly until the mixture was decolorized, at which point the final time was estimated. From the volume of thiosulfate solution required, the volume of thiosulfate, *a*, (determined on another sample) equivalent to the peroxide added to the reaction mixture, and the reaction time (in minutes), a first order rate constant, *k*, was calculated from the equation

$$kt = 2.3 \log \frac{a}{a - x}$$

The unproved assumption that the reaction is first order with respect to peroxides in this medium is based on reasonable analogy.[3] To measure the effect of added water on these reactions, a corresponding series of experiments with 3 cc. of water initially present in the reaction mixture was performed. The results are summarized in Table II. With the exception indicated, each value is the average of three rough determinations. In aqueous solution, with 0.1 *M* iodide and 1 *N* acid, *k* at 25° would be approximately[3b] $0.1(0.7 + 10.5) = 1$. More precise work of this kind should shed some light on acetic acid as a reaction medium and on any kinetic relationships of the organic

TABLE II

Peroxide	H_2O_2 in HOAc	Bz_2O_2 in HOAc	Peroxides in *n*-Bu_2O
k (no added water)	10[a]	1.9	2.5
k (3 cc. added water)	1.6	0.9	0.9

peroxides to hydrogen peroxide; that some simple relationships may exist is obvious from the above data.

Summary

A modified iodometric method for the determination of organic peroxides is described.

Certain observations have been made on the formation and decomposition of peroxides in *n*-butyl ether.

When tri-iodide solution is added to excess sodium thiosulfate in glacial acetic acid, the color fades at a measurable rate. The addition of water of course causes the fading to become practically instantaneous.

Crude rate measurements show that benzoyl peroxide and the peroxides in *n*-butyl ether are about equally reactive toward iodide in glacial acetic acid, and not much less reactive than hydrogen peroxide in the same medium. The addition of water retards all three reactions about equally.

The Dipole Moments and Structures of Chlorine Compounds of Germanium, Chromium, Selenium and Tellurium

BY C. P. SMYTH, A. J. GROSSMAN AND S. R. GINSBURG

The dipole moments of monochloro and dichlorogermane, chromyl chloride, diphenylselenium dichloride and tellurium tetrachloride have been measured with the object of studying the structures of the molecules and obtaining information as to the magnitudes of the bond moments in the molecules. The moments were obtained with the apparatus and methods previously described,[1,2] with the exception of that of monochlorogermane, which was measured in the vapor state by Mr. R. H. Wiswall, Jr., the dielectric constants being determined at three temperatures so close together that the moment was calculated by subtracting a calculated molar refraction from the polarization. The experimental measurements on solutions of dichlorogermane in carbon tetrachloride carried out by Dr. George L. Lewis already have been published and discussed elsewhere. The value of the moment is included in Table II for comparison with that of monochlorogermane.

Preparation of Materials

Benzene[1] and carbon tetrachloride[2] were purified as in the work previously described.

Monochloro- and Dichlorogermane.—A kilogram of germanite containing 6% of germanium dioxide was obtained from the Foote Mineral Company and treated according to a procedure described by Professor J. H. Müller of the University of Pennsylvania in a communication to Professor N. H. Furman of Princeton University, to both of whom the authors wish to express their gratitude. By this procedure germanium was extracted from its ore as the tetrachloride, which was then hydrolyzed to form the dioxide. After the reduction of the latter in an atmosphere of hydrogen, it was combined with magnesium. The resulting germanide, treated with hydrochloric acid in an atmosphere of hydrogen, gave monogermane, which was purified by fractionation and mixed with an equal volume of hydrogen chloride over aluminum chloride as a catalyst according to the method of Dennis and Judy.[3] The resulting monochlorogermane and dichlorogermane were separated by fractionation at low temperatures, between 2 and 3 cc. of monochlorogermane and 1 cc. of dichlorogermane being obtained in the liquid form. In spite of careful fractionation, the samples could not be regarded as very pure. The stability of the monochlorogermane was sufficient to permit of its measurement in the vapor state over a limited temperature range, while decomposition of the dichlorogermane was rendered negligible by measurement in dilute solution.

Chromyl Chloride.—The compound was prepared by the method given by Henderson and Fernelius[4] and distilled at reduced pressure in an apparatus which had been dried by thorough baking.

Diphenylselenium Dichloride.—Material from the Eastman Kodak Company was recrystallized from dry benzene and dried in a vacuum desiccator.

Tellurium Tetrachloride.—Twenty-eight grams of C. P. tellurium in the form of sticks was placed in a distilling apparatus, which was then evacuated and baked. The gently heated tellurium was treated with a slow stream of dry chlorine, which converted it first into a black amorphous mass of tellurium dichloride and then into the white, crystalline tetrachloride. The latter was distilled into a side-arm where it gave an amber liquid, which solidified to white crystals.

Experimental Results

The dielectric constants ϵ and densities d of the solutions containing mole fraction c_2 of the polar solute and the polarizations, P_1 of the solvent and P_2 of the polar solute, are given in Table I. Table II gives values of the molar refractions MR_D for the D sodium line, calculated as the sum of atomic refractions obtained from Landolt–Börnstein or calculated from refraction data in the literature. The errors in MR_D are too small to have appreciable effect upon the values of the moments except in the case of chromyl chloride, the moment of which is enclosed in parentheses because of its uncertainty. The succeeding columns of Table II list the polarizations P_∞ obtained by extrapolating the P_2–c_2 curves to infinite dilution, except in the case of monochlorogermane, where P_∞ was obtained from measurements of the vapor at several different pressures, and the dipole moments μ. The measurements on diphenylselenium dichloride were made at 50° in order to take advantage of the greater solubility at the higher temperature.

TABLE I

DIELECTRIC CONSTANTS, DENSITIES AND POLARIZATIONS

c_2	ϵ	d	P_2
Carbon Tetrachloride–Chromyl Chloride (t = 25°)			
0.00000	2.236	1.5836	(28.35 = P_1)

$TeCl_4$	35	167(25°)	2.54

Discussion of Results

As germanium tetrachloride has been found by means of electron diffraction[5] to be tetrahedral, it is practically certain that monochloro and dichlorogermane are approximately tetrahedral. This means that, with inductive effects neglected, the resultant of the moments associated with the three hydrogen–germanium bonds in the monochlorogermane molecule should be equal to the moment of one bond and should lie in the line of the germanium–chlorine bond moment, that is, (H–Ge) + (Ge–Cl) = μ_{GeH_3Cl}, where the symbols in parentheses represent the bond moments. Also 1.15 (H–Ge) + 1.15 (Ge–Cl) = $\mu_{GeH_2Cl_2}$. If the bond moments depended wholly on intrinsic electronegativities of the two bonded atoms and were uninfluenced by induction, resonance effects and possible unknown factors, the moments of tetrahedral molecules like these germanes should be independent of the central atom and should depend simply on the differences in electronegativity of the attached atoms. This would mean that both methyl chloride and monochlorogermane would have the same moment as hydrogen chloride, 1.05×10^{-18}. The large effect of complicating factors in raising the carbon–chlorine, –bromine, and –iodine bond moments above the values to be expected on the basis of hydrogen bond moments has been pointed out previously.[6] It is evidently even greater in the case of the germanium–chlorine bond moments, as shown by the large moments of these chlorogermanes. In the case of the chlorosilanes[7] and silicobromoform,[2] the complicating factors seem to compensate one another to such an extent that the moments are not far from the values to be expected on the basis of hydrogen bond moments. The value of the moment of monochlorogermane is in accordance with the ideas previously presented[2] in connection with the relation of the moment of dichlorogermane to the moments of carbon, silicon and tin compounds. As the H–C moment is only about 0.3 and as the H–Ge moment is undoubtedly lower than this, possibly, acting in the opposite direction, it may be concluded that the Ge–Cl moment is about 2, or larger than this by the amount of the Ge–H moment.

For comparison of the moments of the two

chlorogermanes, it is desirable to use the gas value 2.34 calculated empirically[2] for dichlorogermane from the solution value given in Table II. In the absence of mutual induction between the dipoles in the molecule, the tetrahedral angle 110° requires a ratio 1.15 between the moment of GeH_2Cl_2 and that of GeH_3Cl as between the moments of the corresponding compounds of carbon, silicon and tin.[6] The observed ratios are: for CH_2Cl_2 and CH_3Cl, 0.85; for SiH_2Cl_2 and SiH_3Cl, 0.91; for GeH_2Cl_2 and GeH_3Cl, 1.15; and for $(C_2H_5)_2SnCl_2$ and $(C_2H_5)_3SnCl$, 1.12, as compared to 1.02 for $(CH_3)_2CCl_2$ and $(CH_3)_3CCl$. Increase in size of the central atom of the tetrahedral molecule with consequent increase in the distance between the attached dipoles evidently decreases the mutual inductive effects of these dipoles, as would be expected.

A moment value as small as that found for chromyl chloride is necessarily uncertain when determined in solution because of neglect of atomic polarization as well as possible solvent effect. The uncertainty of the value in Table II is increased by an uncertainty of 2 cc. in the molar refraction. It is certain, however, that the moment is little larger than 0.5 and probable that it is between 0.5 and 0. If the molecule were tetrahedral and the bond moments unaffected by complicating factors, the moment should be 1.15 times the difference between the Cr–O and the Cr–Cl bond moments. The former bonds are more or less semipolar and should, therefore, have moments not far from 3, although they may have a considerable amount of double bond character, which would lower the moments somewhat. The Cr–Cl bond may be written as a normal covalent bond, but it must be remembered that the Sn–Cl bond was found[6] to have a moment not less than 3.1. It is, therefore, not only reasonable to suppose that the Cr–Cl moment may be of this magnitude but necessary to conclude that it is at least almost as large as this in order to account for the small moment of the CrO_2Cl_2 molecule since the Cr–O moment would be large even if it possessed a good deal of double bond character. The distortion of the tetrahedral structure of this molecule indicated tentatively by electron diffraction,[8] according to which the O–Cr–O angle is about 105° and the Cl–Cr–Cl angle about 113°, would increase the moment of the molecule if the Cr–O moment is greater than the Cr–Cl moment. A large Cr–Cl moment also accounts for the difference between the small CrO_2Cl_2 moment and the considerable value 1.86 found[9] for SO_2Cl_2, which is due to the difference between the fairly large moment of the more or less semipolar S–O bonds and the small moment 0.5 of the normal covalent S–Cl bonds.

The molecules of diphenylselenium dichloride and tellurium tetrachloride present essentially the same structural problem when treated according to the methods used by Pauling.[10] One might expect to find hybridized sp^3 orbitals, which would give a regular tetrahedral structure with the selenium or tellurium atom at its center, or sp^2d orbitals, which would give a square structure around the central selenium or tellurium atom. Either of these two structures could be reconciled with the moment found for diphenylselenium dichloride, but both would obviously give zero moment for tellurium tetrachloride in contrast to the large value observed. If the $TeCl_4$ molecule were tetrahedral in form and had zero dipole moment, the substance should be soluble in carbon tetrachloride and probably in carbon bisulfide and heptane, in all three of which it was found to be too insoluble to permit of dipole moment measurements. Also its boiling point, instead of being 414°, should not be far from the region 60–114°, in which the boiling points of the symmetrical tetrahedral molecules of carbon, silicon, germanium and tin tetrachloride lie. The symmetrical tetrahedral titanium tetrachloride boils at 136.4°. The symmetrical tetrahedral structure for tellurium tetrachloride would thus be ruled out on the score of its boiling point and solubility in the absence of other evidence. The markedly greater solubility of the compound in benzene than in carbon tetrachloride, carbon bisulfide or heptane suggests the possibility of the formation of an intermolecular compound with the solvent, but the solubility, about 0.012 mole fraction of tellurium tetrachloride at 25°, is still so small that it cannot be regarded as evidence of compound formation, the occurrence of which would probably give rise to a considerable moment. Consequently, we feel sufficient confidence in the moment of the tellurium tetrachloride molecule to rule out both the regular tetrahedral and the square structures for it and also for the diphenylselenium dichloride molecule.

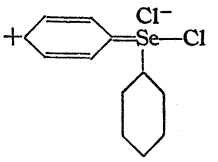
According to a treatment of directed valence communicated to us by Professor G. E. Kimball of Columbia University, the tellurium tetrachloride molecule should be an unsymmetrical tetrahedron, which would, of course, possess a moment. An analogous unsymmetrical tetrahedral structure would be indicated for diphenylselenium dichloride. Professor Linus Pauling, who has very kindly read this manuscript, suggests, in view of the moments possessed by these two compounds, that "the configuration is similar to that of PCl_5 and related molecules; that is, that the four bonds and one unshared pair occupy the five corners of a trigonal bipyramid. The unshared pair would probably occupy one of the equatorial positions rather than one of the apical positions." Such a structure would give an unsymmetrical tetrahedral arrangement of the four atoms or groups attached to the central atom, somewhat different from that given by Kimball's treatment.

In order to give rise to molecular moments as large as those observed, the Se–Cl and Te–Cl moments would have to be much larger than the values, 0.6 and 0.9, respectively, calculated on the basis of the electronegativities of the elements.[11] Comparison with the As–Cl value 1.64 and the Sb–Cl value 2.6 suggests 1.2 and 2.3 as possible values for Se–Cl and Te–Cl, respectively, the higher values probably arising from induced shifts of charge. The small moment of the C–Se bond, 0.9, calculated from that of diphenyl selenide cannot contribute largely to the moment of diphenylselenium dichloride, but the high value of this latter moment may be due, at least in part, to the occurrence of resonance with contributions from twelve polar structures such as



The writers wish to express their indebtedness to Mr. R. H. Wiswall, Jr., for measuring the monochlorogermane and to Dr. J. Y. Beach and Professors G. E. Kimball and Linus Pauling for their advice on the structures of diphenylselenium dichloride and tellurium tetrachloride.

Summary

The dipole moment of monochlorogermane has been measured in the vapor state and the moments of chromyl chloride, diphenylselenium dichloride and tellurium tetrachloride have been measured in solution. The ratio of the moment of monochlorogermane to the previously published value of dichlorogermane shows that the large size of the germanium atom largely eliminates induction between two chlorines attached to it. The considerable value of the moment of the molecule shows that the Ge–Cl bond moment is about 2 or greater than this by the amount of the small Ge–H moment. The very small moment of chromyl chloride shows that the Cr–Cl bond is of the same magnitude as the more or less semipolar Cr–O moment and probably, therefore, as large as 3.

The large moments found for diphenylselenium dichloride and tellurium tetrachloride indicate unsymmetrical tetrahedral structures for their molecules. The Se–Cl and Te–Cl bond moments necessary to produce such moments are much larger than those calculated as the electronegativity differences between the elements.

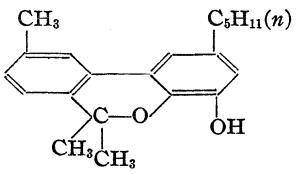
Structure of Cannabidiol, a Product Isolated from the Marihuana Extract of Minnesota Wild Hemp. I

BY ROGER ADAMS, MADISON HUNT, AND J. H. CLARK[1]

(IN COLLABORATION WITH THE TREASURY DEPARTMENT, NARCOTICS LABORATORY, WASHINGTON, D. C., AND DR. S. LOEWE, DEPT. OF PHARMACOLOGY, CORNELL UNIVERSITY MEDICAL COLLEGE)

Marihuana is the term commonly used in the United States to represent those portions of the *Cannabis sativa* or hemp plant which are capable of inducing somatic and psychic changes in humans. It is also familiarly known as hashish, bhang, charas, and ganja. The activity of an extract of the plant is found to vary widely, and to be dependent on the source of the hemp. Previous investigators, for the most part, have studied the resin obtained by working up hashish of Indian origin from the variety of hemp known as *Cannabis indica*. In this investigation, Minnesota wild hemp, cut after flowering had begun and before the seed had "set" in the female tops, was used as a raw material. It was extracted with ethanol and the so-called "red oil" containing the active principle or principles was obtained by distillation under diminished pressure.

Numerous investigators have studied the active red oil from *Cannabis sativa* and *indica* but only a single pure substance other than nonacosane has yet been isolated from the mixture of products present. This was called cannabinol by Wood, Spivey and Easterfield,[2] and was purified through its crystalline acetate. They assigned the formula $C_{21}H_{26}O_2$. This formula was confirmed and the constitution investigated by Cahn,[3] who proposed structure I in which the positions of the hydroxyl and *n*-amyl groups are uncertain.



I

Cannabinol is very toxic but has no marihuana activity. A knowledge of the structure of this compound is significant, however, due to the fact that the active red oil, even though derived from various sources, gives an analysis not substantially different from that of pure cannabinol.

When the red oil from Minnesota hemp was treated to isolate cannabinol according to methods previously suggested, no crystalline cannabinol acetate[3] or *p*-nitrobenzoate[4] could be isolated. Since the red oil contained substances with phenolic groups as shown by qualitative tests, other reagents for phenols were studied. This resulted in observing that a crystalline 3,5-dinitrobenzoyl derivative could be isolated in yields which corresponded to about 33% of the purified red oil used. Analysis indicated this derivative to be a *bis*-3,5-dinitrobenzoate of a dihydric phenol of the formula $C_{21}H_{30}O_2$ or $C_{21}H_{32}O_2$, the analysis not allowing distinction between them. It was readily purified. Upon ammonolysis of the purified *bis*-3,5-dinitrobenzoate by means of ammonia in toluene, the isolation of a pure compound was accomplished. It proved to have one of the two empirical formulas suggested above and has been given the name cannabidiol. It has none of the physiological activity typical of marihuana. The product is optically active, $[\alpha]_D$ $-119°$, and gives a very strong alkaline Beam test somewhat different from and more intense than that exhibited by purified red oil. Numerous other color tests applied to cannabidiol and purified red oil are given in Table I. It is obvious that the colors given by the red oil are dependent in part on substances other than cannabidiol.

By comparison with the formula of cannabinol, it is obvious that cannabidiol contains merely four or six more hydrogen atoms. The presence of two hydroxyls, presumably phenolic, is shown by the *bis*-3,5-dinitrobenzoate derivative and further was confirmed by the preparation of a crystalline *bis*-*m*-nitrobenzene sulfonate, a dimethyl ether, and a Zerewitinoff determination.

Methylation by means of repeated treatments with excess methyl iodide in acetone and potas-

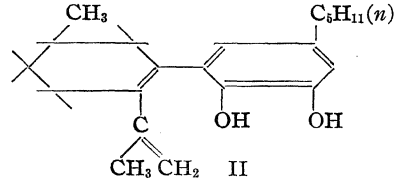
[a] Tests have not previously been used on red oil. References are to the description of the tests on simply polyhydroxy benzenes.

sium carbonate resulted finally in formation of a dimethyl ether. Oxidation with permanganate in acetone gave *n*-caproic acid, which represents strong evidence for an *n*-amyl group in a phenolic ring. From these few facts alone, it may be concluded that one-half of the molecule of cannabidiol probably corresponds to the right-hand half of cannabinol (I). However, both hydroxyls are free in the cannabidiol so that the possibility of a pyran ring such as exists in cannabinol is excluded. On the assumption that the cannabidiol resembles cannabinol in entirety, the other half of the cannabidiol molecule may be postulated as a partially hydrogenated methylisopropylbenzene nucleus. Thus, formula II expresses satisfactorily the available experimental facts.



II

If the correct formula is $C_{21}H_{30}O_2$ (II), then two double bonds or the equivalent must be present. The positions assigned them in II are essentially fortuitous as no sound evidence has yet been revealed whereby to place them. The possibility of one double bond and a three-, four-, or five-membered ring, such as occurs in many terpenes, is not excluded. On the other hand, if the formula of cannabidiol is $C_{21}H_{32}O_2$, only one double bond in the left-hand ring can be present. The analyses of cannabidiol and its derivatives, the esters and ether, do not make possible a definite conclusion about the formula though $C_{21}H_{30}O_2$ agrees somewhat more uniformly with the analyses and, therefore, appears the more likely. Hydrogenation experiments, which should lead to the detection of one or two double bonds, have as yet proven indecisive. It is hoped, however, that a

careful reduction study now under way may clarify the question of unsaturation.

Red oil probably contains other products closely related to cannabinol or cannabidiol in structure, such as partially hydrogenated cannabinols, isomers of cannabidiol, or molecules like cannabidiol with less unsaturation. A large number of closely related compounds is possible. The active marihuana principle or principles may be among this group of substances. On the other hand, the possibility of the presence in red oil of a very potent active compound, entirely unrelated structurally to cannabinol or cannabidiol, is not excluded.

Experimental

The hemp used in these experiments grew wild in Minnesota during the season of 1938. It was cut in August, after flowering had begun but before seed had "set" in the female tops. It was stored for six weeks in a room where a fan assured circulation of air in order to dry it completely. No molding occurred. The material was then beaten and shaken to remove the coarse stems which amounted to about one-third of the total dry weight. The stems were discarded and the relatively fine material that remained was extracted with 95% ethanol in the manner described below.

Four 20-gallon (75-liter) crocks, each holding approximately 23 lb. (10 kg.) of material, were set up in series for countercurrent extraction. Each crock held approximately 61 liters of solvent of which about 41 liters were withdrawn at each transfer, the remainder being retained by the hemp. Once the process had become uniform in operation, the extract received from crock no. 4 at each transfer reached a concentration of approximately 2 g. per 100 cc. Transfers were made once or twice a day as conditions warranted. The most concentrated extract thus obtained was passed to a concentrator where most of the solvent was "flashed off" under vacuum. It was never heated above 50°. The evaporation was carried out at about 30°. The concentrated solution contained in this case 23.1 g. of solids per 100 cc. and 1 cc. was equivalent to 4.13 g. of hemp extracted. The operations just described were carried out by Dr. John R. Matchett and his assistants in the Narcotics Laboratory of the Treasury Department, Washington, D. C. They kindly furnished us with a generous supply of ethanol extract.

The red oil from these extracts was obtained as follows. Into a 1-liter Claisen flask, with a wide short neck, filled with glass wool was poured ethanolic extract until two-thirds full. The bath temperature was raised gradually from 90–140° while the pressure was diminished slightly. The ethanol distillate was discarded and the flask again filled to two-thirds capacity. This process was repeated until a maximum of 1600 cc. of extract had been added and all the ethanol was distilled. The temperature was then gradually raised to 200° and when distillation of the last traces of ethanol ceased, the bath was lowered to 180° and the pressure gradually reduced to 30 mm. Great care was necessary to prevent the liquid from foaming over. The temperature was gradually raised to 200° (30 mm.) until distillation ceased. The bath was then cooled to 170° and the pressure reduced to 2–5 mm. The residual product was then distilled. Considerable care was necessary to keep the bath at the lowest temperature at which the oil distilled regularly since there was a particular tendency to foam when the superheating was excessive. The material distilled between 100–220° (3 mm.) with the bath temperature at 170–310°; yield 180–200 g.

This crude red oil was dissolved in 500 cc. of petroleum ether (b. p. 30–60°) and extracted twice with water. The aqueous extract was saved and worked up for water-soluble materials. The petroleum ether layer was distilled and the residue fractionated through a good column with an outside heating unit. The first fraction boiled at 115–150° (2 mm.) (bath temperature 190–210°); yield, 70–80 g. The second fraction boiled at 150–175° (2 mm.) (bath temperature 215–225°); yield 25–35 g. The residual material in the flask was removed while still hot by dissolving in ethanol and filtering from the glass wool. The ethanol was removed and the product distilled from a 250-cc. flask, b. p. 175–195° (2 mm.) (bath temperature 220–270°); yield 90–110 g. This last material was considered as purified red oil.

Cannabidiol *bis*-3,5-Dinitrobenzoate.—A solution of 50 g. of purified red oil, b. p. 175–195° (2 mm.), in 200 cc. of dry pyridine was poured rapidly with shaking and cooling on 85 g. of 3,5-dinitrobenzoyl chloride. The mixture was heated on a steam cone for two hours with occasional shaking and was then poured into ice and hydrochloric acid (200 cc. of concentrated hydrochloric acid, 500 cc. of ice). It was filtered or decanted and the insoluble material was washed several times with dilute hydrochloric acid. The residue was dissolved in 600 cc. of benzene and filtered. The insoluble material consisted mainly of 3,5-dinitrobenzoic acid.

The benzene solution was washed with dilute hydrochloric acid, then with aqueous sodium bicarbonate and finally with water. Considerable trouble was encountered with emulsions which broke with difficulty. The benzene was evaporated and the residue was dissolved in 500 cc. of dry ether. This solution was treated with norit (20 g.), filtered, and then concentrated to 300 cc. On cooling in an ice–salt mixture with constant stirring, crystallization set in. After one hour, the product was filtered and washed with cold dry ether. It was purified by recrystallizing from 800 cc. of a mixture of methanol and methyl acetate (2:1); white rods, m. p. 106–107° (corr.).

Anal. Calcd. for $C_{21}H_{28}(OCOC_6H_3(NO_2)_2)_2$: C, 59.82; H, 4.88; N, 7.97. Calcd. for $C_{21}H_{30}(OCOC_6H_3(NO_2)_2)_2$: C, 59.64; H, 5.15; N, 7.95. Found: C, 59.74; H, 5.00; N, 7.96. *Rotation.* 0.057 g. made up to 5 cc. with acetone at 27° gave α_D −1.73°; l, 2; $[\alpha]^{27}D$ −76°.

Cannabidiol.—A solution of 50 g. of cannabidiol *bis*-3,5-dinitrobenzoate in 100 cc. of toluene was placed in the glass liner of a high pressure bomb. The mixture was cooled by dry-ice and about 100 cc. of liquid ammonia passed into it. The liner was then placed in the bomb and the cover quickly fastened. The bomb was allowed to stand for five hours at room temperature. At the end of that time the excess ammonia was allowed to escape and the product, which had set to a solid mass, was digested with 400 cc.

of petroleum ether (b. p. 60–110°). The solid 3,5-dinitrobenzamide was filtered and washed with two 50-cc. portions of petroleum ether. Filtrate and washings were combined and extracted six times with 150-cc. portions of boiling water to remove the last traces of 3,5-dinitrobenzamide. The petroleum ether was then evaporated and the residue distilled, b. p. 187–190° (2 mm.) (bath temperature 220°), d^{40}_4 1.040; $n^{20}D$ 1.5404. Cannabidiol is a pale yellow resin; yield 17–19 g.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62. Calcd. for $C_{21}H_{32}O_2$: C, 79.69; H, 10.19. Found: C, 80.08, 80.29; H, 9.87, 9.41. *Rotation.* 0.0378 g. made up to 5 cc. with 95% ethanol at 28° gave α_D −0.90°; *l*, 1; $[\alpha]^{28}D$ −119°.

A Zerewitinoff determination showed two active hydrogens.

Cannabidiol is soluble in all common organic solvents, ether, benzene, ethanol, methanol, chloroform, and petroleum ether, but insoluble in water and 10% hot or cold aqueous sodium hydroxide.

That no rearrangement or deep-seated decomposition had taken place by this method of hydrolysis was demonstrated by the fact that the product readily could be reconverted in essentially quantitative yields to the same *bis*-3,5-dinitrobenzoate.

Cannabidiol *bis*-*m*-Nitrobenzene Sulfonate.—To a solution of 0.2 g. of cannabidiol in 5 cc. of dry pyridine, 0.35 g. of *m*-nitrobenzene sulfonyl chloride was added. The mixture was warmed on a steam cone for one hour and was then poured into ice and hydrochloric acid. The product was filtered, washed with dilute hydrochloric acid, aqueous sodium bicarbonate and then with water. It was purified by recrystallization from ethanol: white rods, m. p. 119–120° (corr.); yield 0.17 g. This same derivative could be obtained directly from purified red oil.

Anal. Calcd. for $C_{21}H_{28}(OSO_2C_6H_4NO_2)_2$: C, 57.87; H, 5.30; N, 4.09. Calcd. for $C_{21}H_{30}(OSO_2C_6H_4NO_2)_2$: C, 57.70; H, 5.58; N, 4.08. Found: C, 57.72; H, 5.49; N, 4.39.

Cannabidiol Dimethyl Ether.—A solution of 11.25 g. of cannabidiol in 75 cc. of acetone was refluxed for four hours with 12 g. of methyl iodide and 15 g. of anhydrous potassium carbonate. A deep purple color present at the beginning of the reaction had changed to a pale yellow at the end of this time.

The potassium carbonate was filtered, washed with ether, and the filtrate and washings combined. The solution becomes cloudy due to the precipitation of salts dissolved in the acetone. About 300 cc. more of ether was added and the mixture extracted with water. The solvent was then removed and the product distilled. Five cuts of approximately equal volume were taken since temperature changes were not significant. The refractive indices of these fractions ranged from 1.5330 to 1.5372, indicating that some reaction had taken place but that the product was not homogeneous.

The distillate was dissolved again in acetone, treated with excess methyl iodide and potassium carbonate and refluxed for periods of ten, twelve, forty-eight, and sixty hours. After each treatment the progress of the reaction was followed by the refractive index as described above. At the end of a total of one hundred and thirty-four hours of refluxing the refractive index of the main portion of the distillate was found to have reached a constant value. The material thus obtained was a pale yellow oil, much less viscous than cannabidiol; b. p. 175–177° (3 mm.) (bath temperature 200°); yield 3.3 g.; n^{20} D 1.5254; d^{20}_4 0.9823.

Anal. Calcd. for $C_{21}H_{28}(OCH_3)_2$: C, 80.65; H, 10.01; OCH_3, 18.12. Calcd. for $C_{21}H_{30}(OCH_3)_2$: C, 80.17; H, 10.53; OCH_3, 18.02. Found: C, 80.52; H, 10.08; OCH_3, 18.2. *Rotation.* 0.0535 g. made up to 5 cc. with 95% ethanol at 28° gave α_D −1.42°; *l*, 1; $[\alpha]^{28}D$ −133°.

Cannabidiol dimethyl ether is insoluble in water, difficultly soluble in cold 95% ethanol, and readily soluble in petroleum ether, acetone, and ether.

An attempt was made to prepare the monomethyl ether by refluxing cannabidiol in acetone solution for eight hours with over twice the theoretical amounts of methyl iodide and potassium carbonate. The product was worked up as described above and carefully fractionated. That portion of the distillate which seemed, on the basis of refractive indices, to be homogeneous was found to give a very satisfactory value for methoxyl content, but a consistently poor value for carbon. The material was a clear viscous oil, b. p. 177–179° (2 mm.) (bath temperature 200–210°); $n^{20}D$ 1.5311.

Anal. Calcd. for $C_{21}H_{29}O(OCH_3)$: C, 80.44; H, 9.82; OCH_3, 9.45. Calcd. for $C_{21}H_{31}O(OCH_3)$: C, 79.94; H, 10.37; OCH_3, 9.39. Found: C, 79.67, 79.50; H, 9.65, 9.79; OCH_3, 9.41. *Rotation.* 0.0455 g. made up to 5 cc. with 95% ethanol at 26° gave α_D −2.14; *l*, 2; $[\alpha]^{26}D$ −118°.

Oxidation of Cannabidiol.—To a solution of 5 g. of cannabidiol in 25 cc. of acetone was added a saturated solution of 8 g. of potassium permanganate in 50% aqueous acetone and 5 g. of sodium bicarbonate. The mixture was heated for thirty minutes on a steam-bath. Ethanol was added to remove the last traces of the permanganate, the mixture filtered and acidified with hydrochloric acid. The acid solution was extracted with ether and the ether solution in turn extracted with aqueous sodium bicarbonate.

The aqueous sodium bicarbonate solution was acidified with hydrochloric acid and extracted with ether. The ether solution was dried over anhydrous magnesium sulfate, the solvent removed and the product distilled. It boiled at 200–203° (750 mm.) and weighed 1.15 g. (64% based on one molecule of *n*-caproic acid per molecule of cannabidiol). The anilide was prepared for identification purposes, m. p. 95–96°, and proved to be identical with an authentic sample of *n*-caproanilide.

Summary

A new compound, cannabidiol, present in the purified red oil of *Cannabis sativa* has been isolated through the *bis*-3,5-dinitrobenzoate. This diester is a crystalline, easily purified compound. Ammonolysis of it gives cannabidiol which has the formula $C_{21}H_{30}O_2$ or $C_{21}H_{32}O_2$, the former probably being the correct one.

Cannabidiol is oxidized to *n*-caproic acid, methylated with difficulty to a dimethyl ether and

converted to a *bis-m*-nitrobenzenesulfonate. It is concluded that this substance is closely related to cannabinol in structure. Half the molecule is probably a dihydroxy *n*-amylphenyl, the other half probably an unsaturated alicylic nucleus.

The Preparation and Properties of 3(α),11-Dihydroxy-12-ketocholanic Acid

BY BERNARD B. LONGWELL[1] AND O. WINTERSTEINER

The isolation of naturally occurring steroids in which an oxygen atom is believed to occupy position 11[2,3,4] renders of interest the study of model substances in which ring C carries a functional group in this, and only in this, position.

The original aim of this investigation was to prepare 3,11-dihydroxycholanic acid by elimination of the keto group of 3,11-dihydroxy-12-ketocholanic acid, which has been described recently by Marker and Lawson.[5] Although this object has not been accomplished, we are reporting here the preparation and properties of the starting compound because our results not only extend but in some points fail to confirm the work of these authors. Their procedure is essentially analogous to that of Wieland and Posternak[6] for the preparation of 11-hydroxy-12-ketocholanic acid. They[5] acetylated 3-hydroxy-12-ketocholanic acid, and then brominated it in position 11. The bromo acid was hydrolyzed to 3,11-dihydroxy-12-ketocholanic acid. Neither of the two intermediates was isolated. In our hands this abbreviated procedure failed to yield the end-product in crystalline form. We found it necessary to conduct the reaction in two separate steps. We furthermore had to modify the method of bromination in order to limit the reaction to a substitution with only one bromine atom. Although the bromo acid thus obtained was amorphous and its bromine content still slightly too high, its hydrolysis yielded the desired 3,11-dihydroxy-12-ketocholanic acid without any difficulty. The over-all yield from 3-hydroxy-12-ketocholanic acid was over 50%, whereas Marker and Lawson obtained in 35% yield a product which melted 9° lower than ours.

In order to eliminate any doubt regarding the site of the new hydroxyl group, the monobromo acid was subjected to debromination with anhydrous sodium acetate in analogy to the experiment of Barnett and Reichstein[7] on 11-bromo-12-ketocholanic acid. The ultraviolet absorption spectrum of the resulting compound (m. p. 201°) exhibited a maximum at 241 mμ (ϵ = 9000, solvent alcohol), which is characteristic for α,β-unsaturated ketones. The unsaturated compound is, therefore, $\Delta^{9,11}$-3-acetoxy-12-ketocholenic acid. Furthermore, the acid 3-succinate of methyl 3,11-dihydroxy-12-ketocholanate was oxidized with chromic acid to the corresponding 11,12-diketone. The ultraviolet absorption spectrum of the resulting compound is similar to that reported by Barnett and Reichstein for methyl 11,12-diketocholanate (maximum at 284 mμ, ϵ = 135; minimum at 250 mμ, ϵ = 80, solvent alcohol). Saponification of the diketo ester failed to yield a crystalline compound.

When we tried to repeat the preparation of the 3-monoacetate of 3,11-dihydroxy-12-ketocholanic acid described by Marker and Lawson, we observed that the reaction takes a more complicated course than the report of these authors indicates. Our acetylation product showed the same melting point (268°) as their monoacetyl derivative, but the analysis indicated the loss of a molecule of water as well as the esterification of one hydroxyl group. We are unable to explain the considerable discrepancy between the carbon value of our analyses and that reported by Marker and Lawson, but it must be pointed out that the values assigned in their paper to the monoacetyl acid, $C_{26}H_{40}O_6$, with which their experimental figures agree, are incorrectly calculated (C, 70.5; H, 8.8, instead of C, 69.60; H, 8.99). Furthermore, our substance, in contradistinction to the starting compound, is insoluble in aqueous sodium carbonate. Hydrolysis at room temperature

with standard alkali resulted in the neutralization of two equivalents of base and recovery of the original acid. The neutral compound is, therefore, either an 11-(or 12-enol)-lactone or a dimolecular anhydride, more likely the latter.[8] When the compound was boiled for an hour with 33% acetic acid, an acid extractable with aqueous sodium carbonate and melting at 106° was obtained in good yield. According to the analysis, which conforms with $C_{26}H_{40}O_6 \cdot 1/2H_2O$, this acid represents, in all probability, the true monoacetate of 3,11-dihydroxy-12-ketocholanic acid.

Besides the anhydride, which can be obtained in 20–30% yield by direct crystallization of the acetylated material, an acidic product, which would not crystallize, was formed in the acetylation reaction. Analyses and titration data indicated that this product is a diacetyl derivative of the starting acid. When the acetylation reaction was conducted in pyridine, this acidic substance was the only reaction product.

Both the anhydride and the amorphous diacetoxy acid yielded the starting acid on alkaline hydrolysis. Careful comparison of the specific rotations of the two hydrolysis products and of the original preparation revealed no significant differences. This finding precludes the possibility that the simultaneous formation of neutral and acidic reaction products on treatment with acetic anhydride is due to the existence of two 11-epimers in the original preparation, one of which might be amenable to acetylation at C_{11} under the conditions employed.

All our attempts to prepare keto derivatives of 3,11-dihydroxy-12-ketocholanic acid have been unsuccessful. The preparations of the semicarbazone, the hydrazone, and the oxime were essayed, but in each case the starting material was recovered unchanged. Marker and Lawson claimed to have prepared a semicarbazone melting at 232° in 18% yield, but no analysis of the product is reported. We have experienced consistent failures in our attempts to prepare this semicarbazone by the method of Marker and Lawson. We also tried, without success, to let the acid react with semicarbazide acetate in cold pyridine solution, in boiling butyl alcohol, and in alcohol at 190° in a bomb tube. Apparently the steric hindrance exerted by the groups on the adjoining carbon atoms is too great to permit reaction with the 12-keto group.

Treatment of the acid with hydrazine hydrate and sodium ethylate at 200° resulted in the formation of a compound, m. p. 162°, with two oxygen atoms less than the starting product. Obviously the keto group at C_{12} had been eliminated, but at the same time the hydroxyl at C_{11} was lost by a dehydration reaction.

Experimental

3-Hydroxy-12-ketocholanic acid was obtained in good yield from desoxycholic acid by the method of Kaziro and Shimada[9] as modified by Cortese,[10] m. p. 162–163°. The 3-acetyl derivative was prepared by treatment with acetic anhydride in pyridine, m. p. 197–198°. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{26}H_{40}O_5$: C, 72.18; H, 9.32. Found: C, 72.01; H, 9.18.

3(α)-Acetoxy-11-bromo-12-ketocholanic Acid.—Five grams of 3(α)-hydroxy-12-ketocholanic acid was refluxed for one hour in a mixture of 15 cc. of glacial acetic acid and 2.5 cc. of acetic anhydride. The reaction mixture, after dilution to 50 cc. with glacial acetic acid, was treated with 0.7 cc. of bromine in 40 cc. of glacial acetic acid. The solution was stirred mechanically during the dropwise addition of the bromine, which required three to four hours. The temperature was maintained at 50–60° during this period and thereafter for four to five hours, while stirring was continued. After cooling to room temperature, 250 cc. of water was added slowly with stirring. The reddish-yellow gum which separated was dissolved in 350 cc. of 95% ethanol, and this solution was poured slowly into 2450 cc. of water. The resulting milky suspension formed a flocculent precipitate upon the addition of 16 cc. of glacial acetic acid. On filtering and washing once with a solution of ethanol, water and acetic acid (3.5, 24.5, and 0.16 parts, respectively), and twice with water, 5.82 g. of the amorphous bromo acid was obtained, which melted with decomposition at 159°. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{26}H_{39}O_5Br$: Br, 15.62. Found: Br, 16.1, 16.3, 16.86.

3(α),11-Dihydroxy-12-ketocholanic Acid.—The bromo acid (5.82 g.) was refluxed for twenty minutes in 115 cc. of 20% methyl alcoholic potassium hydroxide solution. The hydrolysate was poured into 1150 cc. of ice water. On acidification with hydrochloric acid a flocculent precipitate formed, which was separated by filtration and washed with water; yield 4.4 g. It was dissolved in 325 cc. of hot 95% ethanol and 825 cc. of water was added to the hot solution. On slow cooling a crystalline precipitate formed; yield 2.94 g. Several recrystallizations from aqueous ethanol yielded plates, m. p. 202°, $[\alpha]^{24}D$ +65.7° (2.5% in 95% alcohol). Further recrystallization from 95% ethanol produced blunt rods, m. p. 205°, $[\alpha]^{27}D$

(8) Professor Reichstein (private communication) has observed the formation of dimolecular anhydrides, which could be hydrolyzed with acetic acid, on acetylation of hydroxy acids of a similar type. We are highly indebted to him for this information.

(10) Cortese, unpublished experiments. The coöperation of Dr. Cortese in permitting us the use of his method prior to publication is gratefully acknowledged.

+67.1° (1.3% in 95% alcohol). The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{24}H_{38}O_5$: C, 70.9; H, 9.42; neut. equiv., 406. Found: C, 70.8; H, 9.41; neut. equiv. (115.4 mg.), 412.

Methyl 3(α),11-Dihydroxy-12-ketocholanate.—An ether solution of 20 mg. of the acid was treated with diazomethane in ether. After two hours in the refrigerator, the excess diazomethane was removed by gentle heating and the ether was washed with 5% sodium carbonate solution and with water. Evaporation of the ether yielded 18.7 mg. The ester crystallized from methanol in triangular plates, m. p. 157°. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{25}H_{40}O_5$: C, 71.39; H, 9.59. Found: C, 70.97; H, 9.36.

3(α),11-Diformoxy-12-ketocholanic Acid.—A solution of 69.8 mg. of the acid, m. p. 202°, in 0.5 cc. of 98–100% formic acid, was allowed to stand at room temperature for twenty-four hours. When 0.4 cc. of 95% ethanol and 1.1 cc. of water were added, an oil separated out which was extracted quickly with ether. The residue of the washed and dried ether solution was freed from traces of formic acid *in vacuo*. After several recrystallizations from aqueous ethanol, needles were obtained, m. p. 146–148°. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{26}H_{38}O_7$: C, 67.51; H, 8.28. Found: C, 67.41; H, 8.43.

Acetylation of 3(α),11-Dihydroxy-12-ketocholanic Acid.—A solution of 678 mg. of the acid (m. p. 199–201°) in 21 cc. of acetic anhydride was boiled under reflux for one and one-half hours. The acetic anhydride was decomposed with ice water. The gummy, white precipitate was centrifuged, washed, and dissolved in a minimal amount of hot 95% ethanol. A crystalline precipitate formed on standing overnight in the refrigerator. This was removed by centrifuging and washed with 95% ethanol and ether (116 mg.). The supernatant and washings were poured into 50 cc. of water and thoroughly extracted with ether. The ether solution was then extracted exhaustively with 5% sodium carbonate solution, then with water and brought to dryness (257 mg.).

The combined sodium carbonate extracts were acidified with hydrochloric acid and extracted with ether. The residue from the washed and dried ether yielded 431 mg.

The yields of alkali insoluble and alkali soluble fractions represent approximately a 50% partition, a finding which was uniform in several experiments. In this experiment 17% of the starting material was obtained as the crystalline anhydride. In other experiments yields of 27, 32, and 26% were obtained.

The Crystalline Anhydride.—The crystalline product from the acetylation reaction was purified by recrystallization from 95% ethanol, m. p. 268°. It crystallized in fine, white needles, soluble in hot 95% alcohol and insoluble in ether and aqueous alkali. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{26}H_{38}O_5$: C, 72.52; H, 8.90. Found: C, 72.18; H, 8.78. C, 72.11; H, 8.84. C, 72.14; H, 8.89. *Titration.* A solution of 14.5 mg. (0.0337 millimole) in absolute alcohol reacted neutral to phenolphthalein. Standard alkali was added and the excess titrated back after forty-four hours. Alkali neutralized: calculated, 0.067 milliequiv.; found, 0.0668 milliequiv. The titration mixture was acidified and extracted with ether. The ether was washed with water and evaporated, and the residue was crystallized from aqueous ethanol, m. p. 203–204°. $[\alpha]^{24}D$ +67.2° (0.33% in 95% alcohol).

3(α)-Acetoxy-11-hydroxy-12-ketocholanic Acid.—A solution of 18 mg. of the anhydride (m. p. 268°) in 6 cc. of 33% acetic acid was boiled under reflux for one hour. The reaction mixture was extracted with ether and the ether in turn extracted with 5% sodium carbonate solution. The alkaline extract was worked up in the usual way; yield, 14.4 mg. This product crystallized from aqueous ethanol in needles, m. p. 106°. The sample for analysis was dried *in vacuo* at 61°.

Anal. Calcd. for $C_{26}H_{40}O_6 \cdot {}^1/_2H_2O$: C, 68.24; H, 9.03. Found: C, 68.35; H, 9.14.

The Acidic Fraction from the Acetylation Reaction.—Efforts to crystallize the acidic fraction from the original separation of the acetylation mixture were unsuccessful. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{28}H_{42}O_7$: C, 68.54; H, 8.63. Found: C, 68.47; H, 9.41.

In the hope that the ester might be obtained in crystalline form the compound was esterified with diazomethane. An oily product which could not be crystallized was obtained.

Titration. A solution of 41.8 mg. of the ester (0.0828 millimol.) in absolute methanol was neutral to phenolphthalein. Standard alkali was added and the excess titrated back after sixty hours. Alkali neutralized: calculated, 0.2485 milliequiv.; found, 0.2247 milliequiv. A solution of 55.3 mg. (0.1096 millimol.) was treated similarly. Alkali neutralized: calculated, 0.3288 milliequiv.; found, 0.352 milliequiv.

The acid was recovered from the titration mixture by extraction with ether, and was crystallized from aqueous ethanol, m. p. 203–204°; $[\alpha]^{23}D$ +63.4° (0.68% in 95% alcohol). All later runs yielded preparations with the higher value (+67°).

Acetylation in Pyridine.—A solution of 54 mg. of the starting acid in 2 cc. of pyridine was treated with 1.8 cc. of acetic anhydride. After standing overnight at room temperature, the acetic anhydride was decomposed with water, and the reaction products taken up in ether. The ether solution was washed with 5% hydrochloric acid, and then extracted with 5% sodium carbonate solution. Upon acidification and extraction with ether the alkaline extract yielded 63 mg. of a colorless oil. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{28}H_{42}O_7$: C, 68.55; H, 8.62. Found: C, 68.55; H, 8.50.

$\Delta^{9,11}$-3(α)-Acetoxy-12-ketocholenic Acid.—A solution of 400 mg. of the amorphous bromo acid and 200 mg. of fused sodium acetate in 2.5 cc. of glacial acetic acid was heated in a bomb tube at 185–190° for seventeen hours. The acetic acid of the reaction mixture was partially neutralized with sodium carbonate, and the reaction products were extracted with ether. The ether solution was filtered to remove tar, and then extracted with 5% sodium car-

bonate solution. A precipitate separated in the alkaline solution, which was removed by centrifuging. The aqueous solution of the precipitate was acidified with hydrochloric acid, and extracted with ether. The ether extract, after washing and drying, yielded 98.5 mg. Since the residue did not crystallize well, it was subjected to three additional precipitations as the sodium salt. The acid finally obtained on decomposition of the latter was crystallized from aqueous ethanol until the melting point became constant at 201°. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{26}H_{38}O_5$: C, 72.52; H, 8.90. Found: C, 72.63; H, 9.00.

Acid Succinate of Methyl 3(α)-Hydroxy-11,12-diketocholanate.—A solution of 275 mg. of crystalline methyl 3,11-dihydroxy-12-ketocholanate and 655 mg. of succinic anhydride in 10 cc. of dry pyridine was allowed to stand at room temperature for twenty hours. It was then heated under reflux at 135° (bath temperature) for one-half hour. The reaction mixture was poured into water and extracted with ether. After removal of the pyridine by repeated washing with 5% hydrochloric acid, the ether was evaporated. The residue was dissolved in 7.5 cc. of glacial acetic acid, 0.5 cc. of water and 100 mg. of chromic acid added. After standing at room temperature for twenty hours, the reaction mixture was diluted with water and extracted with ether. The ether solution was then extracted with 5% sodium carbonate solution, which, after removal of the acetic acid, resulted in the precipitation of the reaction product as the sodium salt. This was converted into the free acid in the usual way (76 mg.). Crystallization from 80% methanol yielded plates, m. p. 194–196°. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{29}H_{42}O_8$: C, 67.16; H, 8.16. Found: C, 66.65; H, 8.39.

Saponification with alkali did not yield any crystallizable products.

Attempted Preparation of the Semicarbazone.—A solution of 100 mg. of 3(α),11-dihydroxy-12-ketocholanic acid, 110 mg. of semicarbazide hydrochloride and 110 mg. of potassium acetate in 2.4 cc. of 83% ethanol was refluxed for fifteen hours, and then worked up in the usual way. After recrystallization, 86.5 mg. of the starting acid was recovered, m. p. 200–202°. Attempts to prepare the semicarbazone in pyridine solution, by refluxing in butyl alcohol, and by heating at 190° in a bomb tube, were similarly unsuccessful. Furthermore, all efforts to prepare the hydrazone and the oxime met with failure.

Treatment of 3(α),11-Dihydroxy-12-ketocholanic Acid with Sodium Ethylate and Hydrazine Hydrate.—A mixture of 500 mg. of the acid, 500 mg. of sodium in 17.5 cc. of absolute alcohol, and 2.5 cc. of hydrazine hydrate was heated in a bomb tube at 197–200° for eight hours. The reaction mixture was poured into water, acidified with hydrochloric acid, and extracted with ether. The ether was washed with water, dried over sodium sulfate, and evaporated to yield an oil which could not be crystallized. The entire product was dissolved in 17 cc. of pyridine together with 1.275 g. of succinic anhydride, and was heated under reflux at 130–135° (bath temperature) for one hour. After cooling, the reaction mixture was poured into water and extracted with ether. The ether solution was extracted with 5% sodium carbonate solution, and the alkali soluble material recovered in the usual way (600 mg.). Crystallization from aqueous ethanol yielded 78 mg. of plates melting at 227° with decomposition. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{23}H_{42}O_6$: C, 70.85; H, 8.92. Found: C, 70.80; H, 8.75.

Titration. 17.93 mg. (0.0378 millimol.); neutralization equivalent, calculated 237; found 241. After subsequent saponification with excess alkali, calculated 0.0377 milliequiv.; found 0.0370 milliequiv. of base neutralized.

Saponification of the acid succinate with 0.1 *N* sodium hydroxide produced an acid which softened at 135° and melted at 162–163°. The sample for analysis was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{24}H_{38}O_3$: C, 76.96; H, 10.25. Calcd. for $C_{24}H_{38}O_3 \cdot {}^1/_2H_2O$: C, 75.15; H, 10.35. Found: C, 75.63; H, 10.48.

The analyses reported in this paper were performed by Mr. William Saschek.

Summary

The procedure of Marker and Lawson for the preparation of 3,11-dihydroxy-12-ketocholanic acid has been modified so as to give better yields. The intermediate 11-bromo acid was isolated in amorphous form. The position of the new substituent group was confirmed by conversion of the bromo acid into $\Delta^{9,11}$-3-hydroxy-12-ketocholenic acid, and of the dihydroxy acid into the acid 3-succinate of methyl 3-hydroxy-11,12-diketocholanate. The acetyl derivative of 3,11-dihydroxy-12-ketocholanic acid described by Marker and Lawson is actually a neutral compound, that is, either a 3-acetoxy lactone or a dimolecular anhydride. On hydrolysis with acetic acid this substance yields the true 3-acetoxy-11-hydroxy-12-keto-cholanic acid. The 11-hydroxy group is also capable of acylation as evidenced by the preparation of a crystalline diformyl and of an amorphous diacetyl derivative.

All attempts to prepare the semicarbazone of 3,11-dihydroxy-12-ketocholanic acid, described by Marker and Lawson, as well as other ketone derivatives, failed. Treatment of the acid with sodium ethylate and hydrazine hydrate at 200° resulted in elimination of both oxygen atoms in ring C.

Semiquinone Radicals of the Thiazines

BY L. MICHAELIS, M. P. SCHUBERT AND S. GRANICK

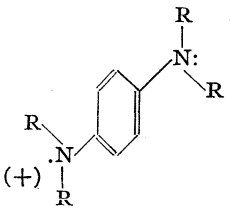
The formation of semiquinone radicals as intermediary reduction products in reversibly reducible dyestuffs, although considered an exceptional phenomenon some years ago, has now been recognized to occur so frequently that the differences in the behavior of various reversible dyestuffs can be looked upon only as quantitative, not qualitative. Among the more familiar classes of reversible dyestuffs it is only the thiazines and oxazines in which formation of semiquinones has not yet been demonstrated experimentally. This paper is to fill in this gap.

The general ideas about stability of semiquinone radicals have been clarified so far that one may start the topic by predicting the conditions under which the formation of semiquinones of these dyestuffs should be most conspicuous and then testing the theory by experiment. To increase the stability of a free radical it has to be put into such a state of its various possible levels of acidic ionization as to bring about equivalent resonance. This term requires some comment.

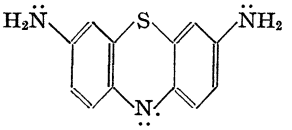
An equivalent resonance is a resonance between two limiting structures which are quite equivalent, that is to say, which, if written by the customary structural formulas, are indistinguishable except for orientation of the molecule as a whole in space. Two types of equivalent resonance may be distinguished. One of them occurs in the regular quinonoid dyestuffs, containing one benzenoid ring (or two) and one quinonoid ring. The resonance consists in the ambiguity as to which ring is the quinonoid one and which is the benzenoid. This resonance stretches over two rings (or three, in the triphenylmethane dyes) and may be designated as quinone–benzene resonance.

The other type of equivalent resonance occurs in the semiquinone radicals. It is restricted, or at least it may be restricted, to a single ring. There is one unpaired electron, and the ambiguity as to the place of this electron on writing down a structural formula is what underlies the resonance. An equivalent resonance occurs when there is a pair of possible structural formulas, or "limiting states," which are indistinguishable. There may be several pairs of equivalent limiting structures as has been recently discussed for Wurster's radicals.[1] An equivalent resonance has a greater stabilizing effect than a non-equivalent one.[2]

In speaking of equivalence, it is not necessary that it refer to the whole molecule. It is sufficient if there is equivalence only with respect to that part of the molecule within which the exchange of electrons resulting in resonance takes place. So, in a Wurster's radical (I), resonance stretches from one N atom across the conjugated double bonds of the ring to the other N atom.[3] The four R's may be different atoms or atom groups without appreciably diminishing the stabilizing of resonance, *provided each N is combined with two R's.*



(I)



(II)

These ideas may be applied to the thionine radical. Its simplest structural formulation is (II), with an odd electron at the N. It resembles the diphenyl-nitrogen radical. In this state, there is no resonance of the equivalent type,[4] since the bridge N and the amino N are bonded to a different number of atoms. Yet equivalence can be produced by adding protons to the N atoms. In a slightly acid solution, one of the two NH_2 groups will attach a proton (III). This does not improve the stability. However, when in a more acid solution a second proton is attached, it will prefer a position such as to bring about equivalent resonance (IV). This structure would be in equivalent resonance with (V), since (IV) can be changed to (V) by moving electrons only, keeping all nuclei in place. Another pair of equivalent resonating limiting states would be (VI) and

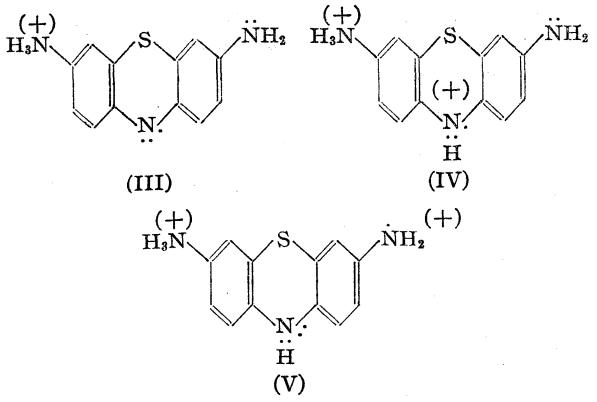
(2) See, for instance, L. Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca, New York, 1939.

(3) In all formulas, letters stand for atomic kernels, not for full atoms; a dash, or a pair of dots for an electron pair; a single dot is an unpaired electron.

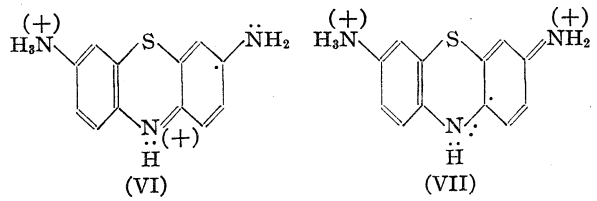
(4) The regular resonance within each benzene ring may be neglected for the present purpose.



(III) (IV)

(V)

(VII), which also arise from (IV) by shifting electrons only. The left-hand ring does not take



(VI) (VII)

part in the resonance. The right-hand ring is benzenoid in the pair IV, V; it is quinonoid in the pair VI, VII. Both the resonance IV, V, and the resonance VI, VII, are equivalent, since there are two N atoms attached to the right-hand ring, and each of these N atoms is attached to two more atoms, and there is no steric hindrance with respect to coplanar arrangement. This radical may be considered as a Wurster's radical (I), in which the two right-hand R's are H, and of the two left-hand R's one is H, the other an aromatic ring, attached furthermore by the S-bridge.

For a regular Wurster's radical, a slightly acid solution is sufficient to bring about the state of equivalent resonance, namely, the singly charged cation. For thionine, a doubly charged cation is the necessary condition for equivalent resonance. For this reason a much higher acidity will be requisite to bring about the most stable form of the thionine radical than for a regular Wurster's radical, not only because any second constant of ionization is liable to be weaker than a first one, but also because the basicity of the bridge N atom between two aromatic rings, such as in diphenylamine, is very weak.

It would be interesting to compare this state of affairs for the thiazines with that of indamines and indophenols.[5] This discussion will be reserved for a later review of the whole problem.

(5) G. Schwarzenbach and L. Michaelis, THIS JOURNAL, **60**, 1667 (1938).

The condition predicted for obtaining a possibly stable semiquinone radical from thionine is a rather strongly acid solution. This prediction is confirmed by experiment. The range of acidity necessary for the purpose is rather high, so high indeed that it was never included in the experimental works of previous authors, either for dyestuffs of this class,[6] or for any other, for the obvious reason that extremely strong acid solutions present difficulties with respect to the measurement and even the definition of *p*H. The knowledge of *p*H has so far always been desirable for a rational interpretation in problems concerned with oxidation potentials. We have to work in a range of just such an inconveniently extreme acidity as can no longer be safely measured in terms of the *p*H scale, namely, in 10 to 25 *N* sulfuric acid or in almost concentrated hydrochloric acid. The radical obtained by partial reduction of thionine in such an acid solution is yellow, has very distinct absorption bands (Figs. 5 and 6) in the blue region of the visible spectrum, which fortunately do not overlap with the bands of the oxidized form of the dye.

The degree of separation of the two steps of reduction depends very greatly on the acidity; in a 25 *N* sulfuric acid solution the separation is so complete that the potential curve shows a definite jump at 50% reduction and in the second half of the titration the pure yellow color of the radical appears without being overshadowed by the intense bluish-green color of the quinonoid form. Spectroscopically, the radical can be detected even in mixture with the quinonoid form under not too unfavorable conditions. At the end-point of reductive titration all color disappears, the leuco dye being colorless.

The radical derived from methylene blue is spectroscopically quite similar to that of thionine. Its formation, at least to an easily recognizable extent, requires a still higher acidity than in the case of thionine. It is striking that the methylation of the amino groups of thionine does not cause any distinct shift of the absorption bands of the radical.

As acidity decreases, the formation of the radical is very rapidly diminished. However, even in neutral solution it never vanishes entirely. Here, the radical must have a structure lacking equivalent resonance, and be less stable. Yet

(6) W. M. Clark, B. Cohen and H. D. Gibbs, *Publ. Health Report*, **23** 1131 (1925).

even then it is not a labile molecule inclined to undergo irreversible destruction, but perfectly stable in time to such an extent as is compatible with its equilibrium with the quinonoid dye and the leuco dye. The smallness of the concentration of this form of the radical in equilibrium with the large amount of an intensely colored substance would be sufficient to make its detection by optical methods difficult. Moreover, this form of the radical having no equivalent resonance may not be expected to exhibit any, or at least any appreciable, absorption in the visible spectrum.

Oxazines seem to behave quite similarly. Preliminary optical observation on commercial Capri blue, in the partially reduced state, showed absorption bands quite similar to those of the thiazines, but displaced toward longer wave lengths. The degree of acidity to attain this condition must be still higher.

Thiazines, particularly methylene blue, have been very much used as catalysts for oxidation, especially respiration. They increase the rate of respiration of slowly respiring cells such as erythrocytes. It has been the tendency of the authors to correlate such an effect of a dye with its faculty of being reduced in successive univalent steps.[7] Such an occurrence had not yet been demonstrated previously for the thiazine dyes. Now the suggestion concerning the mechanism of the catalytic effect of these dyestuffs is supported.

Experimental Part

1. **Preparations.**—Thionine (Lauth's violet), was prepared by dissolving 18 g. (0.1 mole) of *p*-phenylenediamine dihydrochloride in 3 liters of cold 3 *M* hydrochloric acid saturated with hydrogen sulfide. Half of a solution of 180 g. of ferric chloride hexahydrate in 400 cc. of water was stirred in, the mixture aerated to remove hydrogen sulfide and then the other half of the ferric chloride solution added. The mixture was set on ice, the precipitate filtered off and extracted with 1600 cc. of boiling water. The filtered solution is chilled and 40 cc. of 6 *M* hydrochloric acid is added, precipitating the product in crystalline condition. The product is recrystallized similarly, yield 2.5 g. The product is dried in a desiccator over calcium chloride, ground up finely and again dried over calcium chloride at 1 mm. pressure. *Anal.* Calcd. for $C_{12}H_{10}N_3SCl\cdot H_2O$: N, 14.91; S, 11.37; Cl, 12.60. Found: N, 15.03; S, 11.43; Cl, 12.37. Nitrogen by micro Dumas gave very low results but Kjeldahl determinations were satisfactory when stannous chloride was added before the digestion.

Methylene blue is prepared similarly except that 20 g. (0.1 mole) of *p*-aminodimethylaniline is dissolved in 1 liter of cold 3 *M* hydrochloric acid. The dye is salted out at the end of the reaction with 300 g. of sodium chloride. It is recrystallized twice from 400 cc. of boiling water, yield 4 g.

The essential claim as to the purity of methylene blue is that it should not be contaminated with less methylated thiazines which easily arise from it in alkaline solutions. The non- or less-methylated thiazines not being quaternary bases, can be extracted from an alkaline aqueous solution by benzene, staining it red. If a methylene blue solution is made alkaline with sodium hydroxide, it stains benzene red because it quickly decomposes. On choosing a proper *p*H one can obtain a condition where the free base of the less methylated compounds is extractable and still no decomposition of methylene blue is noticed for a sufficiently long time. When a 1 to 1000 solution, say of thionine or toluidine blue, in phosphate buffer of *p*H 7.5 is extracted with an equal volume of benzene by vigorously shaking for ten seconds, the benzene, after separating it from the aqueous phase, is pink. When methylene blue is treated in the same way the result depends on its purity. The best preparation obtained from outside (kept in the laboratory for some years) produced a very faint pink tint; our own preparation left benzene quite colorless. In a mixture of our preparation of methylene blue with commercial toluidine blue the latter could be detected easily in a proportion 1 to 50. At 1 to 100 the test was doubtful.

Every author working with methylene blue has had trouble in obtaining a really satisfactory elementary analysis. This may be due to the fact that the water of crystallization easily changes from 1 to 2 molecules, perhaps also 3.

Well ground samples were dried in vacuum over calcium chloride but difficulty was encountered on attempting to weigh out samples as moisture was rapidly absorbed, so the product was allowed to come to equilibrium with the air for a day. Then analysis agreed best with a dihydrate. *Anal.* Calcd. for $C_{16}H_{18}N_3SCl\cdot 2H_2O$: N, 11.80; Cl, 9.97; S, 9.00. Found: N, 11.31; Cl, 10.18; S, 9.19. Some of this material was converted to the iodide by dissolving 1.5 g. in 200 cc. of warm water and adding a solution of 7 g. of sodium iodide in 50 cc. of water. The crystalline product was recrystallized from 400 cc. of hot water. *Anal.* Calcd. for $C_{16}H_{18}N_3SI\cdot 2H_2O$: N, 9.40; I, 28.40; S, 7.16. Found: N, 9.24; I, 28.42; S, 7.45.

2. **Technique of Potentiometric Titration.**—Working with extremely acid solutions entails the difficulties ensuing from the liquid junction potential in a much higher degree than usual. The easiest method of examining the drift of the liquid junction potential in time is this. The potential of an acid solution such as 10 *N* sulfuric acid, at the hydrogen electrode, against a potassium chloride saturated calomel half cell is measured. The contact is established by an agar bridge such as presently will be described (Fig. 1). The end of the agar bridge is first kept above the level of the acid solution, hydrogen is bubbled for a sufficient length of time, then contact is established by pushing the agar bridge down. Any drift of the potential can be ascribed entirely to the drift of the liquid junction potential. The observations made in this way caused us to adopt the following procedure as a routine method.

(7) L. Michaelis and C. V. Smythe, *Ann. Rev. Biochem.*, 1938.

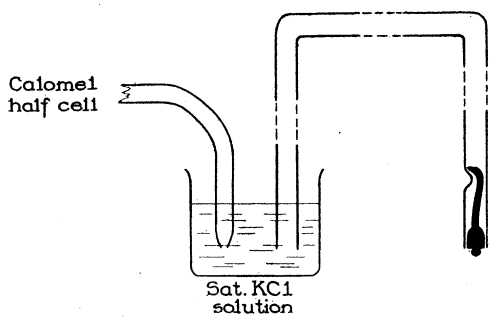


Fig. 1.—Agar bridge.

The calomel half cell and the acid solution are connected by an agar bridge. This consists of a cylindrical, properly bent glass tube, the ends not tapering. At the time when the tube was being filled with the hot liquid agar (3% agar, saturated with potassium chloride), the one end, to be used for contact with the solution in the electrode vessel, had been tightly closed with a ground glass stopper so as to leave only a minute capillary cylindrical agar film for contact. The stopper is locked by a hook fitting into a groove of the tube. This kind of agar tube has been used for many years in this Laboratory. When a freshly prepared agar tube is used as a bridge for extremely acid solutions, there is an enormous drift of potential in the negative direction. After a few hours, the drift becomes much smaller. Now the agar tube is kept for a day under saturated potassium chloride solution. When being used again, the drift subsides after fifteen to thirty minutes so much as to amount to about only one millivolt or even much less, during the period of time carrying the titration from 25 to 75% reduction. Such an agar tube, if kept under saturated potassium chloride solution when not in use, can be used over and over again. To be sure, it never will be in the same condition in parallel experiments but each experiment yields a satisfactory titration curve except for the fact that any reference to a standard potential is impossible. Neither can the oxidation–reduction potential be referred to that of the normal hydrogen electrode, nor can the potential of the solution at the hydrogen electrode be used for the computation of *p*H. We shall, for obvious reasons, use as reference point for each titration curve the potential at its 50% point of reduction. No other specification is required in order to derive the semiquinone formation constant k from the shape of the titration curve. The acidity will be expressed in terms of the normality of the acid, whereby of course one renounces any rational statement as to the relationship of acidity to semiquinone formation constant. What is certain from the experimental data is only that k becomes larger with increasing acidity. In 26 N sulfuric acid, k attains the very high value of 1000; with decreasing acidity it rapidly decreases to values < 1.

The reducing agent used for titrating the dye in such acid solution was titanous chloride. For instance, 0.07 cc. of the commercial solution of titanous chloride in strong hydrochloric acid was diluted with 10 cc. of sulfuric acid of the same concentration as the dye solution; the concentration of acid was varied from 9 to 26 N sulfuric acid. Titrations were carried out in a stream of purified nitrogen.

The other titrations, within the usual range of *p*H, were performed as usual. A very good method appeared to be reductive titration with leuco-Rosindulin GG. If conditions of solubility permitted, it was dissolved in a buffer of the same kind as used for the dye to be titrated; otherwise it was dissolved in pure water to such a concentration as to change the volume of the solution during the titration by not more than 2%, rendering any change in *p*H or ionic strength during the titration negligible.

Results

The results obtained in strongly acid solutions are best presented in the form of diagrams (Figs. 2, 3, 4) with their legends. It is clearly seen that the potential curves become steeper with increasing acidity and, from a certain acidity on, there appear in addition to the point of inflection in the midpoint, two more inflection points, symmetrically located. An acidity higher than 26 N sulfuric acid cannot be used because in this case the end-point becomes unsharp due to overlapping of the potential of the dye with that of the reducing agent. When there is no such overlapping, the curves are symmetric around the midpoint of titration. Figure 2 shows that the shape of the curve remains entirely unchanged by varying the initial concentration of the dye in the ratio 1 to 4. This is evidence for the fact that the intermediate compound is a free radical, and that no dimerization of the radical takes place, at least in the concentration range used.

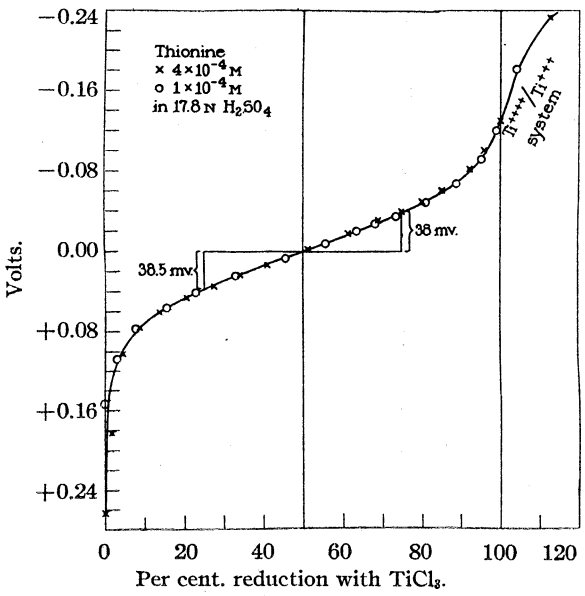

Fig. 2.—Showing independence of potential of the initial concentration of the dyestuff.

According to theory[8] there should be only one

(8) L. Michaelis and M. P. Schubert, *J. Biol. Chem.* **119**, 133 (1938).

point of inflection at 50% reduction, whenever the semiquinone formation constant k is $\leqq$ 16 or, what is the same, whenever the index potential E_i is $\leqq$ 40 millivolts. This expectation is verified as Fig. 3 shows. This is another evidence in justification of the interpretation of the titration curves.

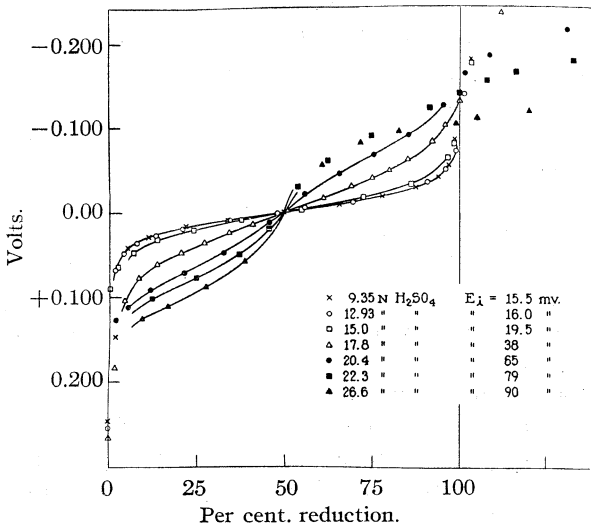

Fig. 3.—Reductive titration curves of thionine in sulfuric acid of varied normality. Reduction by titanous chloride dissolved in sulfuric acid, of the same normality as the dye solution. The drawn out curves are interpolations between all acceptable experimental points. Acceptable points are those in which no overlapping with the potential range of Ti^{++++}/Ti^{+++} occurs. The more concentrated the acid the closer are the potential ranges of Ti and the dye. Appreciable overlapping takes place only for the two highest concentrations of the acid and even here only in the second half of titration. All the other curves show sharp end-points of titration. The point × at 50.0% reduction stands not only for 9.35 N sulfuric acid, but also for 26.6 N. The flattest curve is the one for 9.35 N sulfuric acid. The points for 12.93 N sulfuric acid are distinguishable from the latter on a plot of larger scale. In the scale used here they are so close that no special curve for them has been drawn to avoid crowding. The index potentials, E_i, of the left and the right halves of each curve are equal to each other, in the worst case within one millivolt. For the two highest concentrations of sulfuric acid only the left hand E_i can be determined, and this is possible only because here the 50% point of titration is recognizable due to the fact that the point of inflection at 50% is very distinct. Lateral points of inflection, in addition to the point of inflection at 50% reduction, according to theory, should occur only if $E_i >$ 40 mv. This expectation is verified here.

The results obtained in the ordinary range of pH as established by buffers are shown in Tables II and IV. All titration curves were symmetric around the midpoint of titration, indicated by the fact that the difference of potential at 25% reduction and 50%, and the difference between 50 and 75%, are equal within at least three-tenths of a millivolt and usually better. The symmetry obtains not only from 25 to 75% but throughout the whole potential range as far as quickly established and reproducible potentials are obtained.

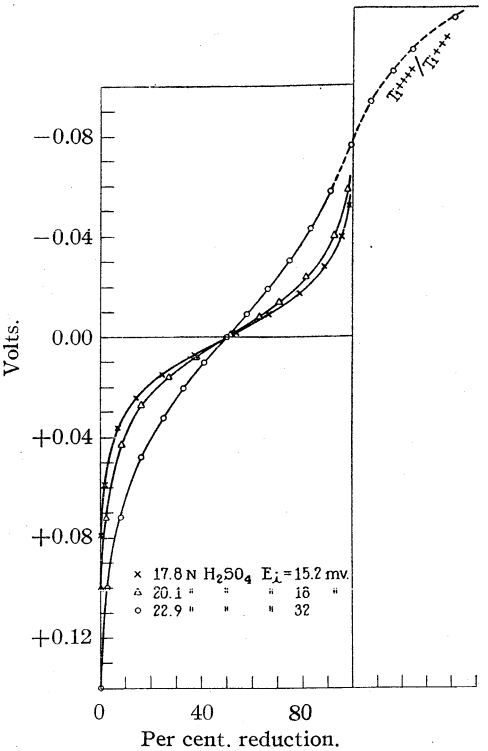

Fig. 4.—Reductive titrations of methylene blue in sulfuric acid of varied normality. Reduction by titanous chloride. The curves become steeper with increasing acidity. To reach the same degree of steepening, a higher concentration of acid is needed than for thionine. Even for the highest concentration of acid used here, the separation is not great enough to cause the appearance of the two lateral points of inflection in accordance with the fact that E_i does not reach the value 40 mv. Still higher concentrations of acids cannot be used because the overlapping of the potential ranges of the dye and Ti becomes too great. For all lower concentrations of acid, the end point is sharp.

This shows that the specimens of the dyes are not contaminated with any measurable amount of some other dyestuff of slightly different normal potential, in which case the overlapping would cause asymmetry. Furthermore, it shows that the molecular size of the oxidized and the reduced form is the same. The fact that all index poten-

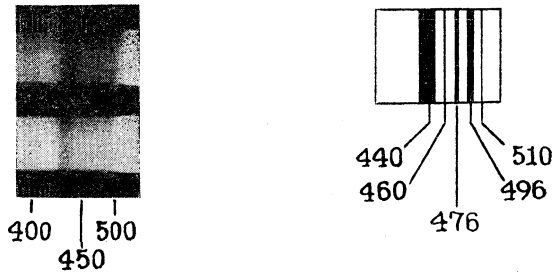

Fig. 5.—Absorption bands of the semiquinone of thionine, as existing in 20 N sulfuric acid, the dye being reduced to approximately 75% by titanous chloride. The two spectrum photographs (by Dr. Lavin) are with various lengths of exposure. The other spectrum is a schematized sketch to show the finer structure more clearly than in the photograph. Wave lengths are in mμ. On direct visual inspection with the hand spectroscope, the 496 band is strongest rather than the 440 band.

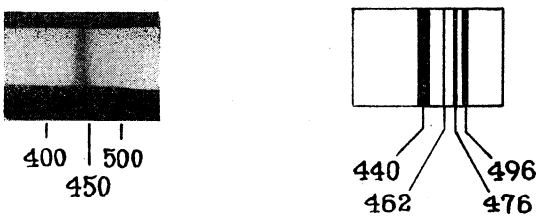

Fig. 6.—Absorption bands of the semiquinone of methylene blue. Conditions were the same as in Fig. 5.

tively interpreted as evidence that the dyestuffs in higher concentration might partially form higher molecular aggregates. This is certainly not so for thionine and methylene blue in such a concentration range as used in our experiments.[12] The potentials are stable, there is no evidence for any decomposition, not even for methylene blue, except in alkaline solution, where the accuracy of the experiments with this dyestuff suffers anyhow from the extremely slight solubility of the leuco dye. The index potential both for thionine and methylene blue in solutions from pH 4 to 7 may be estimated as about 16 millivolts; in any case decidedly not less than 15 mv. Using the methods of calculation previously described,[13] the relationship between the index potential E_i, the semiquinone formation constant k, and the maximum fraction of semiquinone to total dye is

E_i	= 15.0	15.5	16.0
k	= 0.01	0.02	0.05
$s/a_{max.}$	= .05	.065	.10

In a very wide pH range around neutrality, the dye in its half-reduced state contains not less than 5%, probably approximately 10%, as semiquinone. This should be considered as ample to account for the efficiency of the radical in establishing the reversibility of the system and its catalytic effect. It is in agreement with the behavior of other cationic dyestuffs presenting more favorable experimental conditions that k, though rapidly diminishing with increasing pH, does not vanish entirely, but remains constant from a certain pH on. This is due to the fact that the convergence of the E_1 and E_2 curves (normal potential of the lower, and of the higher step of oxidation) with increasing pH gives way to parallelism at the pH corresponding to an ionization constant of the radical.

As additional evidence that index potentials close, but not quite equal, to the theoretical minimum value of 14.3 millivolts are trustworthy within a few tenths of a millivolt, a titration experiment with a univalent oxidation system was performed in which according to the theory no other E_i value than 28.6 mv. can ever be obtained and any deviation must be ascribed to technical insufficiency. A solution of 3×10^{-4} gram atom of iron per liter in the form of ferric ammonium sulfate in a solvent 0.01 M in hydrochloric acid and 1 M in a neutral salt (potassium chloride in one experiment, sodium chloride in another) was titrated with leuco-rosindulin, dissolved in water, in such a concentration that the titration from 25 to 75% reduction required as little as 0.7 cc. for 50 cc. of the solution to be titrated. The change in ionic strength caused hereby during the titration may be considered as quite negligible. The graphic evaluation of the index potentials was as shown; a and b are compu-

	E_i

tations based on different estimations as to the endpoint of titration, this difference being taken as

(12) It can be confirmed that even in a range of low concentrations (from 5×10^{-6} to 150×10^{-6} M) Beer's law is not obeyed. In low concentration, thionine has essentially one band at 593 mμ; and it emits a fluorescence band at about 640. As concentration increases, gradually a second band around 556 develops, and fluorescence diminishes. In alcohol, the effect of increased concentration, both on the decrease of fluorescence, and on the development of the second band, is quite considerably weaker. There is some intermolecular interaction, stronger in water than in alcohol, to the effect that the probability of an unexcited molecule absorbing 556 is increased, as the probability of an excited molecule emitting 640 is decreased. This phenomenon should not be correlated with any change in size of the molecular unit of the dye. This, of course, can be asserted only for our dyestuffs and within the concentration range used.

(13) Summarized by L. Michaelis and M. P. Schubert, *Chem. Rev.*, **22**, 437 (1938).

large as was reasonably compatible with the experimental data. These experiments suggest that any deviation of the index potential exceeding by 2 or 3 tenths of a millivolt its expected theoretical minimum value may be taken as real.

It should now be our task to plot the three normal potentials against *p*H, showing all bends corresponding to the various ionization constants of the dye in each of its three levels of reduction, as shown in many previous cases. This cannot be accomplished satisfactorily because one cannot express either the acidity of highly concentrated sulfuric acid solutions in terms of *p*H or refer the normal potentials to the standard hydrogen electrode. Here we are faced with a problem of a much more general scope, concerning both the scale of oxidation–reduction potentials, and the scale of acidity, to which we intend to devote a special study.

Summary

A semiquinone radical is shown to exist as a univalent reduction product for thionine and for methylene blue. In equilibrium with the dye and the leuco dye, it can exist only to a few per cent. of the total dye *in maximo* over the whole *p*H range covered by the customary buffers. In very strongly acid solution, such as from 10 to 26 *N* sulfuric acid, it is stable to a much higher extent and can be identified by an analysis of the reductive titration curve of the dye and by its color, which is yellow with distinct absorption bands in the blue. The semiquinone formation constant *k* reaches for thionine the value 1000 in 26.6 *N* sulfuric acid but rapidly decreases to values < 1 in less acid solutions. For methylene blue, this constant reaches in 22.9 *N* sulfuric acid only the value 6. In a wide *p*H range around neutrality, *k* is for both dyestuffs approximately 0.05. The greater stability of the radical in very acid solution is ascribed to the formation of a bivalent cation having a structure, exhibiting equivalent resonance, of the same type as a Wurster radical.

The existence of this radical is correlated with the reversibility of oxidation–reduction of thiazines, and with their catalytic effect in biological oxidations.

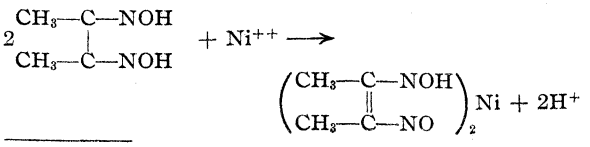
Amperometric Titrations. II. The Titration of Nickel with Dimethylglyoxime Using the Dropping Mercury Electrode as Indicator Electrode

BY I. M. KOLTHOFF AND A. LANGER

In a previous paper[1] the general characteristics of amperometric titrations and the titration of lead with dichromate or chromate have been described. It is expected that many of the modern organic precipitants will be useful in the amperometric titration of several metals, especially since many of these organic reagents are specific for a limited number of inorganic ions. In the present paper the amperometric titration of nickel with dimethylglyoxime is described, using the dropping mercury electrode as indicator electrode. In ammoniacal and weakly acid medium dimethylglyoxime reacts with nickel to form the insoluble red, microcrystalline precipitate of nickel dimethylglyoxime.



(1) I. M. Kolthoff and Y. D. Pan, THIS JOURNAL, **61**, 3402 (1939).

Besides nickel, only palladium and platinum form slightly soluble compounds with dimethylglyoxime. Several metal ions, such as cobalt and ferrous iron, react with the glyoxime to form soluble complexes and may interfere in the titration of nickel. The interference by other metals has been considered in this paper.

Experimental

The general set-up was similar to that described in a previous paper.[1] The current was measured with a d'Arsonval galvanometer, the sensitivity of which could be changed with an Ayrton shunt. In a few instances a microammeter was used. A saturated calomel electrode connected with the titration cell by means of an agar salt bridge served as an external anode. The applied e. m. f. was measured with the aid of a potentiometer. In most practical work, in which the applied e. m. f., as a rule, has to be known only within 0.05 to 0.1 volt, a suitable voltmeter can be used instead. The reagent was added from a calibrated microburet of the shape given in Fig. 1. The arrangement allowed the storage and the introduction of

the reagent into the titration cell in the absence of air.[2] Before the titration air was removed from the cell by means of a current of nitrogen. For further details, see the previous publication.[1]

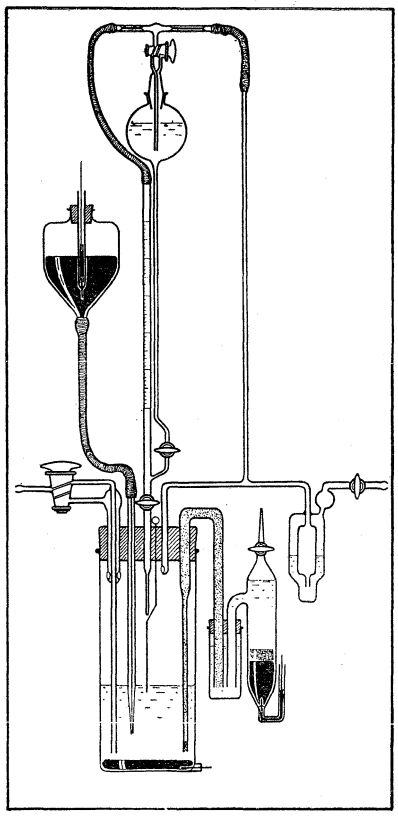


Fig. 1.—Cell allowing the titration to be carried out in the absence of air. The terminal of the agar bridge is made of sintered glass. The gas can pass through or above the solution.

Chemicals Used.—All chemicals used were of C. P. quality. If necessary they were further purified by recrystallization. The stock nickel solution was standardized by classical methods. A 0.1 *M* stock solution of dimethylglyoxime in 96% alcohol was prepared. When protected from evaporation this solution could be kept for more than six months without changing its titer.

Performance of the Titration.—A measured volume (as a rule 50 ml.) of the standard nickel solution in the proper medium was introduced into the cell, nitrogen was passed through for fifteen to twenty minutes, the proper e. m. f. was applied to the cell and the current was measured. Successive amounts of the alcoholic dimethylglyoxime solution were added from the microburet. After each addition the contents of the cell were mixed by passing nitrogen through for half a minute and the current was recorded after it had become constant (two to three minutes). The tip of the capillary was placed close to the bottom of the cell, as the red precipitate had the tendency to agglomerate near or at the surface of the solution. No trouble due to obstruction of the capillary was noticed. In all cases the values of the current, corrected for the volume change, were plotted against the amount of reagent added.

Experimental Results

The most suitable titration medium for nickel was found to be an ammoniacal solution. Consequently, current voltage curves (polarograms) of nickel and dimethylglyoxime were determined at different concentrations in order to find the most suitable range of values of the applied e. m. f. between which the titrations have to be carried out. In Fig. 2 the current–voltage curve of 0.004 *M* nickel chloride in 0.1 *M* ammonium chloride and 0.5 *M* ammonia is given. The wave

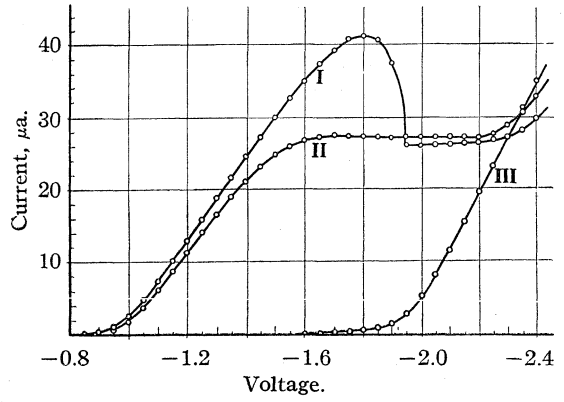

Fig. 2.—Current–voltage curves, temp. 19°, drop time 2.6 sec.: I, 0.004 *M* nickel chloride in 0.1 *M* ammonium chloride and 0.5 *M* ammonia; II, same after addition of three drops of 10% gelatin; III, blank.

is drawn out and shows a pronounced maximum (curve I). This maximum can be eliminated by the addition of a trace of gelatin[3] (0.001%), as is evident from curve II; but the wave remains drawn out. In Fig. 3 the current–voltage curves of 0.001, 0.002 and 0.003 *M* solutions of dimethylglyoxime in 0.5 *M* ammonia and 0.1 *M* ammonium chloride are given with the current–voltage curve of the medium alone (curve 1). With the 0.001 *M* dimethylglyoxime solution a diffusion current was obtained at applied values of the e. m. f. between 1.93 and 2.17 volt (curve 2); the 0.002 *M* solution showed a distinct maximum (curve 3), while the 0.003 *M* solution (curve 4) did not give any indication of a diffusion current. At these higher concentrations the current–voltage curve of

(3) Comp. J. J. Lingane; Thesis, University of Minnesota, 1938; I. M. Kolthoff and J. J. Lingane, *Chem. Rev.*, **24**, 1 (1939).

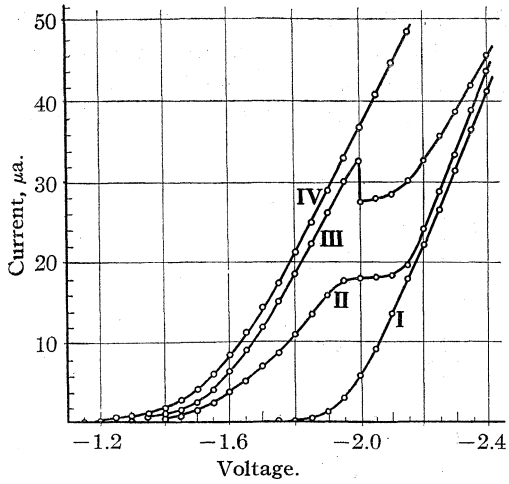

Fig. 3.—Current–voltage curves, temp. 22°, drop time 2.8 sec.: I, 0.1 *M* ammonium chloride and 0.5 *M* ammonia; II, with 0.001 *M* dimethylglyoxime; III, with 0.002 *M*; IV, with 0.003 *M*.

the reagent coincided smoothly with the decomposition current of the medium at higher applied e. m. f. In Fig. 3b it is shown that at an applied e. m. f. of 1.85 volt the dimethylglyoxime current was proportional to the concentration when the latter was smaller than 0.002 *M*. The current

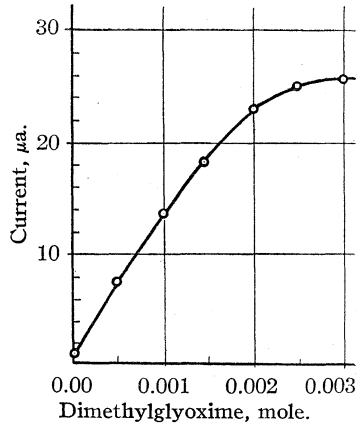

Fig. 3b.—Current at applied voltage of −1.85 v. at different concentrations of dimethylglyoxime in 0.1 *M* ammonium chloride and 0.5 *M* ammonia; temp. 22°, drop time 2.8 sec.

increased only slightly with further increase of the dimethylglyoxime concentration. An applied e. m. f. of 1.85 volt was therefore selected in the performance of the titration. As alcohol was added with the introduction of the reagent, the diffusion current of nickel was determined at $E_{appl.}$ = 1.85 v. in the above medium in the presence of different amounts of alcohol. The diffusion current of nickel remained practically unaltered at alcohol concentrations smaller than 12%.

In Fig. 4 are given the data obtained in the titration of a 0.005 *M* nickel solution in 0.1 *M* ammonium chloride and 0.5 *M* ammonia with 0.1 *M* dimethylglyoxime at an applied e. m. f. of 1.85 v. The ordinate gives the values of the current and the abscissa the volume of reagent added. In the titrations the point of intersection was found after addition of 5.00 to 5.03 ml. of reagent. The results are accurate and precise.

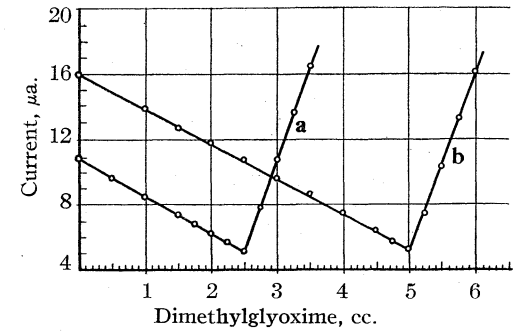

Fig. 4.—Titration curves of 50 ml. of (a) 0.0025 *M*, (b) 0.005 *M*, nickel chloride solutions in 0.1 *M* ammonium chloride and 0.5 *M* ammonia at an applied e. m. f. −1.85 v. with 0.1 *M* dimethylglyoxime; temp. 25°, drop time 2.5 sec.

The concentrations of ammonia and ammonium chloride could be changed within wide limits without affecting the results. Keeping the ammonium chloride concentration equal to 0.1 *M* the residual current at the point of intersection increased only slightly with increasing concentration of ammonia. In 0.5 *M* ammonia it was only 0.85 microampere, in 1 *M* ammonia 1.2, and in 2 *M* ammonia 1.3 microampere. A few data obtained in the titration of 50 ml. of 0.004 *M* nickel chloride with 0.1 *M* dimethylglyoxime in the neighborhood of the end-point are given in Fig. 5. It is seen that in all cases the point of intersection was found after addition of 4.00 ml. of reagent. An increase of the ammonium chloride concentration resulted in a marked increase of the current at the point of intersection. In 0.1 *M* chloride and 0.5 *M* ammonia it was found equal to 0.88 microampere, but in 1 *M* ammonium chloride and 0.5 *M* ammonia it was found equal to 2.2 microamperes. Larger amounts of ammonium chloride apparently increase the solubility of the nickel dimethylglyoxime. In general, it is recommend-

able to keep the ammonium chloride concentration smaller than 0.5 M.

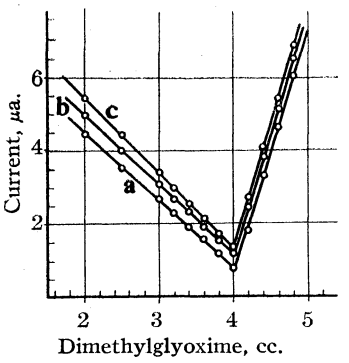

Fig. 5.—Titration curves of 50 ml. of 0.004 M nickel chloride in 0.1 M ammonium chloride and (a) 0.5 M ammonia, (b) 1.0 M ammonia, (c) 2.0 M ammonia solution with 0.1 M dimethylglyoxime at an applied e. m. f. of −1.85 v.; temp. 23°, drop time 3.1 sec.

In Fig. 6 are given the data obtained at various applied e. m. f.'s in the titration of 50 ml. of 0.004 M nickel in 0.1 M ammonium chloride and 0.5 M ammonia. The best results were obtained at an applied e. m. f. of 1.6 to 1.9 v. At an applied e. m. f. of 2.0 v. the current at the end-point was relatively great (5.3 microamp.) corresponding to the current of the medium at this voltage. The data obtained at an applied e. m. f. of 1.4 volts varied in an irregular way. These irregularities are caused by stirring effects which are responsible for the occurrence of the maximum

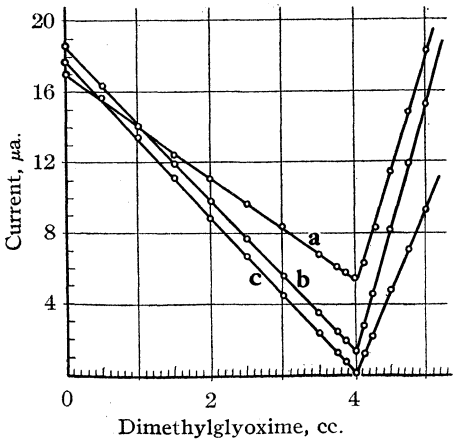

Fig. 6.—Titration curves of 50 ml. of 0.004 M nickel chloride in 0.1 M ammonium chloride and 0.5 M ammonia solution with 0.1 M dimethylglyoxime at an applied e. m. f. of (a) −2.0 v., (b) −1.8 v., (c) −1.6 v.; temp. 25°, drop time 3.1 sec.

in the nickel curve (see Fig. 2). The stirring effect and also the irregularities were eliminated by the elimination of the maximum as is evident from the results shown in Fig. 7. In this titration

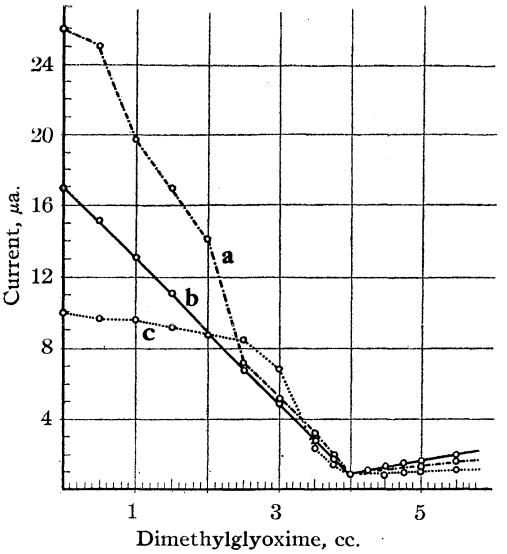

Fig. 7.—Titration curves of 50 ml. of 0.004 M nickel chloride in 0.1 M ammonium chloride and 0.5 M ammonia solution with 0.1 M dimethylglyoxime at an applied e. m. f. of (a) −1.4 v., (b) −1.4 v. and addition of 1 ml. of 1% gelatin, (c) −1.2 v.; temp. 25°, drop time 3.1 sec.

the maximum was eliminated by the addition of 1 ml. of 1% gelatin. The precipitation line was found to be straight until the end-point. After passing the end-point the current increased only slightly, as at an $E_{\text{appl.}}$ of 1.4 v. the currents of dimethylglyoxime solutions were very small (see Fig. 3), although proportional to the concentration of the reagent. The data obtained at an applied e. m. f. of 1.2 v. were very irregular (see Fig. 7) for the same reason as at $E_{\text{appl.}}$ of 1.4 v. A great number of titrations was carried out with 50 ml. of a nickel solution (in 0.1 M ammonium chloride, and 0.5 M ammonia at $E_{\text{appl.}}$ = 1.85 v.) the concentration of which was varied between 0.01 and 0.001 M. The results were precise and accurate within 0.4%. Titrations were also carried out with more dilute solutions, using a 0.01 M solution of dimethylglyoxime as reagent. Some data obtained in the titration of 0.0001 M, 0.0002 M and 0.0004 M nickel solutions are given in Fig. 8.

In these highly dilute solutions the solubility of the precipitate at and near the end-point is distinctly noticeable. However, by plotting the

measurements more than 20 to 40% removed from the equivalence point it is possible to get sufficient data to construct the two straight lines. Although the drop time of the mercury changed somewhat during the titration (up to 10% near the end-point) it was possible to titrate the 0.0001 *M* nickel solution with an accuracy of 1–2%. Solutions more dilute than 0.0001 *M* could not be titrated with a reasonable accuracy, as the solubility effect became too great. The above titrations all have been carried out with a 50-ml. volume of the nickel solution. The accuracy is hardly affected by taking smaller volumes. We have titrated 10-ml. portions containing 0.06 to 0.30 mg. of nickel with an accuracy of 2–3%. By making the proper changes in the apparatus and using still smaller volumes it is possible to use the method for the micro titration of nickel, when the concentration of the nickel is greater than 0.0001 *M* and the volume corrections are considered.

In Table I is given as an illustration the current (corrected for the change of the volume) in the titration of a 0.004 *M* nickel chloride solution.

In Table II is given a summary of some results obtained in the titration of 50-ml. volumes containing varying amounts of nickel. Extensive investigations have been carried out in which attempts were made to titrate the nickel in acetate buffers and in sodium acetate instead of in ammoniacal medium. Although under certain conditions useful results could be obtained in the titration of larger quantities of nickel, the results, quite generally, were much better in ammoniacal medium. For this reason details will not be reported.

Interference by Other Metal Ions.—Metal ions which are electroreduced at the applied e. m. f. used in the titration of nickel interfere when present in larger quantities, even if they do not form complexes with the reagent. It is possible to compensate the current caused by the electroreduction of the foreign metal ions, but the readings of the current during the titration become less accurate due to the relatively large fluctuations of the current during the formation of a drop of mercury. In general the concentration of foreign ions which are reduced at the applied voltage and which do not react with the reagent should not be many times greater than that of the nickel. It is expected that a stationary electrode may have advantages over the dropping electrode in this respect.

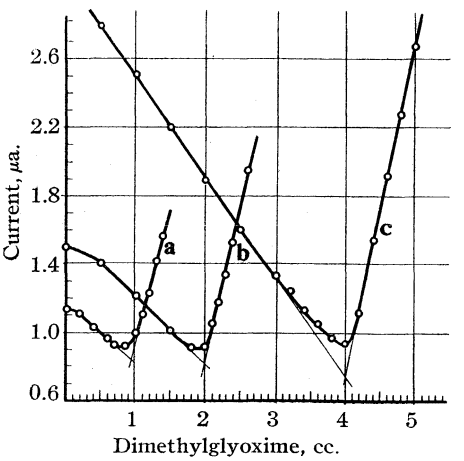

Fig. 8.—Titration curves of 50 ml. of (a) 0.0001 *M*, (b) 0.0002 *M*, (c) 0.0004 *M*, nickel chloride in 0.1 *M* ammonium chloride and 0.5 *M* ammonia solution at an applied e. m. f. of −1.85 v.; temp. 23°, drop time 2.5 sec.

Interference by Cobalt.—A special study was made of the interference caused by cobalt. Cobalt in ammoniacal solution yields a diffusion current at the applied e. m. f. used in the titrations. Moreover, it yields a soluble complex with the dimethylglyoxime. Upon addition of small amounts of the alcoholic reagent to a dilute ammoniacal cobalt solution at an applied e. m. f. of 1.85 v., the current was found to increase in a linear way with the dimethylglyoxime concentration (see Fig. 9). Apparently, the soluble com-

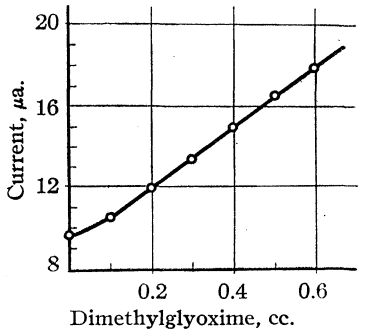

Fig. 9.—Titration curve of 50 ml. of 0.004 *M* cobalt chloride in 0.1 *M* ammonium chloride and 0.5 *M* ammonia solution with 0.1 *M* dimethylglyoxime at an applied e. m. f. of −1.85 v.; temp. 25°, drop time 2.1 sec.

plex seems to be electroreducible at the applied voltage. Although not expected from this behavior, it was found that small amounts of cobalt interfered with the titration of nickel. Some results are given graphically in Fig. 10. When the ratio of cobalt to nickel in the 0.004 *M* nickel solution was greater than 1:20, the end-point could not be found with accuracy. With larger amounts of cobalt the current changed in a highly irregular way during the titration; and increased from the very beginning. In sodium acetate or in acetate buffers containing 50% of alcohol better results were obtained, but no useful procedure was found for the titration of nickel in the presence of larger quantities of cobalt. Although nickel yields a good current–voltage curve with a diffusion current in cyanide solution, it was found

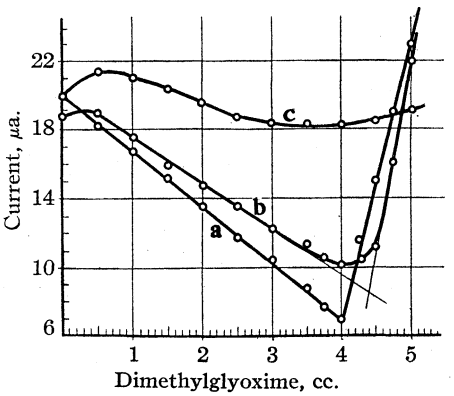

Fig. 10.—Titration curves of 50 ml. of 0.004 *M* nickel chloride in 0.1 *M* ammonium chloride and 0.5 *M* ammonia solution at an applied e. m. f. of −1.85 v. in presence of (a) 0.0002 *M* cobalt chloride, (b) 0.0004 *M*, (c) 0.001 *M*; temp. 25°, drop time 3.1 sec.

that the nickel dimethylglyoxime does not separate from such a medium when little nickel is present. On the other hand it was found that although nickel (and cobalt) do not yield a diffusion current in a solution which was 0.05 *M* in sodium pyrophosphate (see Fig. 11), the nickel complex precipitated readily from such a medium.

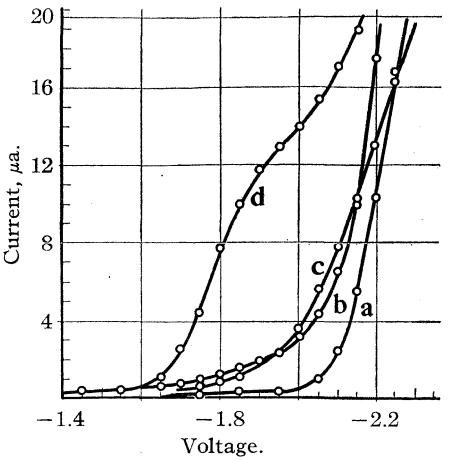

Fig. 11.—Current–voltage curves of: (a) 0.05 *M* sodium pyrophosphate, (b) with 0.004 *M* nickel chloride, (c) with 0.004 *M* cobalt chloride, (d) with 0.004 *M* dimethylglyoxime; temp. 25°, drop time 2.5 sec.

When a nickel titration was carried out in 0.05 *M* sodium pyrophosphate at an applied e. m. f. of 1.7, the titration lines had a slope as given in Fig. 12.

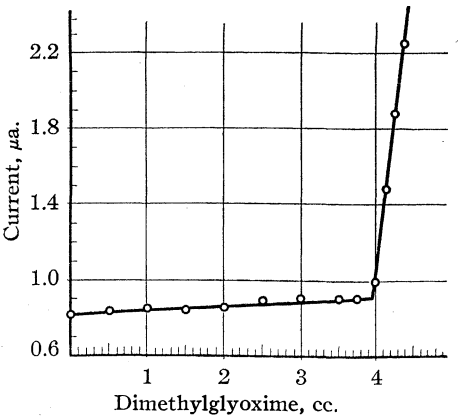

Fig. 12.—Titration curve of 50 ml. of 0.004 *M* nickel chloride in 0.05 *M* sodium pyrophosphate solution with 0.1 *M* dimethylglyoxime at an applied e. m. f. of −1.7 v.; temp. 24°, drop time 2.5 sec.

The end-point could be found with an accuracy of 1–2%. Again, however, relatively small amounts of cobalt interfered. When the amount of cobalt

is more than 5% that of the nickel, it is necessary to remove it by chemical separation. Satisfactory results were obtained by removing the cobalt as potassium cobaltinitrite. To the solution, acidified with acetic acid, was added a large excess of potassium nitrite. After the precipitate had settled it was filtered and washed (or an aliquot part of the filtrate was taken), and the filtrate was evaporated to dryness in the presence of enough hydrochloric acid to remove all of the nitrite. The latter interferes with the nickel titration as it is electroreduced at the applied e. m. f. used in the titrations. The nickel was titrated in ammoniacal medium at an applied voltage of 1.65 in the presence of 1 ml. of 1% gelatin. Taking mixtures with a ratio of cobalt to nickel of 10 to 1, results were obtained which were accurate to within 0.5%. Even when the ratio was 100 to one the results were entirely satisfactory.

Interference by Other Metal Ions.—Metal ions, such as ferric iron, aluminum and chromium, which are precipitated in ammoniacal medium can be present in small quantities (about double the amount of nickel). When present in larger quantities low results are found, as the hydrous oxides adsorb nickel. The errors found in the titration of 50 ml. of 0.004 *M* nickel in the presence of 1 ml. of 0.1 *M* solutions of ferric iron, aluminum, chromium and manganese, respectively, were −0.25, −0.5, −2.5, and +0.8%. Larger amounts of the above ions must be removed by classical chemical methods. We have applied the nickel titration to the determination of nickel in nickel steel. After dissolving the sample, oxidation of the iron and reprecipitation from ammoniacal medium in the presence of ammonium chloride, the nickel content was found to be 3.44%, in good agreement with the value 3.47% given by the Bureau of Standards. It is simpler to remove the iron by the ammonium benzoate method.[4] The residue of the solution of the steel (1.16 g.) after oxidation and evaporation was taken up in 0.1 *N* hydrochloric acid, dilute ammonia was added until beginning turbidity, then 5 ml. of glacial acetic acid and 100 ml. of 10% ammonium benzoate. After boiling for five minutes the precipitate was filtered and washed with dilute ammonium benzoate in 30% acetic acid. The filtrate and washings were evaporated, the residue taken up in ammonium chloride and ammonia and the whole diluted to 250 ml. in a volumetric flask. Fifty-ml. portions were titrated with 0.1 *M* dimethylglyoxime. As an average from four titrations the nickel content was found to be equal to 3.48 ± 0.04%.

Cadmium and zinc do not react with the dimethylglyoxime, but they are reduced at the applied e. m. f. at which the titration is carried out. Still, it was found possible to titrate 0.004 *M* nickel solutions in the presence of the same amounts of cadmium and zinc with an accuracy of 1%.

Cupric copper was found to interfere badly. It has to be removed from the solution before titrating the nickel.

Solubility of Nickel Dimethylglyoxime.—An attempt has been made to determine the solubility of the red precipitate in various solutions polarographically. The determination should be carried out at an applied e. m. f. at which both nickel and dimethylglyoxime yield a diffusion current. At such an e. m. f. the diffusion current of nickel is: $i_{d_{Ni}} = k_{Ni}C_{Ni}$, and of dimethylglyoxime $i_{d_{D.G.}} = k_{D.G.}C_{D.G.}$ The k values can be determined empirically by determining the diffusion currents of nickel and dimethylglyoxime at different concentrations. It is then simple to calculate the solubility from the current measured with the saturated solution (1 Ni + 2 D.G.). Unfortunately, it was hardly possible to find in the various media a suitable value of the applied e. m. f. at which nickel and dimethylglyoxime (or one of them) yield the diffusion current. The best results were obtained with an acetate buffer of *p*H 4.05 (0.03 *M* in sodium acetate) at an applied e. m. f. of 1.45 v. The results corresponded to a solubility of 9.5 mg. of nickel dimethylglyoxime per liter. The other results are not reported as they are highly approximate for the reasons mentioned above.

Summary

1. The amperometric titration of nickel in ammoniacal medium with an alcoholic solution of dimethylglyoxime, using the dropping mercury electrode as indicator electrode, yields accurate and precise results.

2. The method is especially useful for the titration of very dilute nickel solutions, good results being obtained in a concentration range between 0.01 and 0.0001 *M*.

3. The interference by other metal ions is

(4) I. M. Kolthoff, V. A. Stenger and B. Moskovitz, THIS JOURNAL, 56, 812 (1934).

discussed. Procedures are described for the determination of nickel after removal of large amounts of cobalt and of iron. The procedure given for the determination of nickel in nickel steels yields good results.

Some Alkamine Esters of Disubstituted Methylcarbamic Acids

BY JOHN J. DONLEAVY AND JAMES ENGLISH, JR.

Most prominent among the various types of simple amines exhibiting local anesthetic properties are the benzohydrylamines. Amines of this type ($C_6H_5CH(NH_2)R$) were first found to be active local anesthetics by Ogata[1] and further study by Fourneau and his collaborators led to the development of a whole series of extremely active local anesthetics including numerous alkoxy-substituted benzohydrylamines.[2] Certain compounds of analogous structure have been studied in this Laboratory and found to be quite active although rather irritating. Experience has shown that in some cases[3] mixed, or aliphatic–aromatic, types are often more active than the diaryl or benzohydrylamine derivatives themselves. Hence typical examples of each of these classes were included in the present investigation.

It was thought possible that the introduction of groups on the nitrogen atom in compounds of this type might act to decrease the irritation produced in the test animals and among the groups considered for this purpose was the COOR group. The present paper describes the preparation of several types of disubstituted methylcarbamates in which R is an aminoalkyl group. It was thought that such compounds might combine the high activity of the benzohydrylamines with that of the amino alcohol carbamates, which are known to be local anesthetics.[4]

The compounds prepared were of the type $R_1R_2CHNHCOO(CH_2)_nNR_2$ where R_1 and R_2 are either aromatic or aliphatic radicals. Two methods of preparation have been worked out for the isocyanate intermediate in the synthesis of the type in which R_1 and R_2 are both aromatic. The first is based on a modification of the Curtius reaction of acid azides as developed by Naejeli.[5] This involves the reaction of an acid chloride with sodium azide in dilute acetone solution to give the isocyanate which is immediately treated with the appropriate amino alcohol to give a substituted carbamate. The second method, which was applied also to the aliphatic compounds, consists of the preparation of the isocyanate by the reaction of the alkyl bromide with silver isocyanate and treating this in turn with an amino alcohol. The compounds prepared are listed in Table I.

The pharmacological data will appear elsewhere[6]; it may be said here that the compounds are highly active local anesthetics of toxicity comparable to cocaine; they are somewhat irritating, however.

Experimental

Diphenylmethyl Isocyanate.—Fifteen grams of diphenylmethyl bromide was placed in a flask equipped with a reflux condenser and a mechanical stirrer, care being taken to protect the mixture from moisture at all times. One hundred cc. of anhydrous ether was then added and 12 g. of silver cyanate introduced. The mixture was refluxed and stirred for three hours and refluxing continued overnight. After filtering from the silver bromide, the ether was removed and the product distilled. Diphenylmethyl isocyanate boils at 148° (4 mm.). The yield is 80% of the theoretical.

Amino Alcohol Carbamates.—A dry ether solution of the above isocyanate was treated with the calculated quantity of the desired amino alcohol. The solution was refluxed for three hours to ensure completion of the reaction. On passing dry hydrogen chloride into the cold reaction mixture the hydrochloride of the basic urethan precipitated in a fairly pure state. The products can be recrystallized from dry acetone. They are nicely crystalline salts soluble in water and somewhat hygroscopic.

Amino Alcohol Carbamates from Diphenylacetyl Chloride.—Twelve grams of diphenylacetyl chloride was dissolved in 80 cc. of acetone and the solution cooled to 0°.

TABLE I

SUBSTITUTED ALKAMINE METHYLCARBAMATES

	M. p., °C.	Nitrogen, % Calcd.	Found
$(C_6H_5)_2CHNHCOOCH_2CH_2N(C_2H_5)_2\cdot HCl$	179	7.75	7.63
$(C_6H_5)_2CHNHCOOCH_2CH_2CH_2N(C_2H_5)_2\cdot HCl$	183	7.45	7.26
$(C_6H_5)_2CHNHCOOCH_2CH_2N(C_4H_9)_2HCl$	136	6.70	6.53
$(C_6H_5)_2CHNHCOOCH_2CH_2N\langle CH_2CH_2 \rangle CH_2\cdot HCl$	119	Cl, 9.69	9.58
$(C_6H_5)(CH_3)CHNHCOOCH_2CH_2N(C_2H_5)_2$	B. 178 (5 mm.)	8.60	8.82
$(C_6H_5)(CH_3)CHNHCOOCH_2CH_2CH_2N(C_2H_5)_2$	B. 164 (3 mm.)	8.24	8.29
$(CH_3)_2CHNHCOOCH_2CH_2N(C_2H_5)_2HCl$	114	11.76	11.65

To this was added a saturated aqueous solution of sodium azide and the mixture shaken and cooled in ice for one-half hour. An excess of cold water was then added and the solution extracted at once with ether; the ether extract, after drying briefly over calcium chloride, was filtered and treated with the calculated quantity of the desired amino alcohol. The solution was refluxed for two hours, the ether removed and the residue heated at 100° under diminished pressure to remove unchanged amino alcohol. The free base thus obtained was taken up in dry ether and a stream of dry hydrogen chloride passed into the solution. The hydrochloride precipitated at once and was filtered and recrystallized from acetone. The yield was 64% of the theoretical.

Amino Alcohol Esters of α-Phenylethylcarbamic Acid.—Eighteen grams of α-phenylethyl bromide dissolved in 100 cc. of anhydrous ether was stirred and refluxed with 15 g. of dry silver cyanate for six hours and refluxing continued overnight without stirring. At the end of this time the silver salts were filtered off and the ether evaporated. The residual oil could be distilled under reduced pressure; in this way 10.5 g. of phenylethyl isocyanate (72%) b. p. 96° (18 mm.) was obtained. This was converted to the amino alcohol carbamates by refluxing in ether solution with an amino alcohol as in the case of the diphenylmethyl isocyanate above. The esters so prepared gave hydrochlorides that were extremely hygroscopic and difficult to purify and hence these compounds were purified by distillation of the free bases. For purposes of pharmacological testing the light yellow oils thus obtained were suspended in water and the calculated amount of hydrochloric acid added to give a solution of the hydrochlorides.

β-Diethylaminoethyl Ester of Isopropylcarbamic Acid.—Twenty-four grams of isopropyl bromide in 200 cc. of anhydrous ether was refluxed for forty-eight hours with 30 g. of silver cyanate, after which time the appearance of the suspended salts seemed to have changed. Twenty grams of β-diethylaminoethanol was then added and the mixture refluxed for three hours longer. After filtering from the silver salts and removing the ether, the residue was fractionated *in vacuo*. There was obtained 10 g. of a colorless viscous oil, b. p. 123–125° (5 mm.), consisting of the pure amino alcohol carbamate. When this was treated in dry ether solution with hydrogen chloride there was obtained a crystalline hydrochloride which was purified by crystallization from acetone.

Summary

1. A method has been described for the preparation of alkamine esters of the type $\frac{R_1}{R_2}$>CHNHCOOR.

2. A series of esters has been prepared in which R_1 and R_2 are phenyl or methyl groups and R is an amino alkyl group.

3. Those compounds in which R_1 and R_2 are both phenyl exhibit marked local anesthetic activity.

The Synthesis of Some Alkamine Esters of Alkylthiobenzoic Acids

BY JOHN J. DONLEAVY AND JAMES ENGLISH, JR.[1]

Among the numerous synthetic local anesthetics that have been prepared, those which are found most effective from a practical point of view are the *p*-aminobenzoic acid alkamine esters of the procaine type. Much experimental work has been carried out in an effort to improve the characteristics of these compounds and to correlate structure and physiological activity in this series. A considerable portion of this work has been directed toward modification of the amino alcohol portion of the molecule.[2]

It has been found, however, that the introduction of groups other than the amino group into the benzene ring of this class of compounds may increase their efficiency as local anesthetics. Alkoxy groups, for example, when introduced into the novocaine molecule are reported to increase the activity of this compound as a local anesthetic.[3] Indeed, investigation has shown that the alkoxy group may replace the nuclear amino group in aminobenzoic acid alkamine esters, in some cases increasing the activity of the resulting compound beyond that of the corresponding amino derivative.[4]

There are very few data in the literature on the effect of sulfur-containing groups on the pharmacological properties of local anesthetics and no data on the effect of alkylthio groups in this connection have appeared. In a few instances local anesthetics have been prepared which contain sulfur groupings[5] and these have been found superior to the oxygen analogs in these cases.

In view of the above facts it seemed worth while to prepare a series of alkylthio-substituted benzoic acid alkamine esters in order to determine whether such compounds possess local anesthetic activity and thus to establish the value of the alkylthio grouping in this series. By utilizing several different alkylthio groups as well as several amino alcohols it was hoped that some connection between structure and physiological action could be established in this series of compounds.

The method found most practical for the introduction of the alkylthio group into the benzoic acid nucleus is a modification of that of Leuckart[6] involving the reaction of a diazonium salt with potassium ethyl xanthate and direct alkylation of the reaction mixture. The alkylthiobenzoic acids prepared in this way from the corresponding aminobenzoic acids were converted to the acid chlorides and these were treated with the desired amino alcohol to give the alkamine ester. The basic esters were converted to the hydrochlorides for pharmacological testing.

The detailed report of the local anesthetic behavior of these compounds will be presented elsewhere.[7] It may be said that the compounds reported here are all less toxic than procaine. Furthermore, many of them surpass this local anesthetic in duration of anesthesia when tested on the rabbit cornea. The *o*- and *m*-ethylthio and methylthio compounds are more active than the corresponding *p*-derivatives.

Experimental

Alkylthiobenzoic Acids.—The aminobenzoic acid (ortho, meta, para) was diazotized in the usual manner with sodium nitrite and hydrochloric acid and the resulting diazonium salt solution poured into a hot (70°), freshly prepared solution of one mole of potassium ethyl xanthate containing sufficient sodium carbonate to neutralize the acid in the diazonium salt solution. After the reaction was over, as indicated by the cessation of the evolution of gases, the mixture was cooled. It was then treated with 1.1 moles of sodium hydroxide and one mole of diethyl or dimethyl sulfate. In the case of the higher members of the series two moles of the alkyl halide and an equivalent amount of sodium hydroxide in five times its weight of 70% alcohol was used. The mixture was then refluxed for five hours to complete the alkylation. On acidifying with hydrochloric acid, the crude alkylthiobenzoic acid was obtained in a form pure enough for use in subsequent operations. The yields ranged from 80 to 100% of the theoretical quantity. The pure alkylthiobenzoic acids are best prepared by recrystallization from dilute acetic acid. The compounds are white or slightly yellow crystalline solids, practically insoluble in water and soluble in organic solvents.

Acid Chlorides.—To the dried alkylthiobenzoic acid prepared as above, there was added the calculated quantity of phosphorus pentachloride. A vigorous reaction ensued, and after this subsided the mixture was refluxed for one-half hour to complete the reaction. The phosphorus oxychloride was removed by distillation under reduced pressure and the product distilled. The alkylthiobenzoyl chlorides distill without decomposition at pressures below 5 mm. but on standing for some days they decompose slowly. They are light yellow, viscous oils which turn darker on standing.

Alkamine Esters.—A dry ether solution of the acid chloride prepared as above was treated with a mixture of one molecular quantity of the desired amino alcohol and an excess of pyridine (about 2 moles). After refluxing for three hours the mixture was poured into a cold dilute solution of sodium carbonate and the basic ester extracted with ether. The ether was then dried over sodium sulfate and removed in the usual manner. The products were distilled under reduced pressure. Hydrochlorides of these esters were prepared by passing dry hydrogen chloride into a dry ether solution of the free base. The precipitated salt was filtered and recrystallized from dry acetone. The pure salts are white crystalline compounds, somewhat hygroscopic, especially if not quite pure. The lower members of the series are readily soluble in water; the solubility diminishes with increase in the size of the alkyl groups on sulfur and in the amino alcohol portion of the molecule.

All nitrogen analyses in Table II were done by the Kjeldahl method on a semimicro scale. Chlorine analyses are reported for those compounds not suited to this method.

Summary

1. A general method of preparation of a series of alkylthiobenzoic acids has been described.

2. A series of alkamine esters of these acids has been prepared by action of their acid chlorides on a series of amino alcohols.

3. Preliminary pharmacological investigation has shown these compounds to possess marked local anesthetic activity and low toxicity.

Sterols. LXXXV. Oxidation of Sarsasapogenin Acetate with Potassium Permanganate

BY RUSSELL E. MARKER AND EWALD ROHRMANN

Although the oxidative degradation of the side chain of the steroidal sapogenins using chromic anhydride has been rather extensively investigated, especially with sarsasapogenin, only a few studies have been reported concerning the effect of other oxidizing agents upon the side chain. Several investigators[1,2,3] have studied the action of nitric acid on the side chain and observed that this reagent tends to yield C_{22} lactones. Simpson and Jacobs[2] observed that the side chain of sarsasapogenin is inert to sodium hypobromite. We have substantiated this observation. This is in accordance with the apparent inertness of the side chain in alkaline solutions.

With the hope of gaining further information concerning the nature of the side chain, we have made a brief study of the action of potassium permanganate on sarsasapogenin acetate.

Sarsasapogenin acetate, when treated with potassium permanganate in acetic acid solution at 20°, is readily oxidized to yield the C_{22} keto acid,[4] the C_{22} lactone[5] and sarsasapogenoic acid. Almost identical results were obtained when the reaction was carried out at 50–70°. We find that sarsasapogenoic acid acetate and the C_{22} lactone acetate are relatively inert to potassium permanganate in acetic acid and appear to give none of the C_{22} keto acid. The C_{19} dibasic acid[6] was not encountered in the permanganate oxidation, indicating that permanganate under the conditions used has less tendency to further oxidize a ketonic carbonyl group with subsequent ring rupture than is the case with chromic anhydride.

In striking contrast to the action of permanganate on sarsasapogenin acetate in acid solution is the great stability of the sapogenin to this reagent in neutral or alkaline medium. Sarsasapogenin acetate was unaffected by heating with potassium permanganate in a pyridine–aqueous sodium carbonate medium. The substance also was unaffected by boiling with a pyridine solution of potassium permanganate. These results show further that the sapogenin side chain is non-reactive in alkaline or neutral medium in contrast to its reactivity in acidic medium.[7]

The results on the oxidation of sarsasapogenin acetate with permanganate raise some interesting questions relative to the mechanism of the side chain oxidation. The great ease of the formation of the C_{22} keto acid, the lactone and sarsasapogenoic acid and the fact that neither the lactone nor the C_{22} keto acid are formed from permanganate oxidation of sarsasapogenoic acid,[8] suggests that the oxidation may proceed through the formation of two intermediates. The extreme lability of these intermediates to further oxidation apparently results in carbon–carbon cleavages under relatively mild conditions.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part[9]

To a solution of 1 g. of sarsasapogenin acetate in 100 cc. of acetic acid at 20° was added 50 cc. of 1 *N* aqueous potassium permanganate solution. The temperature was maintained at 18 to 20° for fifteen hours, after which the mixture was diluted with water and extracted with ether. The ethereal extract was washed well with water and then with 3% sodium hydroxide solution.

Evaporation of the ether solution containing the neutral products gave a sirup which was hydrolyzed with hot ethanolic potassium hydroxide. Dilution of the resulting solution with water gave a slight precipitate which was taken up in ether and discarded. The aqueous alkaline solution was acidified with hydrochloric acid and the precipitated material taken up in ether. After sublimation in high vacuum at 160–180° the product was crystallized from ether–pentane to give white needles, m. p. 198–200°. This gave no depression with an authentic sample of sarsasapogenin lactone, m. p. 198.5–200°.

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.25; H, 9.7. Found: C, 76.2; H, 10.0.

The sodium hydroxide washings containing the acidic fraction from the oxidation was heated on the steam-bath for fifteen minutes to complete the hydrolysis. Acidification of the cooled solution with hydrochloric acid yielded a white solid which was taken up in ether and crystallized from this solvent to give 225 mg. of white crystals. The product was recrystallized from methanol to give a product,

(9) Micro-analyses by Dr. John R. Adams, Jr., of this Laboratory.

m. p. 286–288° dec. This gave no depression with a sample of the C_{22} keto acid previously described, m. p. 285–287°.

Anal. Calcd. for $C_{22}H_{34}O_4$: C, 72.9; H, 9.5. Found: C, 72.6; H, 9.7.

The filtrate remaining after removal of the above acid was evaporated and the sirup crystallized from aqueous acetone to give 150 mg. of white crystals, m. p. 185°. The product was recrystallized from ether–pentane as white plates, m. p. 186–188°. This gave no depression with an authentic sample of sarsasapogenoic acid, m. p. 187–189°.

Anal. Calcd. for $C_{27}H_{42}O_5$: C, 72.6; H, 9.5. Found: C, 72.4; H, 9.7.

Similar results were obtained when the oxidation was carried out at 50–70° for two hours.

A solution of sarsasapogenoic acid acetate in acetic acid when treated with aqueous potassium permanganate for three hours at 25° gave no evidence of oxidation. Some oxidation appeared to take place at 70–80° but the only product which could be isolated after mild alkaline hydrolysis was sarsasapogenoic acid.

A solution of sarsasapogenin lactone acetate in acetic acid when heated with aqueous potassium permanganate for one hour and then allowed to stand at 25° for eight hours yielded no acidic products and the lactone acetate was recovered essentially unchanged.

A solution of 1 g. of sarsasapogenin acetate in 50 cc. of pyridine was mixed with a solution of 1 g. of potassium permanganate and 2 g. of sodium carbonate in 30 cc. of water and 20 cc. of pyridine. After heating for one hour at 70° there was no evidence of oxidation. Sarsasapogenin acetate when refluxed for two hours with a pyridine solution of potassium permanganate showed no noticeable evidence of oxidation.

Summary

1. Sarsasapogenin acetate upon oxidation with potassium permanganate yields the C_{22} keto acid, the C_{22} lactone and sarsasapogenoic acid.

Sterols. LXXXVI. Desoxotestosterone and its Conversion to Testosterone

BY R. E. MARKER, E. L. WITTLE AND B. F. TULLAR

Various isomers and epimers of testosterone, such as $\Delta^{5,6}$-androstenol-17-one-3, dehydroandrosterone, *cis*-testosterone, etc., have been prepared in an attempt to obtain greater hormone activity or to learn more of the specificity of testosterone. In this connection it seemed of interest to prepare less oxygenated substances, such as desoxotestosterone and desoxoandrostenedione, which might be converted to testosterone or related substances by oxidation within the body and thus show hormone activity. That such an oxidation is conceivable might be expected from the ease of preparation of 7-keto-cholesteryl acetate from cholesteryl acetate in the laboratory and in the present work by a similar conversion of desoxotestosterone to testosterone. This paper describes the preparation of desoxotestosterone and related experiments.

The starting material, cholesterol, was converted to $\Delta^{5,6}$-cholestene by known processes[1] and after protection of the double bond by bromine the latter compound was oxidized by chromic acid to remove the side-chain. The $\Delta^{5,6}$-androstenone-17 so formed was isolated from the oxidation mixture as the insoluble semicarbazone and the carbonyl group was then regenerated by hydrolysis with dilute sulfuric acid. The insolubility of cholestene dibromide in acetic acid during the oxidation was overcome by the use of carbon tetrachloride and this procedure, together with the absence of substituents in ring A of the sterol molecule, facilitated the oxidation. Reduction of $\Delta^{5,6}$-androstenone-17 with sodium and alcohol gave the hydroxy compound (I) which was converted to the hydrochloride by treatment with dry hydrogen chloride in the cold. Regeneration of the double bond by refluxing this compound with alcoholic potassium acetate gave a mixture of desoxotestosterone (II) and the original $\Delta^{5,6}$-androstenol-17 (I), the former predominating. This mixture could not be separated by direct crystallization, recalling the preparation of the so-called "*allo*"-cholesterol, m. p. 117°,[2] by this method, a substance which was later shown to be a mixture of the true *allo*-cholesterol and cholesterol.[3]

The hydroxy compounds were separated by crystallization of the acetates prepared from this mixture and hydrolysis of the pure acetates. While these isomeric acetates show a depression in melting point when mixed, the hydroxy com-

(1) Mauthner, *Monatsh.*, **28**, 1113 (1907); **30**, 635 (1909).

pounds (I) and (II) do not. $\Delta^{4,5}$-Androstenone-17 was prepared from desoxotestosterone (II) by oxidation of the hydroxyl group to a carbonyl group while protecting the double bond with bromine. It was also prepared by isomerization of the double bond of $\Delta^{5,6}$-androstenone-17 with hydrogen chloride but the resulting mixture of isomers was difficult to separate by crystallization due to the low melting point and greater solubility. These isomeric carbonyl compounds are similar to the acetates in showing a depression in melting point when mixed.

While a double bond such as in neo-cholestene ($\Delta^{2,3}$-cholestene) is completely split into a dibasic acid by chromic acid oxidation, a more highly substituted bond as in cholesteryl acetate is attacked at the α-methylene position to give 7-keto compounds.[4] Thus $\Delta^{4,5}$-cholestene can be converted to cholestenone on oxidation.[5] An analogous oxidation was carried out with desoxotestosterone (II) after acetylation of the hydroxyl group and gave a mixture from which testosterone could be isolated readily. In a repetition of this oxidation, using $\Delta^{4,5}$-androstenol-17 acetate contaminated with some $\Delta^{5,6}$-androstenol-17 acetate, a small amount of an isomer of testosterone acetate was also obtained. The position of the carbonyl group was not definitely known but the compound was regarded as a 6 or 7 keto-androstenol-17 acetate. Since this work was completed an abstract appeared[6] in which 7-keto-$\Delta^{5,6}$-androstenol-17 acetate (IV) was prepared from $\Delta^{5,6}$-androstenol-17 acetate by an oxidation similar to those of the present work. The melting points recorded for 7-keto-$\Delta^{5,6}$-androstenol-17 and the acetate are identical with those of the compound obtained in this work and thus identify it as the 7-keto compound (IV). An oxidation of desoxotestosterone without the protection of the hydroxyl group, or of $\Delta^{4,5}$-androstenone-17, yielded androstenedione in an analogous manner.

Experimental

The Oxidation of $\Delta^{5,6}$-Cholestene Dibromide.—In a 12-liter flask was placed 230 g. of cholestene dibromide and 500 cc. of carbon tetrachloride. When solution was completed, 8 liters of glacial acetic acid was added and the solution was warmed to 45° with stirring. To this stirred solution at 48–50° was added dropwise a stirred solution of 320 g. of chromic anhydride in 350 cc. of water and 800 cc. of acetic acid, over a period of four to five hours. The solution was stirred at 50° for six hours and then cooled with cold water or ice to 30°. Ethyl alcohol (250 cc.) was then added slowly to this stirred solution in about one-half hour and the acetic acid was then removed under reduced pressure until the volume of the solution had been reduced about one-half. During the evaporation the temperature of the solution was kept at 40–45°. The solution was cooled slightly and the unchanged dibromide was filtered off and dried. The filtrate was then further concentrated under reduced pressure at 40° until only a small quantity of acetic acid remained. This residue was diluted with 4 l. of water and 2.5 l. of ether and stirred until all the material was in solution; the water layer was then separated and extracted with 2.5 l. of ether. The combined ether solutions were washed well with 2 l. of water, 3 l. of water containing 300 cc. of concd. hydrochloric acid, and twice with 1.5 l. of salt water, sufficient salt to cause rapid separation of the layers. The ether solution was evaporated to dryness, the last ether being taken off cautiously to avoid undue heat and one liter of acetic acid was then added to the residue with 5 g. of powdered zinc dust. The solution was stirred vigorously and heated to 95° on the steam-bath, when 45 g. of zinc was added to this stirred solution in small portions over a period of forty-five minutes. The solution now was filtered from the caked zinc and this was washed well with acetic acid; the acetic filtrate was evaporated to dryness on the steam-bath and the residue dissolved in two liters of ether. The ether solution was washed twice with water and the acid fraction extracted with 5% sodium hydroxide solution, until all acids were removed. The ether was evaporated to dryness and the residue steam distilled to remove the volatile products. The product was redissolved in ether and the water separated. The ether was evaporated to dryness and the residue dissolved in 200 cc. of 95% ethyl alcohol; 5 g. of semicarbazide hydrochloride and 6 g. of sodium acetate were added, the solution was refluxed on the steam-bath for four hours, and the alcohol concentrated to one-half volume. The

solution was cooled and diluted with 500 cc. of ether. After shaking the suspension for about one-half hour with cooling, 200 cc. of water was added, the solution was shaken and cooled in a salt-ice-bath and filtered with suction. The white solid was washed well with water and then ether. It was refluxed with 50 cc. of alcohol for one hour, cooled, filtered and air dried, yielding 5 g. of white, powdered semicarbazone, m. p. 285–287°.

Anal. Calcd. for $C_{20}H_{31}N_3O$: C, 72.8; H, 9.5. Found: C, 73.0; H, 9.6.

$\Delta^{5,6}$-Androstenone-17.—A solution of 6.7 g. of $\Delta^{5,6}$-androstenone-17 semicarbazone, m. p. 280–285°, in 500 cc. of 95% ethyl alcohol, 35 cc. of concentrated sulfuric acid and 35 cc. of water was refluxed for two and one-half hours on the steam-bath. The solution was diluted with water and the organic product was extracted with ether. The ether solution was washed well with water and sodium bicarbonate until alkaline and evaporated to dryness. The residue was purified by distillation at 80° in a molecular still and crystallization from dilute alcohol to yield 3 g. of $\Delta^{5,6}$-androstenone-17, m. p. 100–105°. This on further purification had m. p. 105–107°.

Anal. Calcd. for $C_{19}H_{28}O$: C, 83.7; H, 10.4. Found: C, 83.5; H, 10.4.

$\Delta^{5,6}$-Androstenol-17.—A solution of 1.7 g. of $\Delta^{5,6}$-androstenone-17 in 26 cc. of refluxing *n*-propyl alcohol was treated with 2.5 g. of sodium in small portions for one-half hour. The solution was poured into water and the white solid was filtered off. This was crystallized from methyl alcohol to yield 1.4 g. of $\Delta^{5,6}$-androstenol-17, m. p. 163–165°.

Anal. Calcd. for $C_{19}H_{30}O$: C, 83.1; H, 11.0. Found: C, 83.0; H, 11.3.

$\Delta^{5,6}$-Androstenol-17 Acetate.—$\Delta^{5,6}$-Androstenol-17 was refluxed for one hour with excess acetic anhydride and then the solution was evaporated to dryness under reduced pressure. The residue was dissolved in hot methyl alcohol and allowed to crystallize, m. p. 133–135°.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.4. Found: C, 80.0; H, 10.5.

Hydrolysis of this acetate gave the original hydroxy compound.

$\Delta^{4,5}$-Androstenol-17 Acetate.—A stream of dry hydrogen chloride was bubbled through a solution of 1 g. of $\Delta^{5,6}$-androstenol-17 in chloroform, cooled to 0°, for several hours. The cold solution was allowed to stand for several hours and then carefully evaporated to dryness under reduced pressure. The white solid hydrochloride was dissolved in ethyl alcohol and refluxed for six hours with 4 g. of fused potassium acetate. The solution was poured into water and the hydroxy compound was filtered off and dried. This product consisted of a mixture of $\Delta^{4,5}$- and $\Delta^{5,6}$-androstenols, m. p. 150–155°, which could not be separated by crystallization. The total product was converted to the acetate by refluxing it with acetic anhydride for two hours. Crystallization of the acetate effected a separation into a small amount of the less soluble $\Delta^{5,6}$-androstenol-17 acetate, m. p. 133–135°, and a larger amount of the $\Delta^{4,5}$-androstenol-17 acetate, m. p. 97–100°.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.4. Found: C, 79.2; H, 10.1.

A mixture of these two acetates gave a depression in melting points, 72–82°.

$\Delta^{4,5}$-Androstenol-17.—A solution of 500 mg. of $\Delta^{4,5}$-androstenol-17 acetate, m. p. 97–100°, in 25 cc. of methyl alcohol was refluxed for one-half hour with a solution of 1 g. of potassium hydroxide in 10 cc. of 50% methanol. The solution was then diluted with water and the product extracted with ether. The ether solution was washed with water and evaporated to dryness. The hydroxy compound was purified by crystallization from methanol, m. p. 146–149°.

Anal. Calcd. for $C_{19}H_{30}O$: C, 83.1; H, 11.0. Found: C, 83.0; H, 11.0.

This product gave no depression in melting point with the $\Delta^{5,6}$-androstenol-17, m. p. 163–165°, but a melting range between the two melting points.

$\Delta^{4,5}$-Androstenone-17.—A solution of 200 mg. of $\Delta^{4,5}$-androstenol-17 in 100 cc. of acetic acid was treated with bromine in acetic acid until saturated and then a solution of 300 mg. of chromic anhydride in 20 cc. of 90% acetic acid was added with shaking. The solution was allowed to stand at room temperature for one hour and then treated with 5 g. of zinc dust on the steam-bath. The solution was filtered, poured into water and the product extracted with ether. The ether solution was washed well with water and dilute alkali and evaporated to dryness. The residue was distilled in a molecular still under reduced pressure and then crystallized from dilute methyl alcohol, m. p. 78–80°.

Anal. Calcd. for $C_{19}H_{28}O$: C, 83.7; H, 10.4. Found: C, 83.4; H, 10.7.

This ketone gave a depression in melting point, 60–65°, when mixed with $\Delta^{5,6}$-androstenone-17.

Testosterone.—To a solution of 2 g. of $\Delta^{4,5}$-androstenol-17 acetate in 75 cc. of glacial acetic acid at 50° was added a solution of 2 g. of chromic anhydride in 25 cc. of 90% acetic acid over a period of one hour. The solution was poured into water and the product was extracted with ether. The ether solution was washed well with water and dilute sodium carbonate solution and then evaporated to dryness. The remaining oil, which showed a high androgenic activity, was treated with Girard's reagent to separate the ketonic fraction. The crude ketones were treated with warm alcoholic hydrochloric acid to remove the acetate radical and then distilled in a molecular still at 0.01 mm. pressure. Crystallization of the product so obtained from ether–pentane or dilute methyl alcohol gave testosterone, m. p. 148–150°, which gave no depression in melting point with the known product.

7-Keto-$\Delta^{5,6}$-androstenol-17 Acetate.—From the neutral product of an oxidation similar to that above using $\Delta^{4,5}$-androstenol-17 acetate contaminated with some $\Delta^{5,6}$-androstenol-17 acetate a small amount of a second crystalline acetate was obtained. It was purified by crystallization from methyl alcohol, in which it is not very soluble, m. p. 215–217°.

Anal. Calcd. for $C_{21}H_{30}O_3$: C, 76.29; H, 9.17. Found: C, 76.30; H, 9.31.

Hydrolysis of this acetate with alcoholic hydrogen

chloride at 80° for several hours yielded the corresponding hydroxy compound, m. p. 141.5–142.5°.

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.2; H, 9.68. Found: C, 79.7; H, 9.89.

This hydroxy ketone was further characterized by the orange colored 2,4-dinitrophenylhydrazone, m. p. 230–232°, which it formed.

Anal. Calcd. for $C_{25}H_{32}N_4O_5$: C, 64.0; H, 6.89. Found: C, 63.2; H, 6.99.

Androstenedione.—To a solution of 2.5 g. of $\Delta^{4,5}$-androstenol-17 in 200 cc. of acetic acid was added at 35–45° and with stirring a solution of 3 g. of chromic acid in 50 cc. of 90% acetic acid. The addition required one-half hour and the solution was then kept at 45° for one-half hour. The solution was poured into water and the product was extracted with ether. The ether solution was washed well with sodium carbonate solution and water and concentrated to a small volume. On cooling this solution for some time crystals formed and were filtered. They were recrystallized from ether to yield androstenedione, m. p. 168–170°, identical with the known product.

Summary

Cholestene dibromide was oxidized to $\Delta^{5,6}$-androstenone-17 which was converted to desoxotestosterone acetate and $\Delta^{4,5}$-androstenone-17. These new compounds on oxidation were converted to testosterone acetate and androstenedione. An isomeric 7-keto-$\Delta^{5,6}$-androstenol-17 was also obtained.

NOTES

An Attempted Synthesis of Morphenol

BY ALFRED BURGER AND S. AVAKIAN

A recent announcement by Gilman and Cheney[1] that these authors are studying the closure of a six-membered ring between positions 1 and 9 in dibenzofuran types prompts us to report unsuccessful attempts to synthesize methylmorphenol through 6-methoxy-9-hydroxy-phenanthrylene oxide and subsequent selective reduction of the 9-hydroxy group. 4-Methoxy-dibenzofuran-1-acetic acid was treated with (a) concentrated sulfuric acid, (b) 85% sulfuric acid, (c) anhydrous hydrogen fluoride at room temperature,[2] and (d) stannic chloride in the cold, and at the boiling point of the condensing agent. The acid chloride was treated with aluminum chloride in ice-cold benzene (e), and the acid bromide with aluminum chloride in nitrobenzene solution at room temperature (f), and with boiling stannic chloride (g), but none of these reactions yielded phenanthrene derivatives. It is possible that Gilman and his coworkers will achieve ring closure by using compounds containing strongly *para*-orienting groups in position 6 of the dibenzofuran system.[1]

Since the distance between sulfur and carbon atoms is greater than that between oxygen and carbon atoms, the positions 1 and 9 in dibenzothiophene should be closer to each other than in dibenzofuran, and ring closure should be easier in the dibenzothiophene series. In investigating the effect of substituting sulfur atoms for —CH=CH— groups in polycyclic aromatic systems we are now studying the intramolecular dehydration and decarboxylation of 1-carboxy-dibenzothiophene-9-acetic acid, which should lead to derivatives of 4,5-phenanthrylene sulfide, a possible isoester of pyrene.

Experimental

4-Methoxydibenzofuran-1-carboxylic acid[3] was converted into the chloride by the action of thionyl chloride. The acid chloride crystallized from benzene–ligroin as colorless needles, m. p. 162.5–163.5°. The yield was 93%.

Anal. Calcd. for $C_{14}H_9ClO_3$: C, 64.48; H, 3.48. Found: C, 64.22; H, 3.62.

The acid chloride was stirred with an ethereal solution of diazomethane for sixteen hours. The diazo ketone crystallized out. Recrystallization from benzene–petroleum ether rendered yellow crystals, m. p. 150–151° (dec.). The yield was 86%.

Anal. Calcd. for $C_{15}H_{11}N_2O_3$: C, 67.39; H, 4.15. Found: C, 67.50; H, 4.00.

The diazo ketone was treated with ammonium hydroxide in dioxane solution according to Arndt and Eistert.[3,4] 4-Methoxydibenzofuran-1-acetamide crystallized from ethanol as colorless needles, m. p. 203°. The yield was 75%.

Anal. Calcd. for $C_{15}H_{13}NO_3$: C, 70.56; H, 5.14. Found: C, 70.93; H, 5.34.

UNIVERSITY, VIRGINIA RECEIVED NOVEMBER 21, 1939

The Preparation of Acetyl Bromide*

BY THEODORE M. BURTON WITH ED. F. DEGERING

Acetyl bromide was prepared as early as 1863 by distilling it as formed from a mixture of glacial acetic acid, bromine and phosphorus.[1]

Investigations have shown, however, that acetyl bromide undergoes substitution with bromine to form bromo-acetyl bromides with decrease in the yield of acetyl bromide. Further improvements designed to increase the yield of acetyl bromide have also resulted in increased bromination in the nucleus.[2]

By the elimination of free bromine it was thought possible to increase the yield of acetyl bromide according to the reaction

$$3CH_3CO_2H + PBr_3 \longrightarrow 3CH_3COBr + P(OH)_3$$

Phosphorus tribromide (b. p. 169–170° at 740 mm.) can be prepared readily in 99.5% yield by slowly adding dried bromine from a dropping funnel into a slight excess of freshly washed and dried red phosphorus placed in a round-bottomed flask equipped with a mechanical stirrer and a reflux condenser.

The acetyl bromide was prepared by adding slowly through the dropping funnel, with stirring, a slight excess of 99.5% glacial acetic acid (3.075 moles of CH_3COOH per mole of phosphorus tribromide) to the cold phosphorus tribromide. The mixture separated into two layers which were distilled separately into a common receiver packed in ice. The crude acetyl bromide was rectified in a modified Podbielniak column to produce a water-white fraction boiling from 73–76° at 740 mm. The yield varied from 71.4 to 73.4% of the theoretical.

In other experiments the phosphorus tribromide was purified before use, but yields were increased only by a slight amount to 74.9% of the theoretical. In an effort to test the effect of temperature, the acetyl bromide was distilled from the reaction mixture at room temperature under reduced pressure. The product was collected in a gas bottle immersed in a bath cooled with solid carbon dioxide. No change, however, was observed in the yield. In all cases large amounts of hydrogen bromide were liberated so that the reaction probably does not proceed as indicated in the above equation.

It was found possible to prepare acetyl bromide without the formation of hydrogen bromide by adding phosphorus tribromide slowly, with stirring, to an excess of boiling acetic anhydride. The boiling point dropped as acetyl bromide was formed and when the addition of phosphorus tribromide was completed, the acetyl bromide was distilled from the mixture and rectified as before. The yield was 81.7% of the theoretical.

By using the readily prepared phosphorus tribromide, instead of free bromine with glacial acetic acid, substitution reactions are avoided and the yield of acetyl bromide can be increased to about 80% of the theoretical.

Hydrogen Bonds Involving the C–H Link. IX.[1] Nitriles and Dinitriles as Solvents for Hydrogen Containing Halogenated Methanes

BY M. J. COPLEY, G. F. ZELLHOEFER AND C. S. MARVEL

Nitriles should be capable of bonding with hydrogen in halogenated methanes of the CH_2X_2 and CHX_3 types and hence should be good solvents for these products. Work reported earlier[1] shows that valeronitrile and benzonitrile do dissolve methylene chloride and monochlorodifluoromethane in excess of the amount calculated from Raoult's law. It is interesting to find that the aliphatic dinitriles, succinonitrile and glutaronitrile, dissolve less than the calculated amounts of these two halogenated methanes. Adiponitrile dissolves almost the exact calculated amount and sebaconitrile takes up more than the calculated amount. These results are interesting when considered with the boiling points of the dinitriles.

TABLE I

SOLUBILITY OF HALOGENATED METHANES IN NITRILES

Theoretical solubility	Formula	B. p., °C.	CH_2Cl_2 G./g.	CH_2Cl_2 M. F., 0.311	$CHCl_2F$ G./g.	$CHCl_2F$ M. F., 0.381
Caprylonitrile	$CH_3(CH_2)_6CN$	198–200	0.462	0.405	0.875	0.420
Benzonitrile	C_6H_5CN	190.7	.463	.359	See Ref. 1	
Succinonitrile	$CN(CH_2)_2CN$	265–267	.199	.158	.231	.152
Glutaronitrile	$CN(CH_2)_3CN$	285–287	.319	.261	.457	.294
Adiponitrile	$CN(CH_2)_4CN$	295	.364	.316	.560	.428
Sebaconitrile	$CN(CH_2)_8CN$	199–200 (15 mm.)	.425	.435	.730	.522

It is obvious that succinonitrile and glutaronitrile are associated to a considerable extent; this undoubtedly is due to bonding between hydrogens of the methylene groups and the nitrogen atom of the nitrile groups. In succinonitrile the $-CH_2-$ group is alpha to one nitrile residue and beta to another and the cumulative effect is sufficient to give labile hydrogen atoms. In glutaronitrile the further separation of the nitrile groups makes their cumulative effect less on each $-CH_2-$ group. In adiponitrile this effect is fairly well overcome by the distance between the nitrile groups. In sebaconitrile the solubility goes above the calculated value but not as much as might have been expected from the solubility of the mononitriles. This evidence for hydrogen bond association in the dinitriles is of interest in view of the recent estimation that hydrogen cyanide is similarly associated to the extent of 3% at the boiling point.[2]

The solubility determinations were made at 32.2° as described earlier[3] and are reported in the table.

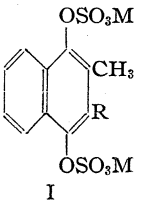
WILLIAMS OIL-O-MATIC HEATING CORPORATION, BLOOMINGTON, ILLINOIS RECEIVED DECEMBER 1, 1939

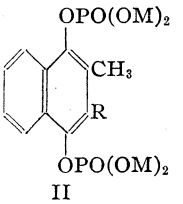
Water-Soluble Antihemorrhagic Esters

BY LOUIS F. FIESER AND EDWARD M. FRY

As a possible means of providing antihemorrhagic compounds which can be administered parenterally in a small volume of aqueous solution, we have prepared a series of water-soluble sulfuric and phosphoric acid ester derivatives of vitamin K_1 and of other quinones of established vitamin K activity. In chick assays conducted by Dr. W. L. Sampson potassium vitamin K_1 hydroquinone disulfate (I, R = phytyl, M = K) was found inactive at a dosage of 500 γ, an observation which perhaps finds a counterpart in the great loss of biological activity attending the conversion of oestrone into oestrone sulfate.[1] Similarly sodium 2,3-dimethyl-1,4-naphthohydroquinone disulfate was inactive at the same high dosage, in contrast to the corresponding quinone which is active at 50 γ. On the other hand, vitamin K_1 hydroquinone diphosphoric acid II (R = phytyl, M = H) shows activity at dosages down to 25 γ, but not at 10 γ, and thus does not fall greatly short of vitamin K_1, which gives a response at 1.5–2 γ by the same procedure. Still more potent is the sodium salt of 2-methyl-1,4-naphthohydroquinone disulfuric acid (I, R = H, M = Na), which shows antihemorrhagic activity at a level of 2 γ (assays at lower dosages are still to be made). The substance crystallizes as a dihydrate, and if the administered material undergoes hydrolysis it could give rise to only 52% of its weight of 2-methyl-1,4-naphthoquinone.



I



II

Of the water-soluble substances previously suggested for use in vitamin K therapy, phthiocol[2] suffers from being only weakly active, and free naphthohydroquinone and aminonaphthol derivatives[3] are highly sensitive to oxidation. The above active ester derivatives are colorless solids which are stable in aqueous solution and not sensitive to air or light. Furthermore, 2-methyl-3-phytyl-1,4-naphthohydroquinone diphosphoric acid can be described as a water-soluble form of vitamin K_1.

In a clinical trial conducted by Drs. H. A. Frank, A. Hurwitz and A. M. Seligman at the

(1) Butenandt and Hofstetter, *Z. physiol. Chem.*, **259**, 222 (1939).
(2) Almquist and Klose, THIS JOURNAL, **61**, 1923 (1939).
(3) Doisy, *et al.*, *ibid.*, **61**, 1932, 2563 (1939).

Beth Israel Hospital, Boston, sodium 2-methyl-1,4-naphthohydroquinone disulfate was given to a patient having a complete biliary fistula. A solution of 10 mg. of the salt in 10 cc. of 0.9% salt solution remained clear after autoclaving at 250°F. and when given intravenously reduced the prothrombin clotting time from 54 seconds to 28.5 seconds in four hours; the lowest level reached was 25 seconds in about twelve hours (normal, 15 seconds).

Experimental Part[4]

Potassium Vitamin K_1 Hydroquinone Disulfate.—A cooled suspension prepared by slowly adding 0.6 cc. of chlorosulfonic acid to 2 cc. of pyridine and 5 cc. of carbon tetrachloride was treated with 0.48 g. of vitamin K_1 hydroquinone. On manipulating the mixture with a stirring rod and boiling for ten minutes, the pyridine salt separated as a viscous mass which went to a sticky solid on cooling and diluting with ether. The liquor and washings afforded 0.17 g. of oil giving no color test with alcoholic alkali. The solid was treated while cooling with sufficient 10 *N* sodium hydroxide to produce a red color, ether was added to dissolve the liberated pyridine, and the sodium disulfate ester was separated by centrifugation as a dark red oil. This was stirred with excess 25% absolute alcoholic potassium hydroxide to effect conversion to the potassium salt, which separated as a light brown crystalline solid after dilution with absolute alcohol. Crystallization from 95% alcohol (Norite) gave colorless plates. The salt gives a clear solution in water. The sample was dried at 80° and 18 mm.

Anal. Calcd. for $C_{31}H_{46}O_8S_2K_2$: C, 54.04; H, 6.73; K, 11.35. Found: C, 54.54; H, 6.71; K, 10.67.

Sodium 2-Methyl-1,4-naphthohydroquinone Disulfate.—A mixture of 0.5 g. of 2-methyl-1,4-naphthohydroquinone with a cooled suspension from 1 cc. of pyridine, 10 cc. of carbon tetrachloride and 0.5 cc. of chlorosulfonic acid was heated for ten minutes on the steam-bath, cooled, and the solvent decanted from the oily yellow pyridine salt. This was treated with a slight excess of 10 *N* alkali, the mixture was extracted with ether, and the residual red oil taken up in a little hot water. Alcohol added in portions precipitated first inorganic material, which was removed, and then the ester salt as tan crystals (0.58 g., 0.27 g. more from the mother liquor). Crystallization from water gave 0.4 g. of colorless product free from inorganic salts, and this was further purified by dissolving it in water and adding alcohol. The air dried material proved to be a dihydrate.

Anal. Calcd. for $C_{11}H_8O_8S_2Na_2 \cdot 2H_2O$: C, 31.89; H, 2.92; Na, 11.10; H_2O, 8.70. Found: C, 31.82; H, 3.20; Na, 11.21; H_2O, 8.29.

Sodium 2,3-dimethyl-1,4-naphthohydroquinone disulfate was prepared as above from 0.5 g. of the hydroquinone. The pyridine salt was obtained on cooling as a highly hygroscopic solid. The sodium salt was crystallized once from water (0.8 g.) and then from water diluted with alcohol, giving colorless plates (air dried).

(4) Microanalyses by Lyon Southworth.

Anal. Calcd. for $C_{12}H_{10}O_8S_2Na_2 \cdot 2H_2O$: C, 33.64; H, 3.29; Na, 10.74; H_2O, 8.41. Found: C, 33.47; H, 3.49; Na, 10.97; H_2O, 9.00.

Sodium 2-Methyl-1,4-naphthohydroquinone Diphosphate (Normal Salt; II, M = Na).—A solution of 0.3 g. of the hydroquinone in 0.8 cc. of pyridine was added by drops with ice cooling to a suspension prepared by adding 0.5 cc. of phosphorus oxychloride with cooling to 1 cc. of pyridine. At the end the mixture was allowed to warm up until the exothermic reaction was over. The white suspension was then treated with 6 cc. of water, added cautiously at first with ice cooling and later heating to dissolve the product. Solid sodium carbonate was added until alkaline to litmus and the pyridine layer which separated was removed. The solution of sodium salts was stirred with absolute alcohol and the solvent decanted, leaving an aqueous solution of greatly diminished volume. The remainder of the water can be removed by stirring either with fresh portions of alcohol or with smaller portions of pyridine, leaving the sodium salt as a gum. Inorganic salts can be largely eliminated by dissolving in the least amount of hot water, cooling in ice, centrifuging and decanting from the crystallizate. Alternately, the gum is treated in the cold with methanol and enough water to bring the oily salt into solution; by adjusting the proportions inorganic salts are left undissolved and are removed by filtration. For crystallization of the product such a methanol–water filtrate was concentrated and cooled, oily salt was brought into solution with a little water, pyridine was added by drops until the solution became cloudy, and on warming on the steam-bath the sodium diphosphate separated as an oil which then crystallized (it is less soluble hot than cold). The colorless crystals were washed with methanol and dried; yield 0.68 g. The substance is very hygroscopic and liquefies on exposure to moist air. The sample for analysis was dried at 150° and 2 mm.

Anal. Calcd. for $C_{11}H_8O_8P_2Na_4 \cdot 2H_2O$: C, 28.83; H, 2.64. Found: C, 28.36; H, 2.21.

Vitamin K_1 Hydroquinone Diphosphoric Acid.—A solution of 0.48 g. of vitamin K_1 hydroquinone in 10 cc. of pyridine was cooled and added to an iced mixture of 1 cc. of phosphorus oxychloride and 5 cc. of pyridine (temperature rise to 15°). The solvent was largely removed in vacuum at 45° and the residue treated with 10 cc. of water and extracted with ether. The ethereal extract was shaken with a slight excess of 1 *N* sodium hydroxide and the alkaline layer separated and acidified with hydrochloric acid, when the diphosphoric acid precipitated. Collected by extraction with ether, the substance was obtained as a light tan amorphous solid (0.4 g.). Repetition of the process of purification by extraction from ether with alkali and precipitation with acid gave a somewhat waxy, nearly colorless solid. It gives a gel with a small amount of water and a clear solution with an adequate quantity. The sample was dried at 100° and 1 mm. (oil).

Anal. Calcd. for $C_{31}H_{50}O_8P_2$: C, 60.76; H, 8.23. Found: C, 60.92; H, 8.20.

The Preparation of Pure Stearic Acid

BY J. P. KASS AND L. S. KEYSER

The preparation of pure stearic acid is complicated by the difficulty of removing final traces of the contaminating palmitic acid, since the separation by physical means is tedious and never unquestionably complete. In a recent study, Guy and Smith[1] considered it necessary to subject "pure" stearic acid to twenty-four recrystallizations from various solvents and to three fractional distillations to obtain a 3.8% yield of final product, m. p. 69.62°, the homogeneity of which was still not beyond question. During the course of our investigations of the chemistry of the fatty acids, we have found it convenient to prepare pure stearic acid totally free from palmitic acid by the catalytic reduction of the readily purifiable octadecenoic acids. Elaidic acid,[2] and especially the α- or β-eleostearic acids,[3] are easily available and may be brought to a high state of purity by a few recrystallizations of the free acids, while pure linoleic acid[4] of theoretical iodine value may be obtained from the crystallizable α-tetrabromostearic acid.[5] Quantitative reduction was effected by shaking the acetic acid solutions of the unsaturated acids for three hours in an atmosphere of hydrogen at room temperature and 45 lb. (3 atm.) pressure in the presence of platinum oxide catalyst. One recrystallization of the product from acetic acid or 85% alcohol yielded a stearic acid melting in a capillary tube at 69.6–70.2° (corr.) and dissolving in concentrated sulfuric acid at 70° without discoloration. A similar procedure was used by Francis, Collins and Piper[6] for the preparation of behenic acid from erucic acid.

The Preparation of *m*-Halogenophenols

BY HERBERT H. HODGSON

The author's attention has been drawn to a recent paper by S. Natelson and S. P. Gottfried[1] in which the preparation of *m*-bromophenol is described in language which implies originality, *viz.*: "Since this paper[1] was written, Smith and Haller[2] have published a method for obtaining *m*-bromophenol in good yield .... Their over-all yield is not as good as that obtained from the procedure described herein[1] nor is their procedure as simple."

It is of interest to note that from January to May of this present year (1939) the preparation of *m*-bromophenol has been described no fewer than three times,[1,2,3] and in only one of them[3] has the work of the present writer been mentioned.

The method apparently claimed as new by Natelson and Gottfried[1] was patented by the author[4] in 1923, and C. F. Koelsch[3] has stated recently that this patent of seventeen years ago is substantially true and that yields of 75–80% may be obtained thereby. Similar confirmations of the patent claim, however, have already been made to the writer by numerous chemists during the past seventeen years, who have found yields of the order of 80–90%.

Yields of over 90% of *m*-chlorophenol from *m*-chloroaniline have been obtained by the patented method[4] in large scale (kilo.) preparations. Subsequent work proved that excellent yields of *m*-fluorophenol[5] could also be obtained from *m*-fluoroaniline, while even the non-steam volatile *m*-hydroxybenzaldehyde[6] was prepared in excellent yield by the process.

The patented method[4] is substantially the same in detail as that described at length by Koelsch,[3] and is probably the best process yet devised for the preparation of steam-volatile phenols, since it is of universal application.

The Freezing Points of Pure High Polymers

BY EDWIN L. LOVELL AND HAROLD HIBBERT

In a recent publication[1] it was shown that the setting points of the polymer-homologous series of polyoxyethylene glycols $HO(CH_2CH_2O)_pH$ followed very exactly the *empirical* equation

$$t_s = P/(a + bP) \qquad (1)$$

(1) Lovell and Hibbert, THIS JOURNAL, **61**, 1916 (1939).

where t_s is the setting point in °C., P the number of repeating units in the chain, and a and b constants. The experimental data covered molecules with from 54 to 558 atoms in the straight chain, a much wider range than has previously been available for pure compounds. At that time it was duly noted that this homologous series did *not* follow the logarithmic freezing point equation deduced from what might be termed "kinetic" considerations by Austin[2] but the authors could offer no explanation for the form of the equation actually obtained.

Very recently, however, a publication has appeared by Huggins[3] concerning the properties of long-chain compounds; it includes the derivation on purely thermodynamic grounds of a general law relating the freezing points in a polymer-homologous series to the number of atoms in the chain. This equation is

$$T_f = (A + Bn)/(C + Dn) \qquad (2)$$

where T_f is the absolute freezing point, n the number of atoms in the straight chain and the other symbols are constants. Inspection of the empirical relationship (1), and substituting for t_s its equivalent $T_f - 273$, reveals that this equation is identical in form with that of Huggins. This provides excellent support for the latter over a very wide range of chain lengths, many times greater than is possible in the n-alkane series, agreement for which (up to C_{70}) is shown by the previous work of Garner[4] and co-workers, who also have attempted to justify their results theoretically.[5] In both series the relation fails for chains of less than 20 atoms.

The agreement thus found between Huggins' thermodynamically derived freezing point equation and the freezing point data for the higher polyoxyethylene glycols is important additional evidence for the purity (uniformity of chain length) of this series of synthetic polymers.

The Conversion of Chlorophyll to Pheophytin

BY G. MACKINNEY AND M. A. JOSLYN

In a previous paper[1] we presented evidence showing the rate of conversion of chlorophyll to pheophytin in 90% acetone was of first order with respect to acid concentration (normality) and possibly of second order with respect to chlorophyll. It was necessary to consider the two chlorophylls as a single component because we did not have the individual components separated. Evidence favored the assumption that the reaction was chiefly a conversion of chlorophyll a to pheophytin a, because the reaction was rarely carried to more than 80% completion. We have now separated sufficient quantities of chlorophylls a and b[2] to repeat previous experiments. Measurements were made at 5350 Å. for chlorophyll a, at 5280 Å. for chlorophyll b, where the respective pheophytin maxima occur.

Results are condensed in Table I. The first and second order rate constants, k_1 and k_2, have been calculated, and each value represents the average of 8–13 determinations over periods of time varying from two minutes to seven hours. The temperature was 28 ± 0.5°. The column Δ indicates the mean deviation of the arithmetic mean of the individual determinations. The values of k/N, whether k_1 or k_2 is taken, clearly show the reaction is of first order with respect to acid concentration, confirming our earlier work.

TABLE I

RATE CONSTANTS FOR CHLOROPHYLL, IN 90% ACETONE, WITH OXALIC ACID

Normality	k_1	Δ	k_2	Δ
	Chlorophyll *a*			
0.002	0.211	0.046	0.0069	0.0010
.004	.539	.072	.0189	.0099
.007	.907	.088	.0332	.0114
.01	1.39	.170	.0562	.0301
	Chlorophyll *b*			
0.01	0.148	0.021	0.0040	0.0007
.02	.328	.126	.0088	.0022
.05	.804	.180	.0271	.0049
.10	1.69	.216	.0580	.0148

We were previously at some loss to decide the order with respect to chlorophyll, because in most cases there was an apparent falling off in the calculated constants with time. The k_2 constants for oxalic acid were reasonably constant which led us to suggest a second order for chlorophyll. We knew only that pheophytin b contributed to the absorption at 5350 Å., but we could not then evaluate the extent of its absorption. Because the a and b mixture used was not highly purified, extensive recalculations are not deemed profit-

(1) Mackinney and Joslyn, THIS JOURNAL, **60**, 1132 (1938).
(2) Details will be published shortly.

able. Assuming, however, that with 0.002 N oxalic acid, for periods up to five hours, there is no conversion of chlorophyll b, we have recalculated some values on the basis of a 25% inert ingredient, *i. e.*, the chlorophyll b. Under these conditions, the oxalic results fall in line with the others, and we are given little preference between k_1 and k_2 for chlorophyll.

A limitation must be remembered, that with the visual B and L spectrophotometer, we cannot vary our chlorophyll concentrations within a wider range than 3 to 5 times without loss of accuracy. Initial concentrations of chlorophyll in the present experiments were 0.5×10^{-4} M, and the acid varied from 0.01 to 0.002 N for chlorophyll a and from 0.10 to 0.01 N for chlorophyll b.

The present values show no falling off with time, indicating there may be an error inherent in our earlier calculations as there could be no accurate compensation for the effect of chlorophyll b. The k_1/N values are in both cases more constant than those for k_2/N, and in two of the acid levels for chlorophyll b, and in three for a, the deviations are smaller for k_1 than for k_2. Furthermore, there is very little trend in the k_1 values, while in some cases there is a definite upward trend for k_2. We are therefore inclined to believe that the reaction is of first order with respect to both chlorophyll components.

An explanation is required for the fact that with 0.01 N oxalic acid, k_1/N for chlorophyll a has a value of 139, for chlorophyll b, 14.8. If the reactions are correctly interpreted on the basis of first order in both cases, the question arises as to the cause of this difference. We hope to throw further light on this in studies on the removal of magnesium from allomerized components, phytol-free derivatives, and the heats of activation.

Conclusions.—For the pure a and b chlorophyll components, it is confirmed that the reaction involving loss of magnesium is of first order with respect to acid. It is probably of the same order with respect to chlorophyll. The two hydrogens replacing the magnesium must therefore enter at different rates, and in all probability the entrance of the first hydrogen is the rate-governing step. This would materially weaken the remaining magnesium–nitrogen bond, in which respect it would then no longer be equivalent to the initial condition, presumably highly covalent in character.

The chlorophyll a reacts from seven to nine times more rapidly than chlorophyll b.

The Synthesis of Amino Acids from Benzoylaminomalonic Ester

BY E. P. PAINTER

The use of benzoylaminodiethyl malonate in the synthesis of amino acids as recently reported by Redemann and Dunn[1] has been found to be superior in many respects to the malonic ester and phthalimido malonic ester methods.[2]

The ester alkylates in absolute alcohol with all alkyl halides tried. The ester or derivatives is readily hydrolyzed with constant boiling hydrochloric or hydrobromic acid. Glycine can be isolated in 85% yields by hydrolyzing the free ester with concentrated hydrobromic acid. To the list of amino acids prepared in good yields by Redemann and Dunn by the use of this reagent may be added norleucine, α-amino-γ-phenoxy-*n*-butyric acid and the lactone of α-amino-γ-hydroxy-*n*-butyric acid. These have been isolated after hydrolysis of the ester alkylated with *n*-butyl bromide, β-bromoethyl phenyl ether and ethylene bromohydrin.

In an attempt to prepare β- and γ-halogen amino acids benzoylaminomalonic ester has been alkylated with methylene dibromide, ethylene bromide and ethylene chloride. The products formed contain some halogen but always less than the theoretical amount and the desired amino acids have not been isolated after hydrolysis.

The aminomalonic ester was prepared by the method of Cerchez,[3] excepting the reduction was carried out in alkaline solution with aluminum amalgam made from aluminum turnings and the amino ester benzoylated in a suspension of sodium carbonate in ether saturated with water. By carrying the reaction straight through to the benzoyl compound without isolating the intermediary products, 40–45% over-all yields may be expected. Redemann and Dunn were able to obtain slightly better yields of benzoylaminomalonic ester, but their procedure is more expensive and not as convenient for many laboratories.

The use of anhydrous reagents in alkylations should be emphasized.

(1) Redemann and Dunn, *J. Biol. Chem.*, **130**, 341–348 (1939).
(2) Painter, Ph.D. Thesis, U. of Minnesota, 1939.
(3) Cerchez, *Bull. soc. chim.*, [4] **47**, 1281 (1930).

From the author's experience and the paper by Redemann and Dunn it appears that benzoylaminomalonic ester should find general use in the synthesis of α-amino acids.

The 3-Nitrophthalates of the Mono Ethers of Ethylene and Diethylene Glycol

BY A. J. VERAGUTH[1] AND HARVEY DIEHL

The problem of identifying the monoethyl ether of ethylene glycol (Cellosolve) arose here recently and was successfully solved by the use of the 3-nitrophthalic anhydride reagent proposed by Nicolet and Sachs[2] for the identification of alcohols. The work has now been extended to the other commercially available monoethers of ethylene glycol ("Cellosolve" series), and of diethylene glycol ("Carbitol" series).

The ethers were obtained from the Carbide and Carbon Chemicals Corporation, and were purified by fractional distillation. A constant boiling fraction was taken, the boiling points and refractive indices checking with recorded values.

The procedure followed for the preparation of the acid 3-nitrophthalate esters of these ether alcohols was essentially that recommended by Nicolet and Sachs.

The anhydride was heated with an excess of the ether alcohol at the boiling point of the latter until all of the anhydride had dissolved and then for fifteen minutes longer. In the cases of those liquids having boiling points above 150°, toluene was added to avoid higher temperatures which cause decomposition of the esters formed; the toluene was then removed by distillation under reduced pressure. The oily layer of ester was then extracted with hot water to remove the unreacted reagents. It was then treated with a hot mixture of water and the least amount of ethyl alcohol necessary to effect complete solution. This solution was allowed to cool slowly with frequent scratching to induce crystallization. The initial crystallization was generally very slow, periods of standing for several days in a refrigerator sometimes being required. Recrystallization was continued until a constant melting point was obtained, generally three to five recrystallizations. Toluene was found to be a better solvent for recrystallization of the monophenyl ether of ethylene glycol than the water–alcohol mixtures.

Molecular weights of the derivatives were determined by titrating, with standard alkali, a solution containing 0.5 g. of the ester in 50% alcohol, using phenolphthalein as indicator. The melting points were taken with standard Anschütz thermometers in a mechanically stirred bath.

White crystalline derivatives were obtained from the monomethyl, monoethyl, monobutyl and monophenyl ethers of ethylene glycol and from the monomethyl ether of diethylene glycol but not from the monobenzyl ether of ethylene glycol or from the monoethyl or monobutyl ethers of diethylene glycol.

The 3-nitrophthalates obtained from the monoethyl ether of ethylene glycol and from the monomethyl ether of diethylene glycol crystallize with one molecule of water. Their water of crystallization was determined by drying a weighed amount of the ester in a vacuum at 100° over anhydrous magnesium perchlorate (Fischer drying pistol). The percentages of water found were 5.89 and 5.83, the calculated values being 5.98 and 5.43, respectively.

TABLE I

3-NITROPHTHALATES OF MONO ALKYL ETHERS OF ETHYLENE GLYCOL

Alkyl	3-Nitrophalates M. P., °C.	Mol. wt. Calcd.	Found
Methyl	128.4–129.0	269	268 ± 1
Ethyl	118.0–118.6	283	284 ± 3
Ethyl (monohydrate)	94.2–94.5	301	302 ± 4
Butyl	121.0–120.6	311	311 ± 1
Phenyl	112.0–113.0	331	330 ± 2

The 3-nitrophthalate monohydrate of the monomethyl ether of diethylene glycol was also a white crystalline solid and melted at 87–90°. The anhydrous 3-nitrophthalate melted at 91.4–92.2° and was found to have a molecular weight of 313 ± 1, as compared with the calculated value of 313. All attempts to induce the liquid reaction products from the monobenzyl ether of ethylene glycol ("Benzyl Cellosolve") and the monoethyl and monobutyl ethers of diethylene glycol ("Carbitol" and "Butyl Carbitol," respectively) to crystallize failed.

COMMUNICATION TO THE EDITOR

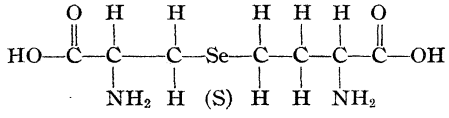
ISOLATION OF A CRYSTALLINE SELENIUM-CONTAINING ORGANIC COMPOUND FROM PLANT MATERIAL

Sir:

Horn, Nelson and Jones[1] and Franke and associates,[2,3] in connection with their study of the diseases of farm animals apparently caused by selenium in grain, have shown definitely that the selenium is present in an organic form intimately associated or combined with protein. It is important to ascertain the chemical nature of this organic selenium compound and to determine the manner in which it is tied up in the plant, and for several years we have been attempting to isolate it. We have now succeeded, after many failures, in obtaining a crystalline selenium compound having the properties of an amino acid. This substance has been obtained repeatedly from different lots of the same source material in the form of well-defined, elongated prisms. Analyses show it to have the percentage composition: C, 33.38; H, 5.83; N, 10.98; Se, 20.62; S, 4.20; O, 24.99 (by difference).

These analytical results correspond to the empirical formula $C_{21}H_{44}N_6Se_2SO_{12}$. The compound gives a strong ninhydrin reaction, and all of its nitrogen is in the amino form. Its equivalent weight is 130.5. It decomposes at 263–265°. It is insoluble in alcohol and organic solvents, and is difficultly soluble in water. The selenium in the compound is notably stable.

The fact that all the nitrogen is in the amino form suggests a compound of a simple type. By substituting selenium for sulfur, the simple formula, $C_7H_{14}N_2O_4Se$, is derived, which suggests that we may be dealing with an isomorphous combination of two compounds, $C_7H_{14}N_2O_4Se$ and $C_7H_{14}N_2O_4S$, in the ratio of 2 to 1, respectively. Such an assumption is in agreement with the structural formula



Whatever its structure, it appears that we are dealing with a naturally-occurring new type of amino acid of unusual scientific and economic interest.

This report is wholly preliminary. Further work is in progress and the results will be published later in greater detail.

NEW BOOKS

Calculations of Quantitative Analysis. By CARL A. ENGELDER, Ph.D., Professor of Analytical Chemistry, University of Pittsburgh. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1939. viii + 174 pp. 15.5 × 23.5 cm. Price, $2.00.

This book contains three hundred problems divided into fifteen groups of twenty problems each. The odd-numbered problems are provided with answers and are intended for home assignments. The even-numbered problems are without answers and are intended for class work, quizzes, or examinations. At the beginning of each section is a short discussion of theory, followed by several examples of typical problems and their solutions. At the end of the book are several tables useful to the student of analytical chemistry.

This book should find ready use in many courses where sufficient emphasis is placed on the solving of problems as a means of learning stoichiometry and other phases of analytical chemistry.

CHESTER M. ALTER

A History of Chemistry. By F. J. MOORE, Ph.D., Late Professor of Organic Chemistry in Massachusetts Institute of Technology. Revision prepared by WILLIAM T. HALL, Associate Professor of Analytical Chemistry in Massachusetts Institute of Technology. Third edition. McGraw-Hill Book Company, Inc., 330 West 42nd Street, New York, N. Y., 1939. xxi + 447 pp. Illustrated. 14.5 × 21 cm. Price, $3.00.

This latest edition of Professor Moore's book is a careful attempt to retain the general characteristics of the earlier editions and at the same time incorporate into the volume recent advances in chemistry, many more biographical notes and valuable additions to the older periods which had been somewhat neglected. In the main part of the book, there are one hundred and twenty more pages printed on thinner paper, giving no increased bulk to handle.

There are but few adverse criticisms. A number of corrections suggested by Professor Oesper in his review of the second edition unfortunately have not been made.[1] In a publication containing so many facts it is hard to avoid a few errors such as the date when Madam Curie was awarded the Nobel prize (p. 355) and the omission of Lomonosov in the index (p. 440). The biographical notes which have been inserted in the text occasionally make the account seem somewhat disconnected but they serve a purpose that is exceedingly important. The bibliographical material includes the more important recent books on history of chemistry, yet all but a few of the references in journals such as *Isis* and *The Journal of Chemical Education* are omitted.

The chapter headings are practically the same except that the concluding one is now a single long chapter combining the three preceding the last of the second edition. This is a wise move as the topics of inorganic chemistry, physical chemistry and radioactivity are inseparably connected. The scattering of the final chapter on Chemistry in the United States with many additions through the entire text where the information is pertinent, not only eliminates the former sense of isolation which was given to American Chemistry but also presents the history too often ignored by foreign writers. The introduction and history of the growth of organic chemistry is more logical and greatly improved. Numerous additions to the biographical material, including the brief life history and contributions of famous living chemists, particularly Nobel prize winners, are a distinct asset since the work of living chemists will be a background for the future. Few histories discuss the work of contemporary chemists. Therefore this book will remain up to date for a longer time. The author also indicates that it is increasingly difficult to keep up with all fields of chemistry so that this biographical material demonstrates that the science is progressing at a rate never before equalled.

There are quite a number of new illustrations and some of the former dubious and less important ones have been eliminated. Instead of feeling that the book is a trifle too brief to be used as an essential purchase by students of the history of chemistry, the new edition contains enough material to make the reviewer feel that it gives a splendid foundation from which to start toward further reading. Both the author and publisher are to be congratulated upon producing so fine a revision without increasing the price.

VIRGINIA BARTOW

(1) R. E. Oesper, *J. Chem. Education*, **8**, 2101–2102 (1931).

Semimicro Qualitative Analysis. By ARTHUR R. MIDDLETON, Ph.D., Professor of Inorganic Chemistry, Purdue University, and JOHN W. WILLARD, B.S. Prentice-Hall, Inc., 70 Fifth Avenue, New York, N. Y., 1939. xi + 446 pp. 7 figs. 16 × 23.5 cm. Price, $3.50.

The text outlines a course of qualitative analysis which can be covered in nine to six hours per week for one semester. The preliminary study of the behavior of the common ions, practice in the solution of solid materials and the removal of interfering ions, analysis of seven practice unknowns (not graded) and of eight unknowns require 32 laboratory periods. At Purdue, an additional 14 laboratory periods are devoted to the analysis of salt mixtures and alloys.

A special section gives a detailed description of the semimicro technique. The working directions are presented in detail and the methods have been tested with large classes. The separations are performed in centrifuge cones and the volumes of precipitates are made the basis for the estimation of quantities. An interesting rigid scheme of elimination is followed in the detection of anions. Only a few organic reagents are used.

The theoretical part, which occupies nearly half of the volume, contains much useful information. The sections on the use of units in chemical calculation and on the precipitation of metallic sulfides are of special interest, and the sharp distinction between homogeneous and heterogeneous equilibria is a commendable feature. While the advisability of the introduction of the definition of acid and base in accordance with the conceptions of Hantzsch may be questioned and the substitution of hydronium ion for hydrogen ion is objectionable as long as the state of hydration of the other ions is not indicated in the equations, the animated presentation recommends the book, which rates among the best of its kind.

A. A. BENEDETTI-PICHLER

Inorganic Syntheses. Volume I. By HAROLD SIMMONS BOOTH, Western Reserve University, Editor-in-Chief, and L. F. AUDRIETH, JOHN C. BAILAR, JR., W. CONARD FERNELIUS, WARREN C. JOHNSON and RAYMOND E. KIRK. McGraw-Hill Book Company, Inc., 330 West 42nd Street, New York, N. Y., 1939. xiii + 197 pp. 31 figs. 16 × 23.5 cm. Price, $3.00.

The dedication in the fly leaf of Volume I of Inorganic Syntheses reads as follows:

> To
>
> the countless unknown but valiant soldiers of science upon whose labors Inorganic Syntheses are based, this series of volumes is dedicated in the hope that it will ease the toil of future legions.

This dedication helps one to realize the amount of labor and enthusiasm which has preceded the compilation of this

book, and the unselfish devotion of the editors, the contributors, and those who have verified the procedures of the contributors.

In this first volume of the series appear sixty-six procedures for the preparation of a diverse assortment of inorganic substances. The arrangement is in Chapters I to VIII for the Groups of the Periodic Arrangement with Chapter IX reserved for materials or techniques of value to chemists. In this volume the only contribution to Chapter IX is No. 67, A Laboratory Cement. Potassium Fluoborate is placed in Chapter III, Mono-chloramine in Chapter V and Silicomolybdic Acid in Chapter VI.

The appearance of the contributions appears to follow their availability rather than any systematic plan arranged by the editors. Nevertheless, a good index makes it possible to quickly find if a desired procedure has appeared, and the necessarily unsystematic order of appearance is not really a serious disadvantage.

Some of the methods offered are new but many are improvements on older procedures. Where it is thought helpful a critical survey of known methods introduces the directions for the synthesis and a summary of the more common properties follows the directions. The most important references are given. It should be regarded as fortunate that exhaustive lists of references are avoided. The plan of checking all of the syntheses in independent laboratories and the critical editing of each synthesis by every editor helps greatly to ensure the reliability of the procedures, and it illustrates the degree of devotion shown by all who are engaged in this enterprise.

This series of volumes of Inorganic Syntheses which is so happily begun in this Volume I is destined to be one of the major contributions to chemistry.

ARTHUR A. BLANCHARD

The Merck Index. Fifth Edition. An Encyclopedia for the Chemist, Pharmacist, Physician, Dentist and Veterinarian. Compiled and published by Merck & Co., Inc., Rahway, N. J., 1940. 1060 pp. 17 × 23.5 cm. Flexible fabric. Price, $3.00.

This new edition of Merck's Index contains so much reference material of extreme value that a brief review cannot possibly do it justice. The list of chemicals and drugs that characterizes the series occupies 592 pages as compared with 570 pages in the Fourth Edition. The descriptions have been simplified, rewritten and rearranged. Many substances of recent importance are included, such as sulfapyridine and α-tocopherol. Structural formulas of many of the complex organic compounds are now given for the first time.

Following this section and not appearing in earlier editions are lists of coal tar colors and dyes used in foods, drugs and cosmetics, with descriptions (4 pages); indicators with properties, including adsorption, mixed, oxidation–reduction and universal indicators (5 pages); important minerals with characteristics, in tabular form (20 pages); and of special usefulness, 350 pages devoted to a list of chemical and clinico-chemical reactions, tests and reagents, listed by names of authors, covering and presumably amplifying the material previously found only in the rare German list "Merck's Reagenzien Verzeichnis." This is supplemented by an 18-page index arranged by names of substances tested for or employed.

In the remaining 70 pages are found descriptive lists of culture media, fixatives and staining solutions with formulas for their preparation, miscellaneous tables of units of measurement and their equivalents; thermometric equivalents, specific gravity comparisons, anti-freeze mixtures, cooling mixtures, constant humidity solutions, boiling and solidification temperatures of common, useful organic materials, refractive indexes and specific gravities of some important liquids and solids, weights per gallon of many organic liquids; and finally antidotes for poisons (12 pages).

The size of type generally used is smaller than that employed in *Chemical Abstracts*, but the arrangement of the vast amount of material collected into these 1060 pages is so clear, well spaced and uncomplicated as to make possible an almost immediate location of desired information. The labors of the compilers, Drs. Rosin, Addinall and Cone must have been great in preparing so comprehensive and essentially useful a volume.

WILLIS A. BOUGHTON

Chemische Gasreaktionen. (Chemical Reactions in the Gaseous Phase.) By H. J. SCHUMACHER, Director of the Physical Chemical Institute of the University of Frankfurt. Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1938. xviii + 487 pp. 53 figs. 125 Tables. Price, RM. 32.25; bound, RM. 33.75.

This monograph is third in a series edited by Professor K. F. Bonhoeffer. The first two dealt with photochemistry and with solids. This is restricted to the kinetics of homogeneous thermal reactions in the gas phase.

The book is encyclopedic in its thoroughness. It contains over a thousand references and covers the fundamental theories and practically all the quantitative researches published in the field up to 1938. The conclusions of the various investigators are given accurately and fairly. Occasionally the author makes a critical comment or suggests a different interpretation but in general he merely abstracts the findings of the different researches.

The first 121 pages are concerned with the theories of chemical kinetics. The chapter headings show the wide variety of subjects covered: the laws of mechanical collisions, application of the classical Boltzmann statistics to the velocity and energy distribution in ideal gases, bimolecular collisions, derivation of thermodynamical quantities from statistical mechanics, transfer of energy in collisions, unimolecular reactions, theory of bimolecular reactions, three-body reactions, the quantum mechanical calculation of the absolute rate of reactions. These theories and their formulas are given clearly but the original papers, which are cited, must be consulted for details and proofs.

The second and larger part of the book describes the results of experimental researches. It may be read independently of the theoretical part, which it supplements and illustrates. The several chapters describe first, second and third order reactions, atomic reactions, free radicals,

tracer experiments with deuterium, ortho-para hydrogen conversion and homogeneous catalysis.

The treatment of chain reactions in the last sixty-eight pages is excellent though handicapped by the exclusion of photochemical reactions.

Free radicals and their part in gas kinetics are treated briefly.

The influence of pressure on the specific reaction rate and the observed change from first to second order at low pressures is reviewed. The theories of Lindemann, Hinshelwood, O. K. Rice, Ramsperger and Kassel are summarized and illustrated with over fifty different gas reactions. In the opinion of the reviewer many of these illustrations which depend on pressure measurements alone will need revision if future experimental work shows the reactions to be more complicated. In some cases at least it is likely that the changes appearing at low pressures may be explained by intermediate chemical steps and wall effects.

All the investigations which make up the kinetics of gas reactions have been treated impartially without nationalism or race prejudice. One wonders however if the author was not handicapped in giving adequate recognition for help in the theoretical part of the book, particularly on the wave mechanical calculation of absolute reaction velocities. The footnote to Chapters X and XI "ferner H. Epstein unveröffentlich" (besides H. Epstein unpublished) may be expressing one of the tragedies of science. With their heritage of internationalism scientists have a special responsibility in helping to bring about a new world order.

The book is clear, complete and well organized, a good example of the thorough German reference books which have done much to bring fundamental science to its present level. Unquestionably "Chemische Gasreaktionen" is the most complete and most up-to-date review of the literature on the kinetics of gas reactions.

FARRINGTON DANIELS

Thorpe's Dictionary of Applied Chemistry. Fourth edition, revised and enlarged, Vol. III. Chemical Calculations–Diffusion. By JOCELYN FIELD THORPE, C.B.E., D.Sc., F.R.S., F.I.C., and M. A. WHITELEY, O.B.E., D.Sc., F.I.C., Imperial College of Science and Technology. Longmans, Green and Company, 114 Fifth Avenue, New York, N. Y., 1939. 608 pp. Price, $25.00.

The first volume of the Fourth Edition of this Dictionary was reviewed in the November, 1937, number of THIS JOURNAL and the second volume in the January, 1939, number. The comments and commendations previously given apply equally well to this volume so that little more needs to be added. The 608 pages of this third volume cover the same part of the alphabet which required 352 pages in the third edition. This volume contains long articles, many of them entirely new, on chemical calculations, chemical warfare, chlorine, chlorophyll, chromium, cinchona alkaloids, colloids, colorimeters, condensers, copper, corrosion of metals, cyanides, deuterium, diazo-compounds, diffusion and many others. The list of about sixty contributors is a roster of distinguished British chemists.

GRINNELL JONES

Compositiones Variae. From Codex 490, Biblioteca Capitolare, Lucca, Italy. An Introductory Study. By ROZELLE PARKER JOHNSON. The University of Illinois Press, Urbana, Illinois, 1939. 116 pp. 18 × 27 cm. Price, $1.50.

The progress of civilization is dependent upon the transmission, to successive generations, of the accumulated knowledge of the past. We are familiar with the main route by which the transmission of chemical knowledge has taken place. The extensive empirical information accumulated by the highly civilized nations of antiquity—Egypt, Chaldea and India—between 3500 and 750 B. C., fertilized by the speculations of the Greek philosophers in the immediately succeeding centuries, found expression in the earliest works on chemistry, namely, those written by the Greek–Roman–Egyptian scientists of northern Egypt in the first, second and third centuries of our era. Most of these, tinged with the alchemical speculations of the period, were destroyed, either as a result of the decree of Emperor Diocletian in 296 against alchemical literature or in the burning of the Serapeum. Some, however, were translated from the Greek into Syrian, into Arabic, and thence finally, in the eleventh century, by scholars in Spain and Italy, into Latin.

There was, however, an alternative route by which the accumulated empirical knowledge of the ancients was transmitted to modern times. Skilled artisans, craftsmen and technicians from the earliest times possessed books of recipes and directions for the prosecution of their art, craft or technology. The earliest surviving example of such a handbook is the collection of Assyrian cuneiform tablets of the seventh century B. C. found in the library of King Assurbanipal at Sardanapalus dealing chiefly with the manufacture of glass and of various pigments. The next surviving example is the Leyden Papyrus X found near Thebes and dating from the third century of our era, composed of a large number of quantitative chemical and technological recipes. It contains little or no theoretical discussion and has distinctly the character of a laboratory manual.

The next representative of this tradition is the manuscript entitled "Compositiones Variae" described in the present book. This manuscript, dating from about 800 A. D., again is a collection of technical and chemical recipes made by the monks attached to the ancient monastery at Lucca in Tuscany. Its 135 recipes deal with dyeing, the preparation of dyes and of pigments, gilding, varnishing, soldering, gluing, the working of metals and their preparation, the manufacture of glass, parchment, etc. These recipes are unsystematic and are often unduly condensed, but the information given is precise and definite. The mysticism and symbolism so prevalent in later books on alchemy, are completely absent. From the nature of the material and the omissions it appears that they were intended chiefly as reminders for those already skilled in the practice of the various arts with which they dealt.

The chief contribution of the present work is to show that these recipes, on the one hand, can be traced back successively to similar recipes found in such antecedents as the Latin Papyrus X and the Assurbanipal Tablets and, on the other hand, are substantially identical with similar recipes published in succeeding centuries, thus demonstrat-

ing beyond question the reality and importance of this route via recipe book or laboratory manual for the transmission of the chemical knowledge of the ancients.

Anyone concerned with the history of chemistry will find this monograph interesting and illuminating and will wish success to the further studies in this connection which the author mentions. It is unfortunate that the parallel references are given only in the original Greek and Latin, as this considerably restricts their interest and usefulness to the general reader who retains but little of his knowledge of these languages.

ARTHUR B. LAMB

Kurzes Lehrbuch der Enzymologie. (Brief Textbook of Enzymology.) By Dr. phil. THEODOR BERSIN, Professor of Physiological Chemistry at the University of Marburg. Second edition. Akademische Verlagsgesellschaft m. b. H., Sternwartenstrasse 8, Leipzig C1, Germany, 1939. viii + 183 pp. 32 figs. 16 × 23.5 cm. Price, RM. 11; bound, RM. 12.80.

Dr. Bersin has expanded his interesting book with new material, which appeared in the literature since the publication of the first edition in 1938 (reviewed in THIS JOURNAL, **60**, 1274 (1938)). The new edition includes brief descriptions and microphotographs of the recently crystallized apozymase, catalase, papain and the several chymotrypsins.

While some references to the literature are given in the book, a more extensive bibliography would greatly improve its value.

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY, STANFORD UNIVERSITY]

Studies of Solutions of Hydrocinnamic Acid and of Lauryl Sulfonic Acid with the Film Balance

BY JAMES W. MCBAIN AND WARREN V. SPENCER

In 1935 McBain and Wilson[1] and Doss[2] showed that the Pockels–Langmuir–Adam trough or film balance invented for insoluble films floating on water, gave highly interesting and unexpected results when applied to clean surfaces of ordinary solutions. The film balance does not measure surface tension of solutions. It has, however, uncovered the fact that while some solutions may have their surfaces enlarged by sweeping, or contracted by compressing with a movable barrier, without in any way affecting the balance or float, others are very sensitive to one or the other or both of these procedures. Often different behavior depends upon the range of concentration of one particular substance, and all the phenomena may go through maxima in intermediate concentration.

Two of the most striking phenomena are, first, the long times, almost infinitely long as compared with processes of diffusion, that are involved in some instances, and not in others or in other concentrations; and, second, the discovery of the formation of a semi-insoluble pellicle upon suitable compression of certain surfaces, exhibiting a well-defined "characteristic final pressure," at or above which only it will dissolve. A simple example of this behavior is normal caproic acid in aqueous solution, one of the most stable compounds of organic chemistry. McBain and Perry[1] ascribed this to orientation.

The phenomena are so novel and complicated that no satisfactory explanation embracing all of them has yet been forthcoming. They are not due to contamination, or to evaporation, for these have been painstakingly avoided, at least in the later work.

Doss considers that diffusion in the surface zone of a solution has to be activated and suggests that a potential barrier is formed by the diffuse double layer. He suggested that if the concentration is doubled the rate of accumulation in the surface should increase more than fourfold. However, we here find for solutions of lauryl sulfonic acid, proceeding from a concentration of 1.55 g./liter, that the velocity is increased either by concentration or by dilution.

To account for the special properties of the pellicle McBain and Perry suggest formation of polymolecular leaflets with the hydrophilic groups not exposed.

The present communication describes experiments upon several specimens of hydrocinnamic acid, cinnamic acid and, most carefully, dodecyl sulfonic acid, the latter being an example of the very large group of modern detergents with Type III curves of surface tension.[3] In these a mere trace lowers the surface tension of water by a large fraction. Upon further addition the sur-

face tension either remains constant or, as in this case, actually rises again. The most concentrated solution studied was only 5 g./liter and the minimum in the surface tension curve lies at 1.55 g./liter.

Apparatus and Method

A Cenco film balance was remodelled. The trough was coated with twenty-five superimposed layers of bakelite lacquer, each baked on for thirty minutes at 135–150°. The level of the liquid was fixed by a capillary tube attached to a suction pump near the end of the trough. The trough was 14 cm. wide and the barrier was always placed originally 40 cm. from the float. For solutions of lauryl sulfonic acid a thin coat of dicetyl was placed on the edges of the trough and the level of the solution kept low.

The float was a strip of platinum–iridium bent longitudinally to form an inverted V, the top of the fold coated with dicetyl and the bottom dipping deeply into the solution. Dicetyl was used with 0.0025 mm. gold foil to make the connection between float and trough. Before assembling, the float was heated to redness. The torsion wire was non-rusting 0.18 mm. phosphor–bronze used within its elastic limit. The barriers were of fused silica 1 cm. square and 26 cm. long, completely coated with bakelite lacquer, with some dicetyl where they touched the edges of the trough when using lauryl sulfonic acid.

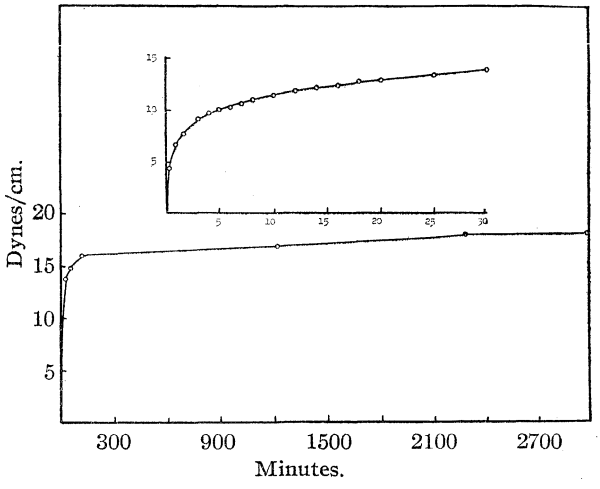

Fig. 1.—Laurylsulfonic acid 1.55 g. per liter, Procedure I.

To eliminate evaporation the entire trough was placed in a tight chamber thermostated at 25° using 42 ft. (12.8 meters) of $1/4''$ (6.4 mm.) copper tubing, through which thermostated water flowed. The bottom of the chamber was an open reservoir of thermostated water into which dipped cloth drapes to help keep the enclosed atmosphere saturated.

Invariably, before each experiment and procedure (except Procedure II), the surfaces on both sides of the float were swept several times by placing a barrier next to the float and sweeping it away. Each barrier in turn was left in place at the end of the trough until another had come back to it. The tests for contamination were described by McBain and Perry. Pure water was always studied for several days before using any solution. If clean, neither sweeping nor compression nor time affects the position of the float.

The routine of operations, abbreviated from the procedures of McBain and Perry is[1] sweeping both sides to begin with, and continuing to sweep the large side, the torsion necessary to keep the float in the zero position is noted. Having thus measured both the maximum pressure difference and the time required for its production, these are confirmed by Procedure II, by the simple expedient of stopping the sweeping and measuring the rate and time for the pressure to fall to zero.

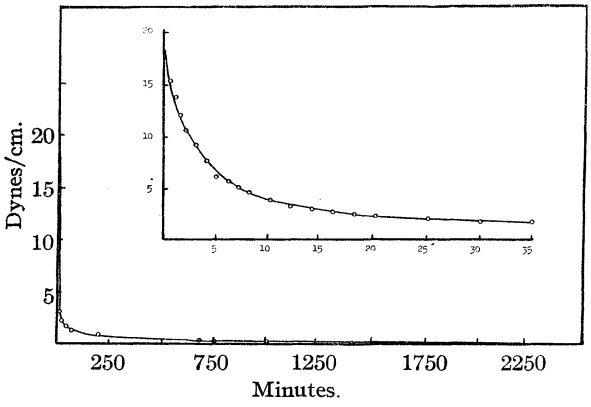

Fig. 2.—Laurylsulfonic acid, 1.55 g. per liter, Procedure II.

Again, both sides being swept and fully aged, the area on the large side is diminished by a definite percentage by moving the barrier toward the float and the initial and final pressure and the rate of change throughout are determined. Other procedures described by McBain and Perry occasionally were used.

Hydrocinnamic and Cinnamic Acids

Results with Eastman Hydrocinnamic Acid.—The hydrocinnamic acid was recrystallized from hot water and the principal results of McBain and Perry were repeated and confirmed. However, very much longer time effects were observed although the results show a close agreement with those of McBain and Perry for similar time intervals. For example, in Procedure I, after thirty minutes of aging, McBain and Perry found a pressure difference of 0.41 dyne per cm. while we now find 0.40, although in 4000 minutes this rises to 2.17 with a change of only 0.02 dyne during the last nineteen hours. In both Procedures I and II, the more rapid change has been accomplished within about five minutes. Classical diffusion phenomena would of course account for less than a second. These extremely slow adjustments are in accord with observations of surface tension of hydrocinnamic acid solutions communicated by McBain, Ford and Mills.[4]

Again, if the surface is compressed and then allowed to stand at constant area for a sufficiently long period, we obtain the same final characteristic pressure as McBain and Perry, namely, 0.42 dyne per cm. The first observable initial pressure occurs at 45% compression as was found by McBain and Perry.

(4) McBain, Ford and Mills, to be published.

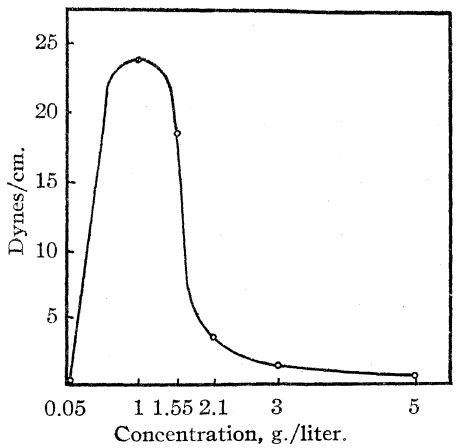

Fig. 3.—Laurylsulfonic acid, Procedure I. Maximum pressures produced on float by sweeping away from float.

Results with British Drug Houses Hydrocinnamic Acid.—The surface properties for all shorter times agreed with the foregoing, but for longer periods the values here were less. With 87.5% compression, the initial pressure for Eastman and British Drug Houses, respectively, was 2.4 and 2.5, falling in 30 min. to 1.18 and 1.15, and giving the final characteristic pressure after standing overnight 0.42 and 0.41.

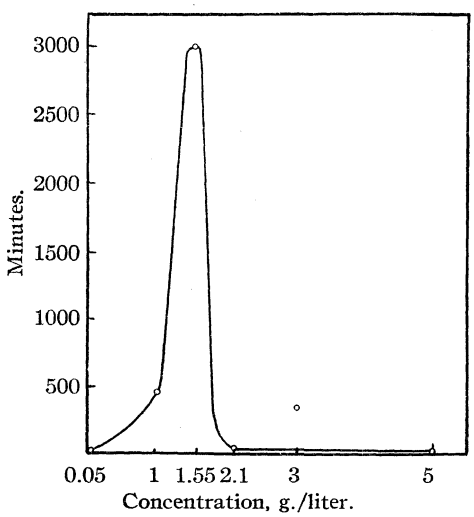

Fig. 4.—Laurylsulfonic acid, Procedure I. Time required for maximum pressure.

Experiments with Cinnamic Acid.—When 0.01 g. of cinnamic acid crystals was sprinkled on 560 sq. cm. of clean water, the spontaneous pressure after twenty minutes was 0.4 dynes/cm. falling off overnight to the final pressure of 0.19. Upon compression by 95%, the initial pressure became 1.03, but this fell to the 0.19 final value overnight.

Now when a solution of hydrocinnamic acid was similarly contaminated with cinnamic acid crystals, a maximum pressure of 2 was produced, which 87.5% compression raised to 3.33, falling to a final pressure overnight of 0.59 (= 0.41 + 0.18!). However, after thorough sweeping, apparently all cinnamic acid was eliminated, for on compressing surfaces aged thirty minutes by 87.5% the initial pressure was 2.5, falling in thirty minutes to 1.10 and giving the characteristic final pressure 0.40; all three values were thus identical with those quoted above for pure hydrocinnamic acid.

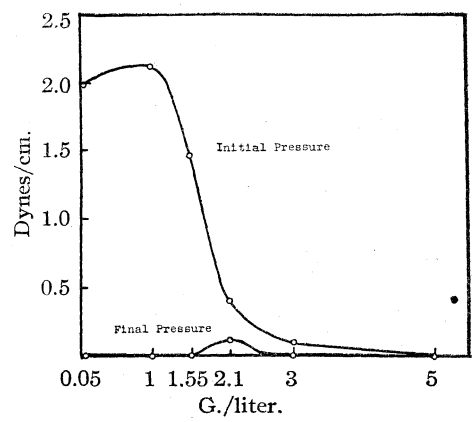

Fig. 5.—Laurylsulfonic acid, Procedure V, compressed 10%.

Spreading of Oil on Solutions of β-Phenylpropionic Acid.—Oil spreads upon a freshly swept solution extremely rapidly, just as on water,[5] and the oil spreads circularly about as fast as the eye can follow. However, when the surface is aged and compressed, the oil again spreads circularly but very slowly. Freshly swept surfaces of solutions of hydrocinnamic acid are quite mobile while the compressed surface shows rigidity.

Similar experiments with oxidized oil and oleic acid were attempted on a solution of lauryl sulfonic acid of minimum surface tension containing 1.55 g./liter. On a freshly swept surface the drop rapidly spreads circularly until several centimeters in diameter. Then islands appear in the oil film which gradually breaks up into a very large number of minute droplets. On compressing and expanding the surface rapidly, these expand and the larger ones again form islands. On a clean aged surface the

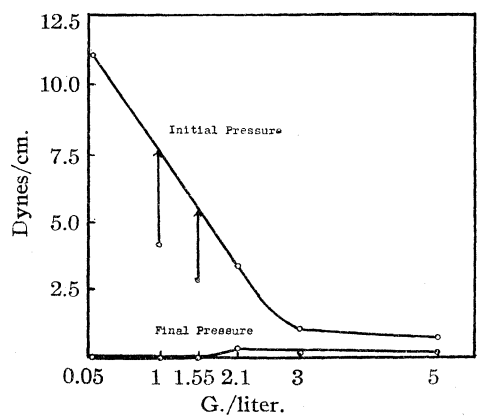

Fig. 6.—Laurylsulfonic acid, Procedure V, compressed 50%.

(5) T. F. Ford and D. A. Wilson, *J. Phys. Chem.*, **42**, 1051 (1938).

drops do not spread at all. Upon compression the surface moves as a whole, showing some elasticity.

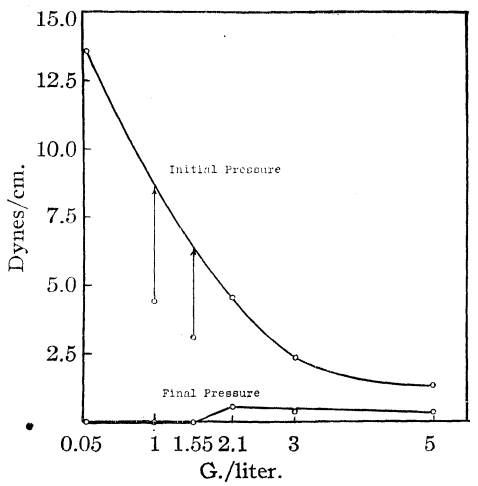

Fig. 7.—Laurylsulfonic acid, Procedure V, compressed 75%.

Dodecyl Sulfonic Acid

Study of Solutions of Dodecyl Sulfonic Acid. Five Grams per Liter.—Fifteen to twenty minutes are required before the effect of sweeping away from the float disappears and the maximum effect is 0.51 dyne per cm.

A pellicle is formed on sufficient compression. It is only after the surface has aged for the above-mentioned fifteen or twenty minutes that the final constant characteristic pressure of lauryl sulfonic acid of 0.51–0.52 dyne per cm. is exhibited upon compression and sufficient standing, then for 87.5% compression the initial pressure is 2.54, falling in about twenty min. to the 0.52 value. There is no initial pressure until compression amounts to 20% and no final pressure at all until the compression is 40%. The final pressure does not reach its characteristic constant value until the compression is 85% or more. The time effects of compression are interesting and unexpected. Both for small and for very high compressions the fall to the characteristic pressure is rapid. For moderately large compressions, the time passes through a high maximum. This is observed again with other dilutions.

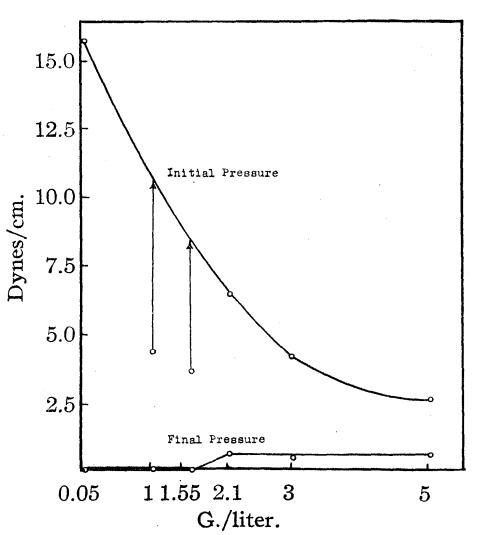

Fig. 8.—Laurylsulfonic acid, Procedure V, compressed 87½%.

Three Grams per Liter.—Instead of the fifteen to twenty minutes above, six hours is here necessary for this solution to recover after sweeping away from the float, and the maximum effect is raised from the 0.51 to 1.34 dynes per cm. Compression again produces a pellicle.

2.1 Grams per Liter.—Once more the effect of sweeping is greater and the pressure upon the float rises to 3.40. However, the solution recovers within thirty minutes. On the other hand, the outstanding observation is that upon compression the initial pressures are again greatly increased, being 7.08 for 92.5% compression. Nevertheless, the final characteristic pressure is 0.51–0.55 attained in about forty-five min.

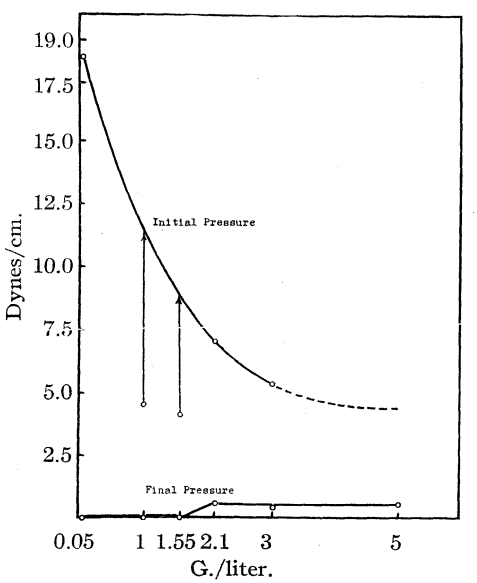

Fig. 9.—Laurylsulfonic acid, Procedure V, compressed 92½%.

1.55 Grams per Liter.—The effect of sweeping clean is relatively enormous, being now 18.02 dynes per cm., and requiring several thousand minutes for recovery. This is illustrated in Figs. 1 and 2.

The most important single observation is the fact that no final pressures are obtained upon compression, however great. Curiously, the time required for the initial pressure produced by compression to disappear rises with amount of compression until a sharp maximum is reached, after which it is very short. As an example, at 10% compression it required only six minutes to drop to zero, whereas at 87.5% compression it required 950 minutes, while at 96.5% compression it dropped to zero in only twelve minutes.

One Gram per Liter.—Now that the minimum surface tension has been passed, the great increases in time required to restore the surface after sweeping clean are no longer observed as in the foregoing series of higher concentrations, but drop again from a few thousand to a few

hundred minutes. However, the initial effect of sweeping is far greater, being 23.54 dynes.

Upon compression there is again no permanent pellicle, but the initial pressures are still greater than with the 1.55 g. concentration. Once more the time for the initial pressure to disappear increases with compression but suddenly falls after 75 to 87.5%.

One-half Gram per Liter.—This very dilute solution still gives definite pressures. Sweeping produces only a slight pressure difference, which disappears in fifteen minutes. However, compression produces enormous initial pressures, up to 18 dynes per cm., much higher than those for the less dilute solutions but they disappear within a few seconds for 10% compression, three minutes for 75% compression and about thirty sec. for 92.5% compression.

Discussion

Considerations of space prohibit reproduction in full of the varied and numerous data[6] (62 tables and 44 graphs). Instead, we can merely supplement the information already given by a series of summary tables and graphs showing how the results depend upon concentration for lauryl sulfonic acid solutions. These should be compared with those given by McBain and Perry for hydrocinnamic acid.

TABLE I

Procedure I. Dodecyl Sulfonic Acid Solution

[c] These concentrations were compressed from 75 to 87.5%, instead of from 0 to 87.5%.

[d] These concentrations were compressed from 87.5 to 92.5%, instead of from 0 to 92.5%.

To sum up, it is evident that but little is known of the properties of the surface layers of solutions. The assumption current during the past twenty years that clean solutions may be regarded as uniform solution right up to a bounding monomolecular film is untenable; and the common interpretations of their hypothetical monomolecular film as gaseous, etc., become very doubtful. This is in complete contrast to the well-established and beautifully simple behavior of oil films on water or insoluble contaminations upon solutions.

Summary

The film balance when applied to ordinary solutions yields a complex series of novel results which bear but little relation to previous conceptions derived from analogy with insoluble monomolecular films floating on water; and thus a new field is open to investigation.

Particularly striking is the fact that the various phenomena of surface pressure and of time frequently pass through a high maximum in an intermediate range of dilute solution. Again, whether a pellicle forms or not depends both upon the concentration and the degree of compression

(6) Stanford University theses are being made available in bibliofilm, U. S. Dept. of Agriculture.

of the surface. Some substances apparently never form it. When it is formed and sufficiently compressed, the final pressure is characteristic only of the substance. On the other hand, the initial pressure may be greatest where the final pressure vanishes.

Observations of Surface Tension in the PLAWM[1] Trough

BY J. W. McBAIN, J. R. VINOGRAD[2] AND D. A. WILSON

In recent years attention has been drawn to the long time effects observed in the surface tensions of solutions. The time effects are of a much higher order of magnitude than can be accounted for by ordinary diffusion. Likewise great interest attaches to solutions whose surface tensions are of Type III. In these, a trace of solute lowers the surface tension to a fraction of that of the solvent, whereupon further addition leaves the surface tension constant or may cause it to pass through a minimum in very dilute solution. In either case, application of the Gibbs theorem, where the slope of surface tension against concentration is zero, would seem to predict zero adsorption, just where the surface tension is most greatly lowered and where adsorption is actually pronounced.[3] About one hundred such cases have been reported.[4]

In attempting to verify the existence of these reported effects it is highly desirable to find a method of measuring surface tension which shall fulfil the requirements that (a) the surface is static and undisturbed, (b) that it is swept free from contamination, (c) that it is observed for an adequate period and (d) that evaporation is avoided. None of the previously existing methods fulfilled all of the first three requirements and every method had been criticized by other authors.[5] For these reasons the PLAWM trough was devised. In this, the superficial floating barrier of the Pockels–Langmuir–Adam surface film trough is replaced by one which is water-tight and yet flexible. This was done by cementing to the bottom and walls of the trough with dicetyl a sheet of vulcanized dipped latex rubber 0.004″ (0.1 mm.) thick of density 1.02 especially made for us by the Miller Rubber Company, Inc., Akron, Ohio. This delicate rubber partition was also fastened to a float in the line of the surface. Thus, the trough is separated into two compartments, one of which may contain water, the other solution; both have plane surfaces which can be swept. If hydrostatic effects are equalized, the only force acting upon the float is the difference of surface tension on the two sides.

Although the PLAWM trough is simple in principle, it is very exacting in practice. However, it here serves its purpose of demonstrating beyond question the existence of Type III curves and it is of much interest to compare the results obtained by this method with those from a number of other current methods.

The Apparatus

As the basis, we used a trough made for us through the courtesy of Dr. N. K. Adam. It consisted of a brass tray 50 × 14 × 2 cm. carrying a compound torsion balance. The tray was given 18 superimposed coats of Bakelite lacquer, each baked on at 150°. The same treatment was given to all other metal parts which might come in contact with liquid, with the exception of the float which consisted of a 12-cm. strip of platinum–iridium folded longitudinally. The rubber membrane was first attached with dicetyl to a U-shaped frame and then at the height of the meniscus to the float; the whole frame was then fitted water-tight into the trough with dicetyl. Two strands of 0.04 mm. silver wire connected the float to the torsion mechanism and mirror.

In the original experiments of Wilson, which are here referred to only briefly, the rubber membrane was made with folds so voluminous that it was found experimentally that the hydrostatic pressure on both sides was equalized within fifteen to forty-five minutes, after addition of more water or solution, as was shown by the float returning to the original zero point. In the present experiments only about 1 cm. extra of rubber was allowed on both sides and under the float, but the two compartments of the trough were connected by a siphon of 2 cm. bore which could be closed with stopcocks.

All the measurements were made in an atmosphere which was practically saturated with water vapor. The case

surrounding the trough had been made water-tight by coating with paraffin, and water was allowed to stand on the floor to a depth of a few centimeters. Streamers of cheesecloth dipped into this pool of water and extended to the top of the case. A hygrometer always read 100% relative humidity. Access to the instrument was made by means of small sliding doors.

Experimental Technique

To begin each run the trough was rinsed repeatedly with distilled water which was drawn out through the top of the siphon. Conductivity water from a Barnstead still was then added to both sides, and the surfaces were swept at least five times. Three Bakelited quartz sweeps were manipulated so that two were always in position near the immersed ends of the siphon but on the side toward the float. The stopcocks of the Pyrex siphon were not closed until the light beam of the optical indicator came to rest. After closing the stopcocks the surfaces were again swept and the light beam was observed over a time interval similar to one considered in the measurement. The experiment was begun only if the position of the optical indicator and thus that of the float did not change.

A sweep was placed within 3 mm. of the platinum–iridium float and a measured amount of solid was added to the water in the large compartment outside this sweep. In the case of the slowly soluble hydrocinnamic acid the solid was finely ground and then sprinkled on the surface through a platinum gauze. This considerably enhanced the rate of solution which otherwise for concentrated solutions might require days. The solution was then stirred until it was homogeneous, using a quartz rod cleaned by heating to redness. The experiment was begun by drawing the sweep over the large surface from the float position to a position near the end of the trough. The moment of sweeping was considered the beginning of the experiment.

For the period of observation the light beam and thus also the float were maintained at a fixed position by adjusting the torsion wire. The experiment was in some cases repeated by sweeping the solution surface a second time. The observation of each solution was continuous for some hours, with the object of ascertaining when the value became constant. At the conclusion of the surface tension readings, the solutions were analyzed, the hydrocinnamic acid by the Zeiss interferometric refractometer and the lauryl sulfonic acid by titration with potassium hydroxide.

Experimental Tests

In the actual experiments the siphon was kept closed after the initial equalization of hydrostatic pressure. However, preliminary observations were made as follows.

With the siphon open the displacement of the float due to the addition of 5 cc. of water is nullified in one minute.

With the siphon closed when 5 cc. of water was removed the original position of the light beam was reëstablished when the water was replaced in the trough.

The float returned to the original position after stirring as soon as the violent disturbance died down.

The addition of water to one side gave a definite effect proportional to the amount of water added, 1.02 dynes/cm./g. of water. An increment of 0.60 dyne/cm./g. was observed when varying amounts of sucrose up to 10 g. were added. The effect of the maximum amount of sucrose used on the surface tension of water is 0.05 dyne/cm. and this was below the sensitivity of the apparatus. While the addition of pure water influences the float only through the effect of increased depth upon hydrostatic pressure, the addition of soluble solids influences it partly through the change produced in depth but also through the change in density of the solution and these effects may reinforce or partly neutralize each other depending upon the actual volume effects for the particular case. The results obtained were corrected for this hydrostatic effect.

The apparatus was calibrated frequently by hanging weights on the lever arm of the torsion balance. With the 0.18 mm. phosphor-bronze torsion wire used in experiments on hydrocinnamic acid the conversion factor was 0.136 dyne/cm. per degree torsion. In view of the large surface tension lowering of lauryl sulfonic acid, 0.25 mm. phosphor–bronze wire was used. The corresponding factor was 0.648 dyne/cm. per degree torsion. Since torsions could be read to 0.1 degree the uncertainty in the readings for lauryl sulfonic acid solutions corresponds to 0.25 dyne/cm.

Materials

The potassium laurate was a special preparation made by Kahlbaum mentioned in previous communications. The hydrocinnamic acid was made by Eastman Kodak Co. and was purified in the usual manner by cooling an aqueous solution saturated under 50° (18 g./liter) toward room temperature, rejecting the crystals separating but taking those formed on further cooling to 0°. Sodium butylbenzene sulfonate was prepared by the method of Neville and Jeanson.[6] The lauryl sulfonic acid was a specially pure specimen prepared by M. E. Synerholm under the direction of Dr. C. R. Noller.

Preliminary Results

In the experiments of Wilson in 1936 a Lloyd and Scarth ring tensiometer was also incorporated in the PLAWM trough. The surface tensions so measured were in agreement with those yielded by the PLAWM trough.

Of much interest was the observation that whereas soap solutions commonly exhibit a pronounced minimum in their surface tension curves,[7] and the potassium laurate behaved likewise, addition of 0.0116 *N* potassium hydroxide, added with the intention of suppressing hydrolysis, eliminated this sharp minimum occurring at about 1 g./liter by causing all the higher concentrations to remain at this low value.

The results with sodium butylbenzene sulfonate are given in Fig. 1, both trough and tensiometer exhibiting a minimum similar to that described by Neville and Jeanson.[6] Here the minimum occurs in much less dilution and it remains to be

(6) Neville and Jeanson, *J. Phys. Chem.*, **37**, 1001 (1933).

(7) "International Critical Tables," Vol. V, McGraw-Hill Book Co., Inc., New York, N. Y., 1929, p. 449–450.

proved whether further purification (hydrolysis is of course impossible) might flatten out the minimum. However, Wood[3] found a very definite minimum in more dilute solution with moderately pure butylbenzene sulfonic acid.

Results with Solutions of Hydrocinnamic Acid

These solutions of β-phenylpropionic acid exhibit a surface tension which changes over long periods of time. Whereas until recently it has always been taken for granted that the surface tension of ordinary dilute solutions would change from the perfect dynamic or instantaneous value, almost equal to that of the solvent, down to the final or equilibrium value as fast as the concentration of the surface zones could be adjusted by classical processes of diffusion, a matter of a small fraction of a second, we here have another clear case like that of Adam and Shute[8] showing that the surface tension is not fully lowered until after enormously greater periods of time.

It is equally difficult to measure the perfect dynamic surface tension of a solution and its perfect final static or equilibrium surface tension. All existing measurements probably fall between the two. Drop number and drop weight and maximum bubble pressure upon which many investigators have relied prove to be semi-dynamic. The ring methods are better in that the surface may be aged for days before the ring is pulled through the surface, but this latter process is accompanied by stretching and formation of new surface.

We are fortunate in being able to present in Fig. 2 data obtained by Dr. Donald Purdie of Cambridge, England, with a Sugden maximum bubble pressure equipment, together with the data of Professor E. A. Hauser of Massachusetts Institute of Technology with his pendant drop method, the measurements of Drs. R. C. Swain and C. R. Bacon with the drop weight method, those of Dr. G. F. Mills with the ring method of Harkins and Jordan, together with our own results

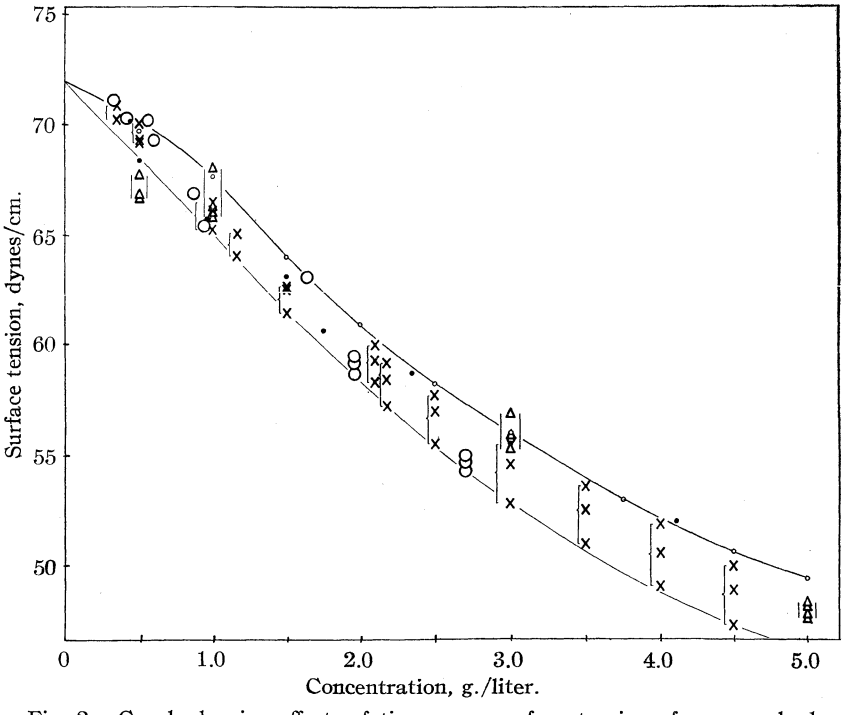

Fig. 2.—Graph showing effects of time upon surface tension of aqueous hydrocinnamic acid as studied by many methods: ×, ring method, uppermost point at age of surface 5 min., next point below at 1 hr., lowest point 9 hrs.; ○, drop weight at 30 sec.; ●, maximum bubble pressure for releasing bubbles; Δ, pendant drop method, uppermost at 15 sec., followed in order by 60, 120 and 300 sec.; ◯, PLAWM trough, for 2 and 2.7 g./liter at 15 min., 60 min. and 120 min. in order, but for the more dilute solutions only one determination between 30 to 60 min.

using the PLAWM trough. It is abundantly clear that the surface tension of any one solution is a function of time over long periods and that no method of measuring surface tension measures either the true initial or the true final value.

With the sessile bubble, etc., the surface is small in comparison with the bulk of the solution

(8) Adam and Shute, *Trans. Faraday Soc.*, **34**, 758 (1938).

and impurities may concentrate therein without possibility of sweeping. With the PLAWM trough there is a large area (560 sq. cm.) whose surface tension is found to be but little affected by stirring or by disturbing a small portion of it. It may be swept an indefinite number of times to eliminate surface contamination. These latter points may and should be adopted in the ring method, which then would become with the precautions indicated by Mills perhaps the most informative and trustworthy method of measuring surface tension.

In Fig. 2 we have drawn the uppermost curve through the data for drop weight obtained with drops thirty seconds old. The bottom curve is that for the surface tensions by the ring method at the ostensible age of nine hours. Between these two arbitrary curves all the other data are bracketed. The methods that are capable of showing change with time show it. In plotting the data, all measurements were arbitrarily corrected to 25° by adding the difference in surface tension of pure water at 25° and the temperature of measurement. Only the pendant drop and the PLAWM trough were used at 25°. The drop weight and the ring were at 22–23°, and the bubble pressure at 21.5°, so that the data may be easily reconverted.

Results with Lauryl Sulfonic Acid.—Again we are fortunate in being able to present Fig. 3 which critically establishes the existence of Type III curves of surface tension with a minimum in extremely dilute solution. The data given are those of Dr. H. B. Bull of Northwestern Medical School using the Wilhelmy method, those of Dr. L. A. Wood with the ring method (using swept carefully protected surfaces), after periods up to forty-eight hours, those for the PLAWM trough, and two measurements for extremely dilute solutions by Professor Grinnell Jones and Dr. W. A. Ray of Harvard with their precision capillary method which gave for 0.0285 and 0.2225 g./liter, respectively, 0.9936 and 0.9141 times that of water for 25°.

Once more the surface tension is a function of time over very long periods, but for the present purpose we are only interested in the proof that the equilibrium surface tension curve is of this form.

Differential Results with Lauryl Sulfonic Acid.—Since it has been shown that observed surface tensions of solutions are somewhat arbitary values dependent upon time and the method of measurement, a new approach was made to establish that in the very dilute solutions containing between 1.5 and 2 g./liter the surface tension does actually increase with concentration. For this purpose the surface tension in the PLAWM trough was first measured for a solution containing about 1.55 g./liter and the establishment and reëstablishment of a surface tension of 30 dynes/cm. eighty minutes after each sweeping was observed. As is shown in Fig. 4 the surface tension fell 7 dynes between the first and eightieth minutes.

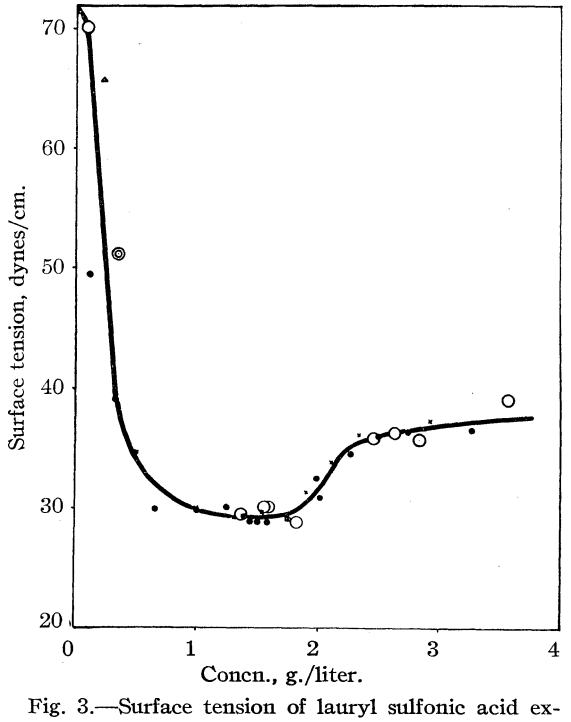

Fig. 3.—Surface tension of lauryl sulfonic acid exhibiting Type III curve with minimum at 1.55 g./liter. The values shown represent the final lowering of surface tension at the times stated: ○, PLAWM trough at 60 min.; ◎, PLAWM trough at 10 hrs.; ×, Wilhelmy method at at least 45 min.; ●, ring method at 1 to 2 days; △, capillary rise method, time not stated.

Thereupon, additional lauryl sulfonic acid was put in to bring the concentration to about 2.5 g./liter. Figure 4 shows that now the surface tension was 36 dynes/cm., almost independent of age or sweeping. This differential method which upon repetition yielded the same results proves critically the existence of the minimum in the surface tension curve which has led to the unsolved contradiction between the thoroughly established[8] actual positive adsorption and the zero

and negative adsorptions apparently demanded by the Gibbs theorem.

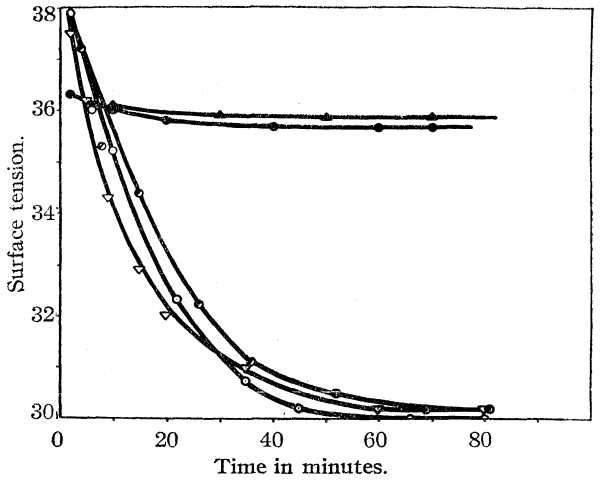

Fig. 4.—Differential method with PLAWM trough to establish existence of minimum in surface tension of aqueous lauryl sulfonic acid: ○, ▽, ◐, surface tension observed after first, second and third sweepings, respectively, for 1.575 g./liter, showing surface tension falling from 38 to 30 dynes/cm. in 80 min.; thereupon for 2.460 g./liter showing surface tension raised to and remaining at 36 dynes for 80 min., and also up to 260 min., ●, for first sweeping; ▲, after second sweeping.

Tartar and Cadle reported at the Sixteenth National Colloid Symposium, 1939, even more striking minima in their surface tension curves for the sodium straight chain alkyl sulfonates. Likewise, Adam and Shute[9] find definite minima for aqueous cetyltrimethylammonium bromide at 0.045% and for sodium dodecyl sulfate at 0.01 *N;* their time effects are similar to ours. It is of interest to note that, owing to the long time required for dilute solutions of lauryl sulfonic acid to exhibit full lowering of surface tension as compared with the almost immediate attainment of it in solutions containing over 2.5 g./liter, Wood found for very short times a Type I curve rapidly sagging down into the position shown by our Type III curve in Fig. 3. Naturally the thermodynamic theorem of Gibbs refers only to the final equilibrium value and not to any arbitrary value between that and the initial instantaneous dynamic surface tension.

Other Uses of the PLAWM Trough.—Since it has been abundantly shown[9] that the ordinary film balance strikingly fails to measure surface tension of solutions and that complicated time effects reach their maximum in an intermediate range of dilute solution, it becomes of great interest to carry out similar experiments with the PLAWM trough which of necessity measures the actual surface tension and the influence thereon of such procedures as sweeping and compression. Indeed, this will be necessary in order to interpret the results obtained with the film balance. However, the latter is sufficient to show that the effect of sweeping the surface of a solution of lauryl sulfonic acid, while negligible in infinite dilution and again at solutions containing 2.5 g./liter, is so great in a solution containing 1.5 g./liter that an error of over 2 dynes remains if the surface tension is measured as soon as one hour after sweeping.

Summary

The PLAWM trough, consisting of a film balance divided into two compartments by a watertight flexible float, has been applied to solutions of hydrocinnamic acid, potassium laurate, sodium butylbenzene sulfonate and lauryl sulfonic acid.

In conformity with data by other recognized methods kindly supplied us by other workers, it has been shown that the surface tension of solutions of hydrocinnamic acid is not fully established until after periods of time enormously greater than those expected from classical diffusion processes.

The existence of Type III curves with a minimum has been critically established. In these a trace of solute reduces the surface tension of the solvent to a fraction of its value, whereupon further small addition raises the surface tension again to a still low maximum or constant value. This has been shown for lauryl sulfonic acid (and also for sodium butylbenzene sulfonate), again in conformity with data kindly supplied us by other workers. With potassium laurate addition of alkali appears to lower the flat maximum to the value of the minimum.

It is pointed out that the PLAWM trough will be invaluable in repeating and interpreting the surprising results obtained with clean solutions of soluble substances with the Pockels–Langmuir–Adam film balance.

Ionization Constants of Acid–Base Indicators in Ethanol

BY L. S. GUSS AND I. M. KOLTHOFF

In a buffer system containing the acid–base system, A and B and the indicator system I_a and I_b, we define a concentration equilibrium constant by the equation:

$$K = \frac{c_{I_b}\, c_A}{c_{I_a}\, c_B} \qquad (1)$$

and a thermodynamic constant, K', by a similar equation using activities in place of concentrations

$$K' = \frac{a_{I_b}\, a_A}{a_{I_a}\, a_B} = K\frac{f_{I_b} f_A}{f_{I_a} f_B} \qquad (2)$$

According to the limiting Debye–Hückel expression

$$-\log f_{ion} = \alpha z^2\sqrt{\mu} \qquad (3)$$

From equations (2) and (3), it follows that

$$pK = pK' + 2\alpha(z_{I_a} - z_A)\sqrt{\mu} \qquad (4)$$

where z refers to the charges on the respective molecules. The value of α in water at 25° is 0.5, in methanol, 2.0, and in ethanol, 2.9. Hence, any variation between pK values and ionic strength in water will be magnified by four times in methanol and almost six times in ethanol.

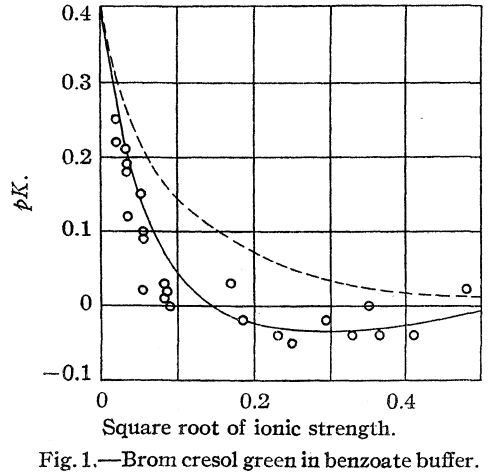

Fig. 1.—Brom cresol green in benzoate buffer. Broken line illustrates corresponding data in methanol.

In a previous study[1] it was shown that equation (4) accounts quantitatively for the change with the ionic strength as long as the latter is small. In his study of indicators in ethanol, Kolthoff[2] hardly found a change of the color equilibrium of sulfonephthaleins in buffers composed of an uncharged acid and a univalent anion base upon dilution from an ionic strength of 0.1 to 0.01. Erroneously, he concluded that dissociation constants remain unchanged on going from infinite dilution to finite concentrations. It is the purpose of this investigation to correct these data in the light of the above discussion and to consider the effect of varying ionic strength on some indicator–buffer equilibria.

Experimental

Reagents.—A good grade of synthetic ethanol, free of aldehydes, was dehydrated by the method of Lund and Bjerrum,[3] followed by distillation over sulfanilic acid. As in the case of methanol, final purity was checked by density measurements with a 100-ml. pycnometer. All alcohol used contained less than 0.05% water. As

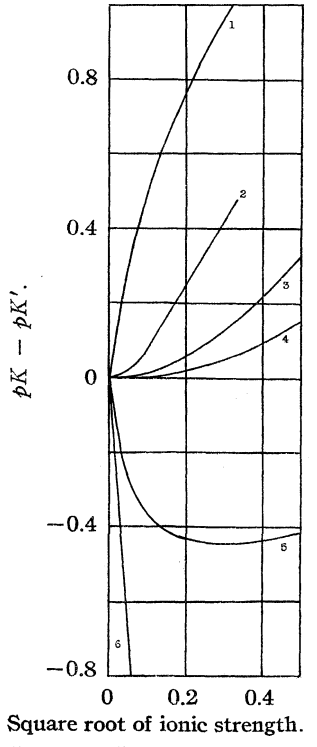

Fig. 2.—Indicator–buffer systems in ethanol: (1) methyl yellow, methyl red, and thymolbenzein in trichloroacetate, neutral red in salicylate; (2) thymolbenzein in veronalate; (3) methyl orange in trichloroacetate; (4) methyl red in benzoate; (5) sulfonphthaleins in uncharged acid buffers; (6) brom cresol green in ammonium.

(3) H. Lund and J. Bjerrum, *Ber.*, **64B**, 210 (1931).

pointed out before,[1] the presence of a trace of water will have no effect on these buffered solutions.

Indicators and acids were purified by methods already described. Ionic strength was controlled by the addition of lithium chloride, precipitated from methanol solution by the addition of hydrogen chloride and fused in platinum in an atmosphere of hydrogen chloride. Sodium ethoxide was prepared by dropping pure sodium into ethanol, the solutions showing no discoloration.

Method.—The general method was that used in the solvent methanol.[1] Values of pK for a given buffer-indicating system were determined over an ionic strength range from about 5×10^{-4} to 0.1. Ionic strengths of 0.01 and less are due to the salt in the buffer, a greater ionic strength being obtained by the addition of lithium chloride. The values of pK were plotted against the square root of the ionic strength and the curve extrapolated to infinite dilution, the final slopes of the curves agreeing with equation (4).

TABLE I

VALUES OF pK IN VARIOUS INDICATOR–BUFFER SYSTEMS IN ETHANOL

[a] Dissociation constant of acid has been obtained from I. M. Kolthoff, *J. Phys. Chem.*, **35**, 2732 (1931). [b] Dissociation constant of acid has been obtained from H. Goldschmidt, *Z. physik. Chem.*, **99**, 116 (1921).

Results.—As an example, the data obtained in an investigation of brom cresol green in benzoate buffer are shown by the solid curve in Fig. 1. From the graph, a value of $pK' = 0.4$ is obtained. Knowing that, for benzoic acid, $pK_A = 10.25$[2], we find pK_I of brom cresol green to be 10.65.

In Table I is given a summary of pK values of indicator–buffer systems at various ionic strengths, as well as the values at infinite dilution. The behavior of indicator–buffer systems is more clearly seen in Fig. 2, where it is found that the systems studied fall into a few well-defined groups.

Discussion

The behavior of acid–base indicators in ethanol is much the same as in methanol. At infinite dilutions, the curves approach the slope of 5.8, required by the Debye–Hückel limiting law. At higher salt concentrations, the ionic diameter and individual molecular characteristics bring about variations that can be expected.

The behavior of sulfonephthaleins in ethanol is in agreement with the extension of the concept of Bjerrum[4] as discussed in a previous paper.[1] This is indicated in Fig. 1, in which the system of brom cresol green in benzoate is compared in methanol and ethanol. Although the general shapes of the curves are the same, the ethanol curve is compressed toward the zero-concentration axis. In other words, the individual effects of the separate charges on a zwitterion become apparent at much lower salt concentrations than in methanol. As a result, although the limiting slope is greater in ethanol, the limiting value of pK above the horizontal portion of the curve is about the same in the two solvents.

The same comparison seems applicable in cases of the other zwitterion indicators, *i. e.*, thymolbenzein, thymol blue in trichloroacetate and methyl orange. The behaviors of the basic indicators, methyl yellow and neutral red, are in accord with present concepts. Methyl red behaves as if the intermediate form (Red II) is a true amino acid and not a zwitterion, in agreement with results found in methanol. In trichloroacetate, it behaves as a cation acid; in benzoate as an uncharged acid.

In Table II is given a summary of the true ionization constants of the indicators studied. These are calculated from the pK' values obtained in this study and accepted values of pK_A found in the literature. The pK_A of veronal was found to be 13.1, from a study of the brom cresol purple–veronalate system. For comparison, the values in methanol and water are also listed. The value for tropeoline 00 was determined in dilute hydrogen chloride.

Summary

1. A study has been made of the dissociation of acid–base indicators in ethanol, especial attention being paid to the effect of ionic strength.

2. Values of thermodynamic ionization constants of these indicators have been measured.

The Conductance of Solutions of Organosubstituted Ammonium Chlorides in Liquid Hydrogen Sulfide

BY E. E. LINEKEN[1,2] AND J. A. WILKINSON

I. Introduction

Organic ammonium salts were found to form conducting solutions in the liquid hydrides of phosphorus, sulfur, and the halogens by McIntosh and Steele,[3] and in the liquid hydrides of the halogens and sulfur by Steele, McIntosh and Archibald.[4] Antony and Magri[5] have reported that solutions of tetramethylammonium iodide, in liquid hydrogen sulfide, conduct. Quam and Wilkinson[6] have reported the conductances of solutions of methylammonium, dimethylammonium, and triethylammonium chlorides at a number of different concentrations in liquid hydrogen sulfide. Their work shows distinctly the

increased conductance of solutions of substituted ammonium chlorides as the number of substituents increases. Their report indicates also an increased molecular conductance with increasing concentration. The present investigation was undertaken to repeat earlier measurements using modern bridge technique, to extend the concentration range for these solutions and to make measurements on solutions of other organosubstituted ammonium chlorides in order to be able to compare the conductances of several series of compounds. The compounds selected were mono-, di-, tri-, and tetramethylammonium chlorides and the corresponding ethyl and *n*-propyl compounds.

The conductances of all solutions in liquid hydrogen sulfide are much lower than those of similar solutions in water. This might be expected on comparison of their viscosities and dielectric constants at somewhat similar temperatures. The conductances of the hydrogen sulfide solutions were determined at −78.5°, which is the equilibrium temperature of the mixture of solid carbon dioxide and ether. At this temperature the dielectric constant of liquid hydrogen sulfide is 9.05 compared to 81.5 for water at 16.3°. The viscosity for hydrogen sulfide at the same temperature is 4.12 millipoises compared to 17.94 for water at 0°.

II. Apparatus, Chemicals and Method

1. Shielded, Alternating Current Wheatstone Bridge.—The shielded bridge was constructed in general according to that described by Shedlovsky.[7] The twin (double) variable air condenser which Shedlovsky used was replaced in this work by two 500 mmf. variable air condensers, one shunting the conductance cell and the other shunting the measuring resistance. The ratio arms were of 5000 ohms each and were a unit from a General Radio Company Type 216 capacitance bridge. No provision was made for reversing the ratio arms. The earthing circuit was made of two 5000-ohm coils similar to those described above, a 20-ohm variable rheostat, and two 500 mmf. variable air condensers. Each instrument comprising the bridge was mounted in a separate covered compartment of a galvanized iron box. The box served for a shield and every precaution was taken to ensure symmetrical shielding. While making a measurement, covers were removed from those compartments containing the balancing resistance, the condenser shunting the balancing resistance, and the detector switch. The conductance cell was not shielded. Terminals leading to the oscillator, the amplifier, and the conductance cell were mounted on the side of the box with adequate bakelite insulation. Wires leading to the oscillator and amplifier were shielded. All connections between shields were soldered and grounded at one point. Connections between parts of the bridge were made through rather large holes cut in the walls of the various compartments of the galvanized iron box.

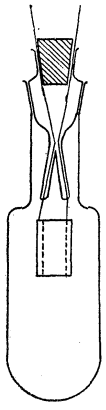

Fig. 1.

The balancing resistance consisted of a Leeds and Northrup decade box, 1–9,999 ohms, and calibrated International Resistance Company Type WW-1 precision wire resistors totaling 1.49 × 10^6 ohms. Resistances larger than 1.5 × 10^6 ohms were determined by shunting the conductance cell with a 5 × 10^5-ohm resistor, measuring the combined parallel resistance, and calculating that of the solution in the cell. During the latter part of the investigation a 1.5 × 10^6-ohm Shallcross resistor was added, permitting a direct balance up to 3 × 10^6 ohms. The use of Shallcross wire wound resistors has been described by Cox, Kraus and Fuoss.[8] When measuring resistances lower than 5 × 10^2 ohms, the 5000 ohm ratio arms were replaced with a Leeds and Northrup Kohlrausch slide wire. The slide wire was used at its midpoint, or at a point not more than five of its one thousand divisions from the midpoint, when measuring resistances between 115 and 500 ohms. Only when measuring resistances less than 115 ohms was it not used at the midpoint. This includes but seven determinations, the highest four of the tetrapropyl, the highest of tetraethyl, and the highest two of the tetramethyl compounds.

2. The Oscillator and Amplifier.—The oscillator was designed according to that described by Jones and Josephs.[9] The two-stage amplifier was constructed according to the design described by Bickford.[10]

3. Conductance Cells.—The cell used for all measurements excepting those for the monosubstituted ammonium chlorides contained electrodes in the form of two concentric cylinders of platinum separated at a distance of about one millimeter by glass bead-like separators. The leads of platinum wire were sealed into glass tubes which protruded downward from the ground-glass stopper of the electrode vessel. The leads were brought out through the top of the cell stopper and were held apart by a rubber stopper. This arrangement is shown in Fig. 1. The rubber stopper served also to prevent moisture from condensing in the tubes supporting the electrodes, thereby short-circuiting the electrodes. The electrode vessel had a volume of approximately 100 ml. The constant of the cell was approximately 0.01. Because of its removable electrodes, this cell had to be restandardized at frequent intervals. No more than four runs were made without restandardizing the cell, and usually less than this. Only twice were four runs made based on one standardization

The cell used in measuring the monosubstituted compounds contained three concentric platinum cylinders 80 mm. long and 17, 19 and 21 mm. in diameter.[8] The electrodes were separated by glass beads as before. The leads were of heavy platinum wire and were brought out

through the cell walls on opposite sides of the cell where the constriction takes place. The leads then passed into glass tubes which extended far enough above the stopper so that they would be at about room temperature to minimize condensation of moisture. The glass tubes were sealed into small mercury cups. The stopper was of glass ground into the electrode vessel. The heavy platinum leads supported the electrodes and the possibility of more than a very slight movement of the electrodes as a unit was obviated by a number of tips of glass projecting inward from the walls of the vessel. The constant of this cell was 0.001.

The cell having the higher cell constant was standardized directly against a 0.01 demal solution of potassium chloride at 25.0° according to the data of Parker and Parker.[11] The cell having the lower constant was standardized by comparing the resistance of conductivity water in it and in the first cell.

4. Preparation of Liquid Hydrogen Sulfide.—Figure 2 shows the arrangement of apparatus for the preparation, purification, and liquefaction of hydrogen sulfide. Concentrated hydrochloric acid was added from the dropping funnel B to powdered calcium sulfide in the three-liter distilling flask A. Accumulations of calcium chloride solution could be removed by applying suction to the bottle C and opening the cock D to the atmosphere. The hydrogen sulfide was washed with water in bottles E and F which removed most of the hydrogen chloride. Bottle G was charged with a saturated solution of barium hydroxide and this after being converted to barium hydrosulfide would react with any hydrogen chloride remaining in the gas stream. Towers H and I contained calcium chloride for drying. J contained aluminum sulfide which further dried the gas, liberating at the same time an equivalent amount of hydrogen sulfide, and reacting with any small amount of hydrogen chloride set free from the calcium chloride.[12] K and L contained phosphorus pentoxide. Much of the liquefaction took place in M and was completed in the electrode vessel in N. M and N were cooled with a mixture of solid carbon dioxide and ether. O contained phosphorus pentoxide to prevent condensation in the electrode vessel of water vapor from the air in the form of ice. O was used only infrequently as sufficient hydrogen sulfide escaped liquefaction to prevent the entrance of air into the exit tube.

The average specific conductance of twenty-three samples of liquid hydrogen sulfide prepared as described above was 3.08×10^{-10} mho. This agrees well with the value reported by Bickford,[13] 3.1×10^{-10}. The conductances of these twenty-three samples range from 0.9×10^{-10} to 8.7×10^{-10} mho.

Four other samples, prepared with a smaller and older sample of aluminum sulfide in bottle J showed specific conductances ranging from 9×10^{-10} to 44.41×10^{-10} mho. These values are cited as evidence that aluminum sulfide plays an important part in purifying the gas.

5. The Substituted Ammonium Chlorides.—These were prepared or purified carefully. The final drying of each compound was accomplished (after careful washing with absolute ether) by drawing dry air at reduced pressure slowly through the finely ground salt for a number of days. Immediately before use, the compound was transferred to a dry weighing bottle. These salts are hygroscopic but, providing the compounds were very dry to start with and were transferred to the weighing bottle and to the liquid hydrogen sulfide rapidly and only on days when the absolute humidity of the air was low, no detectable absorption of water occurred. The analyses of the compounds are shown in Table I.

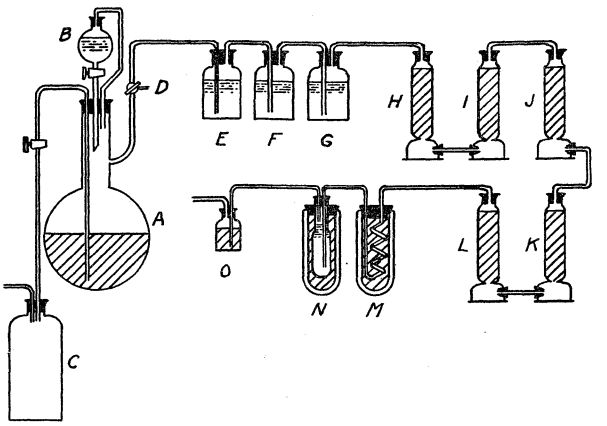

Fig. 2.

[a] Eastman Kodak Co. products, purified in this Laboratory. [b] Prepared and purified in this Laboratory. [c] Methylammonium chloride proved to be non-conducting in liquid hydrogen sulfide and was not further purified.

6. Procedure.—After measuring the resistance of the liquid hydrogen sulfide at the temperature of the cooling bath of solid carbon dioxide and ether (−78.5°),[14] a sample of the finely powdered, dry organosubstituted ammonium chloride was added from a weighing tube. After solution was complete, the resistance of the solution was measured, and the cell was lifted out of its freezing mixture only far enough to permit measuring the distance between a selected point at the top of the cell and the meniscus. The volume of solution in the cell was determined from a calibration

curve comparing distances from the top of the cell to the menisci for known volumes of water at room temperature. The contraction of the glass in cooling from room temperature to that of the freezing mixture is small and was neglected. After completing these measurements for one solution, another weight of salt was added, and the measurements were continued. Sorption effects at the electrodes were assumed to be negligible. They have been shown to be negligible at concentrations above 10^{-5} normal for solutions in several non-aqueous solvents at 25°.[8]

III. Results

The results are shown in Table II where C is the concentration in moles per liter and Λ is the molecular conductance. K_s indicates the conductance of solvent and K that of the solute.

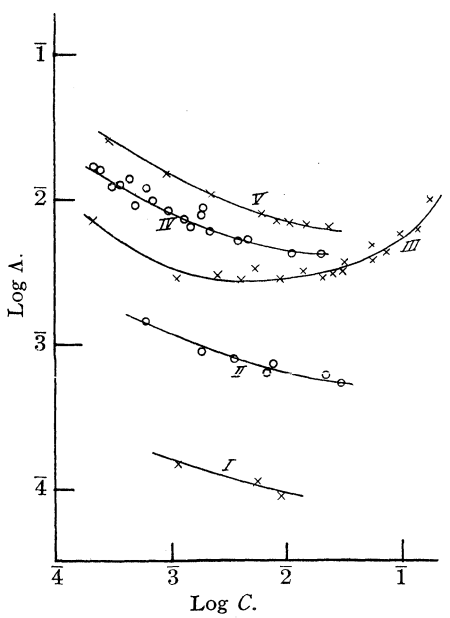

Fig. 3.—Conductance curves for substituted ammonium chlorides in hydrogen sulfide at −78.5°: I, $C_2H_5NH_3Cl$; II, $C_3H_7NH_3Cl$; III, $(CH_3)_2NH_2Cl$; IV, $(C_2H_5)_2NH_2Cl$; V, $(C_3H_7)_2NH_2Cl$.

The specific conductances of the monomethyl and monoethyl compounds are not much greater than that of pure liquid hydrogen sulfide, and those for the propyl compound are about twice that of the pure solvent. With corrections as large as these, the results are not accurate and are given merely to indicate their order of magnitude.

The conductance of the solvent was significant (at greatest, 11% of that of the solution) in measuring the more dilute solutions of the di- and trisubstituted salts. For the tetrasubstituted compounds, the correction was never greater than one part in one thousand, and for most solutions it was negligible.

Figures 3 and 4 show the plots for the data of Table II.

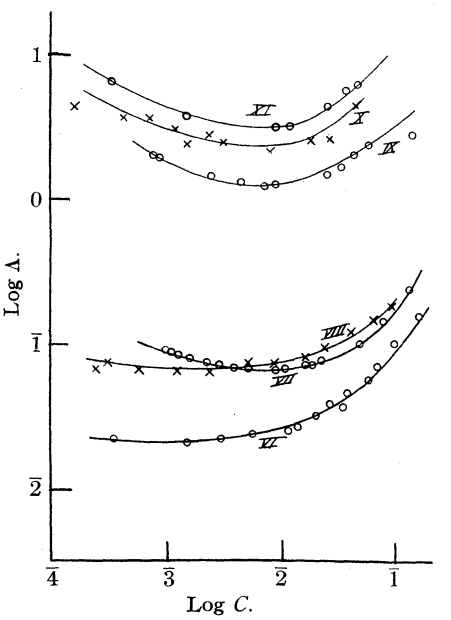

Fig. 4.—Conductance curves for substituted ammonium chlorides in hydrogen sulfide at −78.5°: VI, $(CH_3)_3NHCl$; VII, $(C_2H_5)_3NHCl$; VIII, $(C_3H_7)_3NHCl$; IX, $(CH_3)_4NCl$; X, $(C_2H_5)_4NCl$; XI, $(C_3H_7)_4NCl$.

IV. Discussion of Results

The greater the number of groups substituted in the ammonium radical the greater the conductance becomes. The mono substituted compounds are poor conductors and very little evidence of conductance with the monomethyl compound was observed. This may be due to the fact that the solubility of the compound in liquid hydrogen sulfide is almost nil.

In general the higher the molecular weight of the substituted group, the higher is the value of the conductance. The only exception to this is that the triethyl compound shows higher conductance than the tripropyl ammonium chloride at low concentrations.

The conductance is not greatly altered by changing the substituent from methyl to ethyl to propyl groups. Changing the number of the substituted groups has a greater effect on the magnitude of the conductance, the greatest increase occurring when going from the tri- to the tetrasubstituted compounds.

The compounds in general show an increasing

which do not show this, the monosubstituted salts and dipropyl- and diethylammonium chlorides, would be expected to have increasing conductance in more concentrated solutions. Additional measurements were made extending concentrations to higher values than those reported for dipropyl and diethylammonium chlorides but no increase in conductance with increasing molecular concentration was noticed with these two salts.

Acknowledgments.—The authors are indebted to Dr. W. G. Bickford for help and suggestions while constructing the conductance bridge and its auxiliaries. A substantial part of the experimental work was done in the Chemistry Laboratories of the University of Vermont.

V. Summary

The conductances of solutions of mono-, di-, tri- and tetrasubstituted methyl-, ethyl- and *n*-propylammonium chlorides in liquid hydrogen sulfide have been measured. These show that the molecular conductance increases both with the number and the size of the substituted groups, the number having a greater effect than the size.

The conductance concentration curves show a minimum which is characteristic of solutions of electrolytes in solvents of low dielectric constant.

Chemical Activation by Isomeric Radioactive Transition; the Reaction of Br^{80} (18 min. half-life) with Carbon Tetrachloride

BY JOHN E. WILLARD

Investigations in this Laboratory utilizing radioactive bromine have shown that it undergoes a reaction with carbon tetrachloride. This reaction is not activated by either heat or light but must be accounted for on the basis of chemical activation resulting from the radioactive transition of Br^{80} (4.4 hr. half-life) to Br^{80} (18 min. half-life).

Freshly prepared radioactive bromine contains a mixture of Br^{80} (4.4 hr. half-life), Br^{80} (18 min. half-life) and Br^{82} (34 hr. half-life), all of which may be formed from the common isotopes Br^{79} and Br^{81} by neutron capture. Br^{80} (4.4 hr.) and Br^{80} (18 min.) are radioactive isomers[1,2,3,4] the first of which changes into the second as a result of a loss in nuclear energy. In somewhat less than 70% of the transitions[5] this energy appears as a gamma ray while in the remaining transitions it serves to eject a conversion electron from one of the electron shells of the atom.

It has been shown that the change from Br^{80} (4.4 hr.) to Br^{80} (18 min.) is capable of activating the hydrolysis of *t*-butyl bromide,[2] the rupture of bromate ion,[3] and the decomposition of ethylene dibromide.[6] These reactions result in the preferential splitting out of Br^{80} (18 min.) atoms from the parent molecule. The activation of these processes has been attributed to the recoil energy imparted to the Br^{80} (18 min.) by the ejection of a gamma ray or conversion electron, but in view of a subsequent determination[7] of the energy of the conversion electrons involved, this explanation is not tenable.

In agreement with the work cited above, it has been found that Br^{80} (18 min.) is the reactive bromine species in mixtures of bromine isotopes with carbon tetrachloride. Calculations discussed below indicate that only those transitions of Br^{80} (4.4 hr.) to Br^{80} (18 min.) which occur with the emission of a conversion electron result in reaction with the carbon tetrachloride. The electronic rearrangements which follow such emission afford ample energy to account for the activation.

The results which have been obtained emphasize the fact that special precautions must be exercised in the use of certain radioactive elements as isotopic tracers if erroneous conclusions are to be avoided. It is to be noted, however, that Br^{82} (34 hr.) may be used as an isotopic tracer without danger of ambiguity. This isotope may be obtained by allowing mixtures of isotopes to stand until the relatively short-lived Br^{80} isomers have decayed.

It might be expected that reactions caused by the beta rays in solutions of the type under consideration would mask reactions, such as those observed, which preferentially separate one period of activity. This, however, does not occur because the proportion of radioactive bromine to normal bromine is extremely small.

Experimental Procedure

Radioactive Bromine.—Radioactive bromine was produced by irradiating 3 liters of ethyl bromide with neutrons from a Ra (200 mg.)–Be source for twenty-four hours. Following irradiation the ethyl bromide was extracted with 150 cc. of water containing about 0.05 g. of sodium bromide. The water solution was then evaporated to about 0.5 cc. and pipetted into the reaction tube (A) of Fig. 1, together with a small amount of potassium bromate and sulfuric acid. The reagents were frozen with liquid air to prevent reaction until (A) had been sealed shut. The bromine which was liberated in (A) with gentle warming was condensed in (B) with an ice–salt mixture. The reaction tube (A) was then sealed off from the system, the gas-escape (D) was sealed, and the bromine was frozen with liquid air. The system was then evacuated through the tube (H) with the aid of a mercury vapor pump and the bromine was distilled onto phosphorus pentoxide in the trap (C), where it was kept until it was admitted to the carbon tetrachloride in the tubes (F).

Carbon Tetrachloride.—Mallinckrodt "Low Sulfur" carbon tetrachloride was strongly illuminated while saturated with chlorine and chlorine dioxide,[8] washed with sodium hydroxide and with water, and dried over phosphorus pentoxide. It was then distilled into an all-glass reservoir (G) equipped with glass taps which could be opened by a magnetically operated hammer. It was degassed by several repetitions of the process of freezing–evacuating–melting. Samples were taken from the reservoir as desired by distilling into evacuated reaction tubes (F). After a sample was obtained the reservoir was sealed off while the carbon tetrachloride was frozen. About 1 cc. was collected in each tube.

Reaction Mixture.—The bromine which was collected in the trap (C) was transferred to the tubes (F), containing the carbon tetrachloride, by cooling the latter with liquid air and opening the stopcock or glass tap at (E). (Stopcocks were greased with Apiezon grease.) The tubes (F) were then sealed from the system as a unit; their contents were melted, mixed and refrozen, and they were sealed off from one another. Their bromine concentration was about 0.05 *M*.

Analysis.—After the reaction tubes had been allowed to stand for the desired length of time, they were opened and the contents washed three times with 5-cc. portions of 20% potassium iodide to give a colorless carbon tetrachloride layer containing the reaction products. This layer showed no radioactivity if the extraction was made immediately after the bromine was added to the carbon tetrachloride.

The relative radioactivity of samples was determined by means of a Geiger–Müller counter tube the end of which consisted of a thin glass bulb which could be lowered into a cup of the solution to be tested. Counts were made on unextracted carbon tetrachloride–bromine solutions, carbon tetrachloride from which the bromine had been extracted, and on the extraction liquid. Frequent determinations of the background count showed it to be very constant at a value of 10 ± 2 per min. The activities which were measured ranged from several thousand counts per min. down to the value of the background.

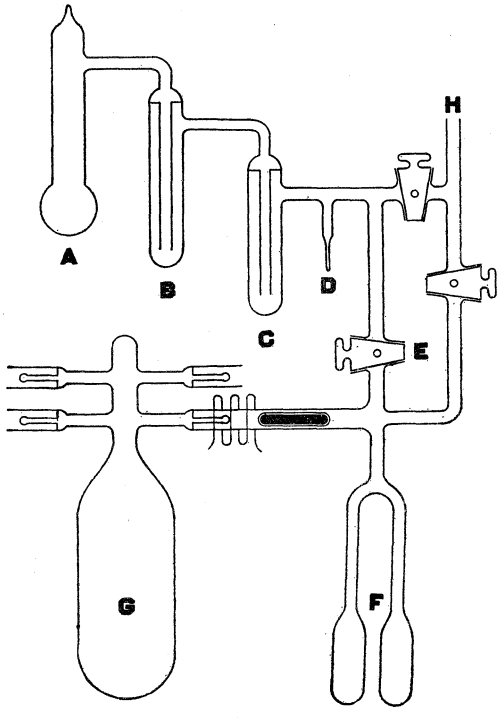

Fig. 1.

Results

Activity Entering Carbon Tetrachloride.—When bromine containing an equilibrium mixture of Br^{80} (4.4 hr.) and Br^{80} (18 min.), some Br^{82} (34 hr.), and a large proportion of non-radioactive bromine is allowed to stand for two hours or more with carbon tetrachloride, between 30 and 40% of the activity measured by the counter described above is found to enter the carbon tetrachloride. This activity is, within the limits of resolution of the apparatus, solely 18 min. activity. A typical decay curve for such a solution is shown in (A) of Fig. 2. The circles represent the experimental data; the line is a calculated curve for the decay of activity with an 18 min. half-life.

Growth of Activity in Carbon Tetrachloride.—If bromine enters the carbon tetrachloride molecule as a result of activation accompanying the transition of Br^{80} (4.4 hr.) to Br^{80} (18 min.) it

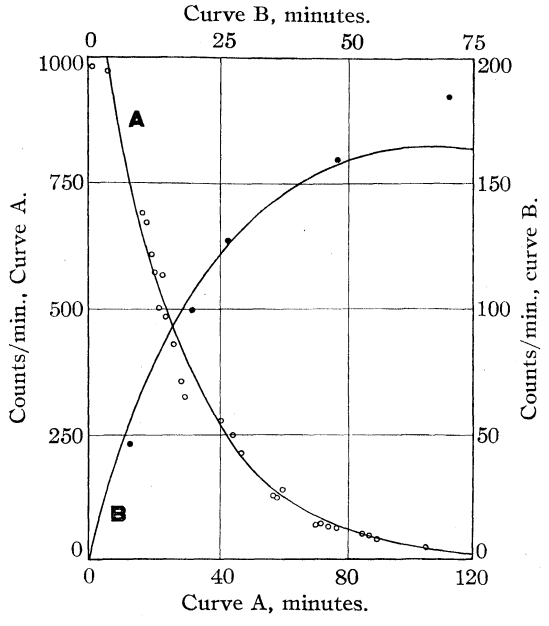

Fig. 2.—Curve A: circles show decay of radioactive bromine which has reacted with carbon tetrachloride. Solid line is calculated decay curve for species with 18 min. half-life. Curve B: points show growth of activity in carbon tetrachloride reacting with radioactive bromine. Solid line shows calculated growth of 18 min. activity from 4.4 hr. activity.

would be expected that a plot of activity entering the carbon tetrachloride against time of contact of the carbon tetrachloride with the bromine would show a growth curve typical of the build-up of 18 min. activity from a relatively long-lived parent. Such a curve is shown in Fig. 2(B). The points were obtained from counts on five samples of the same solution which had been allowed to react for different lengths of time before extraction. The counts have been corrected for the decay which occurred between the start of extraction and the time of taking the counts. The solid line is a theoretical growth curve for the production of 18 min. activity from 4.4 hr. activity.

Activity in Extraction Solution.—The circles of Fig. 3 show the experimentally determined values (less the 34 hr. activity) for the activity of bromine at different times after extraction from a carbon tetrachloride solution in which it had stood for two hours. The activity increases immediately after extraction, passes through a maximum, and finally falls off with a 4.4 hr. decay period. This behavior would be expected if the freshly extracted bromine contained less than the equilibrium amount of Br^{80} (18 min.), that is, if some of the latter had reacted with the carbon tetrachloride.

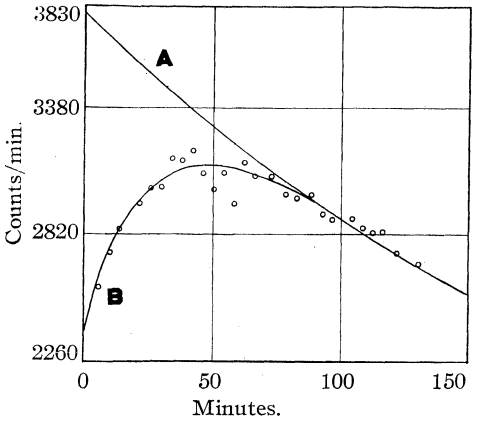

Fig. 3.—Circles show activity of radioactive bromine extracted from carbon tetrachloride solution after standing in the latter for two hours. Curve A: calculated decay of equilibrium mixture of Br^{80} (4.4 hr.) and Br^{80} (18 min.). Curve B: calculated change in radioactivity of extraction solution assuming that 37% of Br^{80} (18 min.) has been removed by reaction with carbon tetrachloride and that radiations from Br^{80} (4.4 hr.) do not register on the counter.

The intersection of the line (A) of Fig. 3 with the zero time ordinate gives the counts per min. which would have been obtained from the extraction solution at the time of extraction if none of the 18 min. activity had reacted with the carbon tetrachloride. It is calculated from the 4.4 hr. decay curve given by the experimental points for times after equilibrium was reëstablished.

Reaction Efficiency.—If the relative efficiency with which the radiations from Br^{80} (4.4 hr.) and Br^{80} (18 min.) affect the Geiger–Müller counter is known, the fraction of the Br^{80} (18 min.) atoms which react with carbon tetrachloride can be obtained readily from the value for the count in the extraction solution at the time of extraction and the value of the intercept of curve (A), Fig. 3, with the zero ordinate.

The 4.4 hr. radiations consist of conversion electrons with energies of 23.6, 35.5, and 47.2 kev., and gamma rays with energies of 48.9 and either 37.1 or 25.3 kev.[7] Calculations show that the fraction of such gamma rays which are absorbed by the counter used in this work is so slight that the number of counts which they produce is negligible. The conversion electrons are also

ineffective in counting because they are almost completely absorbed by the walls of the counter tube before entering the counting chamber.

Therefore it may be concluded that the total count produced by mixtures of Br^{80} (4.4 hr.) and Br^{80} (18 min.) is due to the β rays ejected in the change from Br^{80} (18 min.) to Kr^{80}. These have been found to have a maximum energy of 2 mev.[9]

This conclusion is in agreement with the results of DeVault and Libby[3] and LeRoux, Lu and Sugden,[6] whose data indicate that less than 25 and 10%, respectively, and possibly no part of the total count from radioactive bromine in their counters is due to the 4.4 hr. isomer.

With the knowledge that the radiations from Br^{80} (4.4 hr.) do not affect the counter, it may be determined from the data of Fig. 3 that 0.37 of the Br^{80} (18 min.) atoms formed from Br^{80} 4.4 hr. react with the carbon tetrachloride. This value is in agreement with values of 0.3 to 0.4 obtained by measuring both the activity in the carbon tetrachloride layer and that in the extraction solution immediately after extraction of solutions of radioactive bromine in carbon tetrachloride.

Effect of Temperature and Phase.—If the energy which is made available to a bromine atom by the change from the 4.4 hr. to the 18 min. species is greatly in excess of the activation energy required for a given chemical reaction of the bromine, it is to be expected that the reaction will be independent of temperature. To test this point the maximum fraction of the activity which will enter the carbon tetrachloride has been determined at room temperature, at $-10°$ where the reaction mixture is a liquid, at $-50°$ where it is a solid, and at liquid air temperatures. The results are given in Table I. The values given in the table have been corrected for the background count and for the decay which occurred between the start of extraction and the time of taking the count.

TABLE I

T, °C.	Total counts/min.	CCl_4 counts/min.	% in CCl_4
25	1061	361	34
− 10	518	155	30
− 50	566	45	8
−190	1190	145	12

Different determinations at a single temperature varied as much as 20% from the average, probably due in a large part to the fact that the counter tube was not designed for exactly reproducible comparisons of different samples. The accuracy is adequate, however, to show qualitatively that temperature has little or no direct effect upon the reaction but that the reaction efficiency is reduced to about one-third of its liquid phase value when the reaction system is frozen.

It is to be noted in the table that the reaction does occur even in the solid phase at liquid air temperatures. The amount of reaction at $-10°$ where the mixture is liquid is equivalent to that at 25°. The amount of reaction at $-50°$ where the mixture is a solid is equivalent to that at $-190°$. The change in going from -10 to $-50°$ evidently is due to the change in phase.

If the reaction were a chain reaction with secondary steps for which thermal activation energy was required, it would be dependent on temperature. However, this would not be apparent from the measurements made in this work since they show only the final disposition of Br^{80} (18 min.).

Mechanism of Activation.—It has been suggested[2] that chemical activation by the isomeric transition of Br^{80} is due to the recoil energy which the newly formed Br^{80} (18 min.) atoms acquire as the result of the ejection of a gamma ray or conversion electron when they are formed from Br^{80} (4.4 hr.). Since the publication of this suggestion Valley and McCreary[7] have determined the upper energy of the conversion electrons emitted in this transition to be 47.2 kev. and have concluded from their data that the upper energy of the gamma rays is 48.9 kev.

The recoil energy acquired by a bromine molecule as the result of the ejection of a 47.2 kev. electron is about 3.7 kcal. per mole and the recoil energy made available by the emission of a 48.9 kev. gamma ray is about 0.2 kcal. per mole. These energies are not adequate to account for the observed reaction of bromine and carbon tetrachloride, which are normally very inert to one another.

A larger source of activation energy is, however, available. In emitting a conversion electron a bromine atom initiates an electronic rearrangement of which evidence is given by X-rays[4] and Auger electrons.[5] Such a rearrangement readily can produce highly reactive states of the bromine molecule, atom or ion. A knowledge of the exact nature of the state which leads to the reaction of Br^{80} (18 min.) with carbon tetrachloride is not

(9) Livingston and Bethe, *Rev. Mod. Phys.*, **9**, 245 (1937).

necessary for the purposes of this paper. However, a number of possibilities may be suggested. The molecular ion, formed when a conversion electron, followed by an X-ray, is emitted from a bromine molecule, may have an electronic configuration which makes it capable of reacting directly with a carbon tetrachloride molecule. Alternatively the electronic state may be such as to lead to the dissociation of the molecular ion into a neutral atom and an atomic ion. If this latter process occurs the fragments may part with sufficient kinetic energy to cause them to react with carbon tetrachloride molecules, or the reaction may be accounted for by the electronically excited state of the atomic ion formed. Another possibility is that the reaction is due to a reactive excited state produced when the ion regains an electron.

Whatever the exact mechanism of the activation is, it is necessary to conclude that only those isomeric transitions which occur with the emission of a conversion electron, and consequent electronic rearrangements, can produce reaction.

Siday[5] has found that the fraction of the Br^{80} (4.4 hr.)$\longrightarrow$$Br^{80}$ (18 min.) transitions which emit a conversion electron is slightly more than 0.3. This value sets an upper limit for the fraction of the Br^{80} (18 min.) atoms which can react with carbon tetrachloride, if reaction occurs only following the ejection of an electron. This upper limit is in close agreement with the experimentally determined reaction efficiency discussed above. Therefore it may be concluded that essentially all of those Br^{80} (18 min.) atoms which are formed with the emission of a conversion electron react.

Since the decomposition of radioactive bromate ion[3] and of radioactive ethylene dibromide[6] occur for at least 75 and 90%, respectively, of the Br^{80} (4.4 hr.)$\longrightarrow$$Br^{80}$ (18 min.) transitions and since, according to Siday, a much smaller fraction of these transitions involve the loss of a conversion electron, it appears that some explanation not dependent on the emission of a conversion electron must account for at least part of the observed reaction in these cases. The recoil energy from the transition gamma rays (0.2 kcal.) is insufficient to do so. Therefore, if the observed values for the reaction efficiencies, for the conversion coefficient, and for the energies of the conversion electrons, are valid, some explanation which is not yet apparent must be sought.

Reaction Due to Beta Rays.—Since each beta ray and conversion electron shot out from the radioactive atoms in solution probably disrupts or ionizes several thousand carbon tetrachloride molecules, there must be many reactive fragments capable of combining with bromine in the solution. If more than a very small fraction of the bromine were radioactive, experiments would therefore show a considerable proportion of the 4.4 hr. Br atoms as well as of the 18 min. atoms entering the carbon tetrachloride. However, the proportion of radioactive to non-radioactive bromine atoms in the solution is probably less then $1:1 \times 10^{12}$, so the effect in question is not observable in the measurements of activity.

Neutron–Bromine Reaction.—Incidental to the preparation of radioactive bromine, determinations were made of the rate of decay of the activity of ethyl bromide samples which had just been removed from the Ra–Be source after twenty-four hour exposures. In all cases plots of the logarithm of the activity against time showed the initial decay to have a half-life of the order of twenty minutes, which changed to a half-life of about four and one-half hours after the ethyl bromide had been away from the neutron source for a little over an hour. This indicates that Br^{80} (18 min.) may be formed directly by neutron bombardment, since if all of the 18 min. activity were produced as daughter activity of the 4.4 hr. isomer, the decay curves would be of the 4.4 hr. type from the start.

The author wishes to express his appreciation to Mr. William Van Horne and Mr. Hugh Hulburt for the loan of the counting apparatus used in the foregoing work, to Dr. Joseph O. Hirschfelder for helpful discussions, and to the Wisconsin Alumni Research Foundation for the use of the Ra–Be neutron source.

Summary

1. It has been found that the radioactive transition from Br^{80} (4.4 hr.) to Br^{80} (18 min.) activates bromine in such a way as to enable it to react with carbon tetrachloride.

2. Decay and growth curves of the activities involved give consistent proof of the existence of the reaction.

3. Experiments over a wide temperature range show the reaction to be independent of temperature and to have an efficiency about one-third as great in the solid phase as in the liquid phase.

4. The evidence indicates that only those

Br^{80} (18 min.) atoms react which are produced as the result of the emission of a conversion electron.

5. In the light of new data, the recoil energies previously thought to account for chemical activation by the isomeric radioactive transition of bromine, are found to be too small to do so.

Partial Vapor Pressures from Nicotine Solutions at 25°*

BY L. B. NORTON, C. R. BIGELOW AND W. B. VINCENT

Little information is available on the loss of nicotine by evaporation and the concentration of nicotine vapor which can be built up when a dilute solution of nicotine is applied to foliage as an insecticide. A knowledge of the partial vapor pressures of both water and nicotine through the complete range of their solutions is therefore of great practical importance from that standpoint, and of theoretical interest in showing the thermodynamic behavior of a highly non-ideal solution.

The published values of the vapor pressure of pure nicotine at ordinary temperatures are in very poor agreement. The values at 25° range from 0.02 mm., determined experimentally by Harlan and Hixon,[1] to 0.17 mm. calculated from the equation found by Gorbachev[2] to be valid from 100 to 250°. A similar equation obtained by Young and Nelson[3] gives 0.12 mm. as the vapor pressure at 25°. No data are available on the evaporation of nicotine from solutions, except some approximate determinations by McDonnell and Young[4] of the final concentration and the loss of nicotine from a dilute solution exposed to the air for a long period at room temperature.

Experimental

Materials.—The nicotine was prepared by purifying the commercial 95% alkaloid, furnished by the Tobacco By-products and Chemical Corporation of Louisville, Ky., according to the method of Ratz,[5] and distilling it *in vacuo*. The product boiled at 125° at 17 mm. pressure, was water-white, and had a specific rotation $[\alpha]^{20}D$ −168.90°. Different samples which were purified at intervals during the investigation varied from this rotation not more than 0.2°. Ordinary distilled water was used as the other component.

Apparatus.—The dynamic gas-saturation method was used for the measurements because of the extremely low vapor pressure of the nicotine. The apparatus was arranged as in Fig. 1. Nitrogen, which was used instead

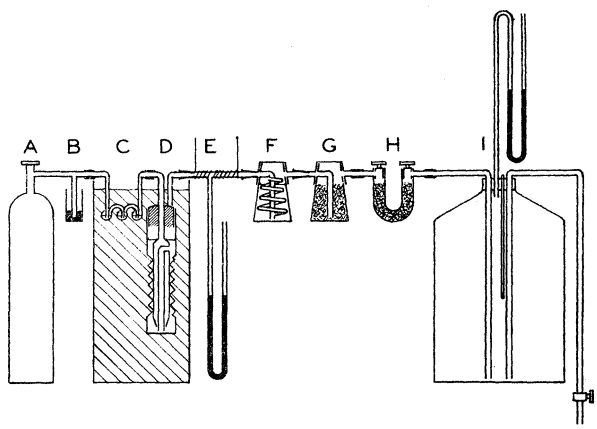

Fig. 1.—Apparatus for vapor pressure measurements.

of air to eliminate slow oxidation of the nicotine, was passed from the cylinder A over the mercury trap B, which served as a safety valve and pressure regulator, and into the vaporizers C and D. C was a series of three small bulbs charged with the solution to be measured, which saturated the gas partially, thus preventing appreciable changes in the concentration of the solution in the main vaporizer D by evaporation losses. D was the main vaporizer, consisting of a Friedrichs spiral gas-washing tower containing 200 cc. of the solution under investigation. The upper part of the tower was packed with glass wool saturated with the same solution to stop any spray and to ensure complete saturation of the nitrogen passing out. Both vaporizers were completely immersed in a water-bath maintained at 25 ± 0.02°. The outlet tube E was heated electrically by a winding of resistance wire to prevent condensation of vapor and was connected with a manometer. The nicotine was absorbed in the modified Turner absorption bulb F, which was filled with dilute sulfuric acid. The second absorption bulb G was filled with anhydrous magnesium perchlorate "Anhydrone" to absorb the water vapor coming from the vaporizer and the first absorber. The U-tube H also contained Anhydrone to absorb any water vapor coming back from the aspirator The aspirator bottle I had a capacity of 40 liters and was fitted with a manometer, thermometer, and siphon tube.

(*) Approved by the Director of the New York State Agricultural Experiment Station for publication as Journal Paper No. 345, October 30, 1939.

All connections from the vaporizer to the last absorber were made with ground glass joints, since rubber has been shown to take up appreciable quantities of nicotine under these conditions. The joints were lubricated only on their outer parts, and the lubricant was kept away from the inlet hole in the nicotine absorber in order to avoid possible absorption of nicotine by the grease.

Procedure.—The nitrogen was bubbled through the vaporizers for thirty minutes before the absorbers were connected to ensure complete thermal and vapor equilibrium. The rest of the apparatus was then assembled, and the units turned on in order, the absence of leaks being indicated by the lack of bubbles through the vaporizers, all of the nitrogen escaping through the trap B. The outlet from the aspirator was opened last, and the outflow adjusted to 8–10 liters per hour. The tube in the mercury trap B was quickly adjusted to such a height that the saturated gas coming from the vaporizer was at atmospheric pressure, as indicated by the manometer at E. The run was continued, with only occasional slight adjustments necessary, until 15 to 35 liters had passed through.

The barometric pressure was read at the beginning and the end of each run. The manometer and the thermometer in the aspirator were read at the end of the run, and the manometer at E, as mentioned before, was maintained continuously at zero pressure difference. Both of the filled absorbers were weighed before and after the run, any lubricant on the joints being removed with benzene. The water displaced from the aspirator was weighed to 5 g. on a large solution balance. The solution from absorber F and a sample of the solution from the vaporizer D were analyzed for nicotine.

Analysis.—Most of the original solutions were analyzed by polarimetric measurements, which were found to be superior to chemical analyses for the concentrated solutions. The rotation was determined by means of a Schmidt and Haensch triple field polarimeter with a sodium vapor lamp, using a 2-dm. jacketed tube through which water at 20° was circulated. The nicotine content was read from a curve of concentration plotted against angular rotation, based on the data of Jephcott.[6] The solutions containing less than 5% of nicotine and the absorber solutions were analyzed by precipitation of the nicotine with silicotungstic acid.[7]

Calculation.—The method of calculation was similar to that of Young and Nelson[3] with the addition of a correction for the vapor pressure of the water in the aspirator and for the difference in pressure between the aspirator and the atmosphere, and the extension of the formula to two different vapors. The calculation corresponded to the formulas

$$\text{V. P. (nicotine)} = 760nPT/(273P'V + 760T(n + w))$$
$$\text{V. P. (water)} = 760wPT/(273P'V + 760T(n + w))$$

where P is the barometric pressure as read; P' the barometric pressure corrected for water vapor and the manometer reading; T the absolute temperature of the aspirator; V the gross volume of nitrogen passed through, as measured by the weight of water displaced from the aspirator; n the volume at standard conditions of the vaporized nicotine (g. absorbed nicotine × 22,400/162); and w the corresponding volume of water vapor (g. absorbed water × 22,400/18). The weight of the absorbed water is taken as the net gain in weight of the two absorbers less the weight of absorbed nicotine found by analysis.

Errors.—The estimated random errors from the experimental measurements were as follows: pressure, 0.2%; temperature, 1%; weights, 0.1%. The errors from analysis varied from less than 1% to 5% in different parts of the range.

A systematic error of less than 0.1% was incurred in the calculation by the assumption of the validity of the ideal gas laws. The most serious systematic errors probably came from incomplete vaporization or absorption of the vapors, giving consistently low results, or contamination of the heated outlet tube from spray or other sources, giving high results. The apparatus was tested for such errors by determining the vapor pressure of pure water. The average value found by several runs was 23.57 mm., as compared with the accepted value of 23.75 mm., indicating the absence of sources of serious consistent errors. Complete vaporization of nicotine was demonstrated by a series of determinations on a dilute solution of nicotine, in which the same value of the vapor pressure was obtained, within the expected error, when different solutions, including pure nicotine, were used in the bulbs preceding the main vaporizer. A second nicotine absorber following the first yielded no test for nicotine, showing complete absorption in the first. It was concluded therefore that subsequent determinations would include only accidental errors of this type, limited to single runs.

Results and Discussion

Pure Nicotine.—Because of the uncertainty of the previously determined values at low temperatures, the vapor pressure of pure nicotine was measured as accurately as possible. Ten determinations were made, including five different samples of nicotine, yielding a value of 0.0425 ± 0.0003 mm. for the vapor pressure at 25°. This result indicates considerable error in the values of Harlan and Hixon[1] which, however, were only intended to be approximate, as well as those calculated from the equations of Gorbachev[2] and Nelson and Young,[3] which are somewhat uncertain at 25° because of the long distance of the extrapolation from the experimental points considered.

The complete series of partial vapor pressure measurements are presented in Table I, and the vapor pressures are plotted against the mole fractions in Fig. 2. It will be noted that the vapor pressures of the two components are plotted on different scales in Fig. 2 since they are of a quite different order of magnitude.

Raoult's Law.—The dotted lines in Fig. 2 represent the ideal curves to be expected if both components followed Raoult's law. The close approach of the upper ends of both experimental curves to these ideal curves shows that either nicotine or water follows Raoult's law reasonably well over a limited range of dilute solutions of the other. Throughout the rest of the range both components show abnormally high vapor pressures. At the lower ends of the curves the very dilute components approximately follow Henry's law over an appreciable range, although the deviations from Raoult's law are very large. Of particular interest is the very abrupt rise in the vapor pressure of nicotine in dilute solutions. Zawidzki[8] obtained a pair of curves from water and pyridine almost identical in form with these.

The Duhem Equation.—The Duhem equation, $d \ln P_1/d \ln x = d \ln P_2/d \ln (1 - x)$, permits the calculation of the partial vapor pressures of the nicotine from those of the water. Following Zawidzki's procedure,[8] we derived the following empirical equation for the partial vapor pressures of the water, neglecting the points at the extreme ends of the curve

$$\text{Log } P_1 = 1.3714 + 1.50 \log x + 0.643(1 - x) - 0.709(1 - x)^2 + 1.23(1 - x)^3$$

where x represents the mole fraction of the water.

From this empirical equation and the equation of Duhem, the corresponding equation for the partial vapor pressures of nicotine is

$$\text{Log } P_2 = -1.3716 + 0.02 \log(1 - x) - 0.643x + 1.14x^2 - 1.23x^3$$

A comparison of the calculated with the observed values is given in Table II.

TABLE II

COMPARISON OF OBSERVED AND CALCULATED VAPOR PRESSURES

Mole fraction nicotine	V. P. water Obsd.	V. P. water Calcd.	V. P. nicotine Obsd.	V. P. nicotine Calcd.

.02	23.2	23.5	.0082	.0078

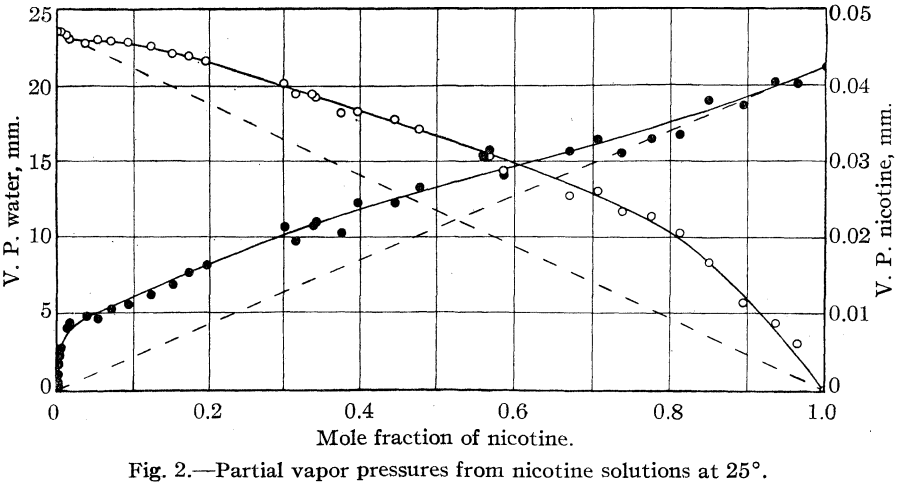

Fig. 2.—Partial vapor pressures from nicotine solutions at 25°.

The agreement of the calculated with the observed values for water shows the faithfulness of the empirical equation. The simultaneous agreement of the corresponding values for nicotine shows that the Duhem equation is valid for this system. The equations are, however, not suitable

(8) Zawidzki, *Z. physik. Chem.*, **35**, 129 (1900).

for calculations at very low or very high concentrations.

Activity.—In view of the extreme abnormality of the lower end of the nicotine vapor pressure curve, it is of interest to calculate the corresponding change in the activity of the nicotine with concentration in this region. The ratio of vapor pressure to mole fraction appears to approach a value of approximately 1.6 in very dilute solutions. The region where $P = 1.6x$ was therefore chosen as the standard state, and the relative activity coefficients calculated as the ratios $P/1.6x$ for solutions up to 0.1 mole fraction, using a large-scale plot of this section of the curve for interpolation of the vapor pressure values. The resulting activity coefficients are shown in Table III.

TABLE III

ACTIVITY COEFFICIENTS OF NICOTINE IN DILUTE SOLUTIONS

Mole fraction nicotine	γ nicotine
0.001	0.90
.005	.63
.010	.45
.020	.26
.030	.19
.040	.15
.050	.13
.100	.08

The activity coefficients decrease extremely rapidly at first with increasing concentration, then show a slow decrease in more concentrated solutions. These values are in satisfactory agreement with the activity coefficients calculated from freezing point data to be published later. It will be noted that the standard state for the nicotine in dilute solution yields an extrapolated value of 1.6 mm. for the ideal vapor pressure of pure nicotine widely different from the actual value of 0.0425 mm.

Rate of Evaporation.—From a practical standpoint the most desirable information is the relative speed of evaporation of the components as a function of the percentage composition. It can be assumed that the rate of evaporation in the open air at low humidity will be roughly proportional to the vapor pressure. The large difference in molecular weight between the components introduces two factors altering the curves in Fig. 2. First, with equal vapor pressures of the two, the evaporation of the nicotine by weight will be nearly ten times as great; second, the lower part of the curves will be greatly lengthened and the higher greatly compressed in changing from mole fractions to percentage composition. Accordingly, after the first rapid rise in the vapor pressure of nicotine at low concentrations, neither the water nor the nicotine changes greatly from 10 to 70%. Even at 90% nicotine, both vapor pressures are about half those of the pure components. The relative losses by evaporation through most of the range will be of the order of 200 of water to 1 of nicotine by weight.

Under actual conditions the ratio will be somewhat less, because of the presence of water vapor already in the air, which will have the effect of subtracting a definite pressure from the effective vapor pressure of the water. The final concentration of any nicotine solution exposed to the air can be determined from the curves as that concentration at which the vapor pressure of the water is equal to the partial pressure of water vapor in the air.

Summary

The partial vapor pressures of nicotine and water in all their binary solutions at 25° have been determined by the dynamic method.

The deviations from Raoult's law are found to be very large and in the direction of higher vapor pressures for both components.

The results are shown to agree with the Duhem equation.

The activity coefficients of nicotine in dilute solutions are found to decrease very rapidly with increasing concentration.

With increasing percentages of nicotine the loss of nicotine relative to that of the water first increases rapidly, then remains nearly constant over a long range, and finally increases very rapidly during free evaporation.

Free Radicals in the Pyrolysis of Acetaldehyde

BY MILTON BURTON, JOHN E. RICCI AND THOMAS W. DAVIS

Leighton and Mortensen[1] have described experiments in which they detected the formation of free alkyl radicals by the transport of radioactivity (due to Ra-D) from a Paneth radio-lead mirror over which the radicals were passed.[2] We have modified their method in regard to the collection of the transported Ra-D and have been successful in this way in establishing the formation of free radicals in the pyrolysis of acetaldehyde at 500°.

Experimental

The apparatus used in this investigation was essentially as shown in Fig. 1.

Eastman Kodak Co. acetaldehyde was distilled into reservoir A immersed in dry-ice from a reservoir cooled with ice and subsequently freed from air by repeated alternate warming and evacuation at dry-ice temperatures. In this way the extensive polymerization caused by freezing in liquid air[3] was largely avoided. Of two samples so prepared, one, used in runs 17 to 25, had a v. p. of ~335.6 mm., and the other, used in runs 26 to 34, had a v. p. of ~334.6 mm. at 0°. Comparison of these values with that of 337 mm. given by Emeleus[4] would indicate that the presence of the polymer, which could be readily discerned as acetaldehyde was removed, decreased the vapor pressure.

Pellets of natural radio-lead (Pb) prepared from spent radon tubes[5] in a manner already described[6] were introduced into the system (beyond the graded seal G) at a fracture at C which was thereafter sealed. The section of tubing extending to the right of the furnace had an internal diameter of ~5 mm. Heavy mirrors, ~5–6 mm. long in runs 16 to 25 and ~1 cm. long in runs 26 to 34 were deposited at B at a distance ≤ 4 cm. from the end of an electrically heated quartz furnace Q. Because of the presence of radioactive materials it was necessary to modify the usual methods of deposition.[2] Before each deposition any remnant of old mirror was removed by external heating with a gas flame while a stream of acetaldehyde vapor passed through the tube via stopcocks 2, 3 and 4. A fresh mirror was then driven ahead of a gas flame toward the furnace in the usual way and deposited instead of the old. This was removed in the manner just described and a new mirror was deposited for the run. In order to remove the last trace of any volatile radioactive compound the system was now pumped out for several hours before the actual commencement of the run. It is known that delay in the use of lead mirrors decreases their sensitivity to free radicals. It is our opinion that, because of the delay, the mirrors so prepared had both variable and limited active surface. As a result, the figures we list in Table I can be compared only qualitatively with one another. Consequently any temperature coefficients derived from them would be without significance.

During runs, with the exception of the blanks 17, 19 and 22, the mirror was heated externally by steam.[7]

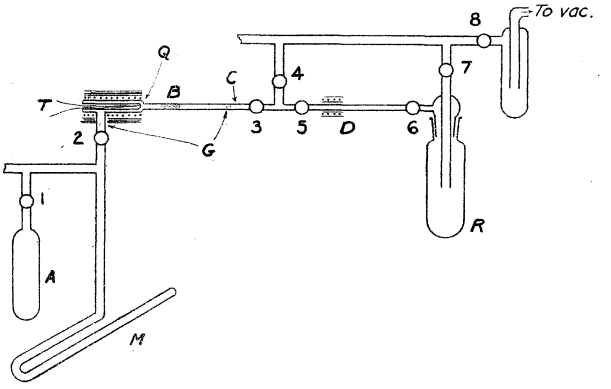

Fig. 1.—Set-up of apparatus.

The temperature of the furnace Q (which was ~10 cm. in length and ~1.2 cm. in internal diameter, and whose well was ~0.8 cm. in outer diameter) was measured with a thermocouple T extending to the tip of the well. Observations, not here recorded, showed a temperature variation along the well with a maximum somewhat higher than at the tip. In the experiments at higher temperature (*i. e.*, ~650°) the maximum was ~50° greater than the observed value while in the lower temperature experiments it was probably no more than 40° above the observed.

During runs, the pressure of acetaldehyde vapor at the stopcock 2, measured on the sloping manometer M, was ~4 mm. The lead tetramethyl presumably formed at the mirror (together with polonium alkyls) was carried by the vapor through stopcocks 3 and 5 to a section of glass tubing heated by the movable heater D to a temperature of 400–500°. Since $Pb(CH_3)_4$ is unstable at such temperatures,[2] free Pb deposited in the tubing near the ends of the "cracking furnace." At the end of a run, stopcocks 1, 3, 5 and 6 were closed, stopcock 4 was opened and the segment of tubing containing the deposited lead was cut out. The lead was dissolved in hot dilute nitric acid and the solution was evaporated to dryness. The radioactivity of the lead nitrate so produced was determined by noting its effect on the rate of discharge of a Lind electroscope into which it was introduced. The net activity (expressed in reciprocal minutes) was in each case corrected for the apparent activity of the empty dish.

In order to check the possibility that a substantial amount of Pb might actually be passing the "cracking furnace" D without deposition, a second such heater was installed to the right of the first and both heated segments of tubing were examined for radioactivity after the runs. In every positive case tested the activity of the right-hand sample was $<1/4$ that of the left-hand sample.

The results of the experiments are summarized in Table I. Each of the runs reported lasted approximately forty-eight minutes. All the pertinent data of the investigation are included in the table; the runs prior to those listed were used in developing the technique of the method. After run 34 the whole system became so seriously contaminated with radio-lead, when the latter was through error introduced into the furnace, that the work had to be abandoned.

TABLE I

TRANSPORT OF RADIO-LEAD IN THE PYROLYSIS OF ACETALDEHYDE

[a] The Pb* mirror was cold in experiments 17, 19 and 22.

Discussion

Runs 17, 19 and 22 were blanks in which both furnace and mirror were at room temperature with acetaldehyde flowing through the system. Runs 24, 26, 27 and 33 were blanks in which the furnace and mirror were both heated (the latter with steam) and no acetaldehyde was flowing. These experiments clearly showed that a negligible quantity of radio-lead was transported either by free flow of vapor or by possible volatilization of Pb* at steam temperature. In runs 32 and 34, with the furnace heated to 352 and 375°, respectively, a negligible transfer occurred, thus demonstrating that only acetaldehyde heated to a sufficiently high temperature, that is, the decomposed substance, was effective in transporting Pb*.

The low net activity in run 20 is perhaps to be attributed to a chance preparation of an insensitive mirror. The average activity, in min.$^{-1}$, observed for the other actual tests (18, 21, 23, 25, 28, 29, 30, 31) is 0.28, with limits 0.11 to 0.70. The average activity for the blank experiments (17, 19, 22, 24, 26, 27, 33) is 0.016, with limits 0.0018 to 0.044. In our opinion the difference is real, and on this basis the results of experiments 32 and 34 can be called negative. The lowest temperature (of the tip of the thermocouple) at which transfer was clearly established was 460°, corresponding to a maximum temperature in the furnace of ~500°.

The lowest temperature at which the pyrolysis of acetaldehyde appears to have been studied is 430°[8] but the more detailed work has been done at slightly higher temperatures (~475°).[9] Staveley and Hinshelwood[10] have stated that "the photochemical production of free radicals, which might in any case be expected, from what we know of other catalysts, to have a catalytic action on the decomposition of acetaldehyde, does not prove their occurrence in the thermal reaction." Neither, it may be said, does the decomposition induced[11] by azomethane. The lowest temperature at which the actual detection of free radicals has been reported hitherto in the pyrolysis of acetaldehyde is 743°.[12] The results here presented, however, seem clearly to demonstrate the existence of free radicals in the products of the pyrolysis at ~500° and it seems probable, therefore, that they exist in the products of the pyrolysis at the lowest temperatures studied, as indicated by the Rice–Herzfeld mechanism.[13]

The data of Table I are sufficient for decision as to the existence or non-existence of free radicals under a particular set of conditions but are not satisfactory for quantitative estimation of numbers or of relative numbers of free radicals formed. Work of a more quantitative nature is being continued with artificial radio-antimony, with which substance complications caused by the existence

of radioactive recoil particles, as from the radiodecomposition of Pb*, can be avoided.

Summary

The method of Leighton and Mortensen employing natural radio-lead in Paneth mirrors has been modified and used for the detection of low concentrations of free radicals.

In this way the existence of free radicals in the pyrolysis of acetaldehyde at 500° has been detected.

The Action of Elementary Fluorine upon Organic Compounds. VII. The Vapor Phase Fluorination of Ethyl Chloride

BY JOHN D. CALFEE, NOBUKAZU FUKUHARA, DEWALT S. YOUNG AND LUCIUS A. BIGELOW

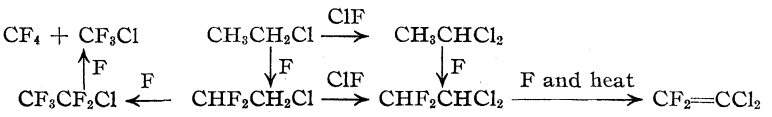
In the third paper of this series,[1] we discussed the vapor phase fluorination of hexachloroethane over copper gauze, which resulted in the substitution of chlorine by fluorine, and yielded *sym*-difluorotetrachloroethane. Since then we have developed an improved technique for the fluorination of organic gases,[2] and this paper deals with the interesting results obtained by applying it to ethyl chloride. Fluorination and chlorination took place simultaneously during the reaction.

Results and Discussion

The ethyl chloride was fluorinated smoothly in a metal apparatus, over copper gauze, under conditions described fully before.[2] The products were condensed by liquid air, transferred to a Booth–Podbielniak low temperature fractionating unit, separated, rectified and analyzed. There were formed carbon tetrafluoride, trifluorochloromethane, CF_3Cl, b. p. −80° (−80°)[3]; pentafluorochloroethane, CF_3CF_2Cl, b. p. −38° (−38°)[4] m. p. −106°; 1,1,2,2-difluorodichloroethylene, $CF_2{=}CCl_2$, b. p. 0° (15°?),[4] m. p. −116°; 1,1,2-difluorochloroethane, CHF_2CH_2Cl, b. p. 35° (35°)[5]; and other products. The observed molecular weights agreed well with the calculated values. The last of these compounds was washed with dilute alkali, dried and distilled in the ordinary way, and the ethylene derivative was passed through a 5% sodium hydroxide solution before analysis. The difluoro- and pentafluoroethyl chloride, as well as the difluorodichloroethylene, have not been obtained before by direct fluorination.

Henne and Renoll[5] gave the boiling point of $CF_2{=}CCl_2$ as 15°, whereas we have found it to be 0°. However, they did not report any molecular weight or analysis, while the values given in Table II leave no doubt as to the composition of the sample which we have examined. The only possible isomer of this compound, CFCl=CFCl, boils at 20.9° according to Booth and collaborators.[6]

In addition to the compounds which were isolated, several others were produced in lesser quantities. A small fraction boiling near 60° was observed repeatedly, and when a larger portion containing this material was distilled at reduced pressure, two small samples were obtained, one of which had a molecular weight of 135, and the other of 98. Now the compound CHF_2CHCl_2 (mol. wt. 135) boils at 60°,[7] and ethylidene chloride CH_3CHCl_2 (mol. wt. 99), distils at 57°. It therefore seemed likely that the two last-named compounds were formed during the reaction. Granting this, a partial mechanism for the fluorination of ethyl chloride may be represented tentatively as



This mechanism involves the substitution of chlorine by fluorine, RCl + 2F ⟶ RF + ClF, and chlorination by chlorine fluoride, RH + ClF ⟶ RCl + HF. The reaction RCl + HF ⟶ RF + HCl may occur, but this seems doubtful.

(7) M. Swartz, *Bull. soc. chim.*, **35**, 1557 (1924).

Several fluorinations were run, using different gas volume ratios of fluorine to ethyl chloride, and in one case the fluorine was diluted with nitrogen. The copper gauze was protected at all times from air and moisture, which decreased its efficiency greatly. This effect was not observed when ethane was fluorinated.[2] Table I shows the proportions in which the more important products were formed expressed in liquid volume per cent. of the total condensate, as has been done previously. The figures have been rounded off to the nearest 5% and are significant.

TABLE I

THE FLUORINATION OF ETHYL CHLORIDE

Liquid volume % of:	Gas volume ratios of $F/C_2H_5Cl/N$ 2/2/0	3/2/0	4/2/0	4/2/4
CF_4	10	10	10	trace
CF_3Cl	5	10	15	trace
CF_3CF_2Cl	trace	5	10	5
$CF_2{=}CCl_2$	0	5	5	trace
CH_3CH_2Cl	70	40	10	20
Residue b. p. > 12°	5	15	20	40
Transition fractions	15	20	30	40

The total volumes of liquid condensate in the four runs were 50, 32, 21 and 26 ml., respectively, calculated on a ten-hour operating basis. The results were in general consistent, since the more highly fluorinated products increased in quantity as the ratio of F/C_2H_5Cl increased, and decreased sharply when the fluorine was diluted. The material boiling above 12° was collected together and subsequently redistilled.

Method of Analysis

We believe that the development of a precise, convenient procedure for the quantitative analysis of stable low boiling organic fluoro-chloro gases for both halogens is a matter of importance, and have devoted considerable time to this problem, which is not as simple as might at first appear. The procedure finally adopted was based on the one described by Hubbard and Henne,[8] but differs from it in several important respects, the most significant of which is that our gas samples were weighed. In the older method, gas volumes were measured, which admittedly involved the question of how closely the sample behaved as a perfect gas.

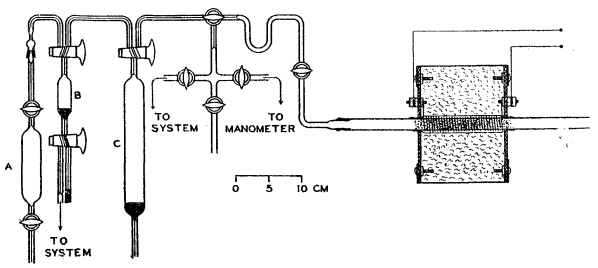

Fig. 1.—Analytical apparatus.

The combustions were run on a semi-micro scale, but the samples were conveniently weighed on an ordinary analytical balance, which necessitated the taking of gas aliquots. The complete apparatus is illustrated to approximate scale in Fig. 1. It was mounted on the same frame as the Booth–Podbielniak unit, and connected directly to that system. The furnace consisted of a 46-cm. length of clear silica tubing with a 13 mm. bore, which was wrapped with asbestos paper, wound directly with no. 24 Chromel wire over about 13 cm. of its length and surrounded by an insulating unit made of aluminum sheet and filled with powdered asbestos. This combustion tube was packed with ground silica, about 20 mesh, held in place at the ends by larger pieces of the same material. It was sealed to the system and also to the absorption apparatus by means of de Khotinsky cement. The maximum temperature in the furnace was maintained at approximately 900° by a calibrated rheostat. The volumes of container A (about 60 ml.) together with the connecting line, and B (about 12 ml.) were determined accurately by calibration with mercury.

The operating procedure was as follows: The container A was exhausted and the sample allowed to expand into it, through B, up to atmospheric pressure, after which it was detached and the gain in weight noted (0.2–0.3 g.). Then B was exhausted and the sample allowed to expand into it, giving a known quantity of material, about one-fifth of the original amount. This gas was next conducted into C, where it was mixed with 100 ml. of oxygen, and then pushed slowly through the furnace during a period of 50 min., and into the absorption vessel. This consisted of a U-tube with a half dozen bulbs, similar to that described before,[8] and contained 10 ml. of 1.0 *N* sodium hydroxide solution and 1 ml. of superoxol. The sample was followed successively by 200 ml. of oxygen, 100 ml. of nitrogen, 200 ml. of hydrogen and finally by nitrogen directly from the tank for one and one-half hours, all at the rate of approximately 200 ml. per hour. The excess of oxygen was necessary to prevent back diffusion of the sample into the nitrogen, with subsequent failure to burn, and the hydrogen was used to reduce silicon oxychloride.[8] Also it was necessary to remove any accumulation of silica deposited in the entrance arm of the absorption apparatus during a combustion, since it tended to retain halogen. Finally, the alkaline solution was washed out, 1 ml. of superoxol added and the mixture heated to boiling. Then it was made up to 200 ml., and aliquot portions of 25 and 50 ml. taken for the determination of fluoride and chloride ions, respectively.

The fluoride ion was titrated with approximately 0.01 *N* thorium nitrate solution, according to the well-known Hoskins and Ferris[9] procedure. Approximately 180 ml. was collected in the distillation, which was made up to 200 ml., and the average value obtained by titrating four or five 25-ml. aliquot portions of this was taken as the correct one. It was found desirable to use a small light box with a blue bulb for constant illumination at the end-point, but care should be taken on account of the heat effect. The chloride ion was titrated with standard silver

nitrate solution using a dichlorofluorescein adsorption indicator according to Kolthoff and collaborators.[10] This method is applicable in the presence of silica, and has proved very efficient. We have not found the Volhard procedure to be satisfactory in this work.

Finally the several products obtained by the fluorination of the ethyl chloride were analyzed and results are summarized in Table II.

TABLE II

ANALYTICAL VALUES

These results leave no doubt as to the composition of the compounds which were isolated in this work.

Summary

Ethyl chloride was fluorinated in the vapor phase over copper gauze under varying conditions, and the relative amounts of the more important products determined.

The compounds CF_4, CF_3Cl, CF_3CF_2Cl, $CF_2{=}CCl_2$ and CHF_2CH_2Cl were isolated from the reaction mixture. The last three of these have not been obtained before by the action of elementary fluorine on an organic compound.

A precise analytical procedure for determining fluorine and chlorine in stable organic gases has been described.

The Electrostatic Influence of Substituents on Reactions Rates. I

BY F. H. WESTHEIMER AND MARTIN W. SHOOKHOFF

Ingold has postulated that the effect of a polar substituent on the rate of saponification of an aliphatic ester, like the effect of such a substituent on the ionization constant of an acid, is largely electrostatic. In 1930[1] he employed Bjerrum's quantitative electrostatic formulation[2] to compute, from the ratios of the rates of saponification of the first and second ester groups, the separation of the carbalkoxy groups in a series of esters of dibasic acids. Ingold's evidence went far toward establishing his hypothesis in those cases in which the molecule is long and the substituent can be regarded as a negative charge.

Kirkwood and Westheimer[3] have recently refined Bjerrum's approximate computations of the electrostatic free energy involved in a chemical reaction; the success of the new equations, while general, has been most conspicuous in the considerations of the ionization constants of short dibasic and of dipole substituted acids,[4] cases for which the older formulation is inadequate. The shortcomings of Ingold's modified equation[5] have been presented previously.

The present paper deals with the rate of alkaline hydrolysis of esters and amides in cases in which the substituent is a negative charge, a positive charge and a dipole, all placed close to the seat of the reaction. When the substituent is close to the ester or amide bond that is broken, the rates of hydrolysis of the substituted and unsubstituted compounds differ by a factor of a hundred or more. Since the measurements were made by conductivity, very slow and very fast reactions were excluded: the former because of action of alkali on the glass of the cell, the latter because of the time required to attain thermal equilibrium. These considerations necessitated a careful selection of the pairs of compounds employed.

To illustrate the effect of a negative charge as substituent, the rate of alkaline hydrolysis of the sodium salt of oxamic acid was compared with the rate for oxamide; to illustrate the effect of a positive charge, the rate of saponification of the chloride of the tertiary butyl ester of betaine was compared with the rate for the tertiary butyl ester of dimethylglycine; and to illustrate the

effect of a dipole, the rate of saponification of the tertiary butyl ester of chloroacetic acid was compared with the rate for the tertiary butyl ester of acetic acid.

The equations of Kirkwood and Westheimer apply accurately only to spheres and to prolate ellipsoids in which substituents and charges are at the foci. Due to the experimental limitations mentioned above, some sacrifice in the shape of the molecule was unavoidable.

Theoretical

Ingold treated the reaction velocity problem by means of Christiansen's theory,[6] that is, as a case in which the local concentration of hydroxide ions differs, due to the presence in the molecule of a polar substituent, from that in the remainder of the solution. The assumptions involved can be more conveniently stated, however, when the problem is formulated in Brönsted's terms.[7]

Brönsted postulated a rapid equilibrium between the reactants and an activated complex, followed by a slow decomposition of the activated complex to form the reaction products. In order to apply the electrostatic theory, it is further necessary to assume that the rates of decomposition will be the same for activated complexes formed from two closely similar molecules.[8] Stated mathematically

$$k_{\text{obsd.}} = kK \text{ and } k'_{\text{obsd.}} = k'K'$$

$k_{\text{obsd.}}$ and $k'_{\text{obsd.}}$ are the observed velocity constants, corrected to infinite dilution, for the bimolecular reactions, and K and K' are the equilibrium constants for the formation of the two activated complexes. If k and k', the rate constants for the decomposition of the activated complexes, are assumed equal, then

$$k_{\text{obsd.}}/k'_{\text{obsd.}} = K/K'$$

In other words, to compute the ratio of the velocity constants at infinite dilution, it is only necessary to compute the ratio of the equilibrium constants for the formation of the critical complexes.

The rest of the argument exactly parallels that given by Kirkwood and Westheimer[3] for the case of the ionization constants of acids with and without polar substituents. $\boldsymbol{k}''T \log_e K - \boldsymbol{k}''T \log_e K'$ is equal to $\Delta w'$, where $\boldsymbol{k}''$ is Boltzmann's constant, T the absolute temperature, and $\Delta w'$ is the average reversible work expended in the transfer of a hydroxide ion from the unsubstituted activated complex to the substituted ester, infinitely separated in the solvent. Part of $\Delta w'$ is an entropy term, arising from differences in molecular symmetry. The electrostatic part of $\Delta w'$, called Δw, is that which can be computed. The part of $\Delta w'$ connected with the intrinsic structure of the molecules is by no means to be overlooked, but it is assumed that, as a first approximation, it will vanish because of cancellations between the substituted and unsubstituted compounds.

It follows, therefore, that

$$\Delta w = \boldsymbol{k}''T \log_e K/\sigma K' = \boldsymbol{k}''T \log_e k/\sigma k' = 2.303\ \boldsymbol{k}''T\ \Delta \log k$$

where $\boldsymbol{k}''$ is the Boltzmann constant, σ is a statistical factor (equal to two in the saponification of esters or amides of dibasic acids) and the equation serves to define $\Delta \log k$.

From the equations of Kirkwood and Westheimer and from the experimental values of $\Delta \log k$, it is possible to compute the distance between the negative charge in the activated complexes, and the positive charge in the chloride of tertiary butyl betaine, the center of the dipole in tertiary butyl chloroacetate, and a positive charge in oxamide, located approximately in the position of the ionizable proton in oxamic acid. These distances are then compared with those obtained from an independent source.

Experimental

Apparatus.—Conductivity was measured with a calibrated Leeds and Northrup bridge, using a slide wire of the Kohlrausch type, and a Clough–Brengle audio frequency oscillator as the source of current. The apparatus was slightly modified[9] from the standard Washburn type, and was capable of measuring resistances with a precision of 0.01%.

The design of the conductivity cells was dictated primarily by the experimental observation that the percentage time rate of change of conductivity due to the solution of the glass in alkali increases with temperature, dilution, and the ratio of surface to volume, as shown in Table I. Cell A, used at alkali concentrations of 0.0003 to 0.003 was spherical, of one liter capacity, and had bright electrodes, 1.8 cm. in diameter and 2 cm. apart. Due to the large size of this cell, at least an hour was necessary to attain temperature equilibrium; it was not, then, very satisfactory for the more rapid reactions. For the concentration range 0.003 to 0.05, cell B was used. It was cylindrical in shape, 3 cm. in diameter and 11 cm.

(6) Christiansen, *Z. physik. Chem.*, **113**, 35 (1924).

(7) Brönsted, *Chem. Rev.*, **5**, 231 (1928).

(8) The application of electrostatic theory to the problem of the change of rate with solvent involves a more limited assumption (Scatchard, *J. Chem. Phys.*, **7**, 657 (1939)). Since the transmission coefficient is usually in the neighborhood of unity, a broader assumption is involved in Eyring's theory (*ibid.*, **3**, 107 (1935)).

(9) Jones and Josephs, THIS JOURNAL, **50**, 1049 (1928).

long, with lightly platinized electrodes 1 cm. in diameter and 8 cm. apart. Cell C was 8 cm. longer than cell B, and the electrodes were 8 cm. further apart; the cells were otherwise identical. Cell D was designed according to Jones and Bollinger.[10] The electrodes were unplatinized and their area and the distance between them were approximately the same as for cell A.

An oil thermostat controlled the temperature to 0.01°.

TABLE I

RATE OF CHANGE OF CONDUCTIVITY OF SODIUM HYDROXIDE SOLUTIONS DUE TO SOLUTION OF GLASS

Cell	Alkali concn., *N*	Change in % per hr., at 30°	at 35°
A	0.002	0.022	
B	.005	.064	
B	.008		0.10
B	.030	.022	
C	.015	.030	.050
C	.050	.012	

Materials.—Tertiary butyl acetate was prepared according to Skrabal and Hugetz,[11] oxamide according to Liebig[12] and oxamic acid according to Oelkers.[13] Dimethylglycine was synthesized by the method of Michaelis and Schubert[14] and the chloride of betaine amide by the method of Renshaw and Hotchkiss.[15] To determine its purity, each was analyzed before use.

Tertiary Butyl Chloroacetate.—While the tertiary butyl chloroacetate used in the velocity determinations was prepared by direct esterification, a more convenient method of preparation follows: 60 cc. of chloroacetyl chloride was placed in a three-necked flask equipped with thermometer, stirrer, dropping funnel and an outlet protected by a calcium chloride tube. A mixture of 100 cc. of dimethylaniline and 75 cc. of tertiary butyl alcohol (m. p. 23°) was added dropwise during the course of an hour, maintaining the temperature at 0° by means of an ice-bath. At the end of this time, the ice-bath was removed and the mixture allowed to stand overnight. Water was then added, and the heavy ester layer separated, washed with water, dilute hydrochloric acid, sodium bicarbonate solution, and water again. The oil was dried over calcium chloride and vacuum distilled: yield, 72 g., or 60%, of the ester. The product is a colorless liquid, slightly heavier than water, boiling at atmospheric pressure at 155° with some decomposition and at 60.2° at 15 mm., $n^{20}D$ 1.4230.

Anal. Calcd. for $C_6H_{11}O_2Cl$: C, 47.8; H, 7.37; Cl, 23.56; sapon. equiv., 150.5. Found: C, 47.6; H, 7.33; Cl, 23.63; sapon. equiv., 150.6.

The material actually used in the velocity determinations had been carefully fractionated at reduced pressure, and was of analytical purity.

An acidified portion of completely saponified ester gave no precipitate with silver nitrate, showing that there is no appreciable hydrolysis of the chlorine during saponification. Another portion of the ester was hydrolyzed, the tertiary butyl alcohol isolated, dried, and identified by melting point and the melting point of a mixture with an authentic sample.

Tertiary Butyl Betainium Chloride.—Twenty grams of tertiary butyl chloroacetate and 62 cc. of a 2.5 molar solution of trimethylamine in dry benzene were mixed with cooling. Although crystals formed in a few minutes, it proved advisable to allow the mixture to stand for twenty-four hours; yield, 18 g. The crude material can be crystallized from acetone or dioxane to which a small amount of water has been added. The product is a white crystalline powder, which, when dry, melts with decomposition around 220°, the exact temperature depending somewhat on the rate of heating.

Anal. Calcd. for $C_9H_{20}O_2NCl$: Cl, 16.91; N, 6.68. Found: Cl, 16.89; N, 6.79.

The material used in the rate determinations had been recrystallized several times, and was of analytical purity.

Tertiary Butyl Dimethylglycinate.—Twenty grams of tertiary butyl chloroacetate and 43 cc. of a 4 molar solution of dimethylamine in dry benzene were mixed, with cooling, and allowed to stand at room temperature for twenty-four hours. The resultant material was extracted with 1:1 hydrochloric acid, and the extract washed once with ether. The aqueous layer was then saturated with potassium carbonate and extracted with ether. The ether extract was dried with potassium carbonate, the ether removed by distillation, and the residue fractionated at reduced pressure. The yield of colorless oil, having a slight ammoniacal odor, was 12 g. The hydrochloride was prepared by adding a slight excess of hydrogen chloride in methanol, and evaporating to dryness under reduced pressure. The residue can be recrystallized from a 10% solution of tertiary butyl alcohol in benzene. The white twice recrystallized material which was used in the velocity determinations melted about 150°, the exact temperature depending somewhat on the rate of heating.

Anal. Calcd. for $C_8H_{18}O_2NCl$: Cl, 18.13; N, 7.16. Found: Cl, 18.08; N, 7.12.

Conductivity water and carbonate free alkali were used throughout. Chemicals other than those recorded here were of reagent grade.

Method.—The usual procedure in the determination of reaction velocity by conductivity is to determine the initial and final conductivities of the solution and to calculate the rate on the assumption that the conductivity of the solution is a linear function of the extent of reaction. In the determinations here described, since it was inconvenient in most cases to measure the initial and final conductivity, each velocity determination was standardized by measuring the conductivity of solutions corresponding in ionic composition to that present at several different times during the reaction.[16] Since the concentrations of the various ions in the standardizing-solution could not conveniently be made exact

(16) A similar standardization procedure has been described by Crocker and Lowe, *J. Chem. Soc.*, **91**, 952 (1907).

duplicates of those at any point during the reaction, a small correction had to be added to the conductivity of each standardizing solution. In order to estimate this correction, it was only necessary to know the ratios of the conductivities of all the ions present to that of hydroxide ion.

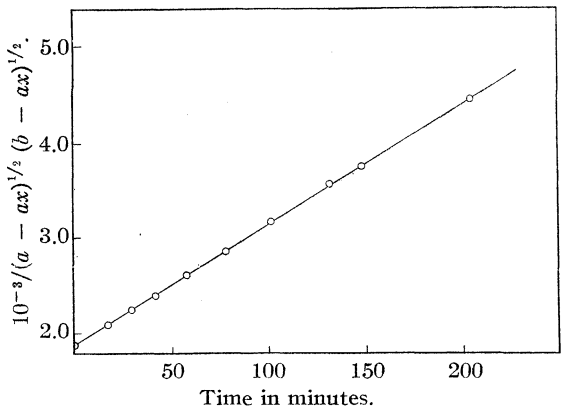

Fig. 1.

The values of the conductances are given in Table II, arbitrarily assigning to hydroxide ion a value of 100 at every temperature. The values in the upper part of the table were calculated from existing data,[17] those in the lower part of the table were measured. Since the correction was in all cases small, comparatively large errors in the relative conductivities of the ions do not affect the final result appreciably. The measurements were made in an ionic environment similar to that in the actual reaction mixtures, except in the case of tertiary butyl betainium chloride, which was measured in a solution containing only the pure compound.

TABLE II

RELATIVE CONDUCTIVITIES OF THE IONS

Ion	Temperature 6.5°	10°	30°
Hydroxide	100.0	100.0	100.0
Chloride	39.0	38.7	
Acetate	20.6		
Oxalate			70.3
Sodium	24.7	24.7	24.7
Ammonium			35.6
Chloroacetate	16.6		
Oxamate			18.7
Dimethylglycinate	12.5		
Betaine amide	19.8		
t-Butylbetainium	17.8		

In some cases there was a slow reaction between the ions of the standardizing solutions. Since the extent of the reaction was always quite small, it was not difficult to extrapolate accurately back to the time when the solution was prepared. The procedure could not be used for tertiary butyl betainium chloride, because of the rapid reaction of the positive ion with alkali; therefore the corresponding amide was used in place of the ester. After determining the relative conductivities of the ester and amide ions, it was possible to estimate the conductivities of the solutions used in the reaction velocity determinations. While the error in this case is probably greater than in any other, it cannot be large, since only 10% of the total conductivity is contributed by the positive ion.

Results

The data for a typical velocity determination, the saponification of tertiary butyl chloroacetate, are given in Table III. Here a is the initial concentration of sodium hydroxide in moles per liter, b the initial concentration of the ester, and x the fraction of the alkali consumed in time, t. The rate constants were obtained graphically by plotting time against $\log(1 - x)/(b - ax)$, or, when the initial concentrations of the two reactants were nearly equal, against $1/(a - ax)^{1/2}(b - ax)^{1/2}$. Figure 1 is a graph of the data in Table III.

TABLE III

DATA FOR THE SAPONIFICATION OF TERTIARY BUTYL CHLOROACETATE

a = 0.000782 Time in min.	b = 0.000835 Conductivity	x
0.0	4462	0.346
17.4	4165	.420
29.1	4000	.461
41.4	3851	.498
57.3	3683	.540
77.3	3510	.583
101.2	3334	.627
131.6	3170	.667
147.7	3094	.686
203.8	2887	.738
262.9	2727	.778

Conductivity in this case is a linear function of the extent of reaction. When $x = 0.010$ the conductivity is 5813 and when $x = 0.660$ the conductivity is 3197. The conductivities are all in arbitrary units.

The solution of glass in alkali changes both the conductivity and the hydroxide-ion concentration. In correcting for the former effect, it was assumed that the percentage time rate of change of conductivity due to reaction with the

glass is constant during a given experiment. In correcting the latter, the hydroxide-ion concentration at each point was reduced by a factor of $1 - pt$, where p is the percentage time rate of change of hydroxide ion and t the time. It was assumed that the change in hydroxide-ion concentration was 1.6 times the change in conductivity given in Table I. While neither of these computations is exact, the total correction is so small that the methods used will cause no serious errors.

In the case of the saponification of the ester of dimethylglycine, the base formed, dimethylglycinate ion, contributes to the hydroxide-ion concentration. So does the ammonia formed in the hydrolysis of sodium oxamate and of oxamide. Furthermore, in this latter case, the hydrolysis of the second amide group will be a complicating factor. However, these corrections are so small that the values of the velocity constants obtained using a standard bimolecular form are not significantly different from those obtained by more complicated equations in which these corrections are, at least to a first approximation, embodied.[18]

The constants for all the velocity determinations are collected in Table IV. Here μ is the initial ionic strength, k the rate constants in inverse minutes and inverse moles per liter. The initial concentrations were varied at least twofold; the constants usually deviate less than 5% from the average. The values in parentheses were not used in averaging.

The observed rate constants for the hydrolysis of sodium oxamate increase with increasing ionic

(18) For the hydrolysis of sodium oxamate and the tertiary butyl ester of dimethylglycine, for example, the following equation takes into account the ionization of the base.

$$kt + C = \frac{1}{[a(a-b)^2 + a^2K_B]}\left\{ -a(a - b + K_B)\log_e(b - ax) + \frac{a(a - b + K_B)}{2}\log_e[a(1-x)^2 + K_B] + b\sqrt{aK_B}\tan^{-1}\frac{ax - a}{\sqrt{aK_B}}\right\}$$

Here a is the initial concentration of sodium hydroxide, b that of the ester, k is the rate constant, K_B the ionization constant of the base, and x the fraction of the sodium hydroxide that has been consumed at time, t. C is a constant of integration. When the second stage hydrolysis of oxamide is taken into account, the equation is even more complex.

strength. Since the reaction is one between two negative ions, Brönsted's theory[7] predicts a positive primary salt effect. However, at the ionic strengths at which the measurements were made, the observed salt effect is less than the theory predicts. Extrapolation of the plot of log $k_{obsd.}$ against the square root of the ionic strength gives a value of 0.0111 for the rate constant; extrapolation of the lowest point using the theoretical limiting slope gives a value of 0.0091. These are an upper and lower value, respectively, for the true value at infinite dilution. For the purposes of the present paper, the mean value, 0.0101, is sufficiently precise. Since the saponification of tertiary butyl betainium chloride was carried out at very low ionic strength, and since the accuracy of these measurements is not very great, extrapolation to infinite dilution does not seem warranted.

The ion $(CH_3)_2N^+HCH_2CO_2C(CH_3)_3$ would be expected to saponify at a rate several hundred times greater than that of the free base. However, an estimate of the base strength of the ester (from the base strength of glycine ethyl ester[19]) indicates that, in solutions of the alkalinity employed in the velocity determinations, no significant part of the rate can be due to hydrolysis of this ion.

The logarithms of the ratios of the rates, corrected for statistical factor, for substituted and unsubstituted compounds ($\Delta \log k$) are assembled in Table V. It is at once obvious that errors of the magnitude indicated for the velocity constants will have no significant effect upon these logarithms.

Discussion of Results

From the data given in Table V and Kirkwood's and Westheimer's equations, it is possible to compute the separation of the polar substituent and the negative charge contributed by the hydroxide ion to the activated complex. In order to carry out these calculations, the volumes of the molecules have been estimated, as usual, by using Traube's rule.[20]

TABLE V

SEPARATION OF CHARGE AND SUBSTITUENT, COMPUTED FROM VELOCITY DATA

Organic reactants	$\Delta \log k$	Separation in Å. R	R_D	R_B
Oxamide Sodium oxamate	1.84	4.15	3.85	1.71
t-Butyl betainium chloride	3.02	4.85	4.05 (glycine)	1.02

t-Butyl chloroacetate *t*-Butyl acetate	2.70	3.15	3.00	0.48

(19) Edsall and Blanchard, THIS JOURNAL, **55**, 2337 (1933).

The computations for oxamide were made on the basis of a spherical model, with the charges on a diameter. The distance between a positive charge placed approximately as the proton in oxamic acid, and the negative charge of the activated complex, is given to the nearest 0.05 Å. by R; it is compared with R_D, the separation of the protons in oxalic acid computed in a similar manner from dissociation constant measurements.

The calculations for tertiary butyl chloroacetate are more complicated. The difference between the carbon–chlorine dipole moment and the carbon–hydrogen moment was taken as 1.86 Debye units.[21] The negative charge of the activated complex was placed arbitrarily on the extension of that carbon to carbon bond nearest the ester linkage in the acid portion of the molecule. The computations were made on the basis of two different assumptions. First, the charge and dipole were placed equidistant from the center on a diameter, and, second, the charge was placed at the center of the molecule.[22] The two methods led to values of R differing by 0.4 Å.; the average is given in Table V. The value of R_D is that obtained from computations based on the ratio of the ionizations constants of chloroacetic and acetic acids.

The computations for the chloride of the tertiary butyl ester of betaine were made both on the basis of an ellipsoid with the charges at the foci, and on the basis of a sphere, with the charges on a diameter, but the positive charge twice as far from the center of the sphere as the negative charge.[23] Again the two methods give values

(21) Smyth, *J. Phys. Chem.*, **41**, 209 (1937).

(22) In this case, the equation for the electrostatic work reduces to the form

$$\Delta \log k = \frac{eM \cos \zeta}{2.303\, k'' T R^2 D_i}$$

where e is the electronic charge, M the dipole moment of the substituent, ζ the angle between the dipole and the line joining it to the center. D_i the "internal dielectric constant," has been assigned the value of 2.00, as previously.

(23) In this case the appropriate value of the "effective dielectric constant" is given by the equation

$$1/D_E = \frac{1}{D_i}\left[1 - \frac{x_1 + x_2}{1 + x_1x_2}\right] + \frac{1}{D}\left[\frac{2(x_1 + x_2)}{1 + x_1x_2} - \frac{x_1 + x_2}{x_1x_2} \log_e (1 + x_1x_2)\right]$$

where $x_1 = r_1/b$ and $x_2 = r_2/b$. r_1 and r_2 are the distances of the first and second charges from the center, b the radius of the sphere,

differing by about 0.3 Å.; the average appears in the table.

There is no value of R_D obtained from ionization constant data which is strictly comparable with this value of R. For, while the ionization constant of betainium chloride is known, the ionization constant of dimethylglycine, due to its zwitterionic structure, cannot be considered that of the corresponding unsubstituted acid. However, the strength of betainium chloride was compared with that of trimethylacetic acid,[17] the "isosteric" structure,[24] in which a carbon atom rather than a nitrogen atom holds the three methyl groups. Neuberger's data show that this is a fair approximation.[25] The length given in Table V is the average of one in which the molecule is regarded as an ellipsoid with charges at the foci, and one in which the molecule is regarded as a sphere with the charges equidistant from the center on radii separated by the tetrahedral angle. Fortunately, these two values of R_D differ by only 0.3 Å. The value of R_D for glycine is placed alongside the approximate one for betaine.

The values of R_B were computed using Bjerrum's[2] and Eucken's[4] equations. In the case of the chloroester, the fully extended model was used in determining the value of R_B.

Inspection of Table V reveals that, despite the approximations made in assigning simple shapes to these esters and amides, the values of R obtained from velocity data are in good agreement with R_D, computed from dissociation constants. It must be stressed that these latter values have previously been shown in all cases to be of reasonable magnitude. The values of R_B, obtained from the Bjerrum equation, are, however, much too small. Since R appears as the square in the equation for the potential of a dipole, the inadequacy of the simple equation in the case of the chloroester, serious as it appears, is actually even more significant.

The retardation caused by a negative charge, the acceleration caused by a positive charge and a dipole in saponification, are not only qualitatively but quantitatively in accord with predictions made on the basis of the electrostatic effect of the substituents.

(25) Neuberger, *Proc. Roy. Soc.* (London), **A158**, 68 (1937).

Summary

1. The electrostatic theory has been applied to the problem of the effect of polar substituents on reaction velocities.

2. The rates of alkaline hydrolysis of the following pairs of compounds have been measured: oxamide and sodium oxamate, tertiary butyl acetate and tertiary butyl chloroacetate, the tertiary butyl ester of dimethylglycine and the chloride of the tertiary butyl ester of betaine.

3. By means of the equations previously developed by Kirkwood and Westheimer, it has been shown that the ratio of the rates for each pair is quantitatively in accord with the hypothesis that the effect of a polar substituent on the velocity of these hydrolyses is primarily electrostatic in origin.

Preparation and Structure of High Molecular Weight Polybutenes

BY R. M. THOMAS,* W. J. SPARKS,* AND PER K. FROLICH*

M. OTTO† AND M. MUELLER-CUNRADI†

The polymerization of isobutene at low temperatures[1,2] with catalysts of acidic nature[3,4,5,6] takes place with almost explosive violence, and is among the most rapidly completed of organic reactions. Under suitable conditions, it is possible to obtain an almost quantitative yield of rubber-like solid from liquid isobutene within a fraction of a second. This transformation is of particular interest in that it is characterized by the absence of any apparent decrease in rate of reaction with lowering of temperature, and also by the fact that polymers of the highest molecular weight as determined by the Staudinger viscosity method[7] are obtainable at the lowest temperatures.

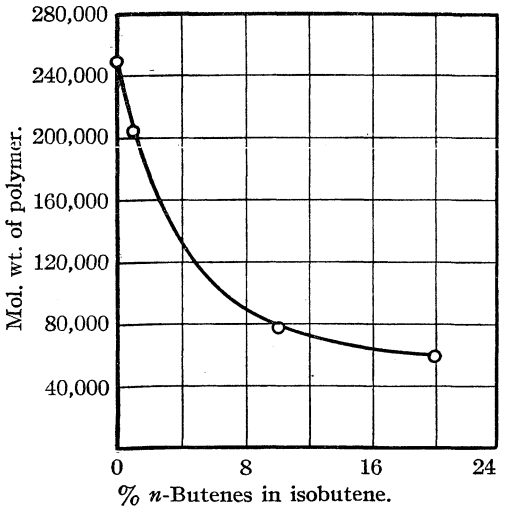

Fig. 1.—Effect of *n*-butenes on the molecular weight of polyisobutenes produced at −95° using BF_3 catalyst.

For example, a sample of isobutene maintained at its boiling point and treated with a slow stream of BF_3 will show a considerable induction period followed by a vigorous reaction to produce an oil, whereas a similar sample precooled to −80° will react immediately on introduction of the BF_3 gas to produce a polymer of much higher molecular weight.

This marked difference in reaction behavior and in the character of the products is indicative of a difference in mechanism between low temperature polymerization and the more common reactions which characterize tertiary olefins. Other important factors in the polymerization of isobutene at low temperature are discussed below.

Purity of Raw Materials.—Under particular test conditions that have been used by the writers, certain compounds have been observed to act as poisons for the reaction. These materials in isobutene reaction mixtures result in a decided lowering of the molecular weight of the polymer product,[8,9] or, in extreme cases, interfere even more seriously with the course of the reaction.

It is of particular interest to note the behavior of pure isobutene intentionally contaminated with other hydrocarbon olefins. Lower olefins such as ethylene and propylene are apparently inert. Normal butenes are more reactive but they differ greatly from isobutene as regards their polymerization characteristics.[10,11] However, they are capable of reacting with isobutene under the low temperature conditions of reaction. This results in a lowering of the molecular weight of the polymer product as shown in Fig. 1.

Similarly, higher olefins may exhibit a depressing effect on the molecular weight of the polymer. For example, very small quantities of diisobutene will greatly decrease both the yield and molecular weight of the polyisobutene. This observation is of special interest since it shows that, although the polymerization must pass through successive stages of chain formation, the possible intermediate stage represented by molecular dimer as obtained by conventional polymerization

methods cannot be present in appreciable quantity during or preceding the polymerization step in the preparation of high polymers. Triisobutene has a similar effect.

In this connection it is also of interest to point out that while dimers or trimers of isobutene are capable of slow polymerization at room temperature to give oily products, when using the low temperature technique discussed here, high polymers have not been obtained.

Other poisons are sulfur compounds such as hydrogen sulfide or mercaptans, and hydrogen halides such as anhydrous hydrogen fluoride or hydrogen chloride. The latter have a marked depressing effect on the molecular weight of the polymer in spite of their well-known promoter action in certain metallic halide catalyzed alkylation[12] or dimerization reactions. At elevated temperatures, the use of hydro-halogen acids has been found beneficial for the polymerization of olefins with boron fluoride.[13]

This difference in behavior of halogen acids in polymerization and in alkylation reactions appears to support the view that the formation of high polymers and the well-known dimerization reactions result from different types of activation. The poisoning effect of hydrogen chloride may therefore result from the formation of diisobutene which is known to be a polymerization depressor in the formation of polyisobutene at low temperatures. The negative action of halogen acids observed here has also been found in the case of the polymerization of styrene by stannic chloride.[14]

Catalysts.—A variety of catalysts for the polymerization of isobutene has been reported.[15] The effectiveness of these depends upon the conditions employed for carrying out the reaction, but good results are generally obtained with such materials as titanium tetrachloride,[16] boron fluoride, and aluminum chloride.

In general, the suitability of a catalyst for the low temperature polymerization of isobutene cannot be predicted. Double compounds of the Friedel–Crafts type catalysts with various polar solvents have been found effective in polymerizing olefins at temperatures in the neighborhood of 0°,[17] but appear to be inactive at considerably lower temperatures.

Temperature.—Temperature control is of great importance in the polymerization process since the reaction is rapid and exothermic. Experimentally, the heat of reaction is somewhat difficult to measure accurately, but it has been established to be in the neighborhood of 10,000 calories per mole at about −78°. Higher values would be expected on the basis of theoretical calculations.

The general effect of temperature upon the molecular weight of isobutene polymers produced under otherwise constant conditions is shown in Fig. 2 for one type of catalyst.[18]

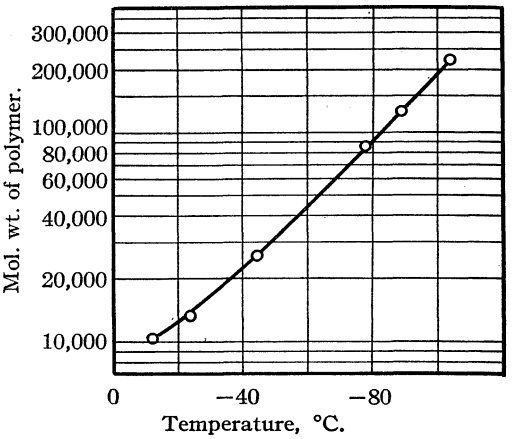

Fig. 2.—General effect of reaction temperature on the molecular weight of polymers produced from isobutene.

Diluents.—Diluents are employed in the polymerization to moderate the violence of the reaction and thereby make for better temperature control, so that products of uniformly high molecular weight can be obtained.[19]

The important role played by diluents in the preparation of polyisobutene is clearly indicated by the data presented in Fig. 3, where, under a given set of experimental conditions, the molecular weights of products obtained are plotted against corresponding amounts of an inert diluent in the reaction mixture. It will be noted from these results that the molecular weight of the product increases acording to an exponential func-

(18) It may be mentioned here that the molecular weights cited throughout this paper, while comparable insofar as the one variable under consideration is concerned, are not necessarily the maximum values obtainable. By proper manipulation of the different reaction variables, it is possible to extend considerably the molecular weight range of the polymers in a number of cases.

(19) P. J. Wiezevich, U. S. Patent 2,138,895 (1938).

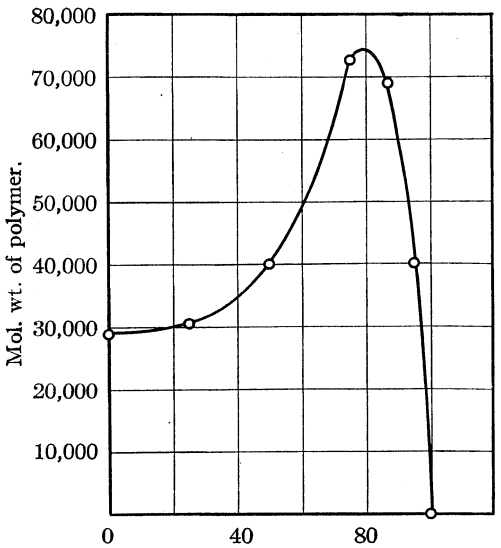

Fig. 3.—General effect of diluent concentration on the molecular weight of polymers produced from isobutene.

tion with increasing proportions of diluent until a limiting concentration of approximately 80% by volume is reached, at which point there occurs a precipitous drop in the molecular weight. Closely similar curves are obtained using different diluents. In some instances, the actual values for molecular weight may be somewhat shifted by as much as 10,000 due to the difficulty in controlling other variables. In all cases, however, the general shape of the curve remains the same.

Catalyst Concentration.—With regard to the concentrations in which catalysts are employed, several interesting effects have been observed. In one specific case, it has been demonstrated that a critical concentration of catalyst (approximately 0.03%) has to be exceeded for the production of polymer. Some idea of the actual quantity of polymer which may be obtained from a given amount of an aluminum chloride catalyst is shown in Figs. 4 and 5, the latter being constructed from the limiting slopes of Fig. 4. The catalyst efficiency is noted to be highest at the greatest dilutions, presumably because of a lower loss due to mechanical occlusion of unreacted catalyst in the polymer. Figure 5 is of interest in giving an extrapolated ratio of about three moles of polymer per mole of aluminum chloride at an infinitely low concentration. However, this should not be taken as definite proof that one molecule of aluminum chloride produces three molecules of polymer, for the data may be subject

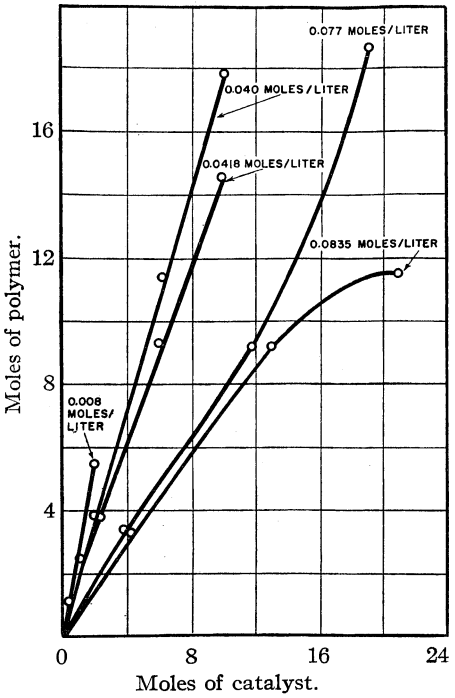

Fig. 4.—Moles of isobutene polymer produced vs. moles of $AlCl_3$ catalyst added for different catalyst concentrations.

to some question because of possible uncertainties involved in the determination of exact molecular weights by viscosity methods.

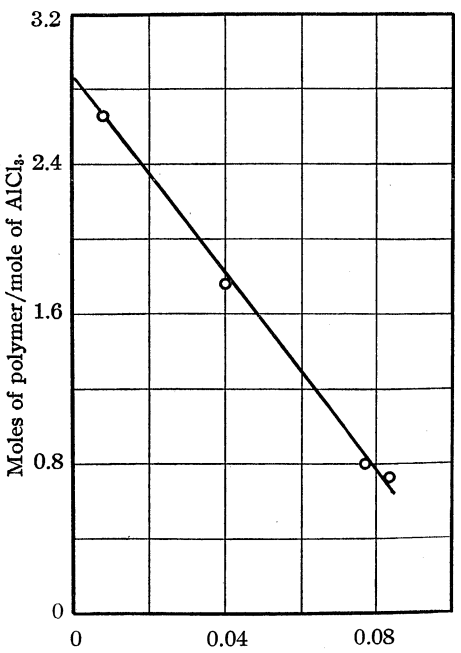

Fig. 5.—Efficiency of catalyst in polymerizing isobutene at −78° as a function of catalyst concentration.

Yield.—The polymerization of isobutene to high molecular weight products can be carried out with yields of 90% or better. Within reasonable limits, the yield to which the reaction is carried has not been found to influence the average molecular weight of the products.

Structure of Polybutene.—A discussion of the low temperature polymerization of isobutene quite naturally raises the question of the structure of the polymers produced by that technique.

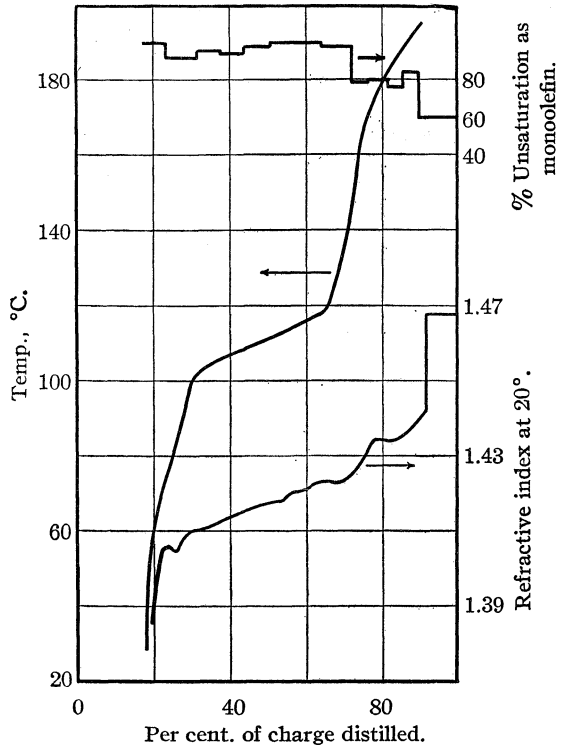

Fig. 6.—Analytical distillation of C_4 to C_{12} hydrocarbons from the thermal decomposition of polyisobutene in an iron still at 350°.

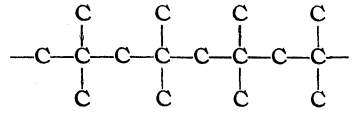
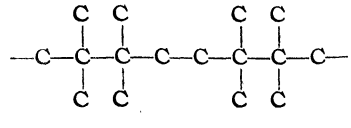
On the basis of numerous observations which would lead too far to be included in a condensed report, it is the writers' belief that the polymers are linear, and that therefore there are only four structural possibilities to consider, namely

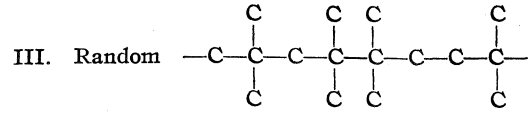
I. Head to Tail



II. Head to Head



III. Random



IV. Mixture of Type I, II or III molecules.

It is assumed that all of these structures include one residual terminal double bond, which seems to be borne out by determination of unsaturation of the product as related to average molecular weight.

Of these various structures, type I is most probable for the polyisobutene molecule. Its decomposition would be expected to give the ordinary diisobutenes, 2,4,4-trimethyl-1-pentene and its -2-isomer. It is a fact that an isobutene polymer of about 20,000 molecular weight on decomposition at 350° gave degradation products, an analytical distillation of which is shown in Fig. 6. The polymer gave about 50% of monomer and about 20% hydrocarbons boiling in the octene range. Figure 7 shows the result of a refractionation of the dimer cut. A portion of fraction 1 reacted with phenol to give a 65% yield of the characteristic tetramethylbutylphenol, m. p. and mixed m. p. 84°.

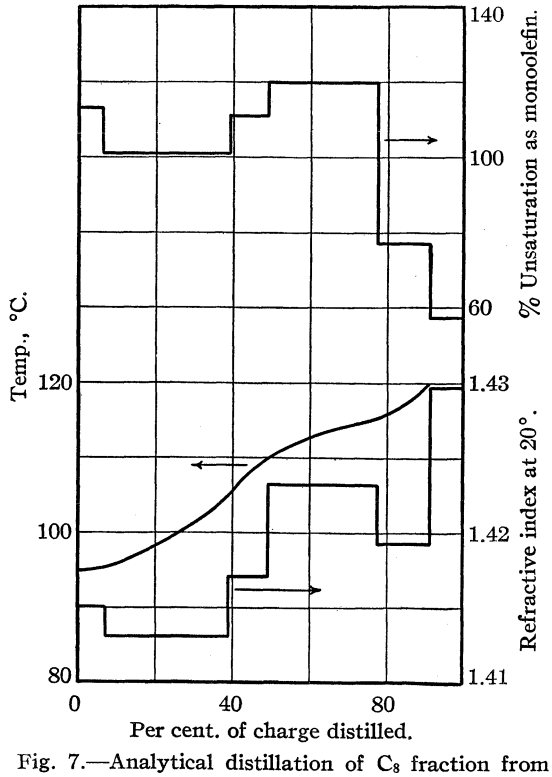


Fig. 7.—Analytical distillation of C_8 fraction from the thermal decomposition of polyisobutene in a glass still at a controlled temperature of 350°.

The occurrence of the higher boiling octenes

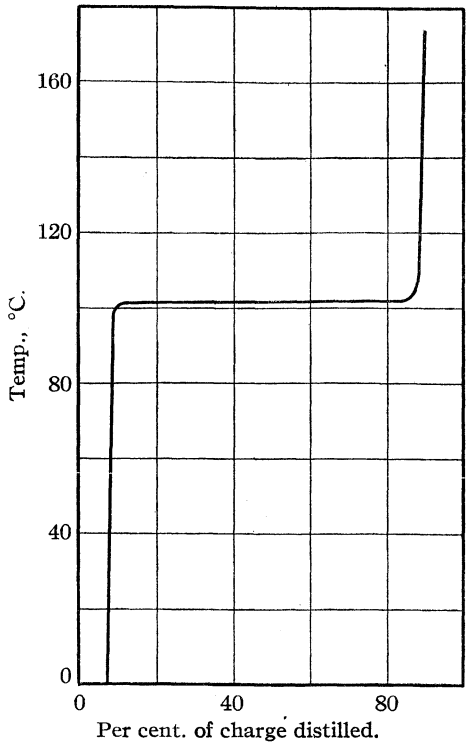

Fig. 8.—Fractionation of 2,4,4-trimethylpentene-1 subjected to a temperature of 350° for one hour.

may be due either to isomerization during the pyrolysis or to the possibility of some random structure (III) in the polymer. The material boiling at 110–115° on ozonization or chromic acid oxidation gave acetone, acetic acid and an odor of fatty acids. This may indicate the presence of 2,5-dimethyl-2-hexene.

The possibility of isomerization of the octenes after their liberation from the polymer was tested by heating diisobutene (b. p. 101.5–101.9°) at 350° for an hour. As shown in Fig. 8, cracking and polymerization took place but there was no noticeable degree of isomerization.

Acknowledgment.—The writers wish to acknowledge the active participation of many of their associates in obtaining the large amount of information from which this paper is abstracted.

Summary

The catalytic polymerization of isobutene at low temperatures to form a homologous series of polymers ranging to very high molecular weights is discussed in detail.

The structure of the polymers is partially established.

The Action of Aluminum Chloride on Aromatic Hydrocarbons. II. The 1,3-Dimethyl-4-propylbenzenes

BY DOROTHY NIGHTINGALE AND BENOIST CARTON, JR.[1]

When the 1,3-dimethyl-4-butylbenzenes are warmed with aluminum chloride, the butyl group migrates to the 5 position.[2] During the rearrangement, the *n*- and *s*-butyl radicals are isomerized to *s*- and *t*-butyl radicals, respectively.

We have now completed a similar study of the 1,3 - dimethyl - 4 - propylbenzenes. The results, showing that both the 4-*n*-propyl and the 4-isopropyl hydrocarbon rearrange to yield 1,3-dimethyl-5-isopropylbenzene, should be compared with those of Baddeley and Kenner,[3] who reported that 1,3,4-tri-*n*-propylbenzene when heated to 100° with aluminum chloride yielded 1,3,5-tri-*n*-propylbenzene. These authors, however, gave no evidence to support their statement that the migrating propyl group did not isomerize to an isopropyl group and, in view of our results, their conclusion is questionable. Similarly, Heise and Tohl's[4] conclusions that *n*-propylbenzene and aluminum chloride yielded *m*- and *p*-di-*n*-propylbenzene are also doubtful.

The present investigation has shown that the *n*-propyl radical in 1,3-dimethyl-4-*n*-propylbenzene does not readily shift to the 5 position but that its migration is accompanied by isomerization. At 55° the rearrangement is far from complete; at 85 and 100° the product appeared to consist largely of 1,3-dimethyl-5-isopropylbenzene along with some of the starting material.

Rearrangement of 1,3 - dimethyl - 4 - isopropyl-

(1) Abstract of a dissertation to be presented by Benoist Carton, Jr., in partial fulfilment of the requirement for the degree of Master of Arts at the University of Missouri.

(4) Heise and Tohl, *Ann.*, **270**, 155 (1892).

benzene to the 1,3,5 isomer took place more readily and was nearly complete at 55°.

In order to be certain of the structure of the rearrangement products, both 1,3-dimethyl-5-isopropylbenzene and 1,3-dimethyl-5-*n*-propylbenzene were synthesized. All of the synthetic hydrocarbons and the rearrangement products were identified by means of their diacetamino derivatives, and by oxidation to a tricarboxylic acid.

Smith and Perry[5] have suggested that during the alkylation of *m*-xylene in the presence of aluminum chloride, a 1,3,4-hydrocarbon is formed initially and is subsequently rearranged to yield finally a 1,3,5-hydrocarbon. If this is true, any alkylation in the presence of aluminum chloride which will lead to the formation of *n*-propylbenzene would be expected to yield a 1,3-dimethyl-5-isopropylbenzene when benzene is replaced by *m*-xylene. If the 1,3-dimethyl-5-propylbenzene is formed directly, such a procedure should yield a product containing a *n*-propyl radical in the 5 position.

There are two alkylating agents which yield *n*-propylbenzene with aluminum chloride as the catalyst: *n*-propyl formate[6] and cyclopropane.[7] *n*-Propyl formate and *m*-xylene yielded 1,3-dimethyl-5-*i*-propylbenzene. Cyclopropane and *m*-xylene yielded 1,3-dimethyl-4-*n*-propylbenzene. Both of these reactions may be interpreted as supporting the above view. It should be noted that the maximum temperatures during these alkylations were 60 and 15°, respectively, and with entirely different alkylating agents. There is considerable evidence in the literature to indicate that the temperature of the reaction as well as the size and type of alkyl group may be an important factor in governing the configuration of the polyalkylbenzenes formed.

Acknowledgments.—The authors wish to express their thanks to E. I. du Pont de Nemours and Company through Dr. Miles A. Dahlen for the *m*-xylene used in this investigation, and to the University Research Council for funds to purchase other necessary chemicals and apparatus to continue the study.

Experimental[8]

1,3-Dimethyl-4-*n*-propylbenzene.—The 4-propionyl-*m*-xylene was prepared by the usual Friedel–Crafts procedure from 60 g. of *m*-xylene, 46 g. of propionyl chloride, 66 g. of aluminum chloride, and 200 cc. of carbon disulfide. The yield of pure ketone was 57 g. (80%), b. p. 112° (10 mm.). The hydrocarbon was prepared from the ketone (50 g.) by the Clemmensen reduction in 50% yield; b. p. 95° (23 mm.); $n^{25}D$ 1.4995.

Anal. Calcd. for $C_{11}H_{16}$: C, 89.12; H, 10.88. Found: C, 88.95; H, 10.95.

The hydrocarbon also was obtained from *m*-xylene, cyclopropane, and aluminum chloride by the procedure of Grosse and Ipatieff[7] for the preparation of *n*-propylbenzene from benzene and cyclopropane.[9] The cyclopropane (22 g.) was bubbled slowly through 120 g. of *m*-xylene and 4.4 g. of aluminum chloride at 0 to 5°. About half of the cyclopropane was absorbed during four and one-half hours. The temperature was allowed to rise to 15°, at which temperature the remainder of the cyclopropane was absorbed rapidly during thirty minutes while the flask was again cooled with ice. The product was decomposed in the usual manner, and distilled under reduced pressure; yield: 28 g. (40%); b. p. 95° (23 mm.).

The diacetamino derivative of this hydrocarbon melted at 284° and did not depress the melting point of the diacetamino derivative of the hydrocarbon prepared from 4-propionyl *m*-xylene. Oxidation of the hydrocarbon yielded trimellitic acid, m. p. 216°.

1,3-Dimethyl-4-isopropylbenzene.—The *m*-xylene (375 cc.) and isopropyl alcohol (47 cc.) were mixed and the flask placed in water cooled with ice. A mixture of 500 cc. of concd. sulfuric acid and 110 cc. of water was added during two hours while the solution was stirred mechanically. The stirring was continued at room temperature for fourteen hours. The xylene layer was separated and washed with dilute alkali and water, dried and vacuum distilled; yield 70 g. (75%), b. p. 77° (13 mm.); $n^{25}D$ 1.4998.

Anal. Calcd. for $C_{11}H_{16}$: C, 89.12; H, 10.88. Found: C, 89.34; H, 11.12.

1,3-Dimethyl-5-isopropylbenzene.—This hydrocarbon is the principal product from three different alkylating agents: isopropyl chloride, *n*-propyl chloride, and *n*-propyl formate.

A mixture of 53 g. of *m*-xylene and 15 g. of aluminum chloride was stirred mechanically while 20 g. of isopropyl chloride was added during an hour. The stirring was continued for an additional three hours. The mixture was decomposed in the usual way, washed, dried and distilled: yield 19 g. (48%), b. p. 83–85° (17 mm.); $n^{25}D$ 1.4930.

Anal. Calcd. for $C_{11}H_{16}$: C, 89.12; H, 10.88. Found: C, 88.91; H, 10.95.

Oxidation of this hydrocarbon yielded trimesic acid, m. p. 365°, and its diacetamino derivative melted at 295°.

The alkylation was repeated, using *n*-propyl chloride in place of the isopropyl chloride: yield of hydrocarbon, 17 g. (46%), b. p. 83–85° (17 mm.); $n^{25}D$ 1.4935. The diacetamino derivative of this product melted at 276° and when mixed with the diacetamino derivative of the hydrocarbon from isopropyl chloride, the melting point was 283°. The trimesic acid formed by oxidation melted at

(9) The cyclopropane was obtained from Mallinckrodt Chemical Works, St. Louis, Mo.

355°. These melting points would indicate that the hydrocarbon was largely 1,3-dimethyl-5-isopropylbenzene, containing perhaps some 1,3,4-isomer.

The procedure of Bowden[6] for the preparation of *n*-propylbenzene from benzene and *n*-propyl formate was followed in detail, with 320 cc. of *m*-xylene in place of benzene: yield of hydrocarbon from 22 g. of ester, 18 g. (50%), b. p. 90° (23 mm.); $n^{25}D$ 1.4930.

Oxidation of this product yielded trimesic acid, m. p. 360°. Its diacetamino derivative melted at 295° and did not depress the melting point of the diacetamino derivative of the hydrocarbon from isopropyl chloride.

1,3-Dimethyl-5-*n*-propylbenzene.—This hydrocarbon was obtained from the reaction of methyl *n*-propyl ketone and acetone in the presence of concd. sulfuric acid, following the procedure for the preparation of mesitylene from acetone and sulfuric acid.[10]

The sulfuric acid (1363 cc.) was added to 1060 cc. of methyl *n*-propyl ketone (tech.) and 1406 cc. of acetone at 0–10°. The material distilling at 150–240° was purified by treatment with sodium, and fractionated at 20 mm.: (I) 50 g. 67–92°; (II) 35 g. 92–94°; (III) 10 g. 94–96°; (IV) 16 g. above 96°. Fraction II was carefully refractionated to yield finally 19 g. of hydrocarbon, b. p. 90–91° (18 mm.); $n^{25}D$ 1.4913.

This product, when oxidized, yielded trimesic acid, m. p. 360°, and its diacetamino derivative melted at 239°.

The procedure of Morton and Fallwell[11] for the preparation of ethylbenzene from benzyl sodium and methyl iodide was followed in detail, substituting 80 cc. of mesitylene for 75 cc. of toluene, and with 78 g. of ethyl iodide. The yield of trialkylbenzene was 5.5 g., b. p. 92–93° (18 mm.); $n^{25}D$ 1.4900.

The diacetamino derivative of this hydrocarbon melted at 239° and did not depress the melting point of the derivative of the hydrocarbon from the ketone synthesis.

The diacetamino derivatives of the hydrocarbons were prepared by the procedure of Ipatieff and Schmerling[12] from 1 cc. of hydrocarbon. Purification was tedious, and the yield of pure product was small.

TABLE I

	Hydrocarbon 1,3-Dimethyl-	M. p., °C.[c]	Diacetamino derivative[a] % nitrogen found
A	4-*n*-Propylbenzene	284	10.81
B	4-Isopropylbenzene	292	10.96
C	5-Isopropylbenzene (isopropyl chloride)	295	10.76[b]
D	5-*n*-Propylbenzene (ketones)	239	10.78
E	5-*n*-Propylbenzene (organo alkali)	239	

[a] Calcd. for $C_{11}H_{22}N_2O_2$: C, 68.70; H, 8.39; N, 10.68. [b] Found: C, 68.80; H, 8.21. [c] Mixed melting points: A + B, 263°; B + C, 255°; A + C, 250°.

Rearrangements with Aluminum Chloride.—The aluminum chloride was added directly to the hydrocarbon, and the mixture warmed in a water-bath. A thermometer was placed in the reaction mixture and during the heating the flask was shaken frequently. After heating, the mixture was poured onto ice, extracted with ether, washed, dried and vacuum distilled. Fraction I contained some *m*-xylene and fraction II the trialkylbenzenes.

1,3-Dimethyl-4-isopropylbenzene.—The hydrocarbon (32 g.) was warmed with aluminum chloride (7 g.) at 55–60° for three hours. The reaction products were distilled at 20 mm. and yielded only two fractions: (I) 1.4 g. up to 85°; (II) 29 g. 85–86°. The boiling point of II was unchanged on redistillation. The diacetamino derivative of II melted at 295°, and did not depress the melting point of the derivative of 1,3-dimethyl-5-isopropylbenzene. This rearrangement product is therefore 1,3-dimethyl-5-isopropylbenzene.

1,3-Dimethyl-4-*n*-propylbenzene.—The hydrocarbon (35 g.) was warmed with aluminum chloride (8 g.) for three hours at 55°. The reaction products were fractionated at 30 mm.; (I) 3.6 g. 45–95°; (II) 14.9 g. 95–105°; (III) 6 g. 132°; residue 2 g.

Fraction II on slow distillation came over at 105° (38 mm.). The diacetamino derivative of this fraction melted at 279° and did not depress the melting point of the derivative of 1,3-dimethyl-4-*n*-propylbenzene. This fraction is therefore mainly unchanged 4-*n*-propyl hydrocarbon.

The reaction was repeated with 28 g. of hydrocarbon and 7 g. of aluminum chloride at 85–90° for four hours. The following fractions were obtained at 15 mm.: (I) 8.7 g. 45–89°; (II) 7.2 g. 89–94°; (III) 5.1 g. 105–110°.

Fraction II formed a diacetamino derivative which melted at 240–250°, and depressed the melting point of the derivatives of both the 4-*n*-propyl and 5-isopropyl hydrocarbons some 20°. The fraction is probably a mixture of unchanged 4-*n*-propyl hydrocarbon and 5-isopropyl hydrocarbon.

To determine whether or not longer heating and a higher temperature would improve the yield and quality of the trialkyl fraction, the rearrangement was carried out with the same amounts of materials at a temperature of 100° for four hours. These are the experimental conditions of Baddeley and Kenner[3] for 1,3,4-tri-*n*-propylbenzene.

The following fractions were obtained at 15 mm.: (I) 6.8 g. 45–92°; (II) 6.7 g. 89–92°; (III) 3 g. 95–97°; (IV) 2.6 g. 97–110°.

The diacetamino derivative of II melted at 280–285°. Mixed with the derivative of the 4-*n*-propyl hydrocarbon, the melting point was 260–265°, and with the derivative of the 5-isopropyl hydrocarbon the melting point was 285°. The trimesic acid obtained from the oxidation of II melted at 330°.

These data indicate that the 1,3-dimethyl-4-*n*-propylbenzene is largely rearranged to 1,3-dimethyl-5-isopropylbenzene and other hydrocarbons in the presence of aluminum chloride at 100°.

Summary

The 1,3-dimethyl-4-isopropylbenzene undergoes rearrangement on warming with aluminum chloride at 55° for three hours to yield 1,3-dimethyl-5-isopropylbenzene as the principal trialkylbenzene.

(10) "Organic Syntheses," Coll. Vol. I, p. 334.
(11) Morton and Fallwell, THIS JOURNAL, **60**, 1429 (1938).
(12) Ipatieff and Schmerling, *ibid.*, **60**, 1476 (1938).

The 1,3-dimethyl-4-*n*-propylbenzene is largely rearranged by aluminum chloride at 100° for four hours to yield 1,3-dimethyl-5-isopropylbenzene. After heating at 85–90°, the trialkyl fraction is a mixture, and at 55° the trialkyl fraction is mainly unchanged 1,3,4 hydrocarbon.

The 1,3-dimethyl-4-*n*-propylbenzene was prepared from *m*-xylene and cyclopropane with aluminum chloride as the catalyst, and by the reduction of 4-propionyl-*m*-xylene.

The 1,3-dimethyl-5-isopropylbenzene was obtained from *m*-xylene and isopropyl chloride, *n*-propyl formate, and *n*-propyl chloride with aluminum chloride as the catalyst.

The formation of the 4-*n*-propyl hydrocarbon from *m*-xylene and cyclopropane and the 5-isopropyl hydrocarbon from *m*-xylene and *n*-propyl formate support the view of Smith and Perry that a 1,3,4 hydrocarbon is the initial product of the reaction when *m*-xylene is alkylated in the presence of aluminum chloride.

The Hydrogenation of Coumarin and Related Compounds

BY PETER L. DE BENNEVILLE AND RALPH CONNOR

γ-Valerolactone at 250° and 100–200 atmospheres of hydrogen over a copper chromite catalyst has been reported[1] to give pentanediol-1,4, the product expected from an ester under these conditions, and a small amount of hydrogenolysis product, pentanol-1. Over nickel, however, γ-butyrolactone and γ-valerolactone gave[2] 9% of tetrahydrofuran and 17% of α-methyltetrahydrofuran, respectively. These seem to be the only known examples, except in cases where other functional groups complicate the reactions, of the formation of ethers and also of the attack of an ester group in the presence of a nickel catalyst. Apparently no other γ-lactones and no δ-lactones have been investigated under these conditions.

The products obtained by the hydrogenation of coumarin and certain related compounds are shown in the flow sheet (Table I). Over copper chromite, the behavior of coumarin was like that of any α,β-unsaturated ester. The formation of dihydrocoumarin (II) at 140–160° was shown by the pressure drop but the hydrogenation was not interrupted to permit its isolation. At 250° there was obtained a good yield of the product expected from a normal ester hydrogenation, γ-(*o*-hydroxyphenyl)-propyl alcohol (V).

Dihydrocoumarin (II) was isolated from the hydrogenation of coumarin over Raney nickel at 100°. In hydrogenations at higher temperatures dihydrocoumarin was not isolated but was formed quantitatively, as shown by the hydrogen absorption, before any subsequent reaction occurred. At 200–250° the main reactions which occurred over Raney nickel were saturation of the benzenoid ring, giving octahydrocoumarin (III), and conversion of the lactone to the cyclic ether, hexahydrochroman (IV). Pure octahydrocoumarin was obtained in 50–55% yields by carrying out the hydrogenation at 200° and interrupting the reaction before the absorption of hydrogen had ceased.[3] Under these conditions 10–15% of hexahydrochroman was formed. Higher yields (up to 35%) of the latter product were obtained by using a relatively long reaction period at 250°.

Since the formation of ethers from esters over nickel is by no means a common reaction, it is of some interest to determine the intermediates in the formation of hexahydrochroman from coumarin. Three possible mechanisms are shown by broken lines in Table I and none of these may be definitely eliminated on the basis of the facts now available. Path (c) agrees with the observation that IV is the sole product obtained by the hydrogenation of III under these conditions. This also agrees with the results previously mentioned with γ-butyrolactone and γ-valerolactone except that the yield of ether from coumarin was

(1) Adkins, "Reactions of Hydrogen, etc.," University of Wisconsin Press, Madison, Wisconsin, 1937, p. 105.

(2) Ref. 1, p. 77.

(3) A plot of time against pressure showed a definite change in slope which seemed to mark the best time to interrupt the reaction. At 250° this point was not observed readily and, while good yields (60–70%) of the octahydrocoumarin fraction were obtained, the refractive index of the product showed that it contained unreacted dihydrocoumarin.

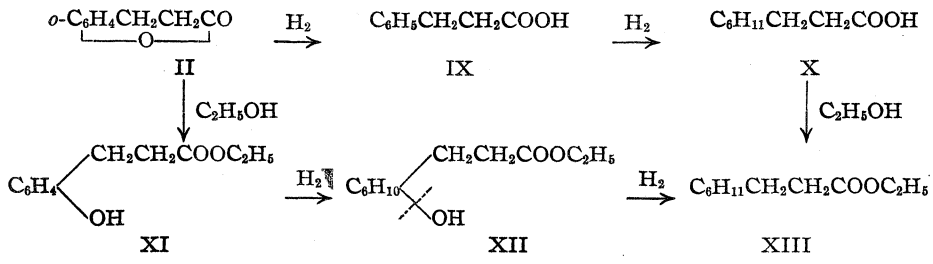
[a] The reactions were carried out under a hydrogen pressure of 100–200 atm. [b] According to the refractive index ($n^{25}D$ 1.5025) this fraction probably contained some dihydrocoumarin ($n^{25}D$ 1.5541). [c] According to the refractive index ($n^{25}D$ 1.4728) this fraction probably contained some β-cyclohexylpropionic acid ($n^{20}D$ 1.4634). [d] Apparently the starting materials were converted completely to the products named but recovery was low because of the high mechanical loss in distilling small amounts of material.

considerably higher than from the γ-lactones. Path (b) seems the least probable of the three in view of the fact[4] that the structure $-\overset{\overset{O}{\|}}{C}-O-Aryl$ is not converted to $-CH_2O-Aryl$ under these conditions. Mechanism (a) represents the attack of the ester group over nickel proceeding according to that over copper chromite. The fact that IV was formed by the hydrogenation of pure V and of pure VI agrees with this mechanism. The formation of IV from V is, however, of some interest since it appears to be the first case of ring closure by dehydration under these conditions. It is noteworthy that nickel apparently catalyzes the ring closure, since no ethers were formed from γ-(*o*-hydroxyphenyl)-propyl alcohol and γ-(2-hydroxycyclohexyl)-propyl alcohol under conditions that were similar except that the catalyst was copper chromite.



The results of typical hydrogenations are reported in Table II. Certain by-products mentioned may require explanation. According to the behavior of esters of phenol,[4] it would be expected that dihydrocoumarin would give some β-phenylpropionic acid (IX) and that β-cyclohexylpropionic acid (X) would be the final product from this reaction. Indications of the presence of the acid were obtained (Table II) in prolonged hydrogenations in the complete absence of alcohol. However, this acid and the saturated lactone (III) have boiling points so close that they could not be separated by distillation and the use of alkali was futile because of the pseudo acid character of III. Additional evidence for the formation of X was obtained by the identification of its more readily isolable ethyl ester (XIII) when alcohol was present.[5] It should be pointed out, however, that except for the analogy to the behavior of aryl esters,[4] there is no evidence to exclude the possibility that XIII was formed by the alcoholysis of dihydrocoumarin, followed by hydrogenation and hydrogenolysis of the hydroxy esters (XI and XII).

The material designated as "polymer" in Table II was formed in larger amounts at 250° and as the time of the hydrogenation was prolonged. It was a thick, slow-flowing, non-distillable material which did not crystallize[6] but remained as the residue from the distillations. The yields of this material reported (Table II) were calculated from the total weight of the distillation residue and include the octahydrocoumarin which was present because of the hold-up of the fractionating column.

Since hexahydrochroman had not been made previously and since it had no reactive functions to facilitate a confirmation of its structure, it seemed necessary to prepare a sample of the material by a more orthodox method. This was done by the hydrogenation of chroman over nickel and the comparison of the physical properties of the two products to show that they were identical (Table III). The methods already described for the synthesis of chroman were not particularly satisfactory and as a matter of convenience a simple synthesis using coumarin as the starting material was devised. This method involved the hydrogenation of coumarin over copper chromite and treatment of the phenolic alcohol (V) with phosphorus tribromide.[7] The yields in these two steps were 90% and 87%, respectively.

These results show that coumarin may be converted to octahydrocoumarin, chroman or hexahydrochroman, depending on the conditions used. Because of the current interest in various natural products related to chromans and coumarins, the

(4) This statement is based upon unpublished data of Wm. R. McClellan and will be described in detail in a forth-coming communication.

(5) Aside from the formation of this ester, no differences were noted in comparison of alcohol and methylcyclohexane as solvents.

(6) Treatment of III with sodium ethoxide gave a thick, sticky product which was presumably a polymeric ester. It seems likely that the high-boiling material formed during the hydrogenations was also composed of polymeric esters. A closer examination of this product wil lbe made.

(7) Semmler[8] prepared chroman from V by treatment with alcoholic hydrogen chloride in a sealed tube.

[a] Saponification number: Calcd., 155; found, 154. Octahydrocoumarin was prepared by another method by Cook and Lawrence,[11] who reported that it boiled at 145° (10 mm.). Since they gave no other physical properties the identity of our product was confirmed by analysis for carbon and hydrogen. [b] The properties of hexahydrochroman from both sources are given, since their similarity serves as a confirmation of the structure assigned to these products. *Anal.* Calcd. for $C_9H_{16}O$: C, 77.07; H, 11.5. Found: C, 76.9, 76.7; H, 11.6, 11.7. [c] The molecular refraction (40.03) of chroman calculated from the results of Semmler[8] is also slightly above theoretical. [d] *Anal.* Calcd. for $C_9H_{18}O_2$: C, 68.4; H, 11.6. Found: C, 68.2, 68.2; H, 11.6, 11.6. [e] Saponification number: Calcd., 184; found, 182. Sabatier and Murat[12] had previously prepared this compound, b. p. 231° (760 mm.), $n^{17}D$ 1.452. The identity of our product was confirmed by comparison of the physical properties with a sample prepared by another method.[4] [f] Semmler[8] reported the boiling point of V as 177–178° (8 mm.) and the melting point of the benzoate as 99–100°. [g] A sample of γ-cyclohexylpropyl alcohol (VIII) was prepared by the hydrogenation of γ-phenylpropyl alcohol (Table II). The product (b. p. 116° (20 mm.), 218° (760 mm.)) gave an α-naphthyl urethan, m. p. 83–84°. A mixed melting point showed that this was identical with the derivative of the hydrogenolysis product reported above. *Anal.* Calcd. for $C_{20}H_{25}O_2N$: N, 4.49. Found, N, 4.31. Waser[13] reported the boiling point of VIII as 110–111° (11 mm.).

reactions described here are being extended to more complex derivatives.

Experimental Part

The coumarin used was purified by recrystallization from a mixture of benzene and ligroin (b. p. 70–90°). Certain samples of coumarin, presumably of natural origin, were hydrogenated to dihydrocoumarin over nickel but gave no further reaction at 200° and very slow reaction at 250°. Recrystallization removed the impurity responsible for this behavior and the results given in Table II were readily duplicated. For hydrogenation over copper chromite, Merck coumarin was used without recrystallization.

Hydrogenations.—The apparatus was similar to those already described[9] and was used in conjunction with a potentiometer-controller temperature-recorder. In the hydrogenations in which alcohol was the solvent, the commercial absolute grade was used. Raney nickel and copper chromite catalysts were made by the conventional methods.[10] The nickel catalyst was stored under alcohol but in the experiments in which it was desired to avoid the effects of alcohol, the catalyst was washed several times with ether and finally with methylcyclohexane. The hydrogenation products were dried over magnesium sulfate and distilled under reduced pressure through a 10-cm. Vigreux column or a Widmer column containing a spiral 11 cm. long. The results of the hydrogenations are given in Table II. Since most of the products did not contain reactive functions and could not be converted to solid derivatives, physical properties and analyses were important factors in identification. Fortunately, these were satisfactory for the elimination of any likely alternative structures. The data obtained are reported in Table III.

Chroman (VI).—A solution of 30.4 g. (0.2 mole) of γ-(o-hydroxyphenyl)-propyl alcohol (V) in 100 ml. of dry benzene was placed in a 500-ml. three-necked, round-bottomed flask fitted with a mechanical stirrer, a dropping funnel and a reflux condenser connected to a trap to dispose of hydrogen bromide. The solution was cooled in a water-bath at 5°, about 2 ml. of phosphorus tribromide added, and the mixture stirred until it had become warm enough for reaction to begin. The reaction flask was kept in the bath of cool water and the remainder of the phosphorus tribromide added slowly enough to avoid a violent reaction. A total of 40.7 g. (0.15 mole) of phosphorus tribromide was used and about one-half hour was required for its addition. The reaction mixture was stirred for an additional two hours, allowed to stand overnight and on the next morning refluxed for one-half hour on the steam-bath. After cooling, the flask was immersed in cold water and a solution of 24 g. (0.6 mole) of sodium hydroxide in 100 ml. of water added cautiously with stirring. This mixture was refluxed on the steam-bath with stirring for three hours and the layers separated. The aqueous layer was washed once with an equal volume of benzene and the combined benzene extracts washed with an equal volume of water. The benzene solution was dried over calcium chloride and distilled. The yield of chroman (VI) was 23.3 g. (87%), b. p. 125–130° (70 mm.). The product was a colorless liquid which contained traces of halogen,[14]

(9) Ref. 1, p. 39.
(10) Ref. 1, pp. 13, 20.
(11) Cook and Lawrence, *J. Chem. Soc.*, 817 (1937).
(12) Sabatier and Murat, *Compt. rend.*, **156**, 752 (1913).
(13) Waser, *Helv. Chim. Acta*, **8**, 123 (1925).

(14) In this state the product was not hydrogenated over nickel but this treatment removed the impurity and the recovered chroman was readily hydrogenated by a second treatment over nickel (Table II).

and turned a straw color on standing. The physical properties of the product are given in Table III and exclude the possibility that it is the isomeric 2-methylcoumaran. The following properties have been reported for chroman[8] and 2-methylcoumaran,[15] respectively: b. p. 93.5° (8 mm.), 208–212°; n_D 1.54437 (20°), 1.5302 (25°); *d*, 1.0587 (20°), 1.028 (25°).

Omission of the treatment with alkali described above reduced the yields of chroman to 70–75%. None of the expected bromide was isolated but the chroman fraction contained large amounts of halogen. However, treatment of γ-(*o*-hydroxyphenyl)-propyl alcohol (V) with hydrobromic acid–sulfuric acid mixture as described[16] for lauryl bromide gave a 50% yield of chroman and 10% of what was probably γ-(*o*-hydroxyphenyl)-propyl bromide, b. p. 165° (23 mm.). The latter could not be purified, since hydrogen bromide was evolved slowly during distillation.

Summary

Products obtained by the hydrogenation of coumarin, or from its hydrogenation products, include dihydrocoumarin, octahydrocoumarin, chroman, hexahydrochroman and a substance believed to be a polymeric ester. Of especial interest is the conversion of δ-lactones and of a 1,5-glycol to cyclic ethers over Raney nickel.

Ephedrine. III. Di-(α-hydroxyl-β-methylaminopropyl)-benzenes

BY STANLEY D. WILSON AND CHEN-TA CHANG

Although a large number of derivatives and homologs of ephedrine have been reported by numerous investigators, we can find no record of such derivatives with two α-hydroxyl-β-methylaminopropyl side chains. This paper reports the preparation of the meta and para compounds of this type. These compounds were prepared from the 1,3- and 1,4-dipropionylbenzenes, respectively, which we made from the corresponding phthalyl chlorides by modifications of Mixin's[1] method. According to this method the phthalyl chlorides were first converted into the diethyldiamides by treatment with diethylamine. These diethyl acid amides were then treated with ethylmagnesium bromide, which converted them into the desired dipropionyl compounds. In the first step Mixin employed ether as a solvent with the para compound but used benzene with the meta compound. The substitution of ether for the benzene in the case of the meta compound resulted in better yields and much greater ease in purification of the product. Mixin reports a yield of 25–30% in the second step from the Grignard reaction when he refluxed for four hours. We obtained yields of 35–40% by refluxing for nine hours.

The dipropionylbenzenes were next treated with bromine, which converted them into two new derivatives: 1,3- and 1,4-di-(α-bromopropionyl)-benzenes. When the bromo compounds were treated with methylamine they were converted into the corresponding di-(α-methylaminopropionyl)-benzenes which also have not been described previously. These amino compounds were then reduced by hydrogen in the presence of platinum to give the desired new ephedrines. The last three reactions have been employed in the preparation of the more normal types of ephedrine homologs by Späth and Göhring,[2] Hyde, Browing and Adams,[3] Wilson and Sun[4] and others.

The free base of the new para ephedrine was a thick oil but that of the meta compound was an amorphous solid. The salts of the para compound crystallized well and had high melting points, while the hydrochloride, sulfate, oxalate, and phosphate of the meta derivative were thick liquids, but the picrate was a somewhat gummy amorphous solid. This agrees with Koller's[5] finding, that salts of *p*-methoxyephedrine were crystalline and had melting points while the salts of *m*-methoxy-*p*-hydroxyephedrine were liquids. These compounds contain four asymmetrical carbons and their resolution into their optical isomers would be an interesting problem.

Experimental Part

Preparation of 1,4-Di-(α-bromopropionyl)-benzene.—8.41 g. of bromine was added gradually to 5 g. of 1,4-

(1) Mixin, *Ann. Chim.*, **9**, 55 (1928).

dipropionylbenzene dissolved in 100 cc. of glacial acetic acid while the solution was heated on the water-bath under a reflux condenser. After the hydrogen bromide was nearly all expelled, the solution was cooled in an ice-bath. The bromo compound separated in colorless plates, which were recrystallized from alcohol, yield 95%, m. p. 109–110°. The compound is insoluble in water, moderately soluble in alcohol and very soluble in benzene and ether.

Anal. Calcd. for $C_{12}H_{12}O_2Br_2$: Br, 45.93. Found: Br, 45.97.

Preparation of 1,4-Di-(α-methylaminopropionyl)-benzene Hydrogen Chloride.—Seven grams of the 1,4-di-(α-bromopropionyl)-benzene dissolved in 200 cc. of benzene was added drop by drop to 3 g. of methylamine in 200 cc. of benzene. The reaction mixture was allowed to stand at room temperature for one hundred hours. Crystals of methylamine hydrobromide separated and were filtered off. A portion of the benzene and the excess of the methylamine were removed by distillation. The residual solution was then treated with a current of dry hydrogen chloride at room temperature. The 1,4-di-(α-methylaminopropionyl)-benzene hydrochloride which separated out was recrystallized from methyl alcohol and ether to give fine colorless plates, which did not melt but decomposed above 320°. The product is slightly soluble in ether, moderately soluble in alcohol and very soluble in water. The yield was 3 g. or 62%.

Anal. Calcd. for $C_{14}H_{22}N_2O_2Cl_2$: C, 52.32; H, 6.91; Cl, 22.08. Found: C, 52.50; H, 6.70; Cl, 21.64.

Preparation of 1,4-Di-(α-hydroxyl-β-methylaminopropyl)-benzene Hydrochloride.—Two grams of the 1,4-di-(α-methylaminopropionyl)-benzene hydrochloride dissolved in 100 cc. of 95% alcohol was reduced by hydrogen in the presence of platinum catalyst. The catalyst was removed by filtration and the solution concentrated by evaporation of a portion of the ethyl alcohol. Upon addition of ether, the new compound separated in a yield of 1.8 g. On recrystallization from methyl alcohol and ether it formed rosets, m. p. 285–287°. The product was insoluble in benzene and ether, moderately soluble in alcohol and very soluble in water.

Anal. Calcd. for $C_{14}H_{26}N_2O_2Cl_2$: C, 51.67; H, 8.06. Found: C, 51.65; H, 8.03.

Preparation of the Free Base.—It was difficult to separate and purify the free base when it was set free from the hydrochloride by addition of potassium hydroxide. On the other hand, the free base of the corresponding ketone was easily obtained by the same treatment and gave the corresponding ephedrine on catalytic reduction. Both bases were slightly brownish, somewhat gummy amorphous substances which decomposed on heating. The sulfate (decomposed above 320°), mandelate (m. p. 214°), and tartrate (m. p. 167–168°), of the ephedrine were prepared easily by treating an alcoholic solution of the base with an alcoholic solution of the corresponding acids. They were recrystallized from mixtures of alcohol and ether. All were white nicely crystallized products.

Preparation of 1,3-Di-(α-hydroxyl-β-methylaminopropionyl)-benzene Hydrochloride.—This compound was prepared from the corresponding 1,3-dipropionylbenzene by an analogous series of reactions. It was found more satisfactory to substitute carbon tetrachloride as a solvent during the bromination of the dipropionyl compound. The bromo compound, the hydrochloride of the amino ketone and the hydrochloride of the ephedrine were all liquids which did not solidify even at −20°. The solubilities were very similar to those of the corresponding 1,4-derivatives.

Anal. Calcd. for $C_{14}H_{26}N_2O_2Cl_2$: C, 51.67; H, 8.06; Cl, 21.81. Found: C, 51.38; H, 7.61; Cl, 22.94.

The Free Base.—In this case the free base was prepared by treating a water solution of the hydrochloride of the ephedrine with potassium hydroxide. It proved to be an amorphous solid which decomposed on heating. This product is soluble in alcohol and benzene but insoluble in water. Treatment of saturated alcoholic solutions of the base with alcoholic oxalic, sulfuric and phosphoric acids gave only liquid products which did not solidify even at −20°. The picrate was an amorphous solid which decomposed on heating.

We wish to thank The China Foundation for the Promotion of Education and Culture for a grant which defrayed the expense of this investigation.

Summary

1. Two new ephedrine homologs, 1,3- and 1,4-di-(α-hydroxyl-β-methylaminopropyl)-benzene, have been prepared.

2. Four new intermediate compounds were obtained: the 1,3- and 1,4-di-(α-bromopropionyl)-benzenes and the 1,3- and 1,4-di-(α-methylaminopropionyl)-benzenes.

Splitting the CONH Linkage by Means of Ultraviolet Light[1]

BY D. C. CARPENTER

Any method which would enable us to break selectively the peptide (CONH) linkage between certain of the various amino acids of a protein, should bring forth a certain amount of information on the arrangement of the individual amino acids within the molecule. Inasmuch as the specific properties of proteins such as insulin probably depend on the presence of a certain sequence of grouping of amino acids in the molecule, a method bearing on the finding of these groupings is of considerable interest and importance. From recent results it appears that ultraviolet light may be a useful tool for opening up the protein molecule in such work.

Rideal and Mitchell[2] showed that stearic anilide $C_{17}H_{35}CONHC_6H_5$ when irradiated as a monolayer with light of wave length 2350–2400 and 2483 Å. was decomposed into stearic acid and aniline. In this experiment the benzene ring functioned as the chromophore group. Inasmuch as the bond energy of the C–N linkage (48.6 kcal./mole)[3] is the weakest linkage in the compound, it is not surprising that breakage occurs at this point. It might be concluded that Rideal and Mitchell's experiment applied directly to the breakage of peptides in a similar manner. However, in the peptides and proteins the benzene ring or other light absorbing group is contained in a side chain and situated several atoms away from the point of splitting. To be of any use in splitting peptides or the main peptide chain in proteins, the matter arises as to whether light energy absorbed by the chromophore group can pass through several CH_2 groups and still cause splitting of the CONH linkage. Norrish and Appleyard[4] irradiated methyl butyl ketone, CH_3CH_2-CH_2CH_2—CO—CH_3, at 2200–3000 Å., where the CO group is the chromophore, and found that $CH_3CH{=}CH_2$ and CH_3—CO—CH_3 were produced. This showed that energy is able to travel along a chain and cause breakage of a molecule at a distant point. How far energy may travel in this way has not been established.

In the present paper[5] we have confirmed the observations of Rideal and Mitchell with respect to the photolysis of stearic anilide. In addition to this we have prepared benzylstearylamine ($C_{17}H_{35}CONHCH_2C_6H_5$) and β-phenylethylstearylamine ($C_{17}H_{35}CONH(CH_2)_2C_6H_5$) and examined the photolysis of these compounds containing one and two CH_2 groups, respectively, interposed between the chromophore and the keto-imino linkage. We have found that both of these latter compounds undergo photolysis at 2537 Å. and therefore it may be expected that peptides and proteins having side chains bearing chromophore groups will behave similarly, and the CONH groups adjacent to the side chain undergo photolysis and the light absorbing amino acid is liberated from the peptide or protein molecule. This behavior would conform to observations that the free amino groups in proteins are increased by irradiation.[6]

Experimental

Preparation of Materials

Stearic Anilide.—This compound was prepared by converting pure stearic acid m. p. 69.3° (cor.) into the acid chloride by adding small portions dissolved in anhydrous chloroform to thionyl chloride and refluxing over a steam-bath for one-half hour. The thionyl chloride was used in 35% excess of the calculated amount. The excess thionyl chloride and chloroform were removed by distillation *in vacuo* over a water-bath.

Stearyl chloride (8.2 g.) was treated with 2.5 g. of aniline dissolved in 30 cc. of dry benzene and warmed on the steam-bath for two to three minutes. The benzene solution was decanted into a separatory funnel and washed successively with water, 5% hydrochloric acid solution, 5% sodium hydroxide solution and finally with water. The benzene was evaporated and the stearic anilide recrystallized several times from petroleum ether, alcohol and finally twice from acetone; 9.0 g. of stearic anilide in white needles m. p. 94° (cor.) was obtained.

Benzylstearylamine.—This compound was prepared in analogous fashion from benzylamine b. p. 184° (cor.) and stearyl chloride, and after recrystallizing as above was obtained as white flakes, m. p. 98.6° (cor.).

β - Phenylethylstearylamine.—β - Phenylethylamine of b. p. 194.5–196° (cor.) prepared by the method of Ladenburg[7] was condensed with stearyl chloride as above and

after several recrystallizations was obtained as white needles, m. p. 91.8° (cor.).

Absorption Spectrum.—The absorption spectrum of each of the compounds was determined in anhydrous ethyl alcohol as solvent by means of a Bausch and Lomb ultraviolet sectorphotometer, suitable dilutions being employed to cover the absorption range. The absorption spectra are shown in Fig. 1. Comparison of our data for stearic anilide with the results of Rideal and Mitchell shows good general agreement for the maximal absorption region, but the latter's results show somewhat greater absorption throughout the entire range. The band is fairly flat between 2360 and 2500 Å. with a maximum close to 2420 Å.

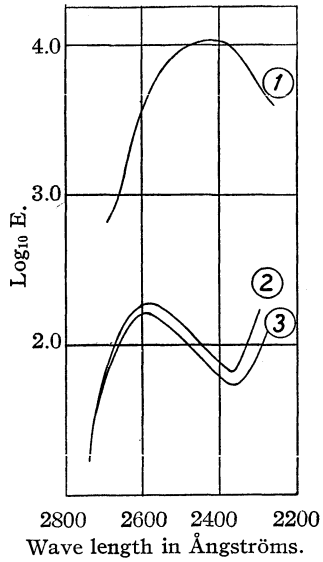

Fig. 1.—Absorption spectra; 1, stearic anilide; 2, benzylstearylamine; 3, β-phenylethylstearylamine.

The absorption spectra for benzylstearylamine and β-phenylethylstearylamine are close together and considerably less than for stearic anilide, the introduction of the first CH_2 group between the ring and the fatty acid residue accounting for most of the decreased absorption and the shift of the maximum toward the visible range. Both of these compounds have an absorption maximum close to 2580 Å.

Irradiation Experiments.—Rideal and Mitchell employed a large quartz monochromator for obtaining monochromatic light. A monochromator of sufficient size to be useful was not available to us, consequently as a source of light in our experiments we have used a quartz-mercury lamp with a combination of light filtering solutions[8] in quartz containers. Rideal and Mitchell record that in the photolysis of stearic anilide no reaction can be detected at 2537 Å. while reactions occur at 2483 Å. They put the threshold for the photochemical reaction near 2500 Å. With the system of light filters we have used, both the 2483 and 2537 Å. lines are transmitted, so we are unable to say definitely whether the photochemical effects we have observed are due to the 2483 or the much more intense 2537 Å. line. We have not observed any effects when using the 2650 and 2700 Å. lines, which are both transmitted when employing a different combination of filter solutions.

(8) Bowen, *J. Chem. Soc.*, 76 (1935).

In our experiments, mono-layers of the substances have been formed by spreading dilute benzene solutions onto normal or tenth normal hydrochloric acid solutions contained in a Pyrex glass trough. The collapse areas of the films have been measured and the theoretical molecular areas calculated. These results are contained in Table I and show that the respective molecules

TABLE I

MOLECULAR AREAS OF SUBSTANCES

	Molecular area, sq. Å. Found	Calcd.
Stearic anilide	23.9	23.7
Benzylstearylamine	30.7	30.4
β-Phenylethylstearylamine	28.6	28.1

are oriented as shown in Fig. 2. In the latter figure the benzene ring is shown with dotted lines but the plane of the ring actually lies at right angles to the plane of the paper as is shown by the solid line. Calculation of the molecular area of

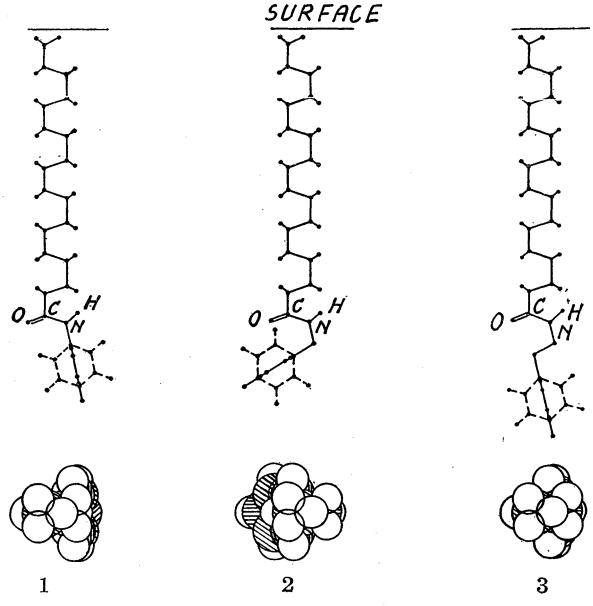

Fig. 2.—Monolayers on 0.1 *n* hydrochloric acid; 1, stearic anilide; 2, benzylstearylamine; 3, β-phenylethylstearylamine.

benzylstearylamine assuming the ring swung out to the right (free rotation about the N–C bond) and as distant as possible from the oxygen atom of the CO group, leads to an area of 36.8 sq. Å., which is altogether too high to agree with the experimental value and we may safely conclude that in a compressed film the ring lies on the same side

as the oxygen atom. The calculated molecular areas agree within 1–2% with the experimental values and this is about as good agreement as can be expected.

The film potential was measured[9] at intervals as the irradiation proceeded and the maximum ΔV values eventually came to around 550 mv. Rideal and Mitchell record a ΔV value for stearic acid of 545 mv. This indicates that the decomposition product remaining in the mono-layer is stearic acid in all cases.

The amines resulting from the photolysis remain in the hydrochloric acid solution substrate, as may be expected. Aniline was identified colorimetrically in the hydrochloric acid solution after irradiation for as short a period as ten minutes by the red color produced by diazotizing and coupling with β-naphthol. Benzylamine and β-phenylethylamine were identified as picrates, m. p. 195° (cor.)[10] and 168° (cor.),[11] respectively, after prolonged irradiation and frequent renewal of the mono-layer. Mixed melting points of each of these were done with the respective pure picrates prepared from the pure amines and confirmed the identity of the photolysis products. Between 4 and 5 mg. of the respective picrates was actually crystallized after about twenty-four hours of irradiation. That the reaction with stearic anilide is a photolysis and not hydrolysis in the presence of hydrochloric acid was definitely proved by inserting a glass filter in the optical system which excluded wave lengths below 3000 Å. Under these conditions no aniline was detected after thirty minutes exposure.

Summary

The absorption spectra of stearic anilide, benzylstearylamine and β-phenylethylstearylamine have been determined and the molecular areas when spread on hydrochloric acid solution have been measured. These substances as monolayers have been irradiated at 2483 and 2537 Å. and found to undergo photolysis at the CONH linkage. The products of the reaction have been identified by film potential measurements (stearic acid) and colorimetric tests (aniline) and as crystalline picrates (benzylamine and β-phenylethylamine).

It seems reasonable to expect that peptides and proteins containing amino acids with light-absorbing side chains may undergo breakage of the adjacent CONH linkages in an analogous manner.

The Heats of Solution, Heats of Formation, Specific Heats and Equilibrium Diagrams of Certain Molecular Compounds

BY A. N. CAMPBELL AND A. J. R. CAMPBELL

A very great number of studies of the freezing point (or melting point) diagrams of binary organic systems has been made.[1] As a result of these studies it appears that a molecular compound frequently is formed. In this connection the question of the relative stability of these numerous compounds has arisen. This question can only be answered with complete precision when the free energy of formation is known and this cannot be obtained readily for the systems under consideration, since the calculation requires a knowledge of the behavior of the specific heats from absolute zero upward. It is known, however, that in condensed systems the heat of formation very often approximates to the free energy of formation. It was thought that determinations of the heats of formation via the heats of solution of some of these organic molecular compounds would give at least the order of magnitude of the free energy change involved. Furthermore, if the specific heats, at room temperature, of reactants and products are known, an approximate calcula-

(1) *Cf.*, for instance, Kremann, *Monatsh.*, **25**, 1215 (1904), and following volumes to 1930.

tion can be made by means of the Kirchhoff equation of the heat of formation at absolute zero, assuming that the difference of molar heats of reactants and products remains constant down to absolute zero. At absolute zero the heats of formation are strictly a measure of the free energy change involved, since at that temperature

$$\Delta H = \Delta F$$

The experimental data required for the evaluation of the above relationships are the heat of formation and the specific heats of reactant and product. In most cases these data were unknown, and we have had to determine them, developing for the purpose methods which are to some extent new, or at least modifications of existing methods, to deal with organic substances, which are for the most part bad thermal conductors.

As this investigation was essentially one of relative stability, using that term in not too precise a sense, we investigated the equilibrium diagrams with a suitable solvent, in certain cases. The effect of this is to extend the information obtained from the freezing curve to a lower temperature. It answers the question of whether or not the compound continues to exist at the lower temperature. In addition it is usually considered that the extent of that portion of the curve, in both cases, along which compound is the stable solid, is a qualitative indication of the stability of the compound, that is, of its distance from a transition temperature. The systems studied were:[2] (1) phenol–urea: compound of 2 phenol:1 urea, congruent melting point, sharp maximum; (2) urea–*p*-toluidine: compound of 1 urea:1 *p*-toluidine, congruent melting point, sharp maximum; (3) β-naphthylamine–*p*-nitrosodimethylaniline: compound of 2 β-naphthylamine:3 *p*-nitrosodimethylaniline, congruent melting point, very flat maximum; (4) salicylic acid–acetamide: compound of 1 salicylic acid:1 acetamide, incongruent melting point, transition temp. 63–65°.

Experimental

Heats of Formation.—Attempts were first made to determine the heats of formation from the heats of combustion, but these were soon abandoned when it was realized that, owing to the large molecular heats of combustion, the difference figure was hopelessly inaccurate. A property of much smaller numerical value per mole was sought and found in the heat of solution, and the heats of formation were determined throughout from this quantity. As all the heats of solution were negative (heat absorbed), the method used was essentially that in which solute and solvent are mixed and the temperature then restored to its original value by electrical heating. The beauty of this method is that a knowledge of the water equivalent is not required. The electrical energy consumed was measured potentiometrically as the fall in potential across a standard ohm in series and across the heating coil of the calorimeter. The energy consumed is then $H = E_1E_2t$, where t is time in seconds and E_1 and E_2 the respective voltage drops. Minor precautions consisted in having large capacity lead accumulators as source of energy, using heavy copper leads, and packing the standard ohm in ice, in case of heating. Currents used were about 0.7 and 1.4 amp., with 2- and 4-volt circuits, respectively. The accuracy of the electrical measurement is said to be 1 in 10,000, certainly 1 in 1000, and therefore much in excess of the accuracy of the thermal measurement, which is 1 in 100 at best. As usual the calorimeter consisted of a dewar flask with beckmann thermometer, but it was found indispensable to immerse the calorimeter in a thermostat at 20°; otherwise radiation losses were appreciable, even through the wall of a silvered vacuum flask. In general, if the temperature of the contents of the dewar fell more than one degree below that of the environment, radiation losses were appreciable. As this was liable to occur when the heavier charges of solute were first introduced, the device was adopted of immediately switching in the 4-volt circuit whereby the temperature was brought to a few tenths below the equilibrium temperature in a few minutes (say, five minutes). The temperature was then restored exactly to its original value by means of the 2-volt circuit (energy input one quarter of the preceding). The energy input in each phase, each of about five minutes duration, was separately determined. A difficulty was encountered in stirring. Blank experiments showed that all kinds of mechanical stirrers raised the temperature several hundredths of a degree during the course of a run. The difficulty was overcome by using as stirring agent a fine stream of air injected through a coarse capillary. The air current passed first through a metal coil and then through a bubbler containing the solvent used in the calorimeter, both coil and bubbler being immersed in the thermostat. The variation of temperature produced by this means was not more than 0.01° during a run. The powdered solute was immersed in the thermostat for some time before its introduction to the calorimeter. In order to allow for any possible existence of a molecular compound in solution, the heats of solution were determined, not only in pure solvent, but also in solvent containing an equivalent amount of the other component.

Preparation of Molecular Compounds.—The lower melting component was melted completely, the calculated quantity of the second component added, the whole stirred until clear, if necessary with further heating, and then allowed to crystallize very slowly. The freezing point, in comparison with the literature, showed the purity of each compound. The molecular compound of *p*-

Chem.*, (2), **111**, 242 (1925). (2) Philip, *J. Chem. Soc.*, **83**, 821 (1903). (3) Kremann, *Monatsh.*, **25**, 1322 (1904); H. Rheinboldt, *loc. cit.* (4) Kremann and Auer, *Monatsh.*, **39**, 466 (1918); Rheinboldt, *loc. cit.*

toluidine and urea is stated to exist in two forms. The form used by us was the high melting and therefore stable form (m. p. 31.1°). This stable form is readily obtained by powdering the samples before use; even mere scratching with a glass rod appears to produce a change in crystalline structure.

Preparation of Materials.—Phenol was distilled repeatedly. One distillation is insufficient and, even then, for specific heat determinations, distillation must be carried out directly into the container, since the slightest trace of water lowers the melting point very abruptly.

Urea was recrystallized from alcohol.

p-Toluidine, taken as pure, m. p. 44.2°.

β-Naphthylamine was recrystallized from benzene.

p-Nitrosodimethylaniline was prepared from dimethylamine, crude product extracted with ether and first crystals separated.

Salicylic acid was recrystallized from water.

Acetamide was distilled several times and protected from access of moist air. The specific heat sample was distilled straight into its container.

Specific Heats.—Perhaps the best method of determining specific heats is to heat the substance electrically in an evacuated container determining the rise of temperature from the increase in resistance of the heating coil. We attempted something similar to this, using, however, a beckmann thermometer and solidifying a large block of substance around the bulb and heating coil, but we found our attempts defeated by the poor thermal conductivity of the materials. If the bulb of the thermometer was near the coil, the thermometer rose rapidly to a high value, and then, when current was cut off, fell to an uncertain final value. If the bulb were far removed from the coil, it commenced to rise only after a considerable interval of time, during which radiation was perhaps considerable and certainly unknown. Determination of temperature from the resistance of the coil would only have made matters worse. This uncertainty in the final temperature led us to adopt the following method, which is a modification of the method of mixtures. From 50 to 100 g. of substance sealed in a bulb of hard glass was placed in a metal container, packed in melting ice and left overnight. The same electrical circuit as was used in the determination of heats of solution was employed, and the same calorimeter, which contained 150 cc. of water, together with the same stirring device. The cooled sample was rapidly introduced into the calorimeter and the 4-volt circuit immediately switched on. The temperature was thus brought to about 0.1° below that of the thermostat, and then brought exactly to the equilibrium value by means of the 2-volt circuit. As the heat of the calorimeter penetrated the badly conducting organic material the temperature again fell but it was not allowed to fall more than 0.1° before the 2-volt circuit was again switched in. In this way radiation loss was reduced practically to zero, despite the comparatively long duration of the experiment (about half an hour). Completion of the experiment was clearly marked by the temperature not dropping, or even rising a little, after the heating current was cut off. In common with all applications of the method of mixtures, this method can only give the specific heat over a range, in this case from 20 to 0°, but, at temperatures so far removed from the absolute zero, the variation of specific heat with temperature will not be great.

Numerical Results.—All measurements were made in a thermostat at 20°.

1. Phenol-Urea

Heats of Solution in Water:

TABLE I

Solvent		Diln. in l. per mole	Heat of soln. in kj. per mole Our value	Lit. value[a]
Phenol	Water	1.79	−11.9	
		2.15	−11.82	
		2.29	−11.26	
		2.02	−11.30 (mean of 12 detns.)	
		∞	...	−10.9
Urea	Water	7.16	−13.81	
	contg.	3.07	−14.0	
	equiv.	1.85	−13.7	
	phenol	4.03	−13.8 (mean of 12)

		4.10	−46.2	
		4.03	−46.58 (mean of 12)	

[a] From "International Critical Tables."

Results

While the heats of solution of phenol and of urea appear to be only slightly dependent on dilution, that of the compound is appreciably greater at the higher dilutions. This is due to the increased dissociation of the compound which is not complete, as can be seen from a comparison of the heat of solution of urea in water containing equivalent phenol and in pure water. Taking the heat of formation of the compound as 10.18 kj. per mole (*cf.* below), the percentage of double compound remaining undissociated at a dilution of about 4 liters per mole is calculated from the difference in the heats of solution of urea in equiva-

lent phenol and in pure water (= 0.85 kj. per mole) as 8.35%. This point was checked by determining the molecular conductivities in water of phenol, of urea, and of the compound. These were:

	μ, mho	Diln. in l./mole
Phenol	0.00921	1.84
Urea	.0464	3.69
Compound	.0578	3.69

Hence, 2 phenol + 1 urea = 0.0648, and the percentage of compound, undissociated, results as 10.8, assuming what is obviously incorrect, that the compound molecules are non-conducting.

Heat of Formation.—Taking mean values for corresponding dilutions, we have

2 phenol + 1 urea = 1 compound + x kj.
$2(-11.3) + (-13.8) = -46.58 + x$ kj.
x = 10.18 kj. = 2.43 kcal./mole

Specific Heats.—

	Sp. ht. in cal./g. Obsd.	Lit. value	Molar heat obsd. in cal./mole
Phenol	0.239	0.561 (liquid)[3]	22.45
Urea	.274	.321[3]	16.4
2 Phenol:1 Urea	.240	...	59.8

Heat of Formation of 2 Phenol:1 Urea, at Absolute Zero (Approximate).—Equation used: $(\Delta H_T - \Delta H_0)/T = C_{products} - C_{reactants}$.

2 Molar heat phenol + molar ht. urea = 61.3
Molar heat compound = 59.8
$C_{products} - C_{reactants}$ = −1.5
T = 293°A.
Hence, ΔH_0 = 1990 cal. = 1.99 kcal.

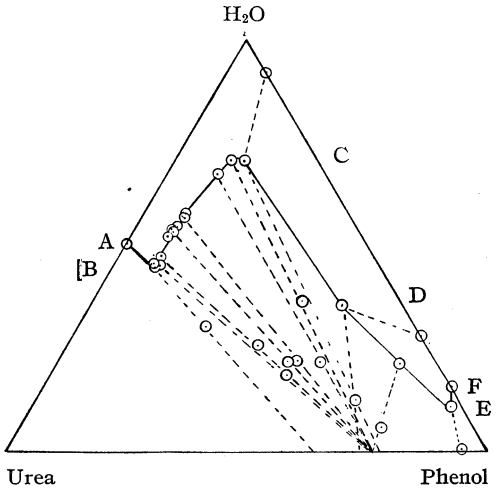

Fig. 1.—AB, urea, solution; B, urea, compound, solution; BC, compound, solution; CD, two liquids, compound; DE, compound, solution; E, compound, phenol, solution; EF, phenol solution.

(3) Magie, *Phys. Rev.*, **16**, 381 (1903), specific heats determined by introducing a weighed portion into one of the cups of the Pfaundler calorimeter.

Equilibrium Diagram.—The complete equilibrium diagram of the system phenol–urea–water was outlined at 20°. Urea was determined by the Kjeldahl method; phenol by the method of Redman, Weith and Brock.[4] The end-point of the latter method was greatly improved by filtering off the precipitated tribromophenol through glass wool, prior to titration. The results are contained in Table II and are expressed graphically in Fig. 1. The diagram has been rendered more complete by the incorporation of the results of Hill and Malisoff[5] for the mutual solubility of phenol/water at 20°.

TABLE II

	Solution % Compn. Phenol	Urea	Wet Solid % Compn. Phenol	Urea	Nature of equil. solid phase
1	...	49.8	...	...	Urea
2	7.85	46.8	Not analyzed		Urea (?)
3	8.5	46.9	26.6	43.7	Urea + compd., invariant pt.
4	9.3	45.3	48.8	32.7	Compound
5	8.7	44.0	39.3	35.1	Compound
6	7.7	40.2	Not analyzed		Compound
7	8.0	38.3	47.4	30.5	Compound
8	7.5	38.2	Not analyzed		Compound
9	8.2	37.0	Not analyzed		Compound
10	7.9	34.6	49.6	28.7	Compound
11	8.2	33.7	Not analyzed		Compound
12	10.15	22.2	54.1	24.1	Compound
13	11.6	17.8	43.2	20.9	Compound
14a	14.35	15.15	66.3	21.2	Two liquid layers +
14b	51.9	12.8	66.3	21.2	compd.
15	70.7	7.95	74.8	19.6	Compound
16	86.8	2.5	94.7	5.1	Compd. + phenol, invariant pt.
17	84.5	0.0	...	...	Phenol

If, in Fig. 1, a line is drawn joining the apex (H_2O) to the composition of the compound, it is apparent that on treatment with water the compound gives rise to two liquid layers; this is, indeed, visibly the case whenever the compound is treated with water.

2. Phenol-*p*-Toluidine

Heats of Solution in Alcohol.—For the determination of heats of solution commercial alcohol was used as solvent. This had d^{20}_4 0.8147, corresponding to 95.5% alcohol by weight.

From the approximate coincidence of the heats of solution of *p*-toluidine in alcohol only and in alcohol containing equivalent phenol, it appears that the compound is completely dissociated in solution.

(4) Thorpe and Whiteley, "Manual of Organic Chemical Analysis," 1925, p. 161.

(5) Hill and Malisoff, THIS JOURNAL, **48**, 918 (1926).

TABLE III

Compound	Solvent	Diln. in l. per mole	Heat of soln. in kj. per mole
Phenol	95.5% EtOH	7.47	− 4.00
		2.18	− 4.25
		1.14	− 4.20
		0.96	− 4.00
p-Toluidine	EtOH	21.0	−14.0

1 *p*-Toluidine		5.2	−22.8
		2.38	−21.9
		1.155	−21.6

Heat of Formation.—Taking the values for the highest concentrations, where the experimental error is least, we have

1 phenol + 1 *p*-toluidine = 1 compound + x kj.
$-4.00 + (-12.6) = -21.6 + x$
$x = 5.0$ kj. = 1.195 kcal.

Specific Heats.—

	Sp. ht. in cal./g. Obsd.	Lit. value	Molar heat obsd. in cal./mole
p-Toluidine	0.277	0.387[a]	29.7
		.232[a]	
Compound: 1 Phenol: 1 *p*-toluidine	.258	....	51.8

[a] "Int. Crit. Tables."

Heat of Formation of Phenol:*p*-Toluidine, at Absolute Zero.—

Molar heat phenol + molar heat *p*-toluidine = 52.1
Molar heat compound = 51.8
$C_{products} - C_{reactants}$ = −0.3
$\Delta H_0 = 1.195 - 0.3(293)/1000$ = 1.11 kcal.

Equilibrium Diagram.—Analytical difficulties rendered the exact working out of the equilibrium diagram (in water) difficult. The results, however, were sufficient to show that the greater part of the diagram is occupied by the equilibrium of two liquid layers: invariance is produced with *p*-toluidine, not compound, as the solid phase.

3. β-Naphthylamine : *p*-Nitrosodimethylaniline

Heats of Solution (in Acetone).—

TABLE IV

Compd.	Solvent	Diln. in l. per mole	Heat of soln. in kj. per mole
β-Naphthyl-amine	Acetone	13.65	−12.0
		4.33	−12.35
		2.86	−11.35
	Acetone contg. equiv. *p*-nitroso-dimethylaniline	4.10	−11.9
p-Nitroso-dimethyl-aniline	Acetone	6.70	−10.9
		3.67	−10.25
		2.77	−11.6
Compound: 2 β-naphthylamine 3 *p*-nitrosodi-methylaniline	Acetone	56.0	−66.3
		24.5	−62.6

The compound is completely dissociated in acetone solution, as an inspection of the heats of solution shows.

Heat of Formation.—The accuracy of the determinations of heat of solution is not good, owing to the slow rate of solution, even in acetone, which was the best solvent found. Mean values are therefore taken for the calculation, despite the fact that in strictness only values for the same dilution should be used; in other words, we assume that the heats of solution do not vary with dilution, and that the observed variations are errors of experiment. The calculation gives

2 β-Naphthylamine + 3 *p*-nitrosodimethylaniline = compound + x kj.
$2(-11.9) + 3(-10.9) = -64.6 + x$
$x = 8.1$ kj./mole = 1.94 kcal./mole

Specific Heats.—

	Sp. ht. in cal./g. obsd.	Molar heat in cal./mole
β-Naphthylamine	0.210	30.1
p-Nitrosodimethylaniline	.329	49.4
Compound	.279	205.0

Heat of Formation of 2 β-Naphthylamine: 3 *p*-Nitrosodimethylaniline at Absolute Zero.—

2 Molar heat naphthylamine + 3 molar heat nitrosodimethylaniline = 208.4
Molar heat compound = 205.0
$C_{products} - C_{reactants}$ = −3.4
$\Delta H_0 = 1.94 - 3.4(293)/1000$ = 0.94 kcal.

Equilibrium Diagram.—Analytical difficulties made the study of the equilibrium diagram impossible. There were, however, indications that the molecular compound lies within the transition interval at 20°.

4. Salicylic Acid–Acetamide

Heats of Solution (in 95.5% alcohol).—

TABLE V

	Solvent	Diln. in l. per mole	Heat of soln. in kj. per mole
Salicylic acid	Alcohol	3.68	−13.0
		1.78	−13.2
		1.17	−13.65
Acetamide	Alc. contg.	3.92	−11.4
	equivalent	1.74	−10.15
	sal. acid	1.04	−10.3
	Alcohol	1.9	−10.6

TABLE V (*Concluded*)

Compound:	Solvent	Diln. in l. per mole	Heat of soln. in kj. per mole
	Alcohol	17.9	−24.3
1 Sali-		6.45	−23.2
cylic		2.79	−23.3
acid		1.87	−24.0
1 acet-		1.41	−24.9
amide		1.13	−24.1

The compound is almost completely dissociated in alcohol solution.

Heat of Formation.—If the assumption is made that the variation in the heats of solution are errors of measurement and the means taken for the calculation, the heat of formation results as +0.1 kj./mole. In view of the smallness of this heat of formation, it was thought better to graph the results for salicylic acid (decreasing with dilution) and for acetamide (increasing with dilution) and to apply the interpolated values to each experimental value for the heat of solution of the compound. In this way the following results were obtained.

Diln.	Heat of formation, kj. per mole
17.9	+1.5
6.45	+0.2
2.79	−0.1
1.87	+0.4
1.41	+1.1
1.13	+0.7

Mean = +0.63 kj. = 0.15 kcal.

Specific Heats.—

	Sp. heat in cal./g.	Molar heat in cal./mole
Salicylic acid	0.1809	24.9
Acetamide	.270	15.9
Compound	.2055	40.5

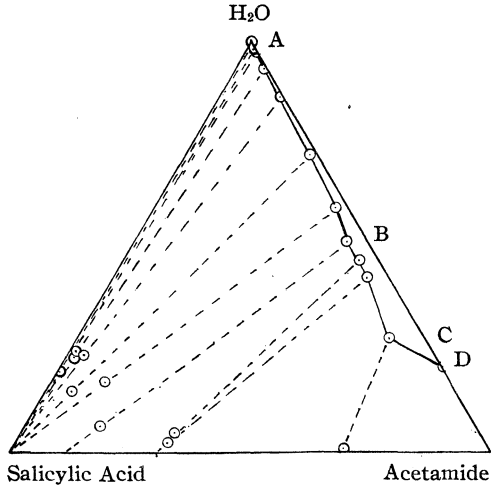

Fig. 2.—AB, Salicylic acid, solution; B, salicylic acid, compound, solution; BC, compound, solution; C, compound, acetamide, solution; CD, acetamide, solution.

Heat of Formation of Salicylic Acid : Acetamide at Absolute Zero.—

Molar heat salicylic acid + molar heat acetamide	=	40.8
Molar heat compound	=	40.5
$C_{products} - C_{reactants}$	=	−0.3
$\Delta H_0 = 0.15 - 0.3(293)/1000$	=	0.06 kcal.

Equilibrium Diagram.—The complete equilibrium diagram for salicylic acid–acetamide–water at 20° was readily determined, the salicylic acid being estimated by titration and the acetamide by distillation with sodium hydroxide. The results are contained in Table VI and expressed graphically in Fig. 2.

TABLE VI

	Solution, % compn.		Wet solid, % compn.		
	Salicylic acid	Acetamide	Salicylic acid	Acetamide	Nature of equil. solid phase
1	0.19	...			Salicylic acid
2	.225	0.4	86.5	0.1	Salicylic acid
3	.28	1.6	79.7	0.6	Salicylic acid
4	.26	2.0	73.4	1.3	Salicylic acid
5	.375	6.2	74.8	1.9	Salicylic acid
6	.53	12.85	72.4	3.5	Salicylic acid
7	1.30	25.9	79.7	5.1	Salicylic acid
8	2.71	37.8	71.7	11.0	Salicylic acid
9	4.13	44.3	78.0	15.3	Sal. acid + compd. invariant pt.
10	4.24	48.9	63.7	31.2	Compound
11	4.91	52.4	66.7	31.2	Compound
12	7.53	64.5	30.4	68.3	Compound + acetamide, invariant pt.
13	..	79.3	..	..	Acetamide

The molecular compound lies within the transition interval.

Numerical Values Obtained.—In work of this kind the possible sources of error are so many that it is difficult to assess the final error with any degree of certainty, but we would represent the results for heat of formation as follows

	System number			
	1	2	3	4
ΔH, in kj.	10.18 ∓ 0.03	5.0 ∓ 0.3	8.1 ∓ 2.4	0.63 ∓ 0.53

The high uncertainty in 3 is due, as mentioned above, to a slow rate of solution in this system.

The only error in the specific heats that we can assess is that of reproducibility in different determinations, which we put at ∓0.01 calorie per gram. The specific heats are all mean values applying to the range 0–20°.

Discussion of Results

It is apparent that the heats of formation of all these double compounds are small, though not

always as small as might be expected from the feebleness of chemical union usually attributed to such compounds. If the rather gross assumption is made that the difference of molar heats of reactants and products remains constant down to absolute zero, then the resulting heats of formation at absolute zero are also the free energies of formation at that temperature. These quantities stand in the relation: 33 : 19 : 16 : 1 for the compounds in the order treated. In agreement with this order, it is found that the compound phenol: urea is by no means completely dissociated in aqueous solution, while salicylic acid: acetamide is. On the other hand the compounds of phenol and *p*-toluidine and of β-naphthylamine and *p*-nitrosodimethylaniline are also completely dissociated in solution. Dissociation in solution, however, is governed by other factors than free energy of formation; neither is it certain that the order of the free energies of formation at absolute zero remains quantitatively or even qualitatively the same at room temperature. The assumption also that the difference $C_{\text{products}} - C_{\text{reactants}}$ remains constant down to the neighborhood of absolute zero is certainly incorrect, so that the values obtained can only be considered crude approximations. Exact calculations can be made by means of the Nernst heat theorem, but this requires an exact knowledge of the behavior of the specific heats between absolute zero and room temperature.

The determination of equilibrium diagrams in the presence of a solvent was only experimentally possible for the systems phenol–urea–water, and salicylic acid–acetamide–water. In the former case the equilibrium solid phase over a large portion of the diagram is the double compound, while in the latter the double compound is still the stable solid phase over a fairly extensive branch of the diagram. Here, again, there is no direct connection between the heat of formation, or free energy of formation, and the portion of the diagram occupied by double compound, other factors, such as solubility, entering in.

Summary

1. The object of this paper is to obtain some measure of the energy change involved in the formation of organic addition compounds.

2. Using the systems phenol–urea, phenol–*p*-toluidine, β-naphthylamine–*p*-nitrosodimethylaniline, and salicylic acid–acetamide, experimental determinations have been made, both for reactants and products, of heat of solution, specific heat, and solubility diagram (in the case of two systems only).

3. The heats of formation at room temperature and at absolute zero, have been calculated, the latter approximately only.

4. The equilibrium diagrams for the systems phenol–urea–water and salicylic acid–acetamide–water at 20°, have been outlined. In both cases the molecular compound is stable at room temperature.

Thermal Data XI. The Heat Capacities and Entropies of Guanidine Carbonate, Glutamic Acid Hydrochloride, Ornithine Dihydrochloride, *d*-Lactic Acid and *l*-Lactic Acid

BY HUGH M. HUFFMAN, EMORY L. ELLIS AND HENRY BORSOOK

In this paper we present the low temperature heat capacity data for the salts of three nitrogen containing organic compounds and the two optically active forms of lactic acid. These data have been utilized in conjunction with an empirical extrapolation formula to calculate the entropies of these compounds at 298.1°K.

Experimental

In principle the method of Nernst was employed with an aneroid calorimeter to determine the "true" specific heat. The details of the method have been described elsewhere[1] so that only a brief account need be given. In brief it consists of supplying, electrically, a measured amount of energy to the gold calorimeter containing the substance under investigation. To ensure rapid attainment of thermal equilibrium, the substance is pressed into dense pellets, about 2 mm. thick, and spaced along the centrally located thermocouple well by means of thin gold disks which are in good thermal contact with the walls of the calorimeter. The electrical measurements of current and voltage are made on a "White" double potentiometer

(1) Parks, THIS JOURNAL, **47**, 338 (1925).

by the proper use of accurately calibrated resistances. Time measurements are made by means of a calibrated stop watch. The temperature measurements are made by means of the White potentiometer in conjunction with a single-junction copper–constantan thermocouple. This couple is periodically standardized against one of the couples calibrated in the investigation of Giauque, Johnston and Kelley.[2]

The guanidine carbonate was an Eastman Kodak Co. product and was used without further purification. Titrations indicated that it was better than 99.8% pure. The ash content was less than 0.1%.

The *d*-glutamic acid hydrochloride was prepared from the glutamic acid used in the investigation of Huffman and Borsook.[3] Titrations indicated that it was better than 99.8% converted to the hydrochloride.

The ornithine dihydrochloride was a commercial product obtained from Hoffman–LaRoche and used without further purification. The stability of the hydrochloride was tested by placing a weighed sample *in vacuo* over phosphorus pentoxide and calcium oxide. The loss observed in twenty-four hours under the above conditions was about 0.01%. The chlorine content, determined volumetrically, was 99.7% of the theoretical. Microkjeldahl nitrogen determinations gave 98.8% of the theoretical.

The lactic acids were prepared from commercial lactic acid sirups according to the method of Borsook, Huffman and Liu.[4] Titrations showed that these preparations were better than 99.7% pure.

Discussion

The results of the heat capacity measurements in terms of the defined conventional calorie appear in Table I. In view of the purity of the compounds and the accuracy of the measurements involved, we estimate the absolute error as less than 1% except in the case of ornithine dihydrochloride.

The data for all of these compounds with the exception of those for ornithine dihydrochloride lie on smooth curves. The curve for this substance shows two humps which correspond to the melting and boiling points of hydrochloric acid and hence may indicate that a small amount of free hydrochloric acid was present. If this is the case we have estimated, from the curve, that 0.04% of hydrochloric acid would account for the humps.

We have determined the entropies of these compounds between 90 and 298.1°K. by graphical integration of a plot of C_p against ln T. In the case of ornithine dihydrochloride we have drawn a smooth curve between 140 and 200°K. The entropy between the experimental curve and the smooth curve was found to be 0.15 entropy unit per mole. If the humps are not characteristic of the substance, we estimate that the total error should not exceed 0.3 entropy unit per mole. The entropy at 90° was obtained by use of the extrapolation formula of Parks, Kelley and Huffman[5] for aliphatic substances (class I). The

entropies thus calculated are given in Table II. Here we estimate that the uncertainty in the experimentally determined part should in all cases be less than 1%. For the extrapolated portion of the entropy it is impossible to make a reliable estimate of the uncertainty, especially in the case of the salts.

In addition to the data given above, we have made one determination of the heat of fusion of *d*(*l*+)-lactic acid. As is well known, this compound is not stable, showing a decided tendency to form a lactone and an anhydride with the elimination of water. For this reason the fusion was not very sharp; furthermore, having once been fused it was impossible, in the calorimeter, to obtain it again in the completely crystalline state. Nevertheless we believe it to be of some interest to present this preliminary value of the heat of fusion, which was found to be 4030 calories per mole.

TABLE II

ENTROPIES OF THE COMPOUNDS PER MOLE IN CAL. DEGREE^{-1} MOLE^{-1}

Substance	S_{90}	$\Delta S_{90-298.1}$	$S_{298.1}$
Guanidine carbonate	22.31	48.28	70.59

The Equilibrium FeO + H_2 = Fe + H_2O at Temperatures up to the Melting Point of Iron

BY JOHN CHIPMAN AND SHADBURN MARSHALL

Equilibria of iron and its lowest oxide with a gas phase containing steam and hydrogen or carbon dioxide and monoxide have been of interest in connection with the reduction of iron ore, the scaling of steel at high temperatures, the behavior of iron catalysts, and the establishment of the water gas equilibrium. Several careful researches on these equilibria have established the free energy of the lowest oxide in the form which occurs in equilibrium with solid iron at temperatures up to about 1360°. Reviews of the literature on this field were included in the papers of Emmett and Shultz[1] and of Chipman and Murphy[2] and need not be repeated here. One noteworthy paper has appeared more recently in which Britzke, Kapustinsky and Schaschkina[3] report measurements extending up to 1225°.

On account of the importance of ferrous oxide in many metallurgical reactions, a determination of its free energy at higher temperatures was undertaken. The plan of this investigation was to establish the equilibrium conditions involving steam, hydrogen, solid iron and liquid oxide over a sufficient range to permit extrapolation to the melting point of iron. At the same time a redetermination below the melting point of the oxide served as a useful check on existing data.

Experimental Method

A weight change method was adopted for the important reason that it permitted a minimum contact of the iron specimen with its support and hence a minimum contamination of either the metallic or non-metallic phase. It proved admirably suited to the problem at high temperatures where the reaction rate was rapid. As shown in Fig. 1 the specimen K was suspended from a balance A mounted directly over the tubular furnace. Commercial hydrogen was passed over platinized asbestos E at 400°, thence through a water saturator C maintained at a controlled temperature in a well-stirred oil-bath and the steam–hydrogen mixture was delivered to the bottom of the furnace. With the furnace at constant temperature, the saturator temperature was adjusted to create a gain or loss in the weight of the specimen, which, when both phases were present in the specimen, indicated respectively oxidizing and reducing conditions. When the saturator temperature was changed slowly and uniformly, it was

(1) Emmett and Shultz, THIS JOURNAL, **52**, 4268 (1930); **54**, 3780 (1932).

(2) Chipman and Murphy, *Ind. Eng. Chem.*, **25**, 319 (1933).

(3) Britzke, Kapustinsky and Schaschkina, *Z. anorg. allgem. Chem.*, **219**, 287 (1934).

possible to observe the change from gain to loss of specimen weight or *vice versa* within a very narrow temperature range. The mid-point of this range was taken as the equilibrium point and the constant was computed from the total pressure (barometric) and the known properties of steam.

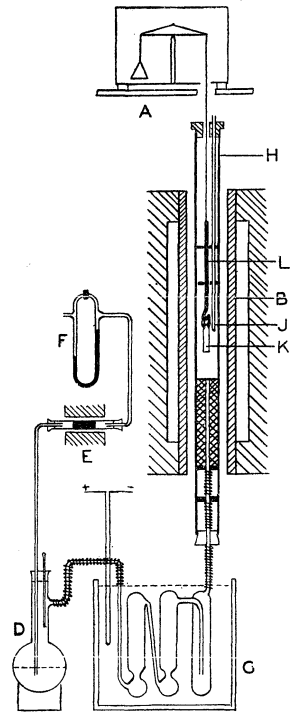

Fig. 1.—Arrangement of apparatus: A, balance; B, globar heating element; C, saturator; D, preliminary saturator; E, platinized asbestos; F, flow meter; H, impervious alumina tube; J, thermocouple protection tube; K, specimen; L, alundum rod.

The iron employed in this study was obtained in the form of rolled carbonyl iron sheet 1.2 mm. thick. This material was cut into strips 3 cm. wide and annealed in dry hydrogen inside a previously annealed Armco iron tube at 1200° for one hundred hours. After this treatment it was found to contain 0.002% oxygen; the annealing was therefore repeated after which the oxygen content was below 0.001%. The strips were cold rolled to 0.27 mm. thickness. Specimens were sheared to the desired size and cleaned in hot hydrochloric acid before use. Several pieces of the annealed strip were analyzed and the following results were the highest that were found: C below 0.005%; S below 0.004%; Si below 0.008%; Mn below 0.003%; Cu, 0.004%; P, 0.002%; Ni, 0.031; O, 0.001; N, nil.

The heating element B, Fig. 1, was a silicon carbide (Globar) tube 5 cm. inside diameter and 55 cm. long. Power was supplied by a motor generator controlled by a variable resistance in the field circuit. By hand regulation it was possible to maintain temperatures constant within ±2° up to 1600°.

Inside the heating element was placed a slightly longer tube H of impervious alumina (Alfrax 2 B). The platinum–platinum–10% rhodium thermocouple was mounted inside a small porcelain tube J (McDanel) which was inserted from the top. Cemented to this tube were two alumina disks which acted as radiation shields. For the same purpose the lower part of the tube was filled with a refractory insulating brick (K-30) the topmost piece of which extended well into the zone of uniform temperature. Between brick and disk was a distance of some 15 cm. within which no temperature differences could be detected by movement of the thermocouple. As further evidence of uniformity it was found in observations through the top of the furnace using blue furnace glasses that objects within this zone could not be distinguished. Specimens of iron 5 cm. long used in melting point determinations showed incipient melting uniformly over their entire length.

Before the first experiment the thermocouple was calibrated at the melting points of copper and nickel by an immersion method and at that of palladium (1555°) by the wire method. After expt. 4 and again after expt. 8 it was checked at the copper and palladium points. Finally, after use at the highest temperature and after several determinations of the melting point of iron, it was rechecked at the palladium point and again after the last run at the nickel and palladium points. In all of these tests the couple agreed with the standard tables within 1° and accordingly all temperatures were read from the table without correction.

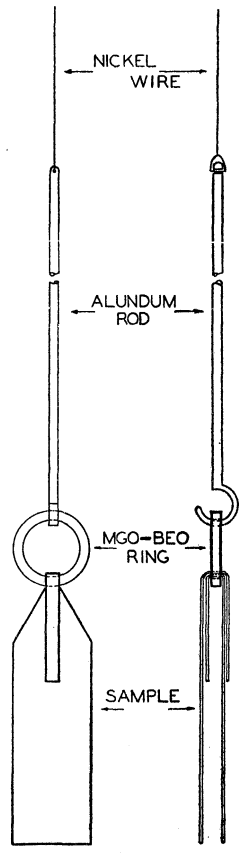

Fig. 2.—Method of suspending sample.

The saturator C was of a type which previously had been used in several investigations and had been found by thorough tests to give complete saturation of the gas. As indicated in Fig. 1, the hydrogen was given a preliminary wetting in a simple bubbler D which was held at approximately the temperature of the saturator. The latter consisted of two towers filled with glass beads and distilled water and a third empty tower which was used as a safeguard against entrainment of spray. The three towers, which were sealed together in an all-glass unit, were immersed in a well-stirred oil-bath whose temperature was controlled by hand regulation of bare wire heating coils. Temperatures were read to 0.01° by means of a four-junction copper–constantan thermocouple which was calibrated over the range used by comparison with a standard resistance thermometer. The e. m. f. of this couple and of that used in the furnace were read with an L. and N. "portable precision" potentiometer.

Several methods of mounting the specimen were tried but that shown in Fig. 2 was the only one that could be used at the highest temperatures. A thin alundum rod ground to the desired size from a larger piece extended from the hot zone to a point near the top of the furnace where it hung from the nickel wire which was suspended from the balance arm. The lower end of the rod was fashioned into a hook which supported a ring of magnesia or beryllia. The iron specimen was cut to such a shape that one end of it could be inserted through the ring and bent downward in an inverted U. Two such pieces were inserted from opposite sides and provided a total surface area of 28 sq. cm. and a weight of 3 g.

In carrying out a series of determinations the specimen was brought to a desired temperature under reducing conditions and the ratio of water vapor to hydrogen was then increased until oxidation began. It was found that the point at which a weight increase was first noted corresponded to a gas composition distinctly on the oxidizing side of equilibrium. The tendency of the metal to exhibit this passivity was quite variable and showed no definite relation to the previous preparation of the surface. In some cases oxidation began promptly and proceeded slowly and in some of the earlier runs this was confused with the equilibrium point. In one extreme case the specimen was exposed to a slightly oxidizing atmosphere at 1360° for thirty-two minutes before oxidation began. When it started suddenly, the specimen gained 0.35 g. in weight in ten minutes.

After an oxide coating had been obtained the saturation temperature was decreased until reduction was noted, then alternately increased and decreased so as to approach equilibrium slowly from each side. The record of one such determination is reproduced in Table I. Here the atmosphere has been changed from oxidizing to reducing and back to oxidizing, passing twice through the equilibrium which must correpond quite closely to the two observations indicated.

In illustration of the method of computation, the average of the two points of Table I will be used, namely, 1510° and a saturator temperature of 77.49°. The barometric pressure was 756.3 mm. (cor.) and the water vapor pressure 320.6 mm., from which P_{H_2O}/P_{H_2} is 0.734. This is the ratio at the saturator temperature which must be corrected for the deviation of water vapor from ideal gas behavior. This correction, which amounts to only 0.8 to 1.0%, was computed from the specific volume of saturated water vapor[4] and was applied to all data. The value of K corresponding to the ratio above is 0.742.

TABLE I

RECORD OF EXPERIMENT 13e

[a] Observations nearest equilibrium.

Results

A summary of all experiments is contained in Table II. The fifth column gives the approximate increase in weight of the specimen at the time of the equilibrium measurement. The last column indicates the manner in which the equilibrium gas composition was estimated, RO signifying that it was during a change from reducing to oxidizing conditions. It will be noted that many of the points constitute duplicate determinations in which the approach has been from both sides.

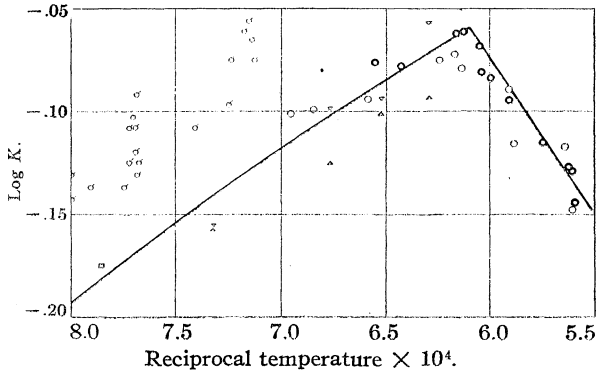

Fig. 3.—Experimental values of log (P_{H_2O}/P_{H_2}): ○, preliminary and approximate results; ●, results considered most dependable; □, Emmett and Shultz; △▽, scaling and non-scaling, Jominy and Murphy; ♂, Britzke, *et al.*

The points are plotted in Fig. 3, in which the more precise experiments are designated by larger circles. Data of other investigators within the range are included for comparison. Since certain results appear to deserve greater weight than others, a brief discussion of each experiment is in order. Experiment 2 must be regarded as a preliminary run without great precision; expt. 3 was more carefully conducted and should have yielded satisfactory results. The one result of 4 appears dependable; the support failed before a second point could be obtained. A similar occurrence prevented a satisfactory check in expt. 5. In the sixth run the equilibrium point was

(4) Landolt-Börnstein, "Tabellen," Vol. II, pp. 1318–1323.

traversed in only one direction, and for this reason the results cannot be given great weight.

It was noted that some of the samples when removed from the furnace bore evidence of diffusion of iron oxide into the magnesia support. Although the specimen was in contact with its support over only a very small area, it seemed possible nevertheless that some contamination of the iron oxide might occur. The effect of such contamination was investigated by Schenck, Franz and Willeke[5] who found that the equilibrium point was very greatly affected by all of the common refractory oxides except beryllia. Accordingly a tube of this oxide was fabricated and cut into rings which were used to support the specimens in the later experiments.

The results of expt. 8 did not differ from those in which a magnesia support was used. Experiments 9 to 12 were made to determine the melting points of iron and its oxide. During 12, two equilibrium points were observed, but these must be ruled out for the reason that a crack was found in the alumina tube after the completion of the run and neither the time of occurrence nor the effect of the crack is known. Experiment 13 was conducted after a careful survey of the possible causes of minor discrepancies in the earlier runs and its results are considered the most dependable of the series.

TABLE II

(5) Schenck, Franz and Willeke, *Z. anorg. allgem. Chem.*, **184**, 1 (1929).

The two lines of Fig. 3 were drawn to conform as nearly as possible to the best experimental points (expts. 3, 4, 8, 13) and to intersect at the melting point of the oxide 1369°. The slightly curved line below the melting point represents the equation which will be deduced in a later section. Attention is called to the rather extended scale upon which log K is plotted and the smallness of the heat of reaction, two factors which combine to render clearly visible the curvature occasioned by a change in heat capacity of only 2.2 calories per degree. It may be noted also that the greatest deviations from the lines do not exceed 0.02 unit in log K, while the mean deviation of all the points tabulated is only 0.0086 unit or 0.04 calorie per degree in the free energy. The uncertainty in the four best runs is somewhat less than this. The straight line above the melting point is expressed by the equation:

$$\log K = 1583/T - 1.021 \qquad (1)$$

Melting Point of Ferrous Oxide.—The lowest oxide of iron does not have the stoichiometric composition required by the formula FeO but instead has a somewhat higher oxygen content and is stable over a range of compositions. This solid solution, which is called "wüstite," has been the subject of a number of investigations among which may be mentioned those of Pfeil[6] and of Jette and Foote.[7] They have shown that the iron-rich extremity of the solid solution field is of the constant composition 76.8% iron and it is the solid solution of this composition which is taking part in the reaction under study.

The melting point of "wüstite" has been variously recorded between 1350 and 1380°. During the course of our expt. 12, an amount of oxide corresponding to about 0.4 g. of oxygen was built up on the specimen at a temperature of 1360° and under slightly oxidizing conditions. The temperature was raised about 1° per minute until a sudden loss of weight indicated the melting and dripping of the highly fluid liquid. This occurred at 1370°. A second specimen, which was coated with oxide equivalent to 0.6 g. of oxygen was heated through the same range at a rate of 0.3° per minute. The oxide dripped off at 1369°.

(6) Pfeil, *J. Iron Steel Inst. (London)*, **123**, 237 (1931).

(7) Jette and Foote, *Trans. Am. Inst. Mining Met. Engrs.*, **105**, 276 (1933).

Another method of estimating the melting point is by the intersection of the two experimental lines shown in Fig. 3. The best lines drawn through the points of expt. 13 meet at 1365°. The direct determination is considered the more dependable and accordingly the lines of Fig. 3 are drawn to intersect at 1369°. This is to be compared with 1370° found by Tritton and Hanson[8] and 1380 ± 5° reported by Bowen and Schairer.[9]

Melting Point of Iron.—Discrepancies in the published values of the melting point of iron may be due in part to impurities in the metal. Oxygen is seldom reported in analyses of iron, yet it is normally present and is generally an important impurity in vacuum-melted iron. From its solubility in liquid iron it may be calculated that its effect on the melting point may be as large as about 10°, exact calculation being impossible in the absence of dependable data on the solid solubility.

The furnace used in the equilibrium study was well adapted to a determination of the effect of oxidation upon the melting point. We did not wish to carry out a determination in dry hydrogen for fear that reduced silicon from the refractories might be transported to the specimen. Accordingly measurements were made in hydrogen containing a limited amount of water vapor, and in a mixture approaching the equilibrium ratio. In neither case was there an appreciable change in the weight of the specimen until the melting point was reached when a drop of metal weighing one to two grams melted off. There was evidence of uniform melting over the entire length of the specimens.

From the results, which are given in Table III, we may extrapolate in both directions to obtain the melting point of oxygen-free and of oxygen-saturated iron. According to Fig. 3 the equilibrium ratio at 1524° is 0.724. Extrapolation to this ratio on the one hand and to zero on the other gives, for the melting point of oxygen-saturated metal, 1524°, and for that of pure iron, 1535°. The latter agrees well with the average of previous determinations,[10] while the former is in agreement with the temperature 1523° reported by Bowen and Schairer[9] for oxidized iron.

Extrapolated			.724	1523.6

Thermodynamic Treatment.—The results reported here, together with published information at lower temperatures, include data on all of the allotropic forms of iron. Thermal data on the metal are summarized in Table IV. The sources of these data have been cited in a previous paper[2] and the only change that seems necessary is a revised equation for the heat capacity of gamma iron, bringing this into agreement with the data summarized by Austin.[11] It may be remarked that the heat effect of the α–β change, which is spread over a considerable temperature range, is lumped at one temperature for the sake of simplicity and without significant loss of accuracy. On the basis of Table IV the difference in free energy of the several forms may be expressed by the equations

$$Fe(\alpha) = Fe(\gamma);\quad \Delta F^\circ = 110 - 3.65T \ln T + 0.00283T^2 + 22.347T \quad (2)$$

$$Fe(\beta) = Fe(\gamma);\quad \Delta F^\circ = 2160 + 2.30T \ln T - 0.00057T^2 + 17.430T \quad (3)$$

The specific heat at low temperatures of an impure ferrous oxide containing 77.24% iron was determined by Millar[12] and that of a similar (probably identical) material at high temperatures by White.[13] The solid oxide which was present in our equilibrium studies was the iron-saturated solid solution "wüstite" which, according to Jette and Foote,[7] has a constant composition of 76.8% iron. These materials were doubtless sufficiently alike to permit the use of the observed specific heats in the present calculation without correction for impurities. The two sets of specific heat data may be represented by the linear equation, $c_p = 0.1663 + 0.000029T$. Now in applying this to our data it must be borne in mind that we are not dealing with a simple compound FeO but with a phase in which the average oxygen atom is combined with approximately 0.95 iron atom. The free energy calculated directly

(11) Austin, *Ind. Eng. Chem.*, **24**, 1225 (1932).

(12) Millar, THIS JOURNAL, **51**, 215 (1929).

(13) White, *ibid.*, **55**, 1047 (1933).

from the equilibrium constant is that corresponding to the formation or reduction of 69 g. of this phase containing 16 g. (23.2%) of oxygen and 53 g. (0.95 g. atom) of iron. For brevity this amount of this phase will be designated "FeO (wüstite)." The corresponding heat capacity is listed in Table IV.

The heat capacities of the two gases are taken from recent calculations based upon spectroscopic data.[14,15] They may be represented with sufficient accuracy for present purposes by the two linear equations of Table IV which are designed to cover the range 298–1700°K.

TABLE IV

THERMAL DATA ON THE REACTING SUBSTANCES

Substance	Molal heat capacity cal. mole^{-1} degree^{-1}	Heat of phase changes, cal.
Fe(α)	$3.90 + 0.00680T$	$\alpha \rightarrow \beta$; $\Delta H_{1033} = 470$
Fe(β)	9.85	$\beta \rightarrow \gamma$; $\Delta H_{1183} = 218$
Fe(γ)	$7.55 + 0.00114T$	$\gamma \rightarrow \delta$; $\Delta H_{1673} = 110$
Fe(δ)	9.85	
FeO(wüstite)	$11.47 + 0.00200T$	
H_2(g)	$6.57 + 0.00074T$	
H_2O(g)	$7.09 + 0.00270T$	

In the temperature range 1183–1642°K. the change in heat capacity in the reaction is $-3.77 + 0.00104\ T$. The free energy equation is then:

$$\text{FeO(wüstite)} + H_2(g) = 0.95\ \text{Fe}(\gamma) + H_2O(g)$$
$$\Delta F^\circ = \Delta H_0 + 3.77T \ln T - 0.00052T^2 + IT \quad (4)$$

The evaluation of ΔH_0 and I will be done graphically by means of a "sigma plot." For this purpose the equation corresponding to the above is:

$$\log K = -\Delta H_0/4.575T - 1.897 \log T + 0.0001137T - I/4.575 \quad (5)$$

from which the log K and the two terms originating in ΔC_p are grouped as "Σ." In order to include available data below 910° an additional term must be included which is found from Equations 2 and 3. Including this term, sigma is defined by the equation

$$\Sigma = \log K + 1.897 \log T - 0.0001137T - 0.95(F_\gamma - F_\alpha)/4.575T \quad (6)$$

Values of Σ are plotted against reciprocal temperature in Fig. 4. The data include for comparison the older work of Eastman and Evans,[16] which is now known to have suffered the unsuspected error of thermal separation of the gases in the static system employed.

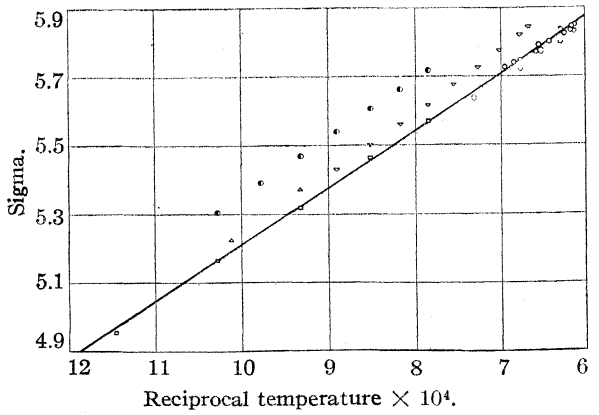

Fig. 4.—Experimental values of *sigma* of equation (6). ○, Authors; □, Emmett and Shultz; ⊙ ◡, Jominy and Murphy; △, Krings and Kempkens; ▽, Britzke, *et al.*; ◐, Eastman and Evans.

The straight line is drawn through our results and those of Emmett and Shultz.[1] The limiting oxidizing and reducing compositions of Jominy and Murphy[17] are in very good agreement with the line. Data of Krings and Kempkens[18] and of Britzke and co-workers[3] (points shown are at round temperatures) form a consistent series which, however, is in disagreement with our results.

The straight line of Fig. 4 is represented by the equation

$$\Sigma = -1653/T + 6.863 \quad (7)$$

from which the free energy change in Reaction 4 is

$$\Delta F^\circ = +7562 + 3.77T \ln T - 0.00052T^2 - 31.398T \quad (8)$$

At temperatures within the range of stability of alpha iron, Equations 2 and 8 combine to give

$$\text{FeO(wüstite)} + H_2(g) = 0.95\ \text{Fe}(\alpha) + H_2O(g) \quad (9)$$
$$\Delta F^\circ = 7457 + 7.24T \ln T - 0.00321T^2 - 52.628T$$

The free energy and heat of formation of wüstite from the elements at 25° may be obtained from the solution of Equation 9 and Rossini's[19] recently published functions for water vapor. The results are

$$0.95\ \text{Fe}(\alpha) + {}^1/_2O_2 = \text{FeO(wüstite)}$$
$$\Delta H^\circ_{298} = -63{,}380 \text{ cal.}$$
$$\Delta F^\circ_{298} = -58{,}420 \text{ cal.}$$

The corresponding value for the entropy of wüstite is 14.06 units. It is not easy to compare these results with calorimetric determinations since the latter have been based upon the erroneous assumption of a simple stoichiometric compound. Roth and his co-workers[20] report 64.2 kilocalories as the heat of formation of FeO

(14) Gordon, *J. Chem. Phys.*, **2**, 65, 549 (1934).
(15) Davis and Johnston, THIS JOURNAL, **56**, 1045 (1934).
(16) Eastman and Evans, THIS JOURNAL, **46**, 888 (1924).
(17) Jominy and Murphy, *Ind. Eng. Chem.*, **23**, 384 (1931).
(18) Krings and Kempkens, *Z. anorg. allgem. Chem.*, **183**, 225 (1929); **190**, 313 (1930).

(20) Roth, Umbach and Chall, *Arch. Eisenhüttenw.*, **4**, 87 (1930).

and Millar[12] reports its entropy as 12.7 ± 2.0 units.

At temperatures above the melting point of the oxide, there are no data on either its heat capacity or its composition. And since the heat effect at the gamma–delta transformation is quite small, the equilibrium involving solid iron and molten oxide may be represented by the following simple equation in which "FeO(l)" represents a quantity of the liquid oxide containing 16 g. of oxygen

$$\mathrm{FeO(l)} + \mathrm{H_2} = \mathrm{Fe}(\gamma \text{ or } \delta) + \mathrm{H_2O}$$
$$\Delta F^\circ = -7240 + 4.67T \qquad (10)$$

The heat of fusion of wüstite is found from the two free energy equations to be 10,000 calories per mole. Here the "mole" contains 16 g. of oxygen but only 53 g. of iron below the melting point and an undetermined amount in the liquid. The calculated heat thus includes the effect of any change in composition of the oxide. It may be pointed out that this is less than half the magnitude of the heat effect calculated from the data of Jominy and Murphy,[17] the discrepancy arising from disagreement in equilibrium data above the melting point of the oxide.

Summary

The equilibrium of iron and its oxide with steam and hydrogen has been investigated in the range 1200–1515°.

Below the melting point of the oxide the new results and those of Emmett and Shultz are expressed by an equation which agrees essentially with the data of Jominy and Murphy.

Above the melting point the value of $K = P_{H_2O}/P_{H_2}$ is given by: $\log K = 1583/T - 1.021$.

The melting point of the equilibrium oxide was found to be 1369°; its heat of fusion 10,000 calories per mole.

The melting points of oxygen-free and oxygen-saturated iron were found to be, respectively, 1535° and 1524°.

An Investigation of the Complex Structure of the O–H Harmonic Bands of Substituted Alcohols, and of the Effect of Temperature on the Relative Intensities of the Multiplet Components

BY LLOYD R. ZUMWALT AND RICHARD M. BADGER

It has been observed that the fundamental and harmonic O–H vibration bands of alcohols and substituted phenols frequently consist of two or more components even in cases of substances which have only one hydroxyl group per molecule.[1,2,3] When this multiplet structure persists under conditions such as to exclude association it has often been attributed to the presence of two or more molecular species with slightly different O–H frequencies. These different species have usually been supposed to represent merely different stable molecular configurations which result from restricted rotation about one or more single bonds.

Such an explanation, however useful in some cases, must be subject to some suspicion and cannot finally be accepted without further tests since in some cases the apparent complexity of the O–H bands is probably due merely to an accidental near superposition of other harmonic or combination bands. In other instances a multiplet band may represent merely a band sequence, as has been shown to be true of the N–H bands of pyrrole.[4]

The criteria by which complex O–H bands due to the presence of several molecular species may be recognized are as follows. First, a similar pattern should be found in fundamental and harmonic regions, but the separations between the components should be roughly proportional to the number of the harmonic. Second, the relative intensities of the components should, in general, be dependent on the temperature, provided of course that equilibrium between the various molecular species is established. Third, the individual bands making up a multiplet should have different rotational structures. Pauling's explanation of the *o*-chlorophenol spectrum[5] stands up under the first two tests. The third criterion seldom can be

(1) Wulf and Liddel, THIS JOURNAL, 57, 1464 (1935).

applied for obvious reasons, but in the case of ethyl alcohol the two components of the O–H bands have obviously quite different structures.[2]

In some simple cases the number of components observed in the O–H bands agrees with the number of stable molecular configurations which are predicted by very reasonable considerations, but unfortunately many of the substances whose spectra have been studied are too complicated to permit of a detailed discussion at present. In view of the present interest in hindered rotation around single bonds, it has seemed worth while to study a number of substances so simple that the observations may be capable of a unique interpretation. To avoid complications due to the solvent and to possible association the investigations have been made on the vapor. Furthermore, in order to give additional support to the explanations invoked, a quantitative study of the temperature effect on the relative intensities of the components of the multiplets has been carried out in three cases. A qualitative study of the effect of temperature on *o*-chlorophenol[6] has already been made, but the small separation between the bands in the fundamental region appears to introduce some difficulty in drawing any quantitative conclusions. Consequently this substance has been included in our investigations with results which are very interesting.

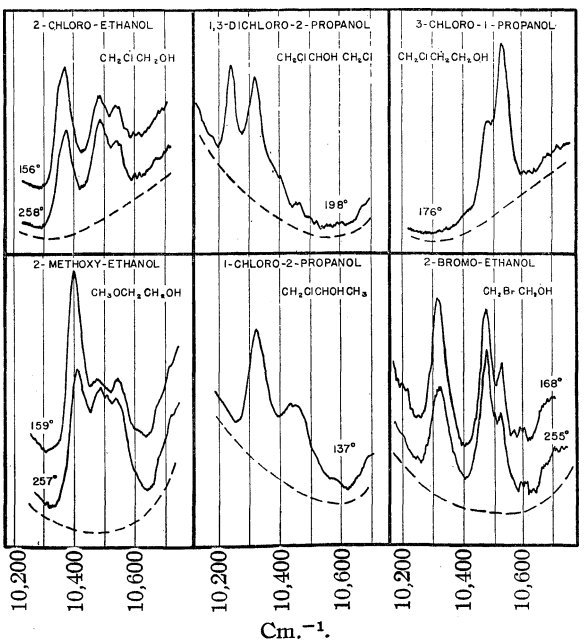

Fig. 1.—Microphotometer curves of the third harmonic O–H absorption bands of the vapors of six substituted alcohols. The temperature of the vapor is indicated in the diagrams. The dashed lines represent the trend of the background blackening.

(6) M. M. Davies, *Trans. Faraday Soc.*, **34**, 1427 (1938).

Materials.—The substances investigated were all Eastman Kodak Co. products unless otherwise specified and the boiling points given are corrected to 760 mm. pressure. The propylene chlorohydrin, ethylene bromohydrin, trimethylene bromohydrin, and *o*-chlorophenol (b. p. 174.3° at 749 mm.) were used without further purification. The refractive indices of the first three were found to be $n^{20.6}$D 1.4370, $n^{20.5}$D 1.4928 and $n^{24.5}$D 1.4885, respectively. The propyl alcohol ("practical"), ethylene chlorohydrin, 2-methoxyethanol (Mefford Chemical Company), and *sym*-glycerol dichlorohydrin ("practical") were purified by fractional distillation and boiled at 97.2, 128.9, 124.1 and 174.4°, respectively.

Measurement of the boiling points of *o*-chlorophenol under reduced pressure gave its entropy of vaporization at 175° as 21.9 cal./deg.

Apparatus and Experimental Procedure.—This investigation was carried out with the use of a Littrow glass spectrograph with a dispersion of about 70 Å. per mm. at λ 9000. Eastman 144-Q and 1-Z infrared plates were used. The absorption spectra were obtained at about one atmosphere with a path length of three meters.

Microphotometer curves for the bands of each alcohol were obtained as well as the curves for plates exposed when the absorption cell was filled with water vapor and when the absorption cell was empty. The latter were taken to get the positions and shapes of the water absorption bands (which might be superimposed on alcohol O–H bands) and to get the curve corresponding to background blackening. The sensitivity of the 144-Q plates changes very markedly with wave length in this region.

Results of Studies on the Substituted Alcohols.—The absorption maxima of the substituted alcohols studied are listed in Table I. Figure 1 gives the microphotometer curves of the O–H third harmonic bands of these alcohols. The microphotometer curves are uncorrected for change in plate sensitivity with wave length. The dashed line below the curves indicates the trend of the background blackening. The different observed trends correspond to different batches of plates used. The only appreciable water vapor absorption occurs always at frequencies a little higher than those of the alcohol O–H

TABLE I

ABSORPTION MAXIMA IN THE O–H THIRD HARMONIC BANDS OF THE VAPORS OF SEVEN SUBSTITUTED ALCOHOLS

Substance	Absorption maxima (cm.⁻¹)		
2-Chloroethanol	10,367	10,485	10,546
2-Bromoethanol	10,318	10,470	10,527
2-Methoxyethanol	10,394	10,472	10,538
3-Chloro-1-propanol	10,467	10,525	
3-Bromo-1-propanol	10,470	10,529	
1-Chloro-2-propanol	10,326	10,460	
1,3-Dichloro-2-propanol	10,243	10,325	

vibrations. The ordinates of the microphotometer curves do not have any absolute significance as they were obtained with different microphotometer settings, plate blackenings, and concentrations of the absorbing substance.

Substituted Ethanols.—From the above data it is evident that the two O–H bands which Badger and Bauer[2] found to be characteristic of primary alcohols persist in 2-methoxyethanol, ethylene chlorohydrin, and ethylene bromohydrin, though there is a slight shift to higher frequencies and considerable change in relative intensities. The weaker component has apparently become the stronger. These two bands we may attribute to molecular configurations in which the environment of the O–H group is similar to that in ethanol. In addition, however, a new strong band has appeared at a frequency around 100 cm.$^{-1}$ lower.[6a]

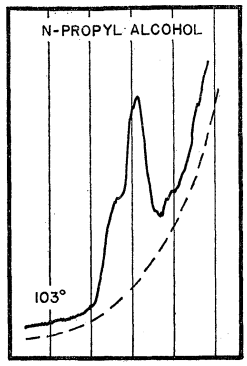

Fig. 2.—Microphotometer curve of the third harmonic O–H absorption bands of *n*-propyl alcohol.

The new band appears to be analogous to the strong long wave component which appears in the O–H bands when a halogen is substituted in the ortho position in phenol. We attribute it to chelation in a five-membered ring through the formation of a hydrogen bond between hydroxyl oxygen and other oxygen, chlorine, or bromine as the case may be. In the three compounds studied the new band is found at increasingly long wave lengths in the order just given, which is reminiscent of the observations of Wulf, Liddel and Hendricks[7] on ortho substituted phenols. As has previously been shown[8] the progressive shift to lower frequencies is an indication of increasing strength of hydrogen bond. Of the series studied the oxygen to oxygen bond appears to be the weakest and the oxygen to bromine the strongest. Possibly this is to be attributed to the differences in size of the electronegative atoms, permitting closest approach to the hydroxyl oxygen in the case of bromine.

As mentioned above, it is evident that in the substituted ethanols two types of configuration have reasonable stability in which the environment of the hydroxyl hydrogen is similar to that found in the unsubstituted primary alcohols. These configurations, however, must be less stable than the chelated structure. This is indicated by the great intensity and low frequency of the new band. Moreover, this is supported by the effect of temperature, which may be seen in Fig. 1. With increasing temperature the intensities of the short wave bands increase greatly at the expense of the low frequency component showing that they correspond to higher energy states. The temperature effect will be discussed more quantitatively below.

Substituted Normal Propyl Alcohols.—Both trimethylene chlorohydrin and trimethylene bromohydrin have O–H bands which appear to be identical with those of ordinary primary alcohols. It seems surprising that there is no indication of a hydrogen bond between halogen and oxygen with the formation of a six-membered ring, but such is the case. We may conclude that in configurations in which the oxygen halogen distance is favorable for the formation of a hydrogen bond the strain arising from the hindered rotation about the C–C single bonds is too great to permit the bond to be formed.

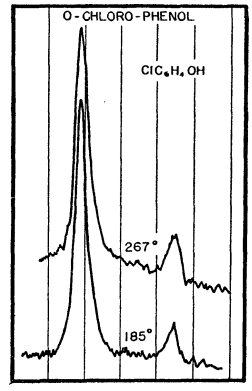

Fig. 3.—Microphotometer curve of the third harmonic O–H absorption bands of *o*-chlorophenol at two temperatures.

Substituted Secondary Alcohols.—Propylene chlorohydrin has the rather broad band characteristic of secondary alcohols and in addition a narrower, more intense component at lower frequencies. The latter may again be attributed to a chelated form with a five-membered ring involving a hydrogen bond between oxygen and chlorine.

On the substitution of the second chlorine in *sym*-glycerol dichlorohydrin the ordinary second-

(6a) Wall and Claussen [THIS JOURNAL, **61**, 2679 (1939)] failed to find any very definite evidence of chelation in ethoxyethanol and believed that they had shown its absence. They could, however, hardly expect to resolve the bands due to chelated and unchelated molecules which in this case should be separated in the fundamental region, by less than 30 cm.$^{-1}$. The chelation should undoubtedly be less in carbon tetrachloride solution than in the vapor but the curves of Wall and Claussen taken at high dilution indicate that it is not entirely absent since the band they observed is shifted to slightly longer wave lengths than normal and seems rather broad.

ary alcohol band has been reduced to a mere trace while a third, new component appears at quite low frequency. We suggest that the 10,325 cm.$^{-1}$ band, as in propylene chlorohydrin, corresponds to a situation in which a hydrogen bond links the hydroxyl oxygen to one chlorine atom, while the 10,243 cm.$^{-1}$ band results from a situation in which the hydroxyl hydrogen interacts with both chlorine atoms. In the latter case we have a double ring chelation.[9]

Investigation of the Temperature Effect.—A quantitative photometric investigation was conducted of the effect of temperature on the relative intensities of the components of the O–H bands of *o*-chlorophenol, ethylene chlorohydrin and propyl alcohol. These experiments involved the keeping of the absorption cell at constant temperature and the regulation of the pressure of the vapor within the cell. The temperature of the cell was read by means of a thermometer inserted in a well in its midsection and could be kept constant by means of automatic voltage control on the heating circuit. It is believed that the actual temperature of the vapor was within three or four degrees of the corrected thermometer readings. The pressure of the vapor was controlled by regulating the temperature of a side tube which contained an excess of liquid and was at all times cooler than the absorption cell. In the experiments on *o*-chlorophenol the side tube dipped in a well agitated oil-bath, the temperature of which was constant to within two-tenths of a degree. In the other cases an auxiliary furnace was used.

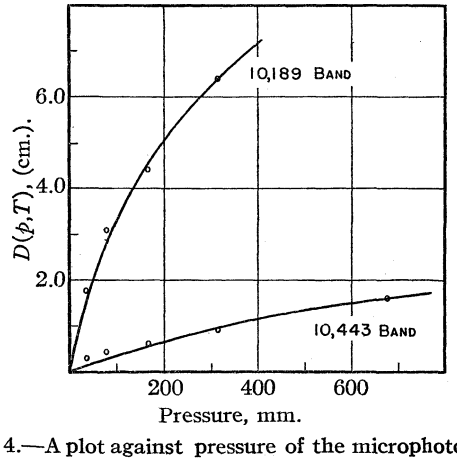

Fig. 4.—A plot against pressure of the microphotometer deflections $D_t(p,T)$ and $D_c(p,T)$ for the *o*-chlorophenol bands at 10,443 cm.$^{-1}$ and 10,189 cm.$^{-1}$, respectively. The data were obtained from a group of exposures taken on one plate with the vapor at approximately 180°, and at a series of pressures.

(9) The crystal structure of glycine indicates the occurrence of a somewhat similar situation in which one of the hydrogen atoms of the NH_3^+ group is attracted about equally strongly by two oxygen atoms; see Albrecht and Corey, THIS JOURNAL, 61, 1087 (1939).

In estimating the pressure of the vapor, data in the "International Critical Tables" were used except in the case of *o*-chlorophenol. As mentioned above, the boiling point of this substance was observed at several pressures.

The Photometric Procedure.—Precise photometry in the infrared with ammoniated plates is rather difficult, but a simplified procedure was devised which worked quite well. It involves certain assumptions which are discussed below, but these seem to be well justified and unlikely to introduce any large error. Difficulties due to the non-uniformity of the plates were largely avoided by taking all exposures of a complete series on one and the same plate, and indeed on a strip down the center of the plate where sensitization was most uniform. All exposures of a series were taken with constant illumination and equal exposure times. The warping of the absorption cell as the temperature was changed necessitated a slight compensating adjustment of one mirror in the optical train, but a fairly satisfactory constancy of background blackening through a series was attained.

Each series of exposures included two groups taken at two temperatures of the absorption cell, T_1 and T_2, respectively, and each group usually included spectra taken at several different pressures. The entire set of spectrograms was run through the microphotometer with the sensitivity of that instrument kept constant.

The interpretation of a series of records will now be described with special reference to *o*-chlorophenol. The difference between the microphotometer deflections at the band maximum and the deflection corresponding to background blackening was taken as a measure of the intensity of a band. This quantity, which is a function of pressure and temperature, we shall designate by $D_c(p,T)$ or $D_t(p,T)$ when referring, respectively, to the 10,189 cm.$^{-1}$ band (arising from molecules in the *cis* form) or the 10,433 cm.$^{-1}$ band of *o*-chlorophenol (arising from *trans* molecules). A plot of these quantities against pressure for a group of exposures taken at approximately 180° may be seen in Fig. 4.

Now the investigations of Wulf and Liddel[1] in the second harmonic region have shown that the total integral molal absorption coefficient for the

two O–H bands of *o*-chlorophenol is practically the same as for the one band of phenol and also for the one band of 2,4,6-trichlorophenol. From this it is most reasonable to conclude that the transition probabilities are practically the same for the *cis* and *trans* forms of *o*-chlorophenol, and that the concentrations of the two forms are in the ratio of the intensities of their corresponding bands.

Owing to experimental difficulties it was not possible to determine integral absorption coefficients or to compare directly the intensity of the two bands. However, if at any given temperature, T_1, the intensity of the "*cis*" band at pressure p_1 is the same as that of the "*trans*" band at p_2, it is evident that the ratio of *cis* and *trans* forms of the molecule at T_1 is given by $(n_c/n_t) = (p_2/p_1)$.

High dispersion studies have shown that the two bands have practically the same shape and breadth.[2] Furthermore, the IZ plates used have a sensitivity which is very nearly constant with wave length over a considerable range. Consequently when $D_c(p_1,T)$ and $D_t(p_2,T)$ are equal the intensity of the "*cis*" band at p_1 is equal to that of the "*trans*" band at p_2 to a good approximation.

It follows that the two curves of Fig. 4 should be practically superposable if the abscissas of the curve corresponding to the 10,443 cm.$^{-1}$ band are reduced by an appropriate factor s. Consequently we may write $(n_c/n_t) = (1/s)$, and the free energy increase for the transformation

o-chlorophenol (*cis*) ⟶ *o*-chlorophenol (*trans*) (1)

is given by the equation

$$\Delta F = RT \ln (n_c/n_t) = RT \ln (1/s) \qquad (2)$$

The energy increase for the same transformation is given by

$$\Delta E = \frac{T_2T_1}{T_2 - T_1} R \ln \frac{(n_c/n_t)_{T_1}}{(n_c/n_t)_{T_2}} = \frac{T_2T_1}{T_2 - T_1} R \ln \frac{(1/s)_{T_1}}{(1/s)_{T_2}} \qquad (3)$$

The evaluation of this expression involves obtaining data at a second temperature T_2. Fewer measurements were made at the higher temperatures owing to greater difficulty in keeping steady conditions, and consequently it was assumed that the shapes of the $D(p,T)$ curves were the same at T_2 as at T_1. This assumption is good unless the *shape* of the band envelopes differs considerably at the two temperatures. This can scarcely be the case. The bands will broaden slightly with temperature but the shape of the envelopes should not change materially.

In the evaluation of the energy difference between *cis* and *trans* forms of the molecule it is not necessary to assume equal transition probabilities for the two molecular species and equal widths and shapes of the two bands. This results from the fact that equation 3 involves the ratio of two concentration ratios.

Possibly the largest error in the determinations arises from the difficulty in precisely estimating the $D(p,T)$ quantities, due to the grain of the plate. This is particularly true in the case of the weaker band where the error of measurement may be as large as 20%.

Results of the Measurements of Temperature Effect.—Three preliminary experiments I, II and III were made on *o*-chlorophenol, and two more extensive studies, IV and V. These are summarized in Table II.

			Weighted av.	2.8	3.9

An average of the several determinations shows that in the temperature range covered the energy increase for the *cis–trans* transformation is 3.9 ± 0.7 kgcal. per mole. For the same reaction the free energy increase is 2.8 ± 0.5 kgcal. per mole and the entropy increase 2.4 E. U. at 180°.

In the study of *n*-propyl alcohol it was found that the change in intensity ratio of the two O–H bands is practically within experimental error. From this we estimate that the difference in energy of the two hypothetical configurations is not greater than about 0.8 kgcal. per mole.

In ethylene chlorohydrin, also, the relative intensities of the two bands characteristic of primary alcohols did not change appreciably. Consequently the data in Table III were used to determine the difference between the average energy of the forms corresponding to these bands and the energy of the chelated structure. The former was found to exceed the latter by 2.0 ± 0.5 kgcal.

Discussion of the Studies on Temperature Effect.—Badger and Bauer have pointed out that there appears to be a convenient relation between the frequency shift in the O–H bands which takes place on the formation of a hydrogen bond and the energy of the bond. In a letter which will be published soon it will be shown that the data here reported confirm the existence of this relation, which will now be applied in a discussion of *o*-chlorophenol.

Our value of 2.8 kgcal. for the free energy difference between *cis* and *trans* forms of *o*-chlorophenol in the vapor state at 180° may at first seem in disagreement with the estimate of 1.4 kgcal. given by Pauling for the substance in carbon tetrachloride solution at room temperature. There is, however, no reason to suppose that this is the case. The percentage frequency difference between the two bands of the substance in solution indicates a difference in energy of two forms of only about 2.9 kgcal. as against our value of 3.9 kgcal. for the vapor. This apparent discrepancy is to be accounted for by the stabilizing effect of the solvent on the *trans* form. When the vapor of a normal alcohol is dissolved in carbon tetrachloride the shift in O–H frequency indicates an energy of interaction between solvent and the hydroxyl group of between one and two kgcal. Consequently it is not surprising that *trans o*-chlorophenol is stabilized to about this extent in carbon tetrachloride solution.

The considerable difference in entropy of the *cis* and *trans* forms is rather surprising. It appears difficult to account for it entirely in terms of the torsional oscillations of the hydroxyl hydrogen about the two potential minima. In the explanation of the double O–H bands of *o*-chlorophenol it has been assumed that there are two distinct molecular species present or, in other words, that the energy levels of the *o*-chlorophenol molecule may be divided into two classes which may be ascribed to molecules in which the hydroxyl hydrogen is performing torsional vibrations about the *cis* or *trans* minima, respectively. It does not seem possible to construct a potential function for the rotation of the hydrogen about the C–O bond which will yield a sufficient number of levels of the second class to account for the entropy difference. It is possible that the high frequency band is partly due to molecules in which the hydrogen is performing complete rotations. In the lower lying levels for which this is the case the atom will spend most of its time on the side of the molecule opposite the chlorine atom, owing to the broad shallow character of the upper minimum. For this reason the O–H frequency in this species of molecule might not differ greatly from that in a vibrating *trans* molecule.

However, a portion, and perhaps the main part, of the entropy difference may be due to another factor. In the *cis* molecular species at least two bending vibrations must have considerably higher frequencies than in the *trans* form, owing to the contribution of the hydrogen bond to the rigidity of the chelated structure.

Summary

1. An investigation has been made of the complex structure of the third harmonic O–H bands of ethylene chloro and bromohydrin, methyl cellosolve, trimethylene chloro and bromohydrin, propylene chlorohydrin, and *sym*-glycerol dichlorohydrin. These substances were all studied in the vapor state. In all cases except trimethylene chloro and bromohydrin the substitution of a halogen or a methoxy group in the alcohol has given rise to one or more new O–H bands.

2. Photometric studies have been made of the effect of temperature on the relative intensities of the components of the O–H bands in *o*-chlorophenol, propyl alcohol and ethylene chlorohydrin. It is found that in the vapor state at 180° the energy and free energy of the *trans* form of *o*-chlorophenol exceed those of the *cis* form by 3.9 ± 0.7 and 2.8 ± 0.5 kgcal., respectively.

Allylic Rearrangements. X. The Reproducibility of the Standard Methods for the Preparation of Butenyl Bromide Mixtures[1]

BY WILLIAM G. YOUNG AND KENZIE NOZAKI

As a result of a recent study[2] of the composition of butenyl bromide mixtures obtained from crotyl alcohol and methylvinylcarbinol by the action of various solutions of hydrogen bromide *under controlled conditions*, a mechanism was proposed for the reaction[3] in which two simultaneous processes were considered. Process 1 assumed an opportunity for resonance of the reacting oxonium ion of the alcohol and hence for the formation of the same mixture of bromides from either the primary or secondary alcohols. Process 2, a normal substitution without resonance, gives only primary bromide from the primary alcohol and secondary bromide from the secondary alcohol. Since the values calculated for M (the fraction of alcohol reacting by Process 2), N_r (the refractive index of the bromide mixture formed by Process 1) and P_r (the percentage of primary bromide in the bromide mixture formed by Process 1 due to resonance) are dependent on the accuracy with which the composition of the butenyl bromide mixtures (prepared by the various standard methods) can be determined, it is highly desirable to test the reproducibility of the standard methods; especially since we have continually pointed out the difficulties encountered by other workers due to the extreme mobility of the bromides.

The results of the present investigation are summarized in Table I along with the results previously reported.[2,3] In general, the average deviation of the refractive index of the butenyl bromide mixture obtained from the same alcohol with a given standard method is ±0.0001 although with the standard method 3 (saturated hydrobromic acid at 0°) the mean deviation is ±0.00016. Two cases were observed where the previous results were in error. The action of hydrogen bromide gas at −20° on methylvinylcarbinol gave a bromide mixture with a refractive index 0.0010 unit lower than that previously reported, showing that a small amount of rearrangement had occurred in the previous case in spite of the special precautions which were taken to avoid it. The discrepancy observed between the results obtained by method 7 (the action of glacial acetic acid saturated with hydrogen bromide at 0°) on crotyl alcohol were traced to a different cause. A preliminary run proved that insufficient time had been allowed for the reaction (twenty-five min.). Hence the product contained traces of unreacted alcohol. This was indicated by a low Carius analysis (Br = 57.7% instead of 59.2%). As a result, the rearrangement of the sample at 100°, to get the corrected refractive index, caused the formation of dibutenyl ether which lowered the refractive index of the sample. Proof of this was found when a mixture of butenyl bromides was contaminated with a quantity of crotyl alcohol comparable with that suspected to be present in the bromide mixture prepared in

(1) This work, which was accomplished with the aid of a grant from the Board of Research of the University of California, was presented before Section C of the Pacific Division of the American Association for the Advancement of Science at Stanford University, June 29, 1939.

	Secondary	1.4740	1.4741	71.8	28.2	

[a] All percentages are the average of the results of both determinations except those enclosed in parentheses which are based on the present work only.

acetic acid by standard method 7. After rearrangement the contaminated bromide possessed a refractive index 0.0003 unit lower than it should, showing that ether had been formed. Consequently the time allowed for reaction by standard method 7 was increased to forty-five minutes. Using the modified procedure, both crotyl alcohol and methylvinylcarbinol gave bromide mixtures free from alcohol (Br = 59.23%). The revised values for the compositions of the bromide mixtures (columns 5 and 6) and for the differences in % primary bromide in the bromide mixtures obtained from the primary and secondary alcohols (column 7) are averages of the results of both investigations except for the two cases discussed above where the results of the present investigation are shown to be more reliable.

The Thermal Rearrangement of the Butenyl Bromides.—One objection to the previous work done in correlating the compositions of butenyl bromide mixtures produced from the butenols (by resonance process 1B) with those of the equilibrium mixtures produced by thermal rearrangement of the primary and secondary bromides under the same conditions, was that the thermal rearrangements were carried out in two-phase systems. Further work on the rearrangement of butenyl bromides (this time dissolved in a solution of hydrogen bromide in glacial acetic acid) gives a product having a refractive index qualitatively in agreement with N_r calculated[3] from the data obtained under the same conditions (standard method 7). When attempts were made to rearrange the primary and secondary butenyl bromides at room temperature in glacial acetic acid saturated with hydrogen bromide, it was discovered that addition of hydrogen bromide occurred faster than rearrangement. As a result the product was a mixture of dibromobutanes. However, at 15° in the presence of a trace of benzoyl peroxide it was possible to obtain a thermal equilibrium of the bromides before too large a quantity of dibromobutane had been formed. Although the last two runs listed in Table II show a qualitative agreement between the equilibrium refractive index of $n^{25}D$ 1.4765 and calculated value n^{25}_r 1.4764, it is recognized that the interpretation may be debatable. It should be recognized, however, that the accuracy of the work was limited in two ways. First, it was difficult to allow sufficient time to establish equilibrium without producing large quantities of dibromobutane; second, it was necessary to effect a quantitative separation of the mono and dibromides at low temperatures to avoid rearrangement of the butenyl bromide portion. Runs 1 and 2 are of little value since they were carried out with short reaction times and obviously had not come to equilibrium.

TABLE II

THE THERMAL REARRANGEMENT OF BUTENYL BROMIDES AT 15° IN GLACIAL ACETIC ACID SATURATED WITH HYDROGEN BROMIDE

Run	Butenyl bromide	$n^{25}D$ of crude bromide before fractionation	$n^{25}D$ of butenyl bromide fraction	$n^{25}D$ after rearrangement at 100°	$n^{25}D$ of butenyl bromide mixt. (corrected)[2]
1	Primary	1.4900	1.4779	1.4774	1.4772
2	Secondary	1.4820	1.4761	1.4766	1.4762
3	Primary	1.4890	1.4768	1.4771	1.4764
4	Secondary	1.4920	1.4771	1.4772	1.4766

Experimental Part

Alcohols.—Crotyl alcohol, b. p. 121–122°, was prepared by the aluminum isopropoxide method.[4,5] Methylvinylcarbinol, 96–97°, $n^{25}D$ 1.4110, was supplied by the Shell Development Company, through the courtesy of Dr. E. C. Williams.

Pure Butenyl Bromides.—Crotyl bromide, and methylvinylcarbinyl bromide were prepared as previously described.[6]

The Synthesis of Butenyl Bromide Mixtures from Crotyl Alcohol and Methylvinylcarbinol by Standard Methods.—The reproducibility of the standard methods reported by Young and Lane,[2,3] for preparing butenyl mixtures under controlled conditions, has been tested. The exact directions described by them for synthesizing and purifying the bromide mixtures have been followed except in the case of method 3 (saturated hydrobromic acid at 0°), and method 7 (glacial acetic acid saturated with hydrogen bromide at 0°) where the total reaction times were extended twenty minutes. This was done to assure completion of the reaction since in a preliminary run with method 7 the bromide mixture contained traces of crotyl alcohol which reacted with the bromide during the rearrangement at 100° and consequently interfered with the determination of the corrected refractive index. After this modification had been made the bromide preparations always contained the correct amount of bromine by Carius analysis.

The Rearrangement of Pure Butenyl Bromides in Glacial Acetic Acid Saturated with Hydrogen Bromide.—Since preliminary attempts to rearrange the butenyl bromides at 25° gave only 2,3-dibromobutane, while runs at 0° gave too slow rearrangement, it was necessary to add benzoyl peroxide[7] to speed up the rearrangement and to choose a temperature at which equilibrium of the bromide could be attained without excessive amounts of dibromides being formed. The final procedure adopted is given below: thirty-five grams of glacial acetic acid was placed in a glass-stoppered oil sample bottle and saturated with hydrogen bromide at 10°. After 8.0 g. of pure primary or secondary butenyl bromide, 0.4 g. of benzoyl peroxide and 1.5 ml. of water were added, the bottle was stoppered and the mixture shaken for fifteen to twenty minutes at 15°. The mixture was then cooled rapidly to 0° and poured over 100 g. of crushed ice and 35 g. of sodium bicarbonate in a 500-ml. separatory funnel. As soon as the initial effervescence had subsided, 35 g. of bicarbonate and more ice were added. The neutralization of the acid took nearly an hour but the ice and salt mixture present maintained a temperature several degrees below zero. The bromide layer was next washed twice with cold bicarbonate solution, then with ice water and placed over anhydrous calcium chloride at −15° for several hours. The resulting crude, dry bromide mixture was partially purified by evaporation at 2 mm. pressure. The butenyl bromide portion was then separated from dibromides by fractionation at 3 mm. pressure through a 20-cm. column which was filled with glass helices and equipped with a Hopkins condenser and an ice-filled jacket. The experimental results are shown in Table II.

Summary

The standard methods developed by Young and Lane[2] for preparing butenyl bromide mixtures from butenols under controlled conditions have been tested with both crotyl alcohol and methylvinylcarbinol. The compositions of the bromide mixtures produced are in good agreement with those previously reported except for two cases which have been explained.

The thermal rearrangement of pure primary and secondary butenyl bromides in glacial acetic acid saturated with hydrogen bromide produces equilibrium mixtures which possess refractive indices qualitatively in agreement with the calculated value of n_r or the bromide mixture produced from the butenols by process 1[3] involving resonance.

The Introduction of Substituted Vinyl Groups. IV. (Primary 1-Alkenyl) Alkyl Malonic Esters

BY ARTHUR C. COPE, WALTER H. HARTUNG,[1,2] EVELYN M. HANCOCK AND FRANK S. CROSSLEY[2]

Previous articles in this series have described practical methods of preparing disubstituted malonic and cyanoacetic esters in which one substituent is a "secondary 1-alkenyl" group, RCH=C(R')—.[3] These esters were produced by alkylating alkylidene esters, obtained by condensing ketones with malonic and cyanoacetic esters.

In order to introduce "primary 1-alkenyl" groups, RCH=CH—, or RR'C=CH—, into malonic ester by a similar process, it would be necessary to start with the condensation products of aldehydes with ethyl malonate.

$$\underset{\text{I}}{RCH_2CH{=}C(COOEt)_2} \xrightarrow[\text{or } NaNH_2]{NaOR,\ Na,} \underset{\text{II}}{[RCH{=}CH{-}C(COOEt)_2]^-Na^+}$$

$$\text{II} + R'X \longrightarrow \underset{\text{III}}{RCH{=}CHC(R')(COOEt)_2} + NaX$$

Ethyl (1-butenyl)-methylmalonate has been prepared in this manner by Kon, Linstead and Maclennan.[4] The utility of the reaction as a general synthetic method remained open to question, however, both because of the ease with which substituted vinyl alkylmalonic esters undergo alcoholysis,[3a,b] and the instability of "primary alkylidene" malonic esters. These alkylidene esters (I), in the presence of alkaline reagents, readily undergo a reversal of the condensation reaction by means of which they are prepared, giving the aldehyde and malonic ester, or products derived from them.

Actually, the synthesis of *vinyl* alkylmalonic esters according to the above equation (R = H) proved to be very unsuccessful, almost all of the ethylidene malonic ester being transformed into a high boiling polymer. With alkylidene malonic esters prepared from propionaldehyde, butyraldehyde, and other higher aldehydes, however, the synthesis is successful if conditions are chosen which minimize alcoholysis and polymerization. The alkylidene esters are preferably added to sodium alkoxide–alcohol solutions at low temperatures, in the preparation of the sodium derivatives, and then alkylated rapidly by adding the alkylating agent in one portion and immediately heating to the boiling point. Under these conditions, a large part of the enolate is alkylated, and the proportion of high boiling polymer is greatly reduced.

The success of these alkylations in alcohol solution is surprising, for similar alkylations of secondary alkylidene malonic esters in alcohol gave poor yields.[3a,b] This difference in behavior on alkylation is probably due to the fact that the branched groups present in enolates derived from secondary alkylidene esters (*i. e.*, $[RCH{=}C(R')C(COOEt)_2]^-Na^+$) hinder the introduction of alkyl groups.[5] Consequently, when such enolates are treated with alkyl halides in alcohol solution, a large part of the reaction which occurs involves the sodium alkoxide with which the enolate is in equilibrium and the alkyl halide. This side reaction converts most of the enolate back into the original alkylidene ester. The primary 1-alkenyl groups present in the enolates (II) derived from primary alkylidene malonic esters, however, present no steric hindrance opposing the introduction of an alkyl group, and the alkylation of these enolates proceeds normally.

The data recorded in Table I show that in this series the yield of alkylated esters (III) depends in part upon the size of the alkylidene group in the ester employed. The yields become higher as the size of the alkylidene group increases, reaching a maximum of 86 to 93% with the isopentylidene ester. The alkylations occur more rapidly with the higher members of the series; as a result the products are in contact with the sodium enolates (and the sodium alkoxides with which they are in equilibrium) for a shorter time, and there is less opportunity for their destruction by alcoholysis.

The use of sodamide in liquid ammonia or in inert solvents is inadvisable for preparing the

[a] In each case, the reaction of the alkyl halide with the sodium enolate was exothermic at the boiling point, and most of the material had reacted in the first few minutes of refluxing. [b] We are indebted to Miss Corris Hofmann for semi-micro combustions. [c] Yield of the mixed ethyl and isopropyl esters obtained by alkylation in isopropyl alcohol was 82%, calculated as the ethyl ester. [d] Yield of the mixed ethyl and isopropyl esters obtained by alkylation in isopropyl alcohol was 83%. [e] The sodium enolate prepared from isobutylidene malonic ester was quite insoluble in alcohol. An impurity was removed from this ester by shaking with concd. aqueous ammonia.

sodium enolates (II) in this series. Apparently, partial decomposition occurs during the reaction with sodamide, and subsequent alkylation gives rather impure products in poor yield. The poor results obtained with sodamide in this series are in contrast with those obtained with secondary alkylidene malonic esters, which are alkylated in the highest yield by the sodamide procedure.[3a,b] Powdered sodium in inert solvents reacts readily with the primary alkylidene esters to give sodium enolates but, as in the series previously described, a part of the ester is reduced in the process, and alkylation gives a product containing the corresponding saturated ester as an impurity.

Experimental Part

The primary alkylidene malonic esters were prepared by condensing aldehydes with ethyl malonate, either in the presence of acetic anhydride,[6] or by a method using amine salts which will be described in a future communication.

Alkylation Procedures. A.—A description of the synthesis of ethyl (1-isopentenyl)-ethylmalonate will illustrate a procedure which gave good results in all of the alkylations. A solution of 8.05 g. of sodium (0.35 mole) in 300 cc. of absolute alcohol contained in a 500-cc. three-necked flask was cooled to −5°. Ethyl isopentylidene malonate, 79.8 g. (0.35 mole), was added dropwise with stirring during ten minutes. The solution was stirred for twenty minutes at −5 to −10°, after which 65.5 g. (0.42 mole) of ethyl iodide was added in one portion and the solution rapidly heated to boiling. The vigorous reaction which took place at the boiling point made it necessary to cool the flask momentarily in an ice-bath. The mixture was practically neutral to litmus after five minutes, and it was refluxed for only twenty minutes. The contents of the flask were cooled and diluted with 800 cc. of water. The ester layer was separated, and the water layer extracted four times with benzene. The combined ester and benzene extracts were washed twice with water, after which the benzene was removed in vacuum and the residue distilled through a Widmer column. The ester so prepared is one of nineteen substituted vinyl alkylmalonic esters described in Table I.

In the first preparations, the esters were shaken with concd. aqueous ammonia before the final distillation, in order to remove any alkylidene ester which might remain in the product. The portion of the alkylidene ester which is not alkylated is usually converted to a high boiling polymer during the reaction, however, and trial showed that the treatment with ammonia is superfluous, as there was no loss in weight on shaking with ammonia and no change in physical constants of the products, except in one case (*cf.* Table I). The alkylations carried out with the less active alkyl halides do not become completely neutral. In such cases, small aliquot portions were removed and titrated with standard acid from time to time. The refluxing was continued until the per cent. neutralization was constant.

In two cases in which relatively low yields of alkylated esters were obtained by the above procedure, alkylations

(6) *Cf.* Schryver, *J. Chem. Soc.*, **63**, 1344 (1893); Kötz, *J. prakt. Chem.*, [2] **75**, 477 (1907); Boxer and Linstead, *J. Chem. Soc.*, 749 (1931).

also were carried out in isopropyl alcohol solution, under conditions recently used for the alkylation of alkylidene cyanoacetic esters.[3c] In both cases the yields were higher in isopropyl than in ethyl alcohol (see footnotes to Table I). This is evidence that alcoholysis is an important factor influencing the yields in this synthesis.

B.—Ethyl butylidenemalonate reacts with powdered sodium in ether or benzene solution, just as isopropylidene malonic ester does,[3a] giving a soluble sodium derivative. Methylation with dimethyl sulfate gave a 50–60% yield of ethyl (1-butenyl)-methylmalonate, b. p. 130–132° (24 mm.). The ester was purified by shaking with ammonia and refractionation, but quantitative reductions required only 86% of the theoretical quantity of hydrogen, showing the presence of a saturated ester in the product. In preparing a disubstituted barbituric acid derivative from this partially reduced ester, by condensation with urea, in one case a small amount of 5-methyl-5-butylbarbituric acid, m. p. 179–179.5° (uncor.), was isolated,[7] proving the presence of ethyl butylmethylmalonate in the ester prepared by this method.

C.—Ethyl butylidenemalonate was treated with sodamide, in liquid ammonia solution and suspended in both ether and toluene. A sodium derivative was formed in each case, but alkylation in ether or toluene with both diethyl sulfate and allyl bromide gave poor yields (10 to 40%) of impure esters.

(7) Summaire, *Bull. soc. chim.*, **33**, 189 (1923), reports m. p. 181°.

Summary

Primary alkylidene malonic esters, $RCH_2CH{=}C(COOEt)_2$, react with sodium ethoxide and sodium isopropoxide to give sodium derivatives of primary 1-alkenylmalonic esters, $[RCH{=}CHC(COOEt)_2]^-Na^+$. These sodium derivatives may be alkylated readily, giving substituted vinyl alkyl malonic esters of the type, $RCH{=}CH{-}C(R')(COOEt)_2$.

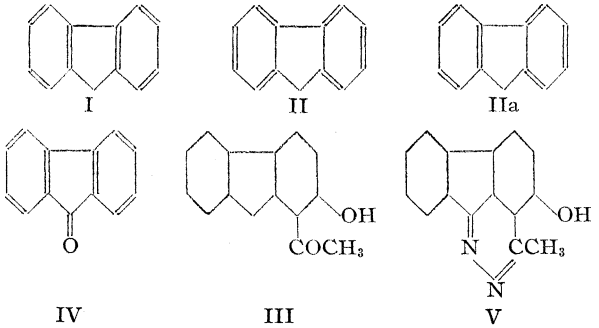
Remarks on the Structure of Fluorene

BY ERNST BERGMANN AND T. BERLIN

W. C. Lothrop has published[1] an interesting paper on the fine structure of fluorene. Some time ago, we experimented on similar lines.[2] Agreeing with the conclusions drawn by Lothrop to the effect that fluorene is not to be represented by exclusively one of the formulas I or II (and possibly IIa), we should like to supplement his evidence by reporting briefly some of our results.



IV III V

In addition to the rearrangement of 2-allyloxyfluorene, we have also studied that of 2-acetoxyfluorene. Under the influence of aluminum chloride, an isomer is formed in moderate yield, to which we ascribe the formula III of 1-acetyl-2-hydroxyfluorene on the basis of its unreactivity toward hydroxylamine, III being an *o,o'*-disubstituted acetophenone.[3] This rearranging reaction appears to take place on form I, which, by the way, is also responsible for the formation of the 9-sodium derivative of fluorene.[4] On the other hand, it has been shown before,[5] that the Kolbe reaction with 2-hydroxyfluorene leads to two isomeric 2-hydroxyfluorenecarboxylic acids, most probably the 1- and the 3-compounds. By the same reasoning as above, they would owe their formation to the fine structures I and II, respectively.

Similar observations have been made in the series of fluorenones, the quinone-like properties of which would be accounted for most fittingly by formula (IV).[6] The rearrangement product of 2-acetoxyfluorenone is 1-acetyl-2-hydroxyfluorenone, as it forms with hydrazine hydrate a pyridazine (V), analogous to that we could obtain from 1-benzoylfluorenone. The rearrangement of 2-allyloxyfluorenone, however, gave two isomers,

orming a well-crystallized molecular compound. After hydrogenation of the allyl double bond, two hydroxypropylfluorenones were separated, apparently the 1- and the 3-propyl-2-hydroxy compounds. This indicates that in fluorenone, too, the double bonds have no fixed position, the form represented by (IV) perhaps being somewhat favored.

Experimental

1-Acetyl-2-hydroxyfluorene (III).—2-Acetoxyfluorene (4.1 g.), prepared from 2-hydroxyfluorene[7] with acetic anhydride according to Claborn and Haller,[8] was heated at 80° for three hours with a solution of aluminum chloride (3.6 g.) in nitrobenzene (30 cc.). The reaction product was decomposed with cold dilute hydrochloric acid, the nitrobenzene removed with steam and the residue dried and extracted with carbon tetrachloride in a Soxhlet apparatus. The product soluble in carbon tetrachloride was triturated with methyl alcohol and some acetone and recrystallized from butyl alcohol or 25% acetic acid as long yellowish needles, m. p. 159°; yield, 0.6 g. *Anal.* Calcd. for $C_{15}H_{12}O_2$: C, 80.3; H, 5.4. Found: C, 79.8; H, 5.3. With hydroxylamine in alcohol, no reaction occurred.

1-Acetyl-2-hydroxyfluorenone.—2-Acetoxyfluorenone[8] (3 g.) was treated with aluminum chloride (2.8 g.) in nitrobenzene (20 cc.) as above. After removal of the solvent, the product was recrystallized from xylene as red, bent crystals, m. p. 206°. *Anal.* Calcd. for $C_{15}H_{10}O_3$: C, 75.6; H, 4.2. Found: C, 76.0; H, 4.3.

Pyridazine Derivative (V).—The diketone (300 mg.) was heated with hydrazine hydrate (64 mg.) in alcoholic solution (5 cc.), for three hours. The solvent was evaporated and the residue, after trituration with toluene containing some methyl ethyl ketone, recrystallized from toluene as yellow crystals, m. p. 197° (dec.). The combustion analysis was unsatisfactory (Calcd. for $C_{15}H_{10}ON_2$: C, 76.9; H, 4.3. Found: C, 75.0; H, 4.6); so was that of the **pyridazine derivative of 1-benzoylfluorenone;** 1-benzoyl-fluorenone[9] (500 mg.; b. p. 245°/0.4 mm.; m. p. 114–116°) was boiled with hydrazine hydrate (56 mg.) in alcohol (5 cc.) for two hours. The product obtained by evaporation of the solvent was triturated with acetone and recrystallized from benzene as yellow platelets, m. p. 181°. *Anal.* Calcd. for $C_{20}H_{12}O_2$: C, 85.7; H, 4.3. Found: C, 84.6; H, 4.5.

It may be mentioned that the rearrangement of 2-acetoxyfluorenone, when carried out at 115°, gave a substance different from the 1-acetyl-2-hydroxyfluorene described above; it crystallized from butyl alcohol, had m. p. 249° and gave analytical figures pointing to the formula $C_{15}H_{12}O_3$ (instead of $C_{15}H_{10}O_3$) (Calcd. C, 75.0; H, 5.0. Found: C, 75.3, 75.4; H, 5.4, 4.9). The structure of this compound (which might be bimolecular) has not been dealt with.

2-Allyloxyfluorenone.—2-Hydroxyfluorenone[7] (4 g.) was heated with allyl bromide (2.7 g.) and potassium hydroxide (2 g.) in alcohol (40 cc.) until neutrality (ten hours). The reaction product, separating on cooling, was dissolved in ether and extracted several times with concentrated potassium hydroxide solution. From light petroleum, containing some acetone, it gave crystals, m. p. 84–85°, yield, 2.2 g. *Anal.* Calcd. for $C_{16}H_{12}O_2$: C, 81.3; H, 5.1. Found: C, 80.7; H, 5.6.

Molecular Compound of 1-Allyl-2-hydroxy- and 3-Allyl-2-hydroxyfluorenone.—The foregoing compound (1 g.) was heated at 200° for three hours and then distilled under 0.05 mm. pressure. The red oil, distilling at 186°, was triturated with light petroleum (b. p. 130°) and recrystallized from benzene or 25% acetic acid as orange-red needles, m. p. 125–126°; yield, 0.6 g. *Anal.* Calcd. for $C_{16}H_{12}O_2$: C, 81.3; H, 5.1. Found: C, 80.9; H, 5.2.

1-Propyl- and 3-Propyl-2-hydroxyfluorenone.—The foregoing compound (2 g.) was treated with a current of hydrogen in boiling propyl alcohol (50 cc.), containing the palladous hydroxide catalyst (1 g.) of Kuhn and Stroebele,[10] for eighteen hours. The solvent was evaporated and the residue recrystallized from aqueous alcohol (1:1) as clusters of yellow needles, m. p. 202° (after repeated recrystallization from the same solvent) crystallized spontaneously (*Anal.* Calcd. for $C_{16}H_{14}O_2$: C, 80.7; H, 6.0. Found: C, 79.3; H, 6.4), while the darker-yellow isomer, m. p. 155°, appeared, when the mother liquor was concentrated. *Anal.* Calcd. for $C_{16}H_{14}O_2$: C, 80.7; H, 6.0. Found: C, 79.6; H, 5.8.

Summary

2-Acetoxyfluorene and 2-acetoxyfluorenone, on Fries rearrangement, give the 1-acetyl-2-hydroxy compounds.

From 2-allyloxyfluorenone, both 1- and 3-allyl-2-hydroxyfluorenones are obtained in the form of a molecular compound.

These facts support the conclusion drawn by Lothrop[1] that no fixed "fine structure" exists in fluorene; the dibenzocyclopentadiene formula, however, seems to prevail.

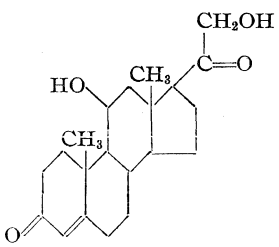
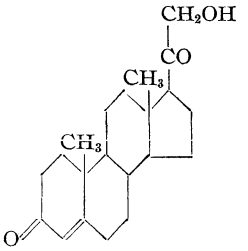
Studies on the Partial Synthesis of Corticosterone. I

BY PURNENDU NATH CHAKRAVORTY[1] AND EVERETT S. WALLIS

Through the pioneering investigations of Rogoff,[2] Swingle[3] and Hartman[4] the existence of a powerful hormone in the adrenal gland, other than adrenalin, was established. The method of Swingle and Pfiffner[5] for the preparation of concentrates of this hormone has been widely used, and has culminated in the isolation of several crystalline products, notably by three groups of investigators led by Reichstein[6] at Zürich, Kendall[7] at the Mayo Clinic and Wintersteiner[8] at Columbia University. Among these crystalline materials which have been isolated some have been found to be inactive and the structures of the few physiologically active compounds are still uncertain on certain points. Corticosterone, the most potent of the crystalline compounds, has been assigned formula I.



I



II

It has been the purpose of our investigations to find a method of synthesis of the above substance, thereby settling the structural question and also providing adequate amounts of the hormone for clinical investigations.

Stieger and Reichstein[9] have prepared a very active compound, "desoxycorticosterone" (formula II) but the starting material is rather difficult to obtain, and recent clinical tests have thrown great doubt on its value for medicinal use. In our efforts to obtain corticosterone we started from desoxycholic acid which is easily available. Of the several methods tried, that shown in the diagram seems to be most promising.

Desoxycholic acid was oxidized in the cold directly to 3-oxy-12-ketocholanic acid III by a method first described by Kaziro and Shimada.[10] The yield was very good and the material so obtained was easy to purify. The methyl ester of this acid prepared for the first time melted at 143° The acetoxy derivative (m. p. 197°) on treatment with bromine either in chloroform or acetic acid solution in the presence of hydrogen bromide gave a bromide, IV, which could be used directly for dehalogenation. The introduction of the double bond was effected with sodium ethylate, the unsaturated keto acid so obtained melting at 173°. Its acetate melts at 199°. An analysis and determination of its absorption spectra showed that it was the desired 3-oxy-12-keto-9,11-cholenic acid, V. If dehalogenation was effected with zinc and acetic acid, the saturated 3-oxy-12-ketocholanic acid was produced in good yields. It is also to be recorded that dehalogenation with sodium acetate and acetic acid failed to give the desired product.

Treatment of the above acid with semicarbazide acetate gave a semicarbazone which melted at 221°. It is interesting to note in this connection that whereas 3-oxy-12-ketocholanic acid gives a semicarbazone only after twelve hours of refluxing with the reagent, this unsaturated acid requires but two hours similar treatment. Thus, as one might expect, the conjugated double bond makes the 12-keto group more reactive. The semicarbazone thus obtained was reduced by heating it with sodium ethylate in a sealed tube for fifteen hours at 180°. On working up the reaction product the corresponding methylenic compound, VI, is obtained in readily crystallizable form. It is contaminated, as would be expected, with a small amount of its epimer, β-3-oxy-9,11-cholenic acid, but this latter compound is removed

by recrystallization from acetone. α-3-Oxy-9,11-cholenic acid crystallizes in needles from acetone which melt at 183–184°. Further reactions of this compound will be reported in a later paper.

Experimental Part

Preparation of 3-Acetoxy-12-ketocholanic Acid.—This acid was prepared according to the method of Kaziro and Shimada[10] as described by Bergström and Haslewood.[10] It was converted into its acetoxy derivative in the usual manner.

Preparation of 3-Hydroxy-12-keto-9,11-cholenic Acid.—Five grams of 3-acetoxy-12-ketocholanic acid was dissolved in 15 cc. of glacial acetic acid, and treated with 15 cc. of a 1.05 *N* acetic acid solution of bromine. A few drops of a 34% aqueous solution of hydrogen bromide were added as a catalyst. The solution was then kept at 70° for four hours and allowed to stand overnight at room temperature. After this time it was poured into ice water and the amorphous powder which precipitated was filtered. After thorough washing with water it was dissolved in ether, and the ether solution again washed to remove all traces of hydrobromic acid. After drying with sodium sulfate the ether was evaporated to dryness and the bromide, which was obtained as a sticky reddish residue, was taken up immediately in absolute alcohol and poured into a boiling solution of sodium ethylate (prepared from 6 g. of sodium dissolved in 70 cc. of absolute alcohol). Immediately the mixture became very dark brown and some sodium bromide precipitated. Refluxing was continued for two hours, after which time a considerable amount of sodium bromide had precipitated. The condenser was then removed and after sufficient water had been added to dissolve the salt the boiling was continued to remove as much of the alcohol as possible. The reaction mixture was then cooled with ice water and to it was added an ice cold solution of 20% sulfuric acid. After standing in the icebox for one-half hour, the precipitated acid so obtained was filtered and washed free from sulfuric acid. It was then taken up in ether and the dried ether solution was decolorized with charcoal. The solution was then concentrated to a small volume and allowed to stand. (If the ether solution is perfectly dry and if the removal of hydrogen bromide has been complete, crystallization of the dissolved acid begins when the solution has reached about half its original volume.) The crystalline product so obtained was filtered and washed with cold ether. A sample of it melted at 160–165°. Recrystallization from ethyl acetate gave a product which melted at 172–173°. A melting point depression was observed when a sample of the material was mixed with a specimen of α-3-hydroxy-12-ketocholanic acid, yield 30%.

An absorption spectra study showed an absorption at wave length 242.5, a wave length which is characteristic for α,β-unsaturated ketones.

Anal. Calcd. for $C_{24}H_{36}O_4$: C, 74.2; H, 9.4. Found: C, 74.2; H, 9.8.

Preparation of 3-Hydroxy-9,11-cholenic Acid.—A portion of the above acid (0.2 g.) was refluxed for two hours with an aqueous alcoholic solution of 0.2 g. of semicarbazide acetate prepared from carbazide hydrochloride and 0.2 g. of anhydrous sodium acetate. The product was worked up in the usual manner. From benzene it came down as a gelatinous precipitate which became crystalline when filtered and washed with ether. A specimen of the crystals melted at 221°. The semicarbazone was not further purified but was directly employed for the Wolf–Kishner reduction. The heating with sodium ethylate (made from 1 g. of sodium and 15 cc. of absolute alcohol) was carried out in a sealed tube at 180° for fifteen hours. After this time the reaction product was taken up in water and boiled for one-half hour on the water-bath. After cooling with ice it was acidified with ice-cold dilute sulfuric acid. The precipitate so obtained was filtered, washed thoroughly with water and then taken up in acetone. On

crystallization needles were obtained which melted unsharply at 175°. Several recrystallizations from acetone gave a product which showed a strong positive Liebermann reaction and which melted at 183–184°, $[\alpha]^{25}D$ +27.0 (63 mg. in 5 cc. of absolute alcohol solution gave a reading of +0.68). When mixed with a specimen of 3-hydroxy-12-keto-9,11-cholenic acid a depression of the melting point was observed.

Anal. Calcd. for $C_{24}H_{38}O_3$: C, 76.96; H, 10.23. Found: C, 76.7; H, 10.5.

We wish to take this opportunity to express our thanks to the Rockefeller Foundation for a grant-in-aid which in part was used in support of this work.

Summary

1. A new route has been suggested to the preparation of sterol derivatives having a hydroxyl group C_{11}. Progress in this direction has been reported.

2. By the debromination followed by saponification of 3-acetoxy-11-bromo-12-ketocholanic acid, an unsaturated acid has been prepared which proved to be 3-hydroxy-12-keto-9,11-cholenic acid. This acid melts at 173° and possesses the characteristic absorption of the α,β-unsaturated keto derivatives.

3. The crude semicarbazone of the unsaturated keto-hydroxy acid, m. p. 221°, has been reduced according to the Wolf–Kishner method to 3-hydroxy-9,11-cholenic acid of m. p. 183–184°.

Steric Hindrance in Ketone–Phenol Condensations. The Condensation of Guaiacol with Cyclic Ketones

BY JOSEPH B. NIEDERL, VICTOR NIEDERL AND JOSEPH GRUMER[1]

In a previous publication[2] the effect of steric hindrance in ketone–phenol condensations has been investigated. It was established that, while the usual condensation product is an alkylidene-diphenol,[3] this is not formed when a reaction system is selected which would lead to the formation of a cycloalkylidene-diphenol in which there is a substituent group in *ortho* position to either one of the two reacting carbon atoms involved in the condensation. In these cases only equimolar condensation is possible, leading to the formation of cycloalkylenephenols or coumarans, respectively.

For a practical application of this hypothesis, a phenolic compound having an alkoxy group in *ortho* position to the free hydroxyl group was condensed with cyclic ketones. Condensation products analogous to the ones isolated in condensations involving an ortho alkylated phenol should be obtainable. As shown in the following, similar types of condensation products could actually be isolated.

Thus, the condensation of guaiacol with cyclohexanone itself and the *m*- and *p*-methylcyclohexanone isomers, yielded the expected alkylidene-diphenols (I, II, III), while the reaction of guaiacol with *o*-methylcyclohexanone resulted in the unsaturated cyclohexenyl-guaiacol (IV).

Of the four primary condensation products (I–IV) the following derivatives were prepared and verified by analysis: crystalline acetates (Ic, IIc, IIIc), benzoates (Id, IId, IIId) and phenylurethans (Ib, IIb, IIIb) of the three alkylidene-diphenols (I, II, III) and a crystalline aryloxyacetic acid (IVa) of the unsaturated monomolecular condensation product of guaiacol with *o*-methylcyclohexanone (IV).

Experimental

Condensation Method

1,1-*bis*-(3′-Methoxy-4′-hydroxyphenyl)-cyclohexane (I).—Molar quantities of guaiacol and half molar quantities of cyclohexanone were dissolved in 100 cc. of glacial acetic acid and the mixture placed in a 1-liter, triple-necked, round-bottomed flask which was provided with a reflux condenser, a thermometer and a gas inlet tube extending to the bottom of the vessel. A vigorous stream of dry hydrogen chloride gas was passed into the system for six hours at room temperature on two consecutive days, then the flask was stoppered and left standing at room temperature for four weeks. Crystals deposited which were filtered and recrystallized from benzene; m. p. 174°; yield, 31%.

Attempts to hydrolyze the ether groups in this compound by refluxing the compound with hydrobromic acid (48%)

as well as with hydriodic acid (sp. gr. 1.7) proved unsuccessful. Guaiacol was obtained in the first and catechol in the second case. This would indicate that the diphenylmethane linkage is weaker than an aromatic ether linkage.

1,1-*bis*-(3′-Methoxy-4′-hydroxyphenyl)-4-methylcyclohexane (II).—Molar quantities of guaiacol and half molar quantities of *p*-methylcyclohexanone were condensed as described above and worked up in a similar manner; m. p. 165.5°; yield, 10%.

1,1-*bis*-(3′-Methoxy-4′-hydroxyphenyl)-3-methycyclohexane (III).—Molar quantities of guaiacol and half molar quantities of *m*-methylcyclohexanone were condensed as described above and worked up in a similar manner; m. p. 149°; yield 27%. In none of the above cases was the filtrate, which consisted chiefly of unreacted starting materials, investigated further.

1-(3′-Methoxy-4′-hydroxyphenyl)-2-methylcyclohexene-1 (IV).—Half molar quantities of guaiacol and *o*-methylcyclohexanone were dissolved in 50 cc. of glacial acetic acid and condensed as described above. There was no deposition of crystals. The mixture was treated on a water-bath with dry hydrogen chloride for another twelve hours. No crystallization occurred, even after standing for another two months. After this time, the reaction mixture was dissolved in 200 cc. of benzene, this solution washed several times with an equal volume of water and then extracted with 150 cc. of Claisen solution. The Claisen solution extract was acidified with dilute hydrochloric acid, the oil which separated was taken up in 100 cc. of benzene, washed with water and dried over calcium chloride. The benzene was distilled off and the residue was distilled at 14 mm. pressure. Three fractions were obtained. The lower boiling fraction (about 30%) consisted of unreacted guaiacol, the fraction boiling between 155–175° proved to be the above unsaturated phenol (IV) (approx. 20%) and the higher boiling fraction, 180°, its polymer (approx. 30%). The unsaturated phenol (IV) polymerizes slowly upon standing.

Aryloxyacetic Acid Derivative (IVa).—This derivative was prepared by dissolving the above compound (IV) in 30% sodium hydroxide solution to which sufficient methyl alcohol was added to effect solution. The calculated amount of chloroacetic acid was added, the reaction mixture gently refluxed for two hours, and worked up according to the directions given in Shriner and Fuson.[4] In testing for unsaturation, Baeyer's permanganate test was employed and found positive.[5]

Phenylurethans (Ib, IIb, IIIb).—One gram of substance was dissolved in 1 cc. of phenyl isocyanate in a test-tube which was sealed and placed in a beaker containing boiling water. The test-tube was opened when its content had solidified and the crystalline material was recrystallized from petroleum ether.

Acetates (Ic, IIc, IIIc).—One gram of the respective phenol was dissolved in 3 cc. of acetic anhydride and refluxed in an all-glass apparatus for four hours. The reaction mixture was poured into an excess of water and allowed to stand overnight, whereupon crystallization occurred. The acetates were recrystallized from 80% alcohol.

Benzoates (Id, IId, IIId).—One gram of the respective phenol was dissolved in 3 cc. of pyridine and 1.5 g. of benzoyl chloride added. The mixture was warmed over a low flame for a few minutes and then poured into 10 cc. of water and stirred thoroughly. After decanting the supernatant solution, the crystals were washed with 5 cc. of 5% sodium carbonate solution and recrystallized from alcohol.

Summary

Studies were made of the effect of substituent groups in cyclic ketones in their condensations with an ortho alkoxyphenol.

Steric Hindrance in Ketone–Naphthol Condensations. The Condensations of the Naphthols with Cyclohexanone

BY JOSEPH B. NIEDERL, VICTOR NIEDERL AND JESSE CHARNEY

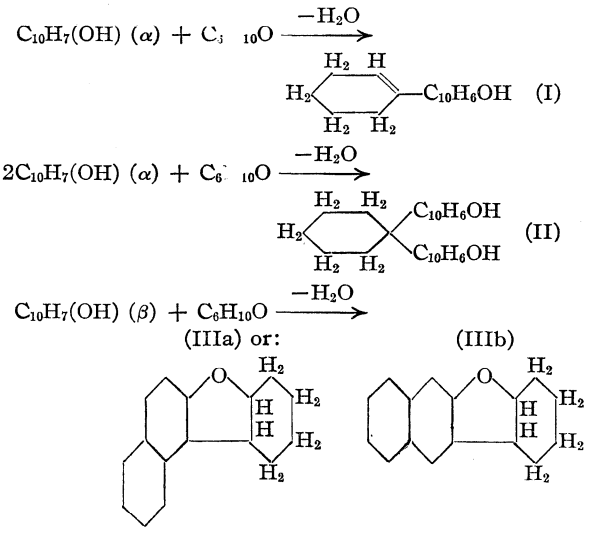
In a previous publication[1] it was asserted that in the condensation of ketones with phenols "the nature of the end product is influenced not only by the type of carbonyl compound employed, but also by the type of phenol used" and that "this influence exerts itself particularly through the position of the second substituent in the benzene ring, *i. e.*, whether it is *ortho*, *meta* or *para* to the hydroxyl group." This hypothesis was fully substantiated in a subsequent communication[2] in which condensations of various phenols with cyclohexanone derivatives were reported. In this it was shown that in cases where the alkyl radical in the final condensation product is adjacent to the carbon carrying the cyclohexenyl radical, steric hindrance effects inhibit the introduction of a second phenolic radical. Thus, instead of the normal di-phenols, unsaturated phenolic products are obtained. Further, it was indicated that when steric hindrance becomes too great, ortho alkylation takes place, leading to the formation of coumarans.

In continuation of these studies of steric hindrance in ketone–phenol condensations and in order to prove the generality of the above conclusion, these investigations were extended to the naphthols.

The results obtained were entirely in accordance with the foregoing postulation. Thus, when α-naphthol was condensed with cyclohexanone, not only was the normal di-naphthol, the 2,2-di-((4′-hydroxy)-naphthyl)-cyclohexane (II) obtained, but the cyclo-alkylene-naphthol, the 1-(4′-hydroxy)-naphthyl-cyclohexene-1 (I) was secured as well. To prove the unsaturated character of the latter, the acetate (Ia) was prepared and brominated, and the resulting crystalline dibromide (Ib) isolated. Titration of this dibromide (Ib) with 0.01 N sodium hydroxide solution gave a neutralization equivalent equal to one half the molecular weight of the compound, indicating the hydrolysis of at least one bromine atom and thus confirming the presence of bromine in the isocyclic side chain.

The condensation of β-naphthol with cyclohexanone was also studied. The condensation was slow, but positive, yielding no phenolic products, but, instead, the 2,3-tetramethylene-4,5[or 5,6]-benzocoumaran (IIIa or IIIb).

The formation of all three types of condensation product may be represented as



Experimental

1-(4′-Hydroxy)-naphthyl-cyclohexene-1 (I).—Half molar quantities of α-naphthol and cyclohexanone were placed in a 1-liter, triple-necked, round-bottomed flask which was provided with a reflux condenser, a thermometer and a gas inlet tube extending to the bottom of the vessel. The mixture was warmed until complete solution took place and then was cooled to below 30°. A vigorous stream of dry hydrogen chloride gas was passed into the system for six hours at room temperature, then the flask was stoppered and left standing for twelve hours, when com-

(1) J. B. Niederl and co-workers, THIS JOURNAL, 61, 348 (1939).
(2) J. B. Niederl and co-workers, *ibid.*, 61, 1785 (1939).

plete solidification had taken place. The mass was then crushed, washed with water and twice leached with 5% sodium hydroxide, after which it was again washed thoroughly with water. The residue was chilled until it was solid and recrystallized from a minimum quantity of 95% ethyl alcohol, separating thus any alcohol-insoluble products. The compound is no longer soluble in Claisen solution, but couples with diazotized *p*-nitroaniline; yield after recrystallization, 80%; m. p. 80°.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.71; H, 7.14. Found: C, 85.42; H, 7.22.

Acetate (Ia).—Ten grams of (I) was dissolved in 50 ml. of acetic anhydride, the solution placed in a ground-glass joint apparatus and refluxed for four hours. Then the mixture was poured into 500 ml. of water and the whole vigorously stirred. After a time the residue solidified and was separated by filtration. The crude acetate was recrystallized from 95% ethyl alcohol. The conversion to the acetate was quantitative, m. p. 94°.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.20; H, 6.77; mol. wt., 266. Found: C, 81.09; H, 6.97; mol. wt., 265.

Di-bromide (Ib).—Ten grams of (Ib) was dissolved in 50 ml. of carbon tetrachloride and placed in a round-bottomed flask, the solution then being cooled to 5° in an ice-water-bath. The solution was stirred vigorously with the aid of a mechanical stirrer while one mole equivalent of bromine dissolved in carbon tetrachloride (1 g. of bromine per 5 ml. of solution) was added at the rate of 1 ml. per minute. When the addition of bromine was completed, the reaction mixture was poured into an evaporating dish and permitted to stand at room temperature until half the solvent had evaporated. By this time most of the dibromide had precipitated out while any substitution by-products remained dissolved. The mixture was then filtered and the crude dibromide was dissolved in the minimum quantity of acetone. A volume of water equal to one-fourth the volume of the acetone solution was added at once and stirred. In a few moments the purified dibromide crystallized from the solution and was separated by filtration; yield, 20%; m. p. 147°.

Anal. Calcd. for $C_{18}H_{18}O_2Br_2$: C, 50.70; H, 4.22; mol. wt., 426. Found: C, 50.73; H, 4.24; neut. equiv., 210.

1,1-Di-((4'-hydroxy)-naphthyl)-cyclohexane (II).—Half molar quantities of *α*-naphthol and cyclohexanone were condensed exactly as described for (I) with the single difference that the condensation was carried out at 100°. After standing for twelve hours in a tightly stoppered flask, the product was treated with 300 ml. of acetone and filtered. The residue was washed with 50 ml. of acetone and dried at room temperature. The compound was insoluble in Claisen solution but coupled with diazotized *p*-nitroaniline; yield, after treatment with acetone, 50%; m. p. 233°.

Anal. Calcd. for $C_{26}H_{24}O_2$: C, 84.78; H, 6.44; mol. wt., 368. Found: C, 84.62; H, 6.72; mol. wt., 381, 377. The molecular weight determination was performed cryoscopically according to K. Rast.[3]

Di-benzoate (IIa).—One gram of (II) was dissolved in 5 ml. of pyridine and 2 ml. of benzoyl chloride was added. The mixture was refluxed very gently for one-half hour and poured into 50 ml. of 5% sodium carbonate solution and vigorously stirred. When the product had hardened, the supernatant liquid was poured off and the residue was washed with water by decantation. A minimum amount of boiling alcohol was added to dissolve most of the residue. The alcoholic solution was then filtered and the filtrate cooled. The benzoate crystallized out and was filtered off. It was then purified by further crystallization from alcohol; m. p. 223°; mixed m. p. with (II), 207°.

Anal. Calcd. for $C_{40}H_{32}O_4$: C, 83.33; H, 5.55. Found: C, 83.48; H, 5.43.

2,3-Tetramethylene-4,5[or 5,6]-benzo-coumaran (IIIa or IIIb).—Half molar quantities of *β*-naphthol and cyclohexanone were dissolved in 80 ml. of acetic acid and condensed as described for (I). After standing for two weeks the flask was opened and the contents poured into a liter of water. The supernatant liquid was decanted and the residue twice leached with 5% sodium hydroxide solution, after which it was washed thoroughly with water. It was then chilled until semi-solid and dissolved in a very large volume of boiling alcohol. The alcoholic solution was chilled in ice. Water was added to cause the separation of the product and the resulting precipitate filtered off. After this treatment was twice repeated, the product was obtained as a nearly-white, amorphous solid; yield, 20%; m. p. 66–68°. The compound was insoluble in Claisen solution and did not undergo diazotization coupling reactions. Acetylation with acetic acid anhydride also was negative.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.71; H, 7.14; mol. wt., 224. Found: C, 85.50; H, 7.45; mol. wt., 249.

Summary

Steric hindrance phenomena encountered in certain types of ketone–phenol condensations were extended to include the condensation systems of the naphthols with cyclohexanone. From such systems and in accordance with previous postulations a cyclo-alkylidene-di-naphthol, a cyclo-alkylene-naphthol and a naphthyl-cyclohexyl-coumaran were isolated and derivatives thereof prepared.

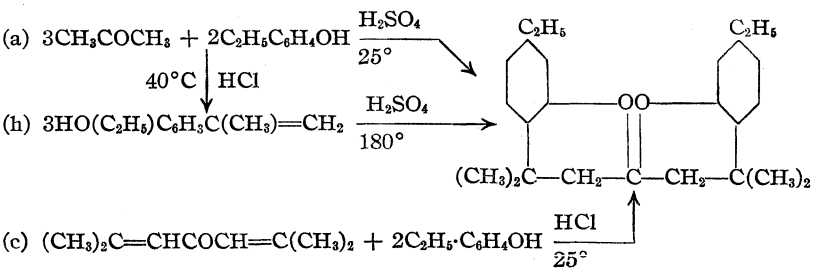
Spirochromans

BY JOSEPH B. NIEDERL AND RICHARD H. NAGEL[1]

The condensation of *m*- and *p*-cresol with acetone[2] was reinvestigated by W. Baker and D. M. Besley in 1939,[3] who not only confirmed both the empirical formulas and the "spirochroman" structures as advanced by J. B. Niederl,[4] but also assigned a similar "spirochroman" structure to their own hydroxyquinol–acetone condensation product.

To determine whether "spirochroman" formation was a phenomenon peculiar to the cresols, or whether it may be a general reaction of meta alkylated phenols with the position ortho to the phenolic hydroxyl group free, *m*-ethylphenol was condensed with acetone (a) and (b) and with phorone (c) in the presence of dry hydrogen chloride, as well as concentrated sulfuric acid. In the acetone condensation, the dimeric methovinylethylphenol, analogous to the dimer of methovinyl-methylphenol was obtained as the intermediate, when the condensation was carried out in the presence of dry hydrogen chloride at 40°. (b) This dimer was converted to the spirochroman according to the method of Böttcher[5] (b), by heating it to 180° with a small amount of sulfuric acid. The phorone condensation was direct and did not appear to have passed through any dimeric stage, which was also true in the case of the *m*- and *p*-cresol–phorone condensations.

Though the phorone product melted at 146° and the acetone compound at 114°, both gave the same tetranitro derivative, as evidenced by quantitative analyses and mixed melting point determinations. Furthermore, there was observed no depression in the melting point of an equal mixture of the two original crystalline condensation products and examination under the microscope showed that, though the crystals differed in form, it was possible to obtain crystallization by seeding a melt of the acetone compound crystals with a phorone compound crystal, and vice versa. This would seem to indicate that the dimorphism previously observed in the *m*- and *p*-cresol–acetone and the *m*- and *p*-cresol–phorone condensations and to be expected from stereochemical considerations is also exhibited by the ethyl homolog, and that the compound obtained in both cases is the 4,4,4′,4′-tetramethyl-7,7′-di-ethyl-bis-2,2′-spirochroman. Thus the course of the reaction may be presented as



Experimental

Acetone-*m*-ethylphenol

Dimeric Methovinylethylphenol (a and b).—One mole (122 g.) of *m*-ethylphenol and one-and-one-half moles (87 g.) acetone were placed in a 1-liter 3-necked round-bottomed flask provided with a reflux condenser and a gas inlet tube. Dry hydrogen chloride gas was passed into the reaction mixture at room temperature for six hours, and then the flask was tightly stoppered to keep the reactants in an atmosphere of the condensing agent, and let stand at room temperature for two weeks, in which time the mixture had turned dark brown in color and became quite viscous. The reaction mixture was poured into water and then repeatedly washed with 5% sodium carbonate solution and finally with distilled water, and then distilled. The main fraction (*ca.* 80 g.) distilled over between 200–207° at 12 mm. pressure, and on cooling an extremely viscous yellow liquid with a characteristic thymol-like odor was obtained.

Anal. Calcd. for $(C_{11}H_{14}O)_2$: C, 81.48; H, 8.64. Found: C, 81.55; H, 8.64.

Conversion to the Spirochroman (b).—Ten grams of the dimer was heated to boiling in a test-tube for half a minute with five drops of concentrated sulfuric acid. After two days, the solidified black mass was dissolved in boiling 95% ethyl alcohol and, on cooling, white rhombohedra crystallized out. These were recrystallized from the same solvent and were found to be insoluble in Claisen solution.

(5) Böttcher, Ph.D. Thesis, University of Berlin, 1930.

The conversion was practically quantitative. The pure product melted at 114° (uncor.).

Anal. Calcd. for $C_{25}H_{32}O_2$: C, 82.42; H, 8.79. Found: C, 82.48; H, 8.92.

Tetra-nitro Derivative.—About 1 g. of the crystals was dissolved in an excess of concentrated nitric acid in an Erlenmeyer flask, warmed on a steam-bath until no more fumes were given off, and then the flask was heated directly with a small Bunsen flame until a clear solution had resulted. Water was added to the cold solution, precipitating a yellow crystalline mass, which was filtered and recrystallized from 95% ethyl alcohol. The yellow crystals melted between 246–248° (uncor.). They were not analyzed, but a mixed melting point determination showed them to be identical with those obtained from the phorone–*m*-ethylphenol condensation product.

Phorone-*m*-Ethylphenol

4,4,4′,4′-Tetramethyl-7,7′-di-ethyl-bis-2,2′-spirochroman.—Three-tenths of a mole (46 g.) of phorone and 0.6 mole (82 g.) of *m*-ethylphenol were placed in a 1-liter 3-neck round-bottomed flask and dry hydrogen chloride gas was passed into the reaction mixture for six hours, the flask was stoppered tightly and allowed to stand at room temperature for one week. An excess of Claisen solution was added, precipitating a brown gelatinous mass which was filtered through a large fluted filter. The residue was washed with distilled water and dissolved in hot 50% ethyl alcohol, and on cooling white plates crystallized out. These crystals could also be obtained, though not so readily, from 95% ethyl alcohol. The crystals are insoluble in Claisen solution and melt at 146° (uncor.).

Anal. Calcd. for $C_{25}H_{32}O_2$: C, 82.42; H, 8.79. Found: C, 82.43; H, 8.68.

Tetra-nitro Derivative.—One gram of the spirochroman was heated on the water-bath in an Erlenmeyer flask with an excess of concentrated nitric acid till no more brown fumes were evolved, then heated directly with a small Bunsen flame until a clear solution resulted. On cooling, yellow needles separated, which were filtered off on a sintered glass filter funnel, and recrystallized from 95% ethyl alcohol. The melting point was 246–248° (uncor.). A mixed melting point with the nitro compound prepared from the acetone condensation product produced no depression.

Anal. Calcd. for $C_{25}H_{28}O_{10}N_4$: C, 55.15; H, 5.15. Found: C, 54.96; H, 5.13.

Summary

The condensation of acetone with meta alkylated phenols was extended to include *m*-ethylphenol. Experimental results were obtained which are in full harmony with previously advanced postulations.

Change of the Ultraviolet Absorption Spectrum of Acrolein with Time

BY A. M. BUSWELL, E. C. DUNLOP, W. H. RODEBUSH AND J. B. SWARTZ

During a study of the ultraviolet absorption spectra of solutions of pure organic compounds, we observed that in the case of acrolein the data were sometimes inconsistent. In one case a solution of a given strength showed less absorption than a solution of half the concentration had shown in a previous test. A check of the records showed that the weaker solution had been examined when freshly prepared, while the stronger solution was a few days old when its absorption was determined. This suggested a systematic study of the change of the absorption spectrum of acrolein with time to determine whether this effect was due to polymerization or some other reaction.

There are several articles in the literature[1] discussing the absorption spectrum of acrolein in the vapor phase, and in solution in alcohol, water and other solvents. They report a weak absorption band at about 3200 Å. and a very strong one extending from a sharp limit at 2500 Å. toward shorter wave lengths. There are no data showing what happens to the spectra of these solutions over a period of time. This point has been investigated and is reported herewith.

Experimental

The instrument used was a Bausch and Lomb medium quartz spectrograph with a sectorphotometer. The light source was a condensed iron–tungsten alloy spark. The cells were of glass with quartz windows and were 5.14 cm. in length.

The data were read from the plates by visual comparison using a hand lens to find the matched lines. The percentage transmission was known from the sector setting and the molecular extinction coefficient was calculated from the Lam-

bert–Beer equation $I = I_0 10^{-\epsilon c d}$ where $I_0 = 100$, I = relative per cent. of light transmitted, ϵ = molecular extension coefficient, c = concentration (molar), and d = length of the path of the absorbing media in centimeters.

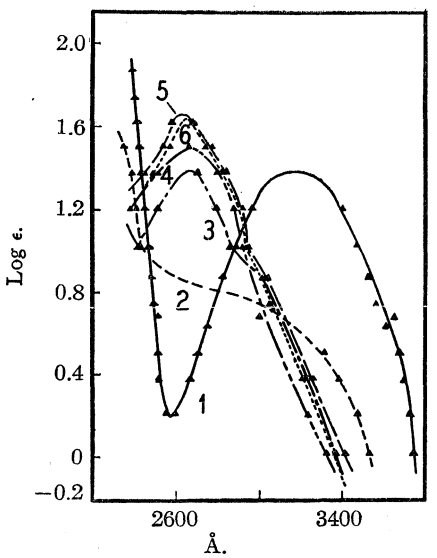

Fig. 1.—Acrolein in 50% ethyl alcohol solution: (1) immediately after making up solution; (2) after 7 days; (3) after 14 days; (4) after 21 days; (5) after 40 days; (6) after 60 days.

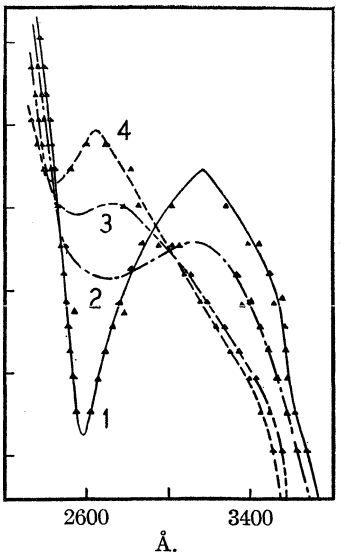

Fig. 2.—Acrolein in water: (1) immediately after making solution; (2) after 14 days; (3) after 30 days; (4) after 49 days.

The acrolein was purified and freshly distilled portions were used in making up all the solutions. The following solutions were made and tested: three solutions in 50% ethyl alcohol containing 1, 0.1 and 0.05 g. of acrolein per liter, respectively; two solutions in doubly distilled water containing 1 and 0.1 g. of acrolein per liter; and three solutions in doubly distilled water each containing 0.1 g. of acrolein per liter. To one of these last solutions a little hydroquinone was added, to another a little tannic acid and the third solution contained only acrolein and solvent. The ultraviolet absorption of each of the solutions was determined immediately after they were prepared. The solutions were then stored in glass-stoppered volumetric flasks and exposed to the diffuse light and temperature of the laboratory. Absorption tests were repeated at seven-day intervals on each of these solutions for periods up to eight weeks. In each test a small portion of the solution was removed, used for the absorption determination, and then discarded.

From the curves, Figs. 1, 2 and 3, it is seen that a definite change has taken place in the period of time indicated. In the original curves the bands correspond to those reported by Luthy[1f] and verified by others. The broad band at 3200 Å. has been assigned as due to the carbonyl and the very intense band extending from 2590 Å. toward the shorter wave length as due to the ethylenic group. There has been no mention of the band at 2670 Å. which appears after a few days. As the age of the solution increased the band at 3200 Å. disappeared and the band at 2670 Å. appeared and increased up to a time of forty days. The shoulder of the peak toward the shorter wave length also is found to diminish with increasing time.

Discussion

The new band at 2670 Å. is due to some reaction that the acrolein has undergone. This new band cannot be due to an acetal form since the same results occur in both alcoholic and water solutions (Figs. 1 and 2). It has been reported by Herold and Wolf[2] that the formation of hemiacetals can be shown by the ultraviolet absorption spectra. We also have shown that this is true for propion-

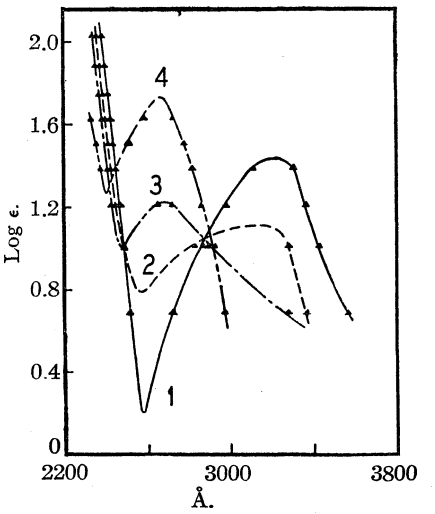

Fig. 3.—Acrolein in water: (1) immediately after making solution; (2) after 7 days; (3) after 14 days; (4) after 38 days. This solution was kept under identical conditions as those for Figs. 6 and 7.

(2) Herold and Wolf, *Z. physik. Chem.*, **12**, 165 (1931).

aldehyde, Fig. 4, where a water solution of the propionaldehyde remained unchanged for forty-two days while in an alcohol solution the absorption of the carbonyl was gradually decreased with time. The absorption of acetal in water solution was determined and is shown in Fig. 5. From these data it is shown definitely that the acrolein does not form the hemiacetal.

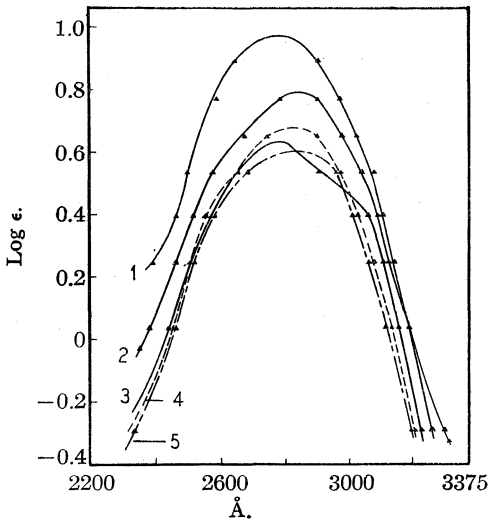

Fig. 4.—Propionaldehyde: (1) water solution remained unchanged for 42 days; (2) 50% ethyl alcohol solution immediately after making solution; (3) the alcohol solution after 9 days; (4) the alcohol solution after 16 days; (5) the alcohol solution after 42 days.

Paraldehyde has been reported as having no bands above 2500 Å. and we have verified this, Fig. 5. Comparing these data with the data for acrolein it is seen that the paraldehyde structure gives no absorption above 2500 Å. while in the aged acrolein solutions there was absorption at 2670 Å. Moreover, the aged solutions gave positive tests with fuchsin-aldehyde reagent and Tollens' reagent, thus indicating the presence of the aldehyde group. The solutions also gave a positive test with 2,4-dinitro-phenylhydrazine reagent but because of the small concentration the derivative was not isolated. This would indicate that the acrolein does not form a molecule of the paraldehyde structure.

No insoluble material formed in the solution, indicating that no long chain insoluble polymer was formed.

The absorption spectrum of allyl alcohol determined by Bielecki and Henri[3] shows that allyl alcohol is nearly transparent above 2400 Å. Since the aged acrolein solutions show absorption at 2670 Å., this eliminates the possibility of the formation of allyl alcohol.

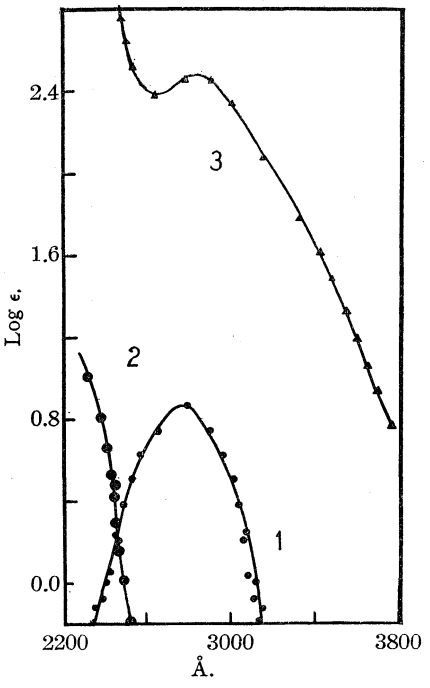

Fig. 5.—(1) Acetal in water; (2) paraldehyde in 50% ethyl alcohol; (3) aldol in 50% ethyl alcohol.

Backes[4] has shown that non-aqueous solutions of aldol show no peak above 2500 Å. while aqueous solutions have a peak at 2800 ± 10 Å. characteristic of the carbonyl group. We have verified the latter part of this statement as shown in Fig. 5 for aldol in 50% ethyl alcohol. The original carbonyl absorption of the acrolein in aqueous solution is changed completely while if the acrolein formed an aldol type of molecule the carbonyl would still be conjugated with the ethylenic linkage and should still absorb at the same wave length but should be diminished because of the disappearance of one-half the carbonyl groups. No one has ever suggested that acrolein would form the aldol and these data indicate no such formation.

From the results of the absorption spectra of the solutions to which a very minute amount of an antioxidant, either hydroquinone, Fig. 6, or tannic acid, Fig. 7, has been added, it is seen that the presence of the antioxidant has slowed down the reaction but has not stopped it. Compare Fig. 3 with Figs. 6 and 7 which show that the absorption at 3200 Å. is slower in disappearing

(3) Bielecki and Henri, *Ber.*, **46**, 2596 (1913).

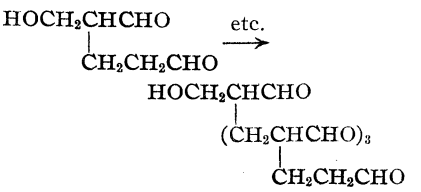
and that at the end of the thirty-eight-day period the new band at 2670 Å. is not as strong in the solutions which contained an antioxidant as it is in the other solution. These data suggest that the reaction may be an oxidation. In this case the product would be an acid, acrylic acid or perhaps a resin acid. The spectrum does not agree with that of acrylic acid as determined by Luthy[1f] and also the *p*H of the solution, which was 6.5 ± 0.3 when the solutions were made up and which remained constant, does not indicate any acid formation.

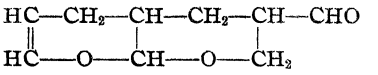
Nothing very definite can be said in regard to the ethylenic group since we have been unable to extend our working range of the spectrum below 2300 Å. In observing the results near 2350 Å., however, we notice that in every case the shoulder is diminished with time and this may be taken as an indication that the ethylenic group is disappearing.

The new band which appears at 2670 Å. is undoubtedly due to a molecule formed by the polycondensation of the acrolein. Several investigators have described the formation of a white product from the polycondensation of acrolein but have made no attempt to characterize the polymer. Gilbert and Donleavy[5] have recently shown that the polycondensation is an equilibrium reaction which they represent by the equations

$$\underset{\text{I}}{CH_2{=}CHCHO} + H_2O = HOCH_2CH_2CHO + \text{I} =$$



Sherlin, *et al.*,[6] have reported on the polymerization of acrolein in anhydrous condition at 170° and have proposed the formula



This molecule, with water added to the double bond, may be in equilibrium with the chain molecule as prepared by Gilbert and Donleavy.[5] The absorption data agree with the equilibrium reaction proposed by Gilbert and Donleavy[5] in which the ethylenic group disappears and the carbonyl group is changed, giving absorption at a shorter wave length. This would be expected since the conjugation disappears, causing the shift to the shorter wave length. The absorption data show that an antioxidant slows down the reaction, which is known to be the case for the above reaction. A sample of the polymer described by Gilbert and Donleavy[5] was prepared and its alcohol solution was found to give an absorption peak at the same wave length as that for the aged acrolein solutions.

Summary

The change in the absorption spectrum of acrolein in water and alcoholic solutions has been determined over a period of time. The effect of hydroquinone and tannic acid on the spectrum also has been determined.

The absorption due to the carbonyl of the acrolein changes with time, and the change is slowed down by the presence of an antioxidant. A band which appears at 2670 Å. is probably due to the carbonyl of the polymer since the product described by Gilbert and Donleavy[5] gives the same absorption band.

Curves for propionaldehyde in water and 50% alcohol solutions, for acetal in water, paraldehyde in 50% alcohol and aldol in 50% alcohol are also given for comparison.

The Action of Ethyl Azide and Phenyl Azide on Fuming Sulfuric Acid[1]

BY K. W. SHERK, A. G. HOUPT[2] AND A. W. BROWNE

The action of hydrogen azide on fuming sulfuric acid has been shown[3] to yield aminomonopersulfuric acid which is capable of acting both as an aminating agent and as a strong oxidizing agent. In the attempt to throw more light upon the structure and nature of this compound and its possible derivatives, a study has been made of the action of fuming sulfuric acid on two derivatives of hydrogen azide: phenyl azide and ethyl azide. This work also was undertaken in the attempt to determine the conditions under which the monazene (NH=) radical or its substitution products might polymerize or condense to form compounds of the diazene series of hydronitrogens, as exemplified by the condensation of RN= residues to form azo compounds.[4]

Phenyl Azide.—The formation of *p*-aminophenol and its *o*-sulfonic acid, respectively, by the action of phenyl azide on dilute and concentrated sulfuric acid, as noted by Bamberger[5] is in a sense analogous to the formation of hydroxylamine as a product of the action of hydrogen azide on concentrated sulfuric acid. Since no hydroxylamine is formed when the fuming acid is used in place of the ordinary concentrated acid, it seemed likely that the phenyl derivative of aminomonopersulfuric acid, rather than *p*-aminophenol, might be obtainable from the action of phenyl azide on fuming sulfuric acid.

The phenyl azide used in the present work was prepared from nitrosyl chloride and phenylhydrazine.[6] It was separated by steam distillation and dried with anhydrous sodium sulfate. The introduction of this reagent into fuming sulfuric acid, even when the acid was cooled in an ice-salt mixture and thoroughly stirred, resulted in considerable charring. At room temperature, each drop of the phenyl azide, as it struck the acid, detonated with a violet flash and formed a purple-black smoke. To overcome these difficulties the phenyl azide was introduced in the form of vapor by drawing a slow stream of dried air through the azide and then through the fuming acid at room temperature. In this way 12 g. of phenyl azide was drawn into 20 ml. of 20% fuming acid in eighteen hours. Almost from the outset evolution of nitrogen took place, and the acid assumed a maroon color. After the azide had been introduced the acid solution was allowed to stand until gas evolution had ceased.

The solution was poured into vigorously agitated, ice-cold, dry ether with the result that a bulky, rose colored precipitate was formed. This was washed with dry ether until the washings were free from sulfate ion. A yield of 11 g. of a very hygroscopic solid was obtained. On exposure to air a sample of this product quickly became blue and sticky.

The solid dissolves in water to yield a solution from which needle-like crystals are at once deposited. These are soluble in dilute sodium hydroxide and reprecipitated by acid. A sample of this product of hydrolysis weighing several grams was prepared, redissolved, reprecipitated, washed with water and alcohol, and dried. Qualitative tests and further analysis proved the compound to be *p*-aminophenol *o*-sulfonic acid monohydrate. *Anal.* Calcd. for *p*-aminophenol *o*-sulfonic acid monohydrate: neut. equiv., 207.1; S, 15.48; N, 6.76; H_2O, 8.70. Found: neut. equiv., 207; S, 15.28; N, 6.76, 6.74, 6.77; H_2O, 8.53.

The original hygroscopic material, when heated, chars without melting. Its aqueous solution gives a positive phenol test, and fails to liberate iodine from acidified potassium iodide solution. It yields at once, even at room temperature, a heavy precipitate of barium sulfate when treated with barium chloride and hydrochloric acid. Although analysis was hindered by the hygroscopic nature of the substance, the following data were obtained. Found: S, 21.75, 21.90, 21.95; N, 4.90, 4.92; atomic ratio S:N, 1.986/1.

In conjunction with the observed formation of *p*-aminophenol *o*-sulfonic acid and sulfuric acid by hydrolysis, this strongly indicates that the original substance was mainly phenylaminomonopersulfuric acid *m*-sulfonic acid. Unlike aminomonopersulfuric acid, this compound does not liberate iodine from potassium iodide in acid solution but hydrolyzes immediately and rearranges to *p*-aminophenol *o*-sulfonic acid. It shows no tendency to form monopersulfuric acid.

Mechanism of the Reaction between Phenyl Azide and Fuming Sulfuric Acid.—The first step may be considered to consist of the coördination of a hydrogen ion to the alpha nitrogen of the azide group.

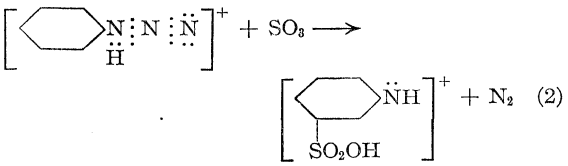
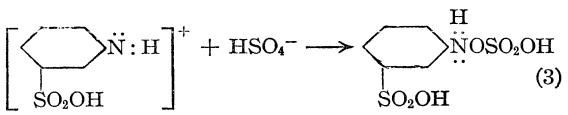
(6) Tilden and Miller, *J. Chem. Soc.*, **63**, 256 (1893).

The coördination link reduces the stability of the azide group with the result that two atoms of nitrogen split off as nitrogen gas. Sulfonation occurs subsequently to the coördination as indicated by the meta position of the sulfonate group.



The unstable residue unites with a bisulfate ion to form phenylaminomonopersulfuric acid *m*-sulfonic acid.



This product probably exists in the isomeric form obtained by a shift of the hydrogen from the nitrogen to the adjacent oxygen as seems likely in the case of aminomonopersulfuric acid.[3]

Ethyl Azide.—This reagent was prepared by the action of diethyl sulfate on sodium azide.[7] It was washed with water to remove ethanol, and was dried with anhydrous sodium sulfate. About 8 g. of the azide in the form of vapor was introduced by means of a current of dry air into 15 ml. of 20% fuming sulfuric acid at 80° in eighteen hours. After the evolution of nitrogen had ceased, the clear, slightly yellow solution was slowly poured into vigorously agitated, ice-cold, dry ether. The heavy yellowish precipitate was washed with dry ether until it was free from sulfuric acid. During this operation the solid gradually assumed an orange color and became sticky. *In vacuo*, over phosphorus pentoxide, it soon changed to a deep-orange paste, and finally, after several days, to a brittle orange-colored glass.

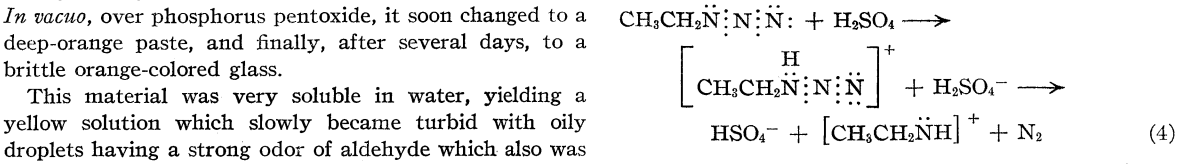
This material was very soluble in water, yielding a yellow solution which slowly became turbid with oily droplets having a strong odor of aldehyde which also was manifested by the glassy solid itself. The solution was strongly acidic and contained sulfate ions. Distillation yielded a clear, colorless, aqueous solution which contained formaldehyde and another aldehyde, assumed under the circumstances to be acetaldehyde. To separate the formaldehyde from the other, a sample of the distillate was treated with an excess of concentrated ammonium hydroxide solution. This converted the formaldehyde to hexamethylenetetramine and the acetaldehyde to aldehyde-ammonia. The solution was made barely acid to methyl red and distilled until no more aldehyde came over. There was no formaldehyde in the distillate. Acetaldehyde was present, however, and was confirmed by the preparation of the *p*-nitrophenylhydrazine derivative.

The residue in the flask was made strongly acid with 1:1 sulfuric acid and distillation resumed. The new distillate gave strong tests for formaldehyde, which was confirmed by the *p*-nitrophenylhydrazine derivative.

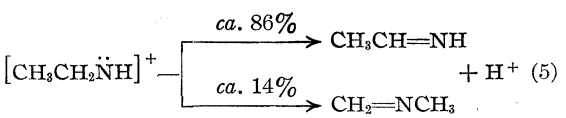
The residue from the distillation of the aldehydes was made alkaline with sodium hydroxide, and distilled into cold water. This distillate contained ammonia and methylamine, which were identified by conversion to benzamide and dinitromethylaniline, respectively. The distillate would not reduce ammoniacal silver nitrate nor Fehling's solution, and therefore contained no hydroxylamine derivatives.

From these results it seems that the unstable yellow solid formed by the action of fuming sulfuric acid on ethyl azide yields, upon hydrolysis, sulfuric acid and a mixture of acetaldehyde, formaldehyde, ammonia and methylamine. No other products such as N-ethylhydroxylamine, ethylidene imine, or ethylene imide could have been present as final products since the volatile bases did not reduce potassium permanganate or ammoniacal silver nitrate solution. The estimation of ammonia and methylamine was accomplished by the method of François[8] in which a solution of the weighed hydrochlorides was used. The mixture was found to contain 0.86 mole of ammonia to 0.14 mole of methylamine. The relative strength of the tests given for acetaldehyde and formaldehyde indicated that these substances were present in a similar ratio.

Mechanism of the Reaction between Ethyl Azide and Fuming Sulfuric Acid.—From the behavior of hydrogen azide and phenyl azide toward fuming sulfuric acid, it was expected that ethyl azide would react with the fuming acid to form ethylaminomonopersulfuric acid, which would hydrolyze to yield N-ethylhydroxylamine. The first step of the reaction is probably the union of a hydrogen ion with the ethyl azide and the subsequent loss of two nitrogen atoms.



The unsaturation of the nitrogen is relieved by a shift of a hydrogen or of a methyl group from the alpha carbon to the adjacent nitrogen, rather than by combination with a bisulfate ion to form a derivative of aminomonopersulfuric acid.



The fact that the solution of the glassy yellow product contained sulfate ions indicates that it was probably a mixture of the sulfates of the bases

(7) Staudinger and Hauser, *Helv. Chim. Acta*, **4**, 872 (1921).

(8) François, *Compt. rend.*, **144** 857 (1907); from "Allen, Commercial Organic Analysis," 5th ed., Vol. V, P. Blakiston's Son and Co., Phila., 1927, p. 287.

shown in equation 5. The hydrolysis of these compounds would account for all of the observed products.

Since no products containing nitrogen linked to nitrogen have been obtained by the interaction of either phenyl or ethyl azide and fuming sulfuric acid, the possibility that diazene or its homologs might be formed by the interaction of hydrogen azide and the fuming acid seems rather remote under the prevailing conditions. The mechanism already suggested for this reaction[3] is confirmed by the behavior of phenyl azide toward the fuming acid.

Summary

1. The action of fuming sulfuric acid upon phenyl azide apparently results in the formation of phenylaminomonopersulfuric acid *m*-sulfonic acid, which on hydrolysis yields *p*-aminophenol *o*-sulfonic acid.

2. The action of fuming sulfuric acid upon ethyl azide results in the formation of products which on hydrolysis yield sulfuric acid and a mixture of acetaldehyde, formaldehyde, ammonia and methylamine.

3. A useful method for the separation of formaldehyde and acetaldehyde has been described.

4. No compounds containing nitrogen linked to nitrogen were obtained as products of either reaction. The analogy between these reactions, particularly that of the phenyl azide, and that of hydrogen azide and fuming sulfuric acid has been noted.

The Heat Capacities, Heats of Transition and Fusion, and Entropies of Ethylene Dichloride and Ethylene Dibromide

BY KENNETH S. PITZER

Internal rotation in ethylene dichloride and ethylene dibromide has been studied by dielectric constant[1] measurements, electron diffraction,[2] and Raman spectra.[3] Although it has been proved that the rotation is considerably restricted, many aspects are yet to be worked out. With this in mind, the low temperature heat capacities, heats of fusion, and heats of transition for both substances have been measured, leading of course to entropy values. Work is in progress on the heat capacities of these substances in the gas phase.

These substances are also interesting because of the transitions they undergo as solids. Ethylene dibromide shows a sharp transition at 249.54° K., while ethylene dichloride has a large peak in its heat capacity curve near 177°K.

Apparatus and Materials.—The vacuum calorimeter used in this investigation already has been described.[4] The value 273.10°K. was taken for the ice point, and the defined calorie, 4.1833 International joules, was used throughout.

The calorimetric samples were purified by washing with water, drying, and repeatedly fractionating. The impurity in each case was estimated from the rise in heat capacity below the melting point, and found to be 0.058% in the case of ethylene dichloride and 0.26% in ethylene dibromide. Although impurities of this magnitude make the true heat capacity below the melting point uncertain, they do not appreciably affect the final entropy values.

Melting and Transition Temperatures.—The melting points were observed for different fractions melted and were corrected for impurities. The transition temperature in ethylene dibromide was similarly measured. The results are presented in Table I together with the values obtained by other observers.

Heat Capacities.—The heat capacities were measured by the usual method and are listed in Tables II and III shown graphically in Fig. 1. The temperature increments employed can be judged by the spacing of the reported results. In the anomaly in ethylene dichloride small increments were necessary to show that the true curve is rounded at the peak. This special series of measurements is included at the end of Table II. The results of other special measure-

ments indicated slow thermal equilibrium near the peak, but no detectable hysteresis.

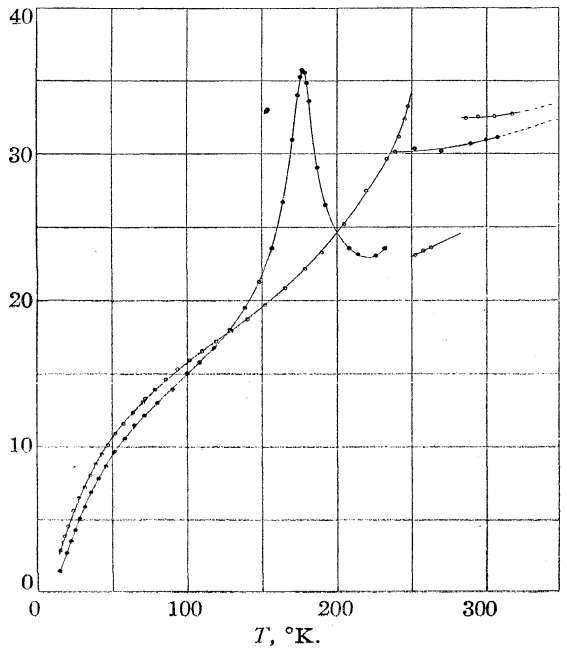

Fig. 1.—The molal heat capacity of ethylene dichloride (solid circles) and ethylene dibromide (open circles) in cal. per degree.

The error in the heat capacities is probably less than 0.2% under optimum conditions. At the highest temperatures rapid heat exchange by radiation is troublesome, while at the lowest temperatures the resistance thermometer is less sensitive. Just below the melting point, the premelting effect obscures the true heat capacity curve. The listed results have been corrected for this effect on the basis of Raoult's law, which may not be followed accurately. This uncertainty is greater in the ethylene dibromide, due to both the larger impurity and the proximity of the transition to the melting point. The observed heat capacities above the transition fit the following expression within experimental error: $C_p = A + BT + C/(T_{M.P.} - T)^2$. In this expression the first two terms represent the true heat capacity, assumed to vary linearly with temperature over this short range, and the third term the "Raoult's law" premelting. Since a series of six evenly spaced observations was available, as compared to three constants, the agreement is real evidence for the correctness of this treatment. It cannot be regarded as conclusive, however, and only the three measurements farthest from the melting point are included in Table III.

While the presence of small impurities renders the heat capacity uncertain just below the melting point, any appreciable error in this region is compensated in the heat of fusion, so that the

total entropy or heat content is not seriously altered.

Heats of Fusion and Transition.—Table IV contains the observed heats of fusion and transition. The temperature intervals and times of heating are also listed. In each heat of fusion a correction was made for the amount "premelted" at the initial temperature. It is believed that the uncertainties given in Table IV are sufficient to cover any calorimetric errors. However, a failure of the premelting effect to even approximate Raoult's law might possibly lead to errors about five times those listed. As stated above, the total entropy is not rendered uncertain by this latter possibility.

TABLE IV

HEATS OF FUSION AND TRANSITION

Temp. interval, °K.	Time of heat input, min.	$\Delta H°$ cal./mole
Fusion of $C_2H_4Cl_2$ at 237.2°K.		
229.22–244.45	24	2112.1

272.47–294.05	25	2614.5
		Av. value 2615.8 ± 5
Transition of $C_2H_4Br_2$ at 249.54°K.		
247.17–258.64	14	465.5
248.97–258.96	10	462.3
247.17–250.29	14	463.7
		Av. value 463.8 ± 2

Entropies.—The entropies were calculated by the usual graphical integrations, together with extrapolations to the absolute zero based on the Debye theory. The heat capacity does not fit a single Debye function (three degrees of freedom) satisfactorily for either substance, but does fit twice a Debye function (corresponding to six degrees of freedom). This latter assumption is consistent with the idea that the tendency of the molecules to oscillate torsionally leads to torsional waves similar to the more common compressional waves. Lord, Ahlberg and Andrews[5] found this assumption very successful in the case of benzene and discussed its justification in greater detail.

Measurements are now in progress on the heats of vaporization of both substances, and on heat capacities as gases. Consequently, it seems best to postpone calculations and discussions of the entropies of gaseous ethylene dichloride and dibromide until these data are available.

Discussion of Transitions.—Some comment seems worth while on the nature of the transition in ethylene dibromide and the gradual transition or anomaly in the chloride. Measurements of the dielectric constant by White and Morgan[6] show only small changes in passing through these regions. The dielectric constant becomes large only above the melting point for either substance. This probably means that the molecules retain configurations of small dipole moment until they melt. Rotation of whole molecules about their long axis might set in, however, without allowing internal rotation. The internal rotation is considerably restricted even in the gas phase.[1,2]

If this explanation is accepted, the results for either substance by itself would seem reasonable, since similar thermal effects have been observed for the beginning of rotation within other crystals. However, the difference seems very great for two such similar compounds. The following explanation is offered as plausible but by no means proved.

If the coöperative or coupling effect between the rotation of one molecule and its neighbors is relatively small, then the whole curve for the chloride becomes understandable and the rather

gradual rise in the bromide curve from 150 to 250°K. is also to be expected. Above 250°K. some fundamentally different crystal structure, based on rotating molecules, becomes more stable for the ethylene dibromide, and a sharp interphase transition of the usual sort occurs. If one considers lattices comprising points which represent only the centers of gravity of the molecules, then the writer proposes that the lattice for ethylene dichloride will be essentially the same above and below the peak or "transition." Probably the lattice for ethylene dibromide below the transition is also similar; however, it is suggested that above the transition the ethylene dibromide lattice is quite different. The marked similarity of the heat capacity curves below 100°K. gives some confirmation to the suggestion that the low temperature lattices are similar. Also a comparison of the extra entropy associated with the peak in ethylene dichloride (about 2.8 cal. per deg.) with that in the abnormal rise and the transition in ethylene dibromide (about 3.7 cal. per deg.) is in reasonable agreement with this picture. The latter might be expected to be somewhat larger because it includes a change in lattice in addition to molecular rotation. Thus the observations are accounted for in a general way, although x-ray studies would be needed to prove that these ideas are correct.

Since submitting this paper for publication, Railing[7] has published results of a somewhat similar investigation. His measurements do not extend below 90°K. and he did not attempt to make an entropy calculation. A comparison of certain results is presented.

		Railing	This Research
Melting point, °K.	$C_2H_4Cl_2$	237.6	237.2±0.1
	$C_2H_4Br_2$	283.03	283.0±0.2
Transition temp., °K.	$C_2H_4Br_2$	250.6	249.54±0.1
Heat of fusion, cal.	$C_2H_4Cl_2$	2090±21	2112.0±2
	$C_2H_4Br_2$	2590±26	2615.8±5
Heat of transition, cal.	$C_2H_4Br_2$	450±9	463.8±2

For the greater part, the heat capacity results agree well within the 1–2% error suggested by Railing. However, near the transitions, melting points, or other irregularities, appreciable discrepancies arise, particularly with the dichloroethane. This is not too surprising when one considers the method of measurement employed by Railing, as described by Stull.[8] Briefly, this involves continuous introduction of energy with temperature measurements at the same time. Under these conditions, temperature gradients certainly exist, and a thermometer reading may not correspond to the temperature which would be attained at thermal equilibrium with the same heat content. In most regions, the error in temperature should remain almost constant, leading to correct heat capacities. However, near transitions, melting points, etc., these temperature gradients may change rapidly, leading to considerable error in the heat capacity results. Since, with the method used in this research, temperatures are measured only when thermal equilibrium has been essentially attained, the results of the present investigation are not subject to this error.

In this connection the writer is not convinced as to the reality of the variation of heat capacity depending on thermal history, which was found by Railing for liquid ethylene dichloride. He reports that one curve is obtained "immediately after melting" and another with liquid which has been cooled to just above the melting point. Presumably, in the first case the introduction of energy is not stopped after the fusion is completed and the liquid heat capacity measurements begin with the thermal gradients that existed under the conditions of melting. These gradients may differ considerably from those of the

(7) Railing, THIS JOURNAL, **61**, 3349 (1939).

(8) Stull, THIS JOURNAL, **59**, 2726 (1937).

recently cooled liquid. The observed differences, depending on rate of freezing, can similarly be explained as arising from differences in heat conductivity within the sample, which depends on the size of crystals among other factors.

The results of the present investigation neither support nor definitely disprove these effects reported by Railing. They do, however, offer strong evidence against the slow *cis–trans* isomerization suggested by him in explanation. The presence of *cis* and *trans* isomers would be expected to produce variations in the melting point and other peculiar effects which were definitely not observed. Also, according to Railing's suggestions, absorption of heat and apparent cooling would be expected after melting the material. No such cooling effect was observed in the heat of fusion experiments.

Summary

The thermal behavior of ethylene dichloride and ethylene dibromide was investigated from 15°K. to room temperature, for which range values of the heat capacities are given. The following melting points (0°C. = 273.10°K.) and heats of fusion were determined: $C_2H_4Cl_2$, 237.2 ± 0.1°K., 2112.0 ± 2 cal./mole; $C_2H_4Br_2$, 283.0 ± 0.2°K., 2615.8 ± 5.0. The following temperature and heat of transition values were determined: $C_2H_4Br_2$, 249.54 ± 0.10°K., 463.8 ± 2.0 cal./mole. From these data, the following values of entropy at 298.1°K. were calculated: $C_2H_4Cl_2$(l), 49.84 ± 0.15 cal./deg. mole; $C_2H_4Br_2$-(l), 53.37 ± 0.20 cal./deg. mole.

Ethylene dichloride shows no sharp transition but has a peak in the heat capacity curve near 177°K. which may correspond partially to the transition in ethylene dibromide. A possible explanation of the transitions is offered.

The Viscosity of Solutions of Electrolytes as a Function of the Concentration. VI. Potassium Bromide and Lanthanum Chloride

BY GRINNELL JONES AND ROBERT ELIOT STAUFFER

The general objective of this paper and of the others of this series is a study of the viscosity of solutions of electrolytes as a function of the concentration, temperature and nature of the salt. The earlier papers[1] should be consulted for a more detailed theoretical discussion and for a description of the experimental technique.

The potassium bromide used in this work was prepared by S. Baeckström.[2]

The lanthanum chloride was originally purified from other rare earths by the late Professor Charles James and had been used in previous investigations in this Laboratory[3] and recovered by precipitation as the oxalate. The oxalate was ignited to the oxide, dissolved in a solution of hydrochloric acid in ethyl alcohol, filtered through a sintered glass filter, chilled with ice and hydrogen chloride gas passed into the solution until the lanthanum chloride was precipitated. The salt was dried by centrifugal drainage and reprecipitated from alcohol in the same manner. The use of ethyl alcohol instead of water gives better yields. A suitable quantity for each solution was placed in a platinum boat inside of a quartz tube and heated to 600° for four hours in a stream of hydrogen chloride gas without fusion. The salt was cooled in an atmosphere of hydrogen chloride gas and then the acid gas replaced by dried air and the boat put into a weighing bottle by the use of a Richards bottling apparatus. The solutions were then made up by weight.

The solutions prepared from the salt dried in this manner had a *p*H of about 6.0 when tested with brom thymol blue, which agrees with the earlier work of Kolthoff and Elmquist,[4] and of Jacques[5] and of Jones and Bickford.[6] No corrections were applied for this slight hydrolysis. Erratic results were obtained at first and the cause was traced to a slight deposit of lanthanum hydroxide in the capillary tube of the viscometer. However, it was found that the deposit was formed during the rinsing of the viscometer with hot water after a series of measurements, which in-

fluenced subsequent measurements with water or other solutions. By rinsing at first with hydrochloric acid instead of with water the tubes were kept clean and more consistent and reliable measurements obtained.

In some cases a correction not exceeding a few hundredths of one per cent. was applied by interpolation to bring the results to the round concentration given, but if the correction required was substantial the actual data are given and the interpolated values at the round concentration are shown in parentheses. The lanthanum chloride solutions were measured at both 25 and 0° but measurements were made at 0° only on the potassium bromide solutions because measurements on this salt at 25° already had been made in this Laboratory.

The kinetic energy correction has been applied to the data, but no correction[7] has been applied for surface tension effects because the surface tension data are not available.

$\eta = 1 + 0.00450\sqrt{c} - 0.15459c + 0.04244c^2$	.5	.005

Interpretation of the Data.—The densities of these solutions can be expressed over the entire range of concentration studied by equations of the form suggested by Root[8] with an average deviation of only 0.002%. These equations are

for KBr at 0°; $d^0_4 = 0.999871 + 0.089603c - 0.003196c^{3/2}$

for $LaCl_3$ at 25°; $d^{25}_4 = 0.997074 + 0.229324c - 0.01184c^{3/2}$

at 0°; $d^0_4 = 0.999871 + 0.23665c - 0.01521c^{3/2}$

These salts give the Grüneisen effect as usual.

(7) The correction factor for this instrument should be computed by the equation

$$f = 1 + 0.0076\,\frac{\sigma_0/\rho_0 - \sigma_c/\rho_c}{\sigma_0/\rho_0}$$

see Jones and Fornwalt, THIS JOURNAL, **60**, 1691 (1938).

(8) W. C. Root, THIS JOURNAL, **55**, 850 (1933).

The solutions of potassium bromide at 0° give another example of a salt which causes a diminution in viscosity at moderate concentration but nevertheless gives an increase in viscosity at extreme dilution.

The viscosity of these solutions relative to that of pure water can be expressed by the Jones and Dole equation; $\eta = 1 + A\sqrt{c} + Bc$ as follows

for KBr at 0°; $\eta = 1 + 0.0045\sqrt{c} - 0.15377c$; valid up to 0.05 N

for $LaCl_3$ at 25°; $\eta = 1 + 0.0304\sqrt{c} + 0.5672c$; valid up to 0.1 M

for $LaCl_3$ at 0°; $\eta = 1 + 0.0278\sqrt{c} + 0.4744c$; valid up to 0.1 M

Table IV gives a comparison of the values of the coefficient of the square root term (A) determined experimentally and that computed by the Falkenhagen and Vernon equation.

TABLE IV

COMPARISON OF THE THEORETICAL AND EXPERIMENTAL VALUES OF THE COEFFICIENT OF THE SQUARE ROOT TERM

	Equiv. cond. used in calcg. cation	anion	A computed	A exper.
KBr at 0°	40.6	43.1	0.0044	0.0045
$LaCl_3$ at 25°	71	76.34	.0280	.0304
	68	76.34	.0288	
$LaCl_3$ at 0°	35.5	41.3	.0270	.0278
	35	41.3	.0272	

These results furnish additional evidence in support of that given in the earlier papers of this series that the Falkenhagen and Vernon equation is essentially correct both as to the influence of valence type and temperature.

Cox and Wolfenden[9] have made a series of measurements on dilute solutions of lanthanum chloride at 18° from which they find an experimental value of A of 0.037 ± 0.002. They compute a theoretical value of 0.0318 but do not state the value of the equivalent conductivities and other parameters which they used in these calculations. They say "Aqueous solutions of magnesium sulfate and lanthanum chloride do not give results in accordance with the Falkenhagen equation and these electrolytes are the first cases to be investigated which have shown an unmistakable divergence. Such a divergence is not unexpected as it is characteristic of the behavior of electrolytes of higher valence-type in respect to other properties such as those of heats of dilution, etc. The discrepancy is presumably associated with the higher terms of the ionic atmosphere theory."

Our data do not confirm this conclusion as to lanthanum chloride. Our experimental data are consistently lower than theirs and agree much better with computed values of A.

The only other measurements on potassium bromide at 0° which we have found in the literature are by Taylor and Ranken[10] on 1, 2 and 3 N KBr. These results are appreciably higher than ours and since data on dilute solutions are lacking they are not significant in determining the experimental value of A.

Summary

1. The absolute densities and relative viscosities of many solutions of potassium bromide have been determined at 0° and of solutions of lanthanum chloride at 25 and 0°.

2. These results confirm the Root equation for densities, the Jones and Dole equation for viscosities and the Falkenhagen and Vernon equation for the influence of the interionic attraction on the viscosity.

The Viscosity of Solutions of Electrolytes as a Function of the Concentration. VII. Silver Nitrate, Potassium Sulfate and Potassium Chromate

BY GRINNELL JONES AND JOHN HENRY COLVIN

The earlier papers of this series[1] should be consulted for a discussion of the objectives and theoretical significance of the work and for a description of the experimental procedure.

Silver nitrate was purified[2] by solution in water, precipitation by the addition of freshly distilled nitric acid, and separation from the mother liquor by centrifugal drainage. This process was carried out three times in succession. It was then fused in a porcelain casserole, taking care to avoid overheating above the melting point, and then poured in small portions into a platinum dish to cool and solidify. Potassium chromate was recrystallized three times with centrifugal drainage, then dried and finally heated just below its melting point. The purified material gave a negative test for sodium, chloride and sulfate. Potassium sulfate was purified in the same manner as the chromate. It gave a negative test for sodium and chloride.

The results are summarized in Tables I to VI in which the concentrations, c, are expressed in gram molecular weights per liter, and viscosities, η, are given relative to that of water at the same temperature. A small kinetic energy correction has been applied to the data but no correction for the effect of surface tension has been made.[3] Figures in parentheses were not actually measured but were estimated by interpolation over a small range of concentration.

The densities of these solutions can be expressed by the equations given in the tables having the form suggested by Root,[4] throughout the entire range of concentration studied and with average deviation of less than 0.002%. It is remarkable that this equation should be valid for

Although silver nitrate solutions at 25° have a viscosity greater than that of water throughout the range of concentration studied, yet at 0° the viscosity is less than that of water in the range from 0.02 M to about 0.6 M, but greater than that of water in both the more dilute and more concentrated ranges.

$\eta = 1 + 0.01104\sqrt{c} - 0.01790c$	0.05	.001
$\eta = 1 + 0.01104\sqrt{c} - 0.023107c + 0.114591c^2$	.5	.003

Both potassium sulfate and potassium chromate solutions have viscosities greater than that of

water at the same temperature throughout the concentration range, and as usual the relative viscosity at 25° for any given concentration is greater than for the same concentration at 0°.

The viscosities of these solutions relative to that of pure water at the same temperature can be expressed by the Jones and Dole equation: $\eta = 1 + A\sqrt{c} \pm Bc$ as follows:

Silver nitrate at 25°: $\eta = 1 + 0.0063\sqrt{c} + 0.04517c$ valid up to 0.1 M

at 0°: $\eta = 1 + 0.00515\sqrt{c} - 0.03542c$ valid up to 0.05 M

Potassium sulfate at 25°: $\eta = 1 + 0.01406\sqrt{c} + 0.19350c$ valid up to 0.1 M

at 0°: $\eta = 1 + 0.01216\sqrt{c} + 0.03390c$ valid up to 0.05 M

Potassium chromate at 25°: $\eta = 1 + 0.013305\sqrt{c} + 0.1521c$ valid up to 0.1 M

at 0°: $\eta = 1 + 0.01104\sqrt{c} - 0.01790c$ valid up to 0.05 M

The following table gives a comparison of the values of the coefficients of the square root term (A) determined experimentally with that computed by the Falkenhagen and Vernon equation.

TABLE VII

COMPARISON OF THE THEORETICAL AND EXPERIMENTAL VALUES OF THE COEFFICIENT OF THE SQUARE ROOT TERM

	Equivalent conductance used in calcg. cation	anion	A computed	A exptl.
$AgNO_3$ at 25°	61.92	71.44	0.0056	0.0063
$AgNO_3$ at 0°	32.9	40.4	.00505	.00515
K_2SO_4 at 25°	73.52	79.8	.0131	.0140[6]
K_2SO_4 at 0°	40.4	41	.0122	.0121[6]
K_2CrO_4 at 25°	73.52	79.3	.0131	.0133
K_2CrO_4 at 0°	40.4	42.6	.0119	.0110

These results confirm the conclusions drawn in the earlier papers in this series that the Falkenhagen and Vernon equation correctly gives the influence of both valence type and temperature on the values of the coefficient of the square root term.

Although earlier measurements[5] on solutions of these salts have been numerous, none of them extend to sufficiently dilute solutions to give a reliable determination of the A coefficient, or are as precise as our measurements.

Simon[6] has proposed a law, "the molecules of isomorphous substances modify equally the viscosity of water in which they are dissolved, at the same temperature and in certain ranges of concentration." He supports this thesis by his own data on potassium sulfate and potassium chromate. Our data show that Simon's rule is a rough approximation only at 25°, but fails grossly at 0°. Thus, for example, at 0° and at a concentration of 0.2 M the solution of potassium chromate has a viscosity of 0.5% greater than that of water, whereas the solution of potassium sulfate has a viscosity 1.6% greater than that of water. Indeed the coefficient of the linear term actually has a different sign for the two salts.

Summary

1. The absolute densities and the relative viscosities of many solutions of silver nitrate, potassium sulfate and of potassium chromate have been determined at 0° and at 25°.

2. These results confirm the Root equation for densities, the Jones and Dole equation for the viscosities, and the Falkenhagen and Vernon equation for the influence of interionic attraction on the viscosity.

3. These results do not confirm Simon's proposed law that isomorphous substances have the same influence on the viscosity.

The Action of Fluorine upon some Simple Aliphatic Chlorinated Hydrocarbons

BY WILLIAM T. MILLER

In beginning an investigation of the reactions of elementary fluorine with organic compounds it was observed that fluorine prepared without especial precautions may contain considerable amounts of oxygen due to the presence of water in the electrolyte.[1] Such a gaseous mixture is unsuitable for reacting with organic compounds because of its very great oxidizing action. To avoid this difficulty a carefully standardized method of preparation was developed and shown by analysis to yield nearly pure fluorine.[2]

The present paper describes a simple technique for bringing fluorine into reaction with organic compounds,[3] and reports the reactions of some chlorinated hydrocarbons with undiluted fluorine obtained using this procedure. This work is part of a research program designed to establish and investigate the general type reactions of fluorine with organic compounds.

Earlier work with the chlorinated hydrocarbons is rather limited. Humiston[4] found that the reaction between chloroform vapor and fluorine over fluorspar sand yielded free chlorine, phosgene (O_2 present?) and unidentified carbon fluorides as well as considerable carbon and tarry material. Similarly, pure fluorine containing compounds could not be isolated from the reaction between fluorine and tetrachloroethylene in carbon tetrachloride solution. Bockemüller,[5] however, has successfully carried out the fluorination of tetrachloroethylene at −80° in difluorodichloromethane solution and at 0° in carbon tetrachloride using fluorine diluted with carbon dioxide. At −80° difluorotetrachloroethane, fluoropentachloroethane and difluoroöctachlorobutane (characterized only as a liquid b. p. 139–142° at 13 mm.) were obtained as reaction products. At 0° no difluorotetrachloroethane was isolatable and only small amounts of fluoropentachloroethane and difluoroöctachlorobutane were found.

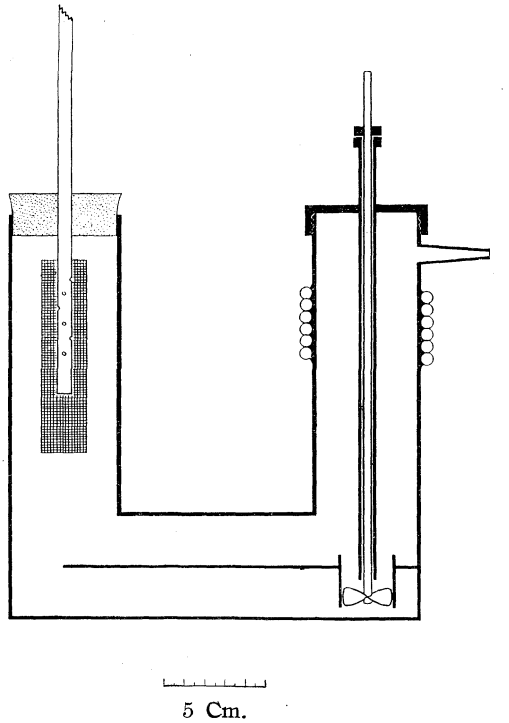
Experimental Results

Materials.—Fluorine was obtained by essentially the procedure previously described.[2]

The chlorinated hydrocarbons were obtained by refractionating C. P. grade materials through a 50 × 1 cm. column packed with glass helices after suitable washing. Fractions with a boiling point range of 0.2° or less were utilized. Boiling points are uncorrected unless otherwise noted.

Samples for halogen analysis were decomposed by fusion with sodium peroxide. Chlorine was then determined gravimetrically and fluorine by titrating aliquots of the carefully neutralized fusion mixture with cerium nitrate solution using a procedure modeled after that of Kurtenacker and Jereuka[6] as modified by Scott and Henne.[7]



5 Cm.

Fig. 1.—Reaction vessel.

General Method.—Reactions were carried out in apparatus of the design shown in Fig. 1, which was constructed from brass tubing with silver soldered joints. One arm of the U-shaped vessel was closed by a rubber stopper which supported the fluorine inlet tube, and the other by a threaded cap which was fitted with a stirrer as indicated in the drawing. The rubber stopper was protected on the inside by a covering of thin copper foil, and in case of a too sudden reaction functioned as a safety

valve. In use the vessels were filled up to the horizontal division. The stirrer then acted as a pump to force a rapid counter-current flow of liquid along the horizontal section which divided the lower part of the vessel. Fluorine was passed in at a 5 amp. rate through a roll of copper gauze[8] and temperature control was obtained by surrounding the reaction vessel with a suitable bath.

Chloroform.—The inertness and high vapor pressure of chloroform make reaction in a suitably packed tube[9] preferable to the procedure used in this work. Small puffs due to sudden reaction occurred at regular intervals. From 150 g. of chloroform which was caused to react for three hours at 0°, 149.5 g. of washed and dried water-white product was obtained. Distillation yielded 21.0 g., b. p. 23–59°, and 0.8 g. of crystalline residue after removal of the main chloroform fraction. Redistillation yielded 8.5 g. of fluorotrichloromethane, b. p. 23.0–25.0° (reported 24.1°).[10] The purified crystalline residue (m. p. 184° subl.) was shown to be hexachloroethane.

Pentachloroethane.—This compound may be heated sufficiently to bring about smooth reaction without at the same time obtaining a too great vapor concentration. From 350 g. of pentachloroethane which was caused to react for ten hours at 90 ± 3°, 297 g. of partially crystalline (at 0°) product was obtained.

Preliminary distillation yielded the following fractions: (1) 7.6 g., b. p. 88–100°; (2) 28.5 g., b. p. 100–130°; (3) 57.4 g., b. p. 130–140° (solid); (4) 11.8 g., b. p. 140–148°; (5) 12.9 g., b. p. 148–156°; (6) 91.6 g., b. p. 156–159°; (7) 45.2 g., oily semi-solid residue. Small amounts of hydrogen chloride gas were evolved during this first distillation. By repeated fractionation the following products were isolated.

sym.-Difluorotetrachloroethane.—5.0 g.: b. p. 91.0–92.0°; $n^{25}D$ 1.4133; m. p. 22–24°. Previously reported: m. p. 24.65°; b. p. 92.8°; $n^{25}D$ 1.4130.[11]

Tetrachloroethylene.—15.6 g.: b. p. 117.5–118.0°. Chlorination in sunlight yielded only hexachloroethane.

Fluoropentachloroethane.—83.1 g.: b. p. 137.0–139.0°. A redistilled sample melted at 99.8–100.0° in a sealed tube. Previously reported: m. p. 101.3°; b. p. 137.9°.[11]

Pentachloroethane.—93.4 g.: b. p. 159.0–160.0°.

Hexachloroethane.—28.5 g.: m. p. 174–181° subl. A recrystallized sample melted 183.0–184.0° subl.; shown to be hexachloroethane.

Decachlorobutane.—Distillation of the residue (8.4 g.), remaining from the above separations, at 2.0 mm. pressure, yielded 4.2 g. of mobile oil, b. p. 100–116°, from which no pure products were isolated. However, by extracting the still residue with hot alcohol and evaporating the filtered extract, 1.9 g. of oily crystalline material was obtained of m. p. 61–69°. This substance was extremely soluble in usual organic solvents but only slightly soluble in glacial formic acid. Three recrystallizations by slow evaporation of its solution in 1:1 glacial formic and acetic acids yielded 0.1 g., m. p. 80.0–81.0°. Calcd. for C_4Cl_{10}: C, 11.92; Cl, 88.07; H, 0.0; mol. wt., 403. Found: C, 12.1; Cl, 88.0; H, 0.11; mol. wt., 397.[12]

Considerably improved recovery was found possible in subsequent runs for which, however, complete separations were not carried out. For example, 343 g. of crude material was obtained from a similar ten-hour reaction starting with 365 g. of pentachloroethane.

Tetrachloroethane.—From 327 g. of tetrachloroethane which was caused to react at 50 ± 2° for fourteen hours, 310 g. of washed and dried product was recovered. Preliminary distillation yielded the following fractions: (1) 7.9 g. to b. p. 90°; (2) 18.4 g., b. p. 90–95°; (3) 5.8 g., b. p. 93–113°; (4) 75.3 g., b. p. 113–118°; (5) 11.4 g., b. p. 118–142°; (6) 168.3 g., b. p. 142–150°; (7) 21.2 g. residue. Continued fractionation yielded:

Trichloroethylene and sym-Difluorotetrachloroethane.—Separation of these substances cannot be accomplished by distillation; however, trichloroethylene was shown to be present and separated by preparing its mercury salt $Hg(CCl{=}CCl_2)_2$, m. p. 82–83°.[13] Difluorotetrachloroethane was obtained slightly impure; m. p. 19–23°, b. p. 92–93°.

Fluorotetrachloroethane.—($CHCl_2CFCl_2$), 67.8 g., b. p. 115.5–116.5°, was obtained from fraction (4). For a redistilled sample of constant b. p. 115.7°: d^{20}_4 1.6218; $n^{20}D$ 1.4487. Previously reported: b. p. 116.6°; d^{20}_4 1.6223; $n^{20}D$ 1.4487.[14]

Tetrachloroethane.—Fraction (6) was principally unreacted tetrachloroethane.

Pentachloroethane.—11.2 g. was obtained from fraction (7); b. p. 159.0–160.0°. No hexachloroethane could be isolated.

Tetrachloroethylene.—From 335 g. of tetrachloroethylene which was caused to react at 0° for twelve hours, 354 g. of washed and dried product was recovered. Complete absorption of the fluorine occurred.

Preliminary distillation yielded the following fractions: (1) 15.4 g., b. p. 40–80°; (2) 58.5 g., b. p. 80–115°; (3) 30.6 g., b. p. 115–120° (the distillation was interrupted at this point because of decomposition to yield some free chlorine, and then continued under reduced pressure without a fractionating column); (4) 138.4 g. to b. p. 125° at 35 mm.; (5) 6.1 g., b. p. 125–155° at 35 mm.; (6) 88.7 g., b. p. 155–173° at 35 mm.; (7) 11.5 g. residue. Careful fractionation yielded the following pure products:

sym-Difluorotetrachloroethane.—55.0 g., b. p. 89–94°. Redistillation yielded 42.7 g., b. p. 92.0–93.0°. A redistilled sample of constant b. p. 92.3° melted at 24.43–24.73° corr.

Fluoropentachloroethane.—49.7 g., b. p. 136.0–138.0°. A redistilled sample melted at 99.0–99.5° in a sealed tube. The yield of fluoropentachloroethane varied considerably between runs and in one case a minimum of 18.0 g. was obtained together with 40.0 g. $C_2F_2Cl_4$ and 50.5 g. $C_4F_2Cl_8$.

Difluoroöctachlorobutane.—(Presumably 1,4-), 66.0 g., m. p. 4.0–5.0°; b. p. 152.5° at 20.0 mm.; $n^{20}D$ 1.5256; d^{20}_4 1.9272: Calcd. for $C_4Cl_8F_2$: Cl, 76.7%; MR_D 59.39.[15] Found: Cl, 76.6%; MR_D 58.86.

A residue of 11.1 g. remained from the above separations, b. p. principally 102–130° at 1 mm.

Tetrachloroethylene in Trifluorotrichloroethane Solution.—Sixty-five grams of tetrachloroethlyene dissolved in 150 cc. of trifluorotrichloroethane[16] was caused to react with a slight excess of fluorine at 0°. Careful fractionation of two such reaction products yielded: 46.9 g. of *difluorotetrachloroethane*, b. p. 91–93°; 10.1 g. of *fluoropentachloroethane*, b. p. 137–138°; 49.5 g. of *difluorooctachlorobutane*, b. p. 152–153° at 20 mm. *Hexachloroethane* also was identified, but was present only as a trace.

Trichloroethylene.—From 340 g. of trichloroethylene which was caused to react at 0° for ten hours, 347 g. of washed and dried product was obtained. Preliminary distillation yielded: (1) Approximately 5 cc. of liquid uncondensed by 11° cooling water but retained by a dry-ice cooled trap; (2) 10.0 g., b. p. 32–40°; (3) 4.6 g., b. p. 40–65°; (4) 40.5 g., b. p. 65–85.5°; (5) 153.9 g., b. p. 85.5–86.5°; (6) 15.6 g., b. p. 86.5–114.0° (mostly 113–114°); (7) 17.7 g., b. p. 48–80° at 93 mm.; (8) 11.6 g., to b. p. 123° at 25 mm.; (9) 48.0 g., b. p. 123–125.5° at 25 mm.; (10) 13.4 g. brown viscous residue.

Fractions (1) and (2) were brominated in sunlight. Distillation of the product yielded 3 g., b. p. 31.0–32.0°, $n^{20}D$ 1.338; an intermediate fraction of 3.5 g. to b. p. 160°; and 0.9 g., b. p. 160–162°, $n^{23}D$ 1.5194, which contained bromine. Reported for fluoro-1,2-dichloro-1,2-dibromoethane: b. p. 163.5°; $n^{23}D$ 1.5160.[14]

Refractionation of samples (4) to (7) inclusive yielded: *1,2-Difluoro-1,2,2-trichloroethane and fluorotrichloroethylene*, 14.9 g., b. p. 71.5–73.0°. Redistilled sample: b. p. 72.3–72.6°; $n^{20}D$ 1.3967; d^{20}_4 1.5555. Previously reported for CHClF—CCl_2F: b. p. 72.5; d^{20}_4 1.5587; $n^{20}D$ 1.3942;[14] for CFCl=CCl_2: b. p. 72.1°; d^{20}_4 1.5541; $n^{20}D$ 1.4360.[11] Chlorination of this product yielded *sym*-difluorotetrachloroethane principally (b. p. 92.0–92.3°, m. p. 22–24°, $n^{25}D$ 1.4135) and a small residue of fluoropentachloroethane (m. p. 75–82°, b. p. 135°).

Fluorotetrachloroethanes.—CHFCl—CCl_3 and $CHCl_2$—$CFCl_2$, 18.7 g.: b. p. 114.0–116.0°. Redistilled sample, b. p. 115.9–116.0°; $n^{20}D$ 1.4488; d^{20}_4 1.6192. Previously reported for CHFCl—CCl_3: b. p. 117.0°; $n^{20}D$ 1.4525;[14] d^{20}_4 1.6253. For $CFCl_2$—$CHCl_2$, see above. Chlorination yielded only fluoropentachloroethane (m. p. 96.0–98.0°).

Hexachlorobutene.—Distillation of sample (9) combined with the residue from the lower boiling fractions yielded: (11) 8.9 g., b. p. 70–122° at 25 mm.; (12) 42.4 g., b. p. 122.0–125.5° at 25 mm.; (13) 5 g. residue. Crystallization of (12) from 30–60° b. p. petroleum ether yielded 20.6 g. of white crystalline material (m. p. 6–9°). Several recrystallizations yielded: 6 g., m. p. 9.5–11.0°; b. p. 125.5° at 25 mm.; $n^{20}D$ 1.5442; d^{20}_4 1.6880. It contained no fluorine. Calcd. for $C_4H_2Cl_6$: C, 18.28; H, 0.76; Cl, 80.94; mol. wt., 262.8; MR_D 50.61. Found: C, 18.3; H, 0.73; Cl, 81.0; mol. wt. (Rast), 261; MR_D 49.17. This substance did not add bromine or chlorine in sunlight, and differs in properties from 1,1,2,3,4,4-hexachlorobutene-2.[17]

The lower melting fraction from sample (12) contained fluorine as well as chlorine.

Octachlorobutane.—Sample (13) partially solidified on cooling to 0° and 2.5 g. of material melting above room temperature was obtained. Several recrystallizations from petroleum ether and from methyl alcohol yielded 1.2 g. of white crystals, m. p. 75.0–76.0°. This compound did not contain fluorine and had no noticeable odor. Calcd. for $C_4H_2Cl_8$: C, 14.40; H, 0.60; Cl, 84.98. Found: C, 14.5; H, 0.65; Cl, 84.7. This substance appeared to have a structure other than 1,1,2,2,3,3,4,4-octachlorobutane.[18]

Trichloroethylene in Trifluorotrichloroethane Solution.—Fifty-five grams of trichloroethylene was dissolved in 160 cc. of trichlorotrifluoroethane[16] and caused to react at 0° for six and one-half hours. The products from three duplicate reactions were combined for distillation which yielded after removal of the solvent to b. p. 50°: (1) 2.9 g., b. p. 50–72°; (2) 29.0 g., b. p. 72–75°; (3) 15.4 g., b. p. 75–114°; (4) 20.9 g., b. p. 114–116°; (5) still residue.

Difluorohexachlorobutane.—Crystallization of sample (5) from 30–60° b. p. petroleum ether with dry-ice cooling yielded 14.6 g. of white crystals, m. p. 47–52°. Several recrystallizations from this solvent and from methyl alcohol yielded 2.5 g., m. p. 55–56°. Calcd. for $C_4H_2F_2Cl_6$: C, 16.01; H, 0.67; F, 12.63; Cl, 70.74. Found: C, 16.0; H, 0.67; F, 12.8; Cl, 70.8.

Lower melting isomers of difluorohexachlorobutane were indicated as being present in the soluble residue from the above separation by distillation, determination of molecular refraction and analysis.

Discussion

The physical as well as chemical properties of fluorine must be taken into account in considering actual reaction conditions. It has been found to be insoluble in carbon tetrachloride within the limit of measurement[19] and in general a slight solubility for fluorine in compounds of this type may be expected from its low boiling point (−188°). Consequently, the reactions observed in this work occur principally in the gas phase and at the liquid surface under essentially "non-ionic" conditions,[20] and radical type mechanisms in which the fluorine molecule is split symmetrically are considered to be of greatest importance. It is suggested that some of the observed differences of kind between the reactions of fluorine with organic compounds and the reactions of the other halogens may be found in this direction.

In addition to the expected substitution products which were obtained from chloroform and pentachloroethane, hexachloroethane and dodecachlorobutane were isolated in small amounts. This converse of the Wurtz–Fittig type of reaction has also been observed to occur when fluoroform reacts by sparking with fluorine.[21]

With olefins the dimerization observed by Bockemüller[5] in the case of tetrachloroethylene was confirmed and also established for trichloroethylene. The products obtained may be termed *dimer addition products*, and it is assumed that in compounds of this type the fluorine atoms are in the 1,4-positions. Chlorine fluoride was formed in the reaction mixtures and substitution and addition products resulting from its action were isolated. Chlorine fluoride seems to add normally to ethylenic compounds without the formation of dimers since no monofluorobutane derivatives were found. In fact, the formation of dimer addition products from simple olefins appears to be a type of reaction peculiar to fluorine among the halogens.

Summary

The reactions of some simple chlorinated aliphatic organic compounds with fluorine have been studied. Using pure fluorine, charring was not observed in any case and reactions were easily controlled. The types of reaction observed were: substitution of hydrogen attached to saturated carbon; substitution of hydrogen attached to double bonded carbon; addition to ethylenic bonds; dimerization of saturated molecules by removal of two hydrogens; dimerization of ethylene derivatives accompanied by the addition of two fluorine atoms; secondary reactions due to the presence of chlorine fluoride.

The reaction conditions used and results obtained are discussed briefly. Essentially "nonionic" conditions prevailed and the hypothesis was advanced that radical type mechanisms of reaction in which the fluorine molecule is split symmetrically are of greatest significance.

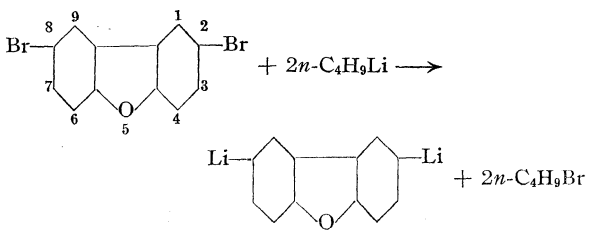
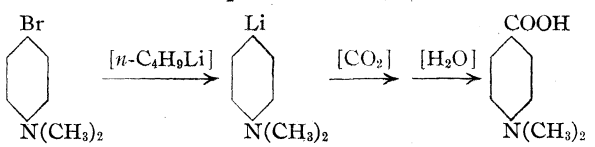
Halogen–Metal Interconversion with *m*- and *p*-Bromodimethylanilines[1]

BY HENRY GILMAN AND IRVING BANNER

The two chief transformations which resulted when an organolithium compound reacted with a nuclear-brominated aryl-alkyl or diaryl ether were: (1) metalation or replacement of a nuclear hydrogen by lithium[2] and (2) halogen–metal interconversion or the replacement of nuclear halogen by lithium.[2,3] The metalation occurred when the halogen was *para* to the ether linkage; and halogen–metal interconversion took place when the halogen was *ortho* to the ether linkage. Subsequently[4] it was shown that it was not necessary to have bromine *ortho* to an ether linkage to have a halogen–metal interconversion, for 2,8-dibromodibenzofuran and *n*-butyllithium gave an excellent yield of 2,8-dibenzodifurylenedilithium. When bromine is *meta* to the ether linkage as in 3-bromodibenzofuran, both metalation and interconversion probably occur, for the acids isolated subsequent to carbonation were 3-dibenzofurancarboxylic acid and 4-dibenzofurancarboxylic acid.[4] The reaction with 1-bromodibenzofuran, in which the bromine is also *meta* to the ether linkage, is exclusively interconversion.[5] Actually, as the accompanying paper[6] on methoxy-halogenodibenzofurans illustrates, interconversion is the predominant reaction of bromo ethers.



We are reporting at this time the reaction of *n*-butyllithium with *m*- and *p*-bromodimethylanilines. Reaction was to be expected because of the related activating effects of dialkylamino and alkoxy groups. In each case a halogen–metal interconversion took place.



Unlike the case with *p*-bromoanisole, there was

no evidence of significant nuclear metalation. The reaction may prove of synthetic value with amines having nuclear halogen, as already has been demonstrated with halogenated carbazoles.[5]

Not only does *p*-bromodimethylaniline react differently from *p*-bromoanisole toward *n*-butyllithium, but it also undergoes a different reaction with another metalating agent, mercuric acetate. Whitmore[7] obtained a 74% yield of N,N-dimethyl-4-bromo-2-acetoxymercurianiline by treating *p*-bromodimethylaniline with mercuric acetate in alcohol at low temperatures for several days.

Experimental Part

Preparation of *o*- and *m*-Bromodimethylanilines.—These bromodimethylanilines were prepared by customary reactions but in yields somewhat higher than those reported.[8]

To a mixture of 100 g. (0.58 mole) of *o*-bromoaniline and 100 cc. of water, contained in a 1-liter, three-necked flask provided with a mechanical stirrer, was added three equivalents (219 g.) of methyl sulfate in the following manner. One equivalent of the methyl sulfate was added with stirring and the mixture allowed to stand until homogeneity was reached. The contents were then carefully neutralized with a 25% solution of potassium hydroxide, during which cooling was effected in an ice-bath. The second equivalent of methyl sulfate was then added and the process repeated, except that a slight excess of base was added. Finally, the third equivalent was added, and the mixture was allowed to stand for one hour after stirring. The alkaline mixture was extracted with ether, and the ethereal extracts were washed with water, dried over potassium carbonate and then distilled at 100–101° (12 mm.). The yield was 81.5 g. or 70%.

The *m*-bromodimethylaniline was prepared in a related manner from 100 g. (0.58 mole) of *m*-bromoaniline and 219 g. of methyl sulfate. The yield of product distilling at 118–119° (8 mm.) was 63 g. or 54%. The melting point of the picrate (134–135°) agreed with that described in the literature.[8]

Pure *p*-bromodimethylaniline was obtained by recrystallization of a commercial product from alcohol. All samples of the bromodimethylanilines were shown to be free of primary and secondary amines. Houben and co-workers[9] have shown that some N-ethylanilines when treated first with ethylmagnesium iodide to form –N(C_2H_5)(MgI) types, and then with carbon dioxide at 225° for twenty-four hours, undergo nuclear carboxylation.

***m*-Bromodimethylaniline and *n*-Butyllithium.**—A solution of 8 g. (0.04 mole) of *m*-bromodimethylaniline in 50 cc. of ether was added to a filtered solution of 0.055 mole of *n*-butyllithium.[10a] The reaction was carried out in a nitrogen atmosphere and in a flask provided with a mechanical stirrer. After refluxing for twenty hours, the mixture was cooled, and then carbonated by adding it jet-wise to solid carbon dioxide.[10b]

The resulting mixture was extracted thoroughly with a 5% potassium hydroxide solution. The ether layer was washed with a little water and the washings combined with the aqueous layer.

The aqueous layer was concentrated, made slightly acidic with acetic acid, and then exhaustively extracted with an ether–chloroform mixture. After drying the ether–chloroform solution over sodium sulfate, the solvents were removed by distillation. The brownish oily residue was crystallized from water to yield 1.7 g. or 26% of *m*-dimethylaminobenzoic acid melting at 150–150.5°. The melting point reported[11] is 151°. The acid was derivatized by preparing the methyl ester hydrochloride, which melted at 175–176°.[12]

The yellowish ether layer yielded 1.1 g. of an as yet unidentified oil distilling between 90–115° (13 mm.).

In a check experiment, the yield of *m*-dimethylaminobenzoic acid was 32%, and the yield of oil from the ether solution was 1.3 g.

***p*-Bromodimethylaniline and *n*-Butyllithium.**—A reaction mixture of 8 g. (0.04 mole) of *p*-bromodimethylaniline in 50 cc. of ether and 0.055 mole of *n*-butyllithium in ether was refluxed for twenty hours, then carbonated, and worked up by the general procedure described for *m*-bromodimethylaniline. The yield of *p*-dimethylaminobenzoic acid (m. p. 240–241°) was 41%, and the compound was derivatized as the methyl ester[13] (m. p. 102°). From the ether layer was obtained an unidentified oil distilling between 100–130° (20 mm.). This oil did not yield a picrate of *p*-bromodimethylaniline, a compound which forms readily from pure reactants in ethanol and melts at 140–141°.

In a check experiment, the yield of *p*-dimethylaminobenzoic acid was 56%, and the yield of oil from the ether extracts was 1.5 g.

Experiments were not carried out with either *m*- or *p*-bromodimethylaniline to establish optimal conditions for the halogen–metal interconversion. However, it is highly probable that the yields can be improved by reducing the time of refluxing with the *n*-butyllithium. In this connection, it is interesting to note that forty seconds are sufficient to give a 23% interconversion in the reaction between 4-bromodibenzofuran and *n*-butyllithium in ether.

Summary

A halogen–metal interconversion takes place in the reaction of *m*- and *p*-bromodimethylanilines with *n*-butyllithium to give *m*- and *p*-dimethylaminophenyllithiums, respectively.

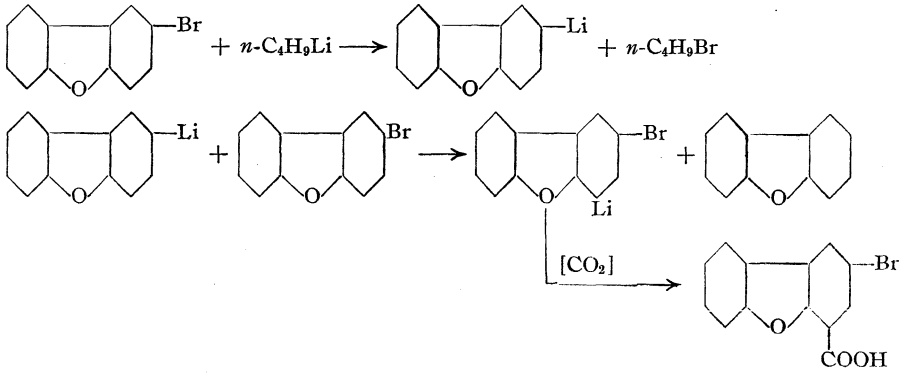
Dibenzofuran. XVI. The Two-Stage Metalation of 2-Bromodibenzofuran[1]

BY HENRY GILMAN, WRIGHT LANGHAM AND H. B. WILLIS

In an earlier study,[2] incidental to an attempt to prepare 2-bromo-6-dibenzofurancarboxylic acid, it was shown that metalation of 2-bromodibenzofuran by *n*-butyllithium gave, subsequent to carbonation, 2-bromo-4-dibenzofurancarboxylic acid. The isolation from that reaction of appreciable quantities of dibenzofuran suggested that a halogen-metal interconversion first took place and that this reaction was followed by metalation as follows.



We are now presenting evidence in support of this two-stage metalation. When 2-bromodibenzofuran is treated with *n*-butyllithium for a short time, reaction (I) occurs predominantly, and carbonation results in the formation of excellent yields of 2-dibenzofurancarboxylic acid to the exclusion of any 2-bromo-4-dibenzofurancarboxylic acid. The bromo-acid probably results in accordance with reaction (II) when the reaction mixture (with equivalent quantities of reactants) is heated for a relatively long period.[2]

The preliminary reaction involving a halogen-metal interconversion is now known to take place quite readily when the halogen is bromine or iodine. This interconversion reaction is not limited to halogenated ethers, but has been observed with simple and multiple halogenated derivatives of aromatic hydrocarbons[3] and with *m*- and *p*-bromodimethylanilines.[4] The first report on such a reaction with *n*-butyllithium was probably the study by Marvel and co-workers[5] with *o*- and *m*-bromotoluenes.[6] The other reported studies on the interconversion reaction have been with *ortho*-bromo ethers.[7]

It is uncertain whether a halogen–metal interconversion precedes all metalations of halogen containing compounds. An examination of the results of metalation, particularly by *n*-butyllithium, of bromo- and iodo-ethers, reveals that in almost every case a halogen–metal interconversion first takes place.[8] However, there is no unequivocal case for interconversion preceding metalation when the nuclear halogen is chlorine or fluorine. In such cases, the rate of direct metalation is apparently decidedly greater than the rate of halogen–metal interconversion.

Two other illustrations of interconversion preceding metalation are the reactions of *p*-bromoanisole and *p*-iodoanisole with *n*-butyllithium. Under conditions reported earlier,[9] carbonation

(5) Marvel, Hager and Coffman, *ibid.*, **49**, 2323 (1927).

(6) Under their conditions (Ref. 5) of long-timed reactions in sealed tubes and with petroleum ether as a medium, they observed that *p*-bromotoluene and *n*-butyllithium gave *p*-*n*-butyltoluene on hydrolysis. With our experimental conditions (short-time, non-sealed containers, and ether as a medium) interconversion took place as usual to give *p*-toluic acid subsequent to carbonation.

(7) Citations to the earlier literature are given in Ref. 3.

(8) Illustrations with some bromo-ethers of dibenzofuran are given in the accompanying paper by Gilman, Swislowsky and Brown, THIS JOURNAL, **62**, 348 (1940).

(9) Gilman and Jacoby, *J. Org. Chem.*, **3**, 108 (1938); Wittig, Pockels and Dröge, *Ber.*, **71**, 1903 (1938); Gilman, Langham and Jacoby, THIS JOURNAL, **61**, 106 (1939).

of the reaction mixture of *p*-bromoanisole and *n*-butyllithium gave 5-bromo-2-methoxybenzoic acid [reaction (IV)]. We are now reporting that by employing a large excess of *n*-butyllithium, and milder conditions, the *p*-methoxybenzoic acid is formed exclusively and in good yields [reaction (III)].

When equivalent quantities of halide and organolithium compound are used, the reaction time is the most important factor in determining the products which result. This is strikingly illustrated in the reaction of *p*-iodoanisole with *n*-butyllithium. In this case, the *p*-methoxybenzoic is formed predominantly if not exclusively in thirty minutes, whereas after six hours only 5-iodo-2-methoxybenzoic acid is isolated. Also, when equivalent quantities of *p*-bromoanisole and *n*-butyllithium are added dropwise and separately to a reaction chamber and then allowed to react but one minute prior to carbonation, a 10% yield of *p*-methoxybenzoic acid (free from any bromo acid) results. It is rather certain that even with a long period of reaction, interconversion is the main reaction when a large excess of *n*-butyllithium is used.

Experimental Part

2-Bromodibenzofuran and *n*-Butyllithium.—To a solution of 2 g. (0.0081 mole) of 2-bromodibenzofuran in 25 cc. of benzene was added approximately 0.009 mole of *n*-butyllithium in 25 cc. of ether. The solution was refluxed for thirty minutes, and then poured upon dry-ice and ether. The yield of the crude 2-dibenzofurancarboxylic acid was 1.7 g. (87.3%). One recrystallization from glacial acetic acid gave a product which melted at 241–242°.

The methyl ester, prepared from the acid and diazomethane in ether, melted at 81–82° after crystallization from dilute alcohol. A mixed melting point with an authentic specimen of methyl 2-dibenzofurancarboxylate was not depressed. Incidentally, the melting point of methyl 2-dibenzofurancarboxylate is 82–83° and not 73–74° as reported previously.[10]

Anal. Calcd. for $C_{14}H_{10}O_3$: OCH_3, 13.72. Found: OCH_3, 13.45.

In a check experiment, the yield of 2-dibenzofurancarboxylic acid was 84.5%.

In another experiment 2-dibenzofuryllithium was prepared as described above, from 0.0081 mole of 2-bromodibenzofuran and 0.009 mole of *n*-butyllithium, and after fifteen minutes an additional 0.032 mole of 2-bromodibenzofuran was added. Upon carbonation after six hours of refluxing, the only acid isolated was 2-bromo-4-dibenzofurancarboxylic acid.

With three equivalents of *n*-butyllithium to one of 2-bromodibenzofuran, in a 1:1 ether–benzene mixture heated for six hours at 50°, the yield of 2-dibenzofurancarboxylic acid was 64%, and no 2-bromo-4-dibenzofurancarboxylic acid was isolated.

p-Bromoanisole and *n*-Butyllithium.—When an ether solution of equivalent quantities of *p*-bromoanisole (0.1 mole) and *n*-butyllithium was heated at 34° for twenty hours and then carbonated, the acids obtained were *p*-methoxybenzoic (10%) and 5-bromo-2-methoxybenzoic (10%). Under corresponding conditions, but with a more concentrated mixture which permitted refluxing at 50°, the yield of 5-bromo-2-methoxybenzoic acid was 28%. In a third experiment, a mixture of 0.05 mole of *p*-bromoanisole and 0.05 mole of *n*-butyllithium in a 1:1 ether–benzene solvent was refluxed for twenty hours at 50°, and then carbonated to yield 22% of 5-bromo-2-methoxybenzoic acid.

In a fourth experiment, two equivalents of *p*-bromoanisole were used. A mixture of 0.18 mole of *p*-bromoanisole and 0.09 mole of *n*-butyllithium in 150 cc. of ether was refluxed for a few minutes; then 150 cc. of dry benzene was added and the temperature of refluxing was 50°. Carbonation of 50-cc. aliquots of the reaction mixture after refluxing for one hour, five hours and ten hours gave 47, 47, and 52%, respectively, of 5-bromo-2-methoxybenzoic acid. Carbonation of the remainder of the reaction mixture after a total of twenty hours of refluxing reduced the average yield to 45%. Possibly some of the organolithium compound is used up in ether cleavage in the extended period of refluxing.

In a fifth experiment two equivalents of *n*-butyllithium were used and the reaction was run in ether at room temperature for ten minutes. From 0.02 mole of *p*-bromoanisole and 0.04 mole of *n*-butyllithium there was obtained 1.6 g. (52%) of crude *p*-methoxybenzoic acid (m. p. 168–171°). Pure *p*-methoxybenzoic acid melts at 183–184°. The crude acid gave a qualitative test for bromine, but no bromo acid was isolated.

In a sixth experiment 0.02 mole of *p*-bromoanisole and 0.02 mole of *n*-butyllithium were added separately and dropwise to a reaction chamber and carbonation was effected at intervals after the reactants had been in contact for one minute. This method gave a total yield of 0.3 g. (10%) of *p*-methoxybenzoic acid which melted at 178–180° and showed no qualitative test for bromine.

***p*-Iodoanisole and *n*-Butyllithium.**—A solution of 0.03 mole of *p*-iodoanisole and 0.03 mole of *n*-butyllithium in 100 cc. of ether was allowed to stand for thirty minutes with no external heating. Carbonation of a 25-cc. aliquot gave a 52% yield of crude *p*-methoxybenzoic acid melting at 176–180°. After one hour of refluxing, carbonation of a 25-cc. aliquot gave a 52% yield of crude *p*-methoxybenzoic acid melting at 172–175°. After six hours of heating, a 25-cc. aliquot yielded 0.45 g. of acidic material with a melting point range of 154–165°. At the end of ten hours of heating there was obtained a 35% yield of 5-iodo-2-methoxybenzoic acid.

The 5-iodo-2-methoxybenzoic acid was identified by a mixed melting point determination with an authentic specimen.[11]

Anal. Calcd. for $C_8H_7O_3I$: neut. equiv., 278. Found: neut. equiv., 278.

(10) Gilman and Van Ess, THIS JOURNAL, **61**, 1365 (1939).

(11) For the preparation of 5-iodo-2-hydroxybenzoic acid see Hübner, *Ber.*, **12** 1347 (1879); Goldberg, *J. prakt. Chem.*, [2] **19**, 368 (1879).

In a second experiment, carbonation at the end of fifteen minutes gave a 50% yield of crude *p*-methoxybenzoic acid, melting at 170–174°. From a third experiment in which the reaction mixture was heated at 50° in a 1:1 ether–benzene solvent for five hours, the yield of pure 5-iodo-2-methoxybenzoic acid was 24%.

Orienting experiments have shown that it is possible to metalate alcohols (like benzyl alcohol), phenols, and primary and secondary amines. Also, halogen–metal interconversions take place with a variety of bromo and iodo compounds containing, in addition, other functional groups like amino, hydroxy, and acids and their derivatives. For example, *o*-bromophenol and *n*-butyllithium give, subsequent to carbonation and hydrolysis, a 60% yield of salicylic acid; and under corresponding conditions *o*-bromoaniline gives a 36% yield of anthranilic acid.

Summary

It has been shown that the metalations reported previously of some halogenated ethers involve a two-stage procedure. First, there is a halogen–metal interconversion, and, second, the organometallic compound formed in this manner then metalates the original halogenated ether. The interconversion reaction is more rapid. For example, in fifteen minutes, 2-bromodibenzofuran reacts with *n*-butyllithium to give excellent yields of 2-dibenzofuryllithium. Upon protracted refluxing, this RLi compound then metalates 2-bromodibenzofuran to give 2-bromo-4-dibenzofuryllithium.

Related observations are reported with *p*-bromoanisole and *p*-iodoanisole.

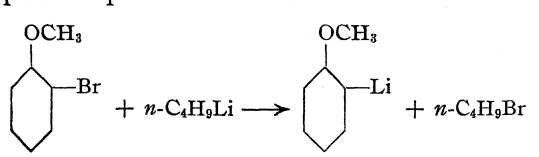
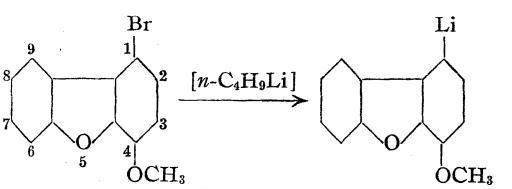
Dibenzofuran. XVII. The Reaction of Bromo-Ethers with *n*-Butyllithium[1]

BY HENRY GILMAN, JACK SWISLOWSKY AND GEORGE E. BROWN

The recent availability of a series of bromomethoxy derivatives of dibenzofuran has provided essential material for an examination of the scope of halogen–metal interconversion reactions. In the first published illustrations of this reaction with bromo-ethers,[2] the bromine replaced by lithium was always *ortho* to an ether linkage. A typical simple illustration is



We are now reporting reactions of *n*-butyllithium with a series of bromomethoxydibenzofurans in which the bromine atoms are disposed in most of the important positions with respect to the ether linkages. In these eight compounds, a bromine atom is not only *ortho*, *meta* and *para* to a methoxy group, but also *ortho* and *meta* to the oxygen bridge in dibenzofuran. We have found that in every case the predominant reaction is a halogen–metal interconversion.



Some of the reactions reported are synthetically valuable. For example, 1-bromo-3,4-dimethoxydibenzofuran has not as yet yielded either an organomagnesium[3] or an organolithium[4] compound when treated with the respective metals under general conditions for the formation of these organometallic compounds. However, *n*-butyllithium reacts promptly with 1-bromo-3,4-dimethoxydibenzofuran to give a satisfactory yield of 3,4-dimethoxy-1-dibenzofuryllithium.

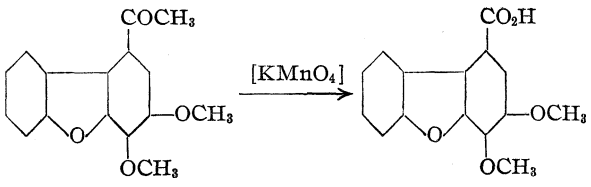
The structures of the several reaction products were established by conventional procedures involving carbonation to the corresponding acids which were in turn compared with authentic specimens. The acid resulting from 1-bromo-3,4-dimethoxydibenzofuran was shown to be identical with 3,4-dimethoxy-1-dibenzofurancarboxylic acid prepared as follows

(1) Paper XVI, THIS JOURNAL, **62**, 346 (1940).

(2) General references on this reaction are contained in the accompanying papers: (a) Gilman and Banner, *ibid.*, **62** 344 (1940), and (b) Gilman, Langham and Willis, *ibid.*, **62**, 346 (1940).

(3) The activated magnesium–copper alloy was not used.

(4) Gilman, Zoellner and Selby, THIS JOURNAL, **55**, 1252 (1933).



Experimental Part

1-Bromo-2-methoxydibenzofuran.—A solution of *n*-butyllithium, prepared from 4.15 g. (0.03 mole) of *n*-butyl bromide and 0.5 g. (0.07 g. atom) of lithium in 20 cc. of ether, was added at once to 2.77 g. (0.01 mole) of 1-bromo-2-methoxydibenzofuran[5] in 40 cc. of warm benzene. A white precipitate formed immediately and the solvent began to reflux gently. Heat was applied, and after ten minutes of refluxing with stirring the mixture was carbonated by addition to solid carbon dioxide. After removal of the solvent by distillation the residue was extracted with hot potassium hydroxide solution, from which was obtained 1.8 g. (73.5%) of acid melting at 135–140°. Two recrystallizations from dilute ethanol gave 1.15 g. (47%) of acid melting at 155–157°. A mixed melting point with an authentic sample of 2-methoxy-1-dibenzofurancarboxylic acid (m. p., 156–157°)[5] showed no depression. The methyl ester, prepared from the acid and diazomethane in ether, melted at 100° and did not depress the melting point of an authentic sample of methyl 2-methoxy-1-dibenzofurancarboxylate (m. p. 99.5–100°).[6]

1-Bromo-4-methoxydibenzofuran.—A solution of *n*-butyllithium prepared from 0.11 g. (0.16 g. atom) of lithium and 10 g. (0.073 mole) of *n*-butyl bromide in 50 cc. of dry ether was filtered rapidly into a solution of 13.85 g. (0.05 mole) of 1-bromo-4-methoxydibenzofuran in 100 cc. of dry benzene. A gray precipitate formed immediately. The suspension was refluxed with stirring for one-half hour, and then carbonated by pouring upon crushed solid carbon dioxide. On working up the mixture in a customary manner there was obtained 8.3 g. (68.5%) of 4-methoxy-1-dibenzofurancarboxylic acid (m. p. 278°). Identification was completed in two ways: first, by a mixed melting point determination with an authentic specimen of the acid; and, second, by conversion to methyl 4-methoxy-1-dibenzofurancarboxylate and comparison of this ester with one prepared from an authentic specimen of the corresponding acid.[7]

Methyl 4-Methoxy-1-dibenzofurancarboxylate.—Addition of an excess of diazomethane solution to a suspension of 0.1 g. of 4-bromo-1-dibenzofurancarboxylic acid in ether gave a quantitative yield of methyl 4-methoxy-1-dibenzofurancarboxylate. This ester melted at 125° after crystallization from methanol.

Anal. Calcd. for $C_{15}H_{12}O_4$: methoxyl, 24.22. Found: methoxyl, 24.18.

3-Bromo-2-methoxydibenzofuran.—An ether solution of *n*-butyllithium (0.015 mole) was added in one portion to 1.39 g. (0.005 mole) of 3-bromo-2-methoxydibenzofuran[5] in 60 cc. of warm benzene. The mixture was stirred and refluxed for fifteen minutes and then carbonated. The 2-methoxy-3-dibenzofurancarboxylic acid isolated melted at 197–199° and weighed 0.710 g. (58.6%). Recrystallization from glacial acetic acid yielded 0.490 g. (40.5%) of acid melting at 206–207°. A mixed melting point with an authentic specimen of the acid (m. p. 206–207°)[5] showed no depression. The methyl 2-methoxy-3-dibenzofurancarboxylate obtained from the acid resulting from the interconversion reaction was shown to be identical with an authentic specimen.[6]

In another experiment in which only one-half the amount of *n*-butyllithium was used and where the time of refluxing was ten minutes, the yield of crude acid was 24.5%.

6-Bromo-4-methoxydibenzofuran.—To 60 mg. (0.000216 mole) of 6-bromo-4-methoxydibenzofuran[8] dissolved in 2.4 cc. of warm benzene was added 1.2 cc. of an ether solution of *n*-butyllithium (0.0005 mole), and the solution was stirred and heated. Just before the boiling point was reached, a white precipitate appeared which gradually became heavier. Carbonation was carried out at the end of fifteen minutes. There was obtained 30 mg. (57.4%) of crude acid which sintered at 210° and melted at 223–225° with decomposition. The pure 4-methoxy-6-dibenzofurancarboxylic acid melts at 243–245°.[9]

The methyl ester prepared from the acid and diazomethane did not depress the melting point of authentic methyl 4-methoxy-6-dibenzofurancarboxylate (m. p. 123–124°).

1-Bromo-3,4-dimethoxydibenzofuran.—A mixture prepared from *n*-butyllithium (0.03 mole) in ether and 4.6 g. (0.015 mole) of 1-bromo-3,4-dimethoxydibenzofuran[8] in 100 cc. of benzene was refluxed with stirring for one-half hour. Carbonation gave 2.22 g. (54%) of acid melting at 234–235°. Crystallization from ethanol yielded needles melting at 236°. The acid was shown to be 3,4-dimethoxy-1-dibenzofurancarboxylic acid by the method of mixed melting points. In addition, the methyl ester was shown by the same process to be identical with an authentic specimen prepared by the oxidation of 1-acetyl-3,4-dimethoxydibenzofuran followed by methylation.[8,10]

3,4-Dimethoxy-1-dibenzofurancarboxylic Acid.—A suspension of 0.27 g. (0.001 mole) of 1-acetyl-3,4-dimethoxydibenzofuran in 75 cc. of water was oxidized by alkaline permanganate to give a 50% yield of 3,4-dimethoxy-1-dibenzofurancarboxylic acid. The acid melted at 236° after crystallization from ethanol.

Anal. Calcd. for $C_{15}H_{12}O_5$: methoxyl, 22.79. Found: methoxyl, 22.40.

Methyl 3,4-Dimethoxy-1-dibenzofurancarboxylate.—This ester was prepared in a quantitative yield from the corresponding acid and diazomethane. On crystallization from dilute ethanol the ester melted at 78°.

Anal. Calcd. for $C_{16}H_{14}O_5$: methoxyl, 32.55. Found: methoxyl, 32.40.

1-Bromo-4,6-dimethoxydibenzofuran.—An ether solution of 0.008 mole of *n*-butyllithium was added to a solution of 2.15 g. (0.007 mole) of 1-bromo-4,6-dimethoxydibenzofuran[11] in 60 cc. of benzene. After refluxing and

(5) Kindly provided by P. R. Van Ess.

(10) Gilman and Cheney, THIS JOURNAL, **61**, 3149 (1939).
(11) Kindly provided by T. H. Cook.

stirring for one-half hour, the mixture was carbonated to give a 60% yield of acid melting at 296°. The identity of the acid as 4,6-dimethoxy-1-dibenzofurancarboxylic acid was established by converting it to the methyl ester and comparing this ester with an authentic specimen.[10]

1,9 - Dibromo - 2,8 - dimethoxydibenzofuran.—This dibromo compound was prepared by bromination of 2,8-dihydroxydibenzofuran and subsequent methylation.[12] The 1,9-positions of the bromine atoms are assigned provisionally on the basis of the behavior of the related 2-hydroxydibenzofuran upon bromination.[13]

To 1.5 g. (0.00389 mole) of the dibromo compound dissolved in 120 cc. of benzene was added an ether solution of *n*-butyllithium (0.035 mole). The mixture was refluxed and stirred for two hours and then carbonated to yield 820 mg. (66.6%) of acid melting at 210–220°. Two recrystallizations from glacial acetic acid raised the melting point to 270–271°, and a mixed melting point with the acid obtained from direct dimetalation of 2,8-dimethoxydibenzofuran[12] followed by carbonation was not depressed. The methyl ester, prepared from the acid, methanol and dry hydrogen chloride melted at 128–129° after crystallization from methanol.

This dimethyl 2,8-dimethoxy-1,9-dibenzofurandicarboxylate did not depress the melting point of the dimethyl ester[12] obtained from the 2,8-dimethoxydibenzofurandicarboxylic acid resulting from direct dimetalation of 2,8-dimethoxydibenzofuran.

3,7-Dibromo-2,8-dimethoxydibenzofuran.—To 0.7 g. (0.00183 mole) of the dibromo-2,8-dimethoxydibenzofuran melting at 260–261° and tentatively designated as the 3,7-isomer,[12] dissolved in 60 cc. of benzene was added an ether solution of 0.018 mole of *n*-butyllithium. After stirring and refluxing for seven hours, the mixture was carbonated. The resulting acidic material weighed 650 mg. and from this was isolated by sublimation several tenths of a gram of benzoic acid.[14] The residual acid, 2,8-dimethoxy-3,7-dibenzofurandicarboxylic acid, was recrystallized three times from glacial acetic acid to yield 0.1 g. (17.5%) of needles which melted at 290° with decomposition.

Anal. Calcd. for $C_{16}H_{12}O_7$: methoxyl, 19.62. Found: methoxyl, 19.62.

Thirty milligrams of the dimethoxy-dibasic acid was esterified by methanol and dry hydrogen chloride to yield 18 mg. (50%) of dimethyl 2,8-dimethoxy-3,7-dibenzofurandicarboxylate. This ester crystallized from methanol as needles melting at 183–184°.

Anal. Calcd. for $C_{18}H_{16}O_7$: methoxyl, 36.05. Found: methoxyl, 36.50.

(12) Unpublished studies.

(13) Gilman and Van Ess, THIS JOURNAL, **61**, 1365 (1939).

Summary

The halogen–metal interconversion reaction has been shown to be the predominant reaction with a series of bromo-ethers of dibenzofuran in which a bromine is not only *ortho*, *meta* and *para* to a methoxy group, but also *ortho* and *meta* to the oxygen bridge.

Although no organomagnesium or organolithium compound can be prepared from 1-bromo-3,4-dimethoxydibenzofuran with magnesium or lithium, respectively, under ordinary conditions, a reaction takes place readily and satisfactorily with *n*-butyllithium to give 3,4-dimethoxy-1-dibenzofuryllithium.

(14) It is known that benzene and *n*-butyllithium give on protracted refluxing small quantities of phenyllithium, the carbonation of which yields benzoic acid.

The Synthesis of 3,5-Difluoro- and 3-Fluoro-5-iodo-*dl*-tyrosine

BY JAMES ENGLISH, JR., JAMES F. MEAD AND CARL NIEMANN

Tyrosine and thyronine are different from all other amino acids in that they alone are found in nature as nuclear substituted halogen derivatives and in all cases it has been observed that the halogen atoms are contiguous to either a phenolic or aryloxy group.[1] Until recently the only halogenated amino acid of unambiguous physiological importance was the hormone thyroxine. However, the synthesis of 3-fluorotyrosine by Schiemann and Winkelmuller[2] and the subsequent pharmacological investigations of G. Litzka, K. Kraft, and W. May[3] have shown that other halogenated amino acids must be added to this category. As part of a study on the halogenated tyrosines and thyronines this communication describes the synthesis of 3,5-difluoro- and 3-fluoro-5-iodo-*dl*-tyrosine.[4]

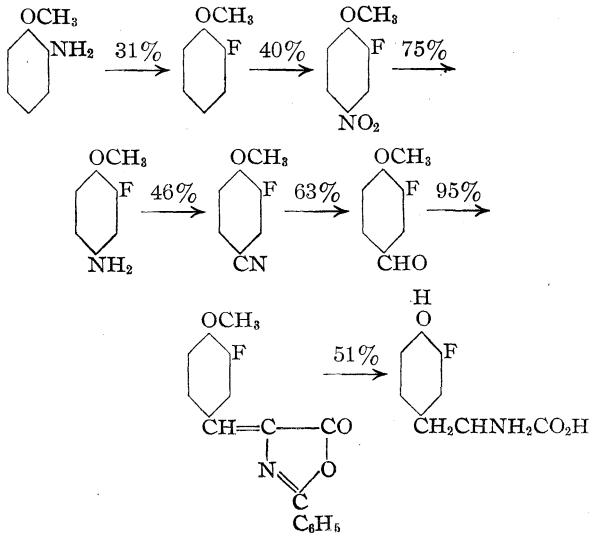
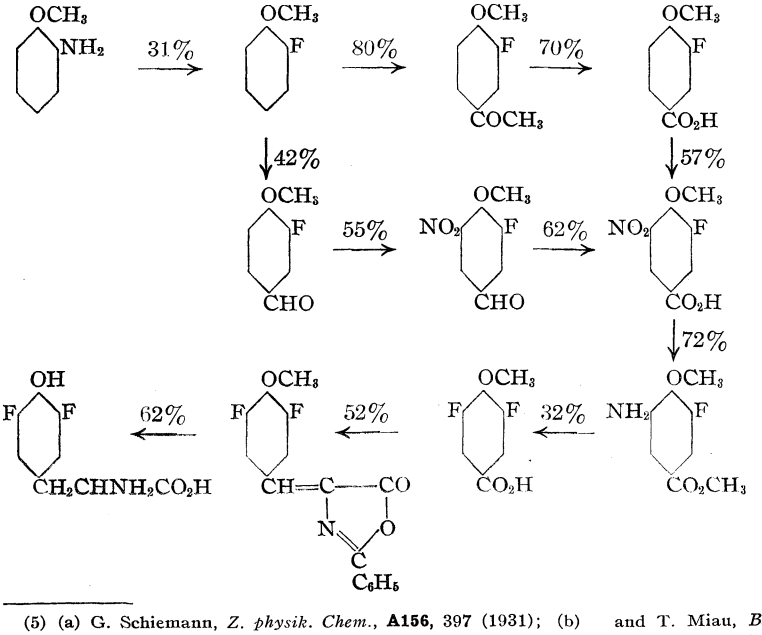
(4) This research is being conducted as a coöperative project with Professor Paul Phillips of the University of Wisconsin.

3-Fluoro-5-iodo-*dl*-tyrosine was prepared by the direct iodination of 3-fluoro-*dl*-tyrosine. The latter amino acid was prepared by two methods. The first was a modification of a synthesis described by Schiemann[2,5] and differed only in starting with *o*-anisidine rather than *o*-phenetidine. A second synthesis was based upon the reactions



The synthesis of 3,5-difluoro-*dl*-tyrosine was attended with some difficulty; however, after several unsuccessful attempts this amino acid was obtained in a 0.73% yield from *o*-anisidine by the following series of reactions



(5) (a) G. Schiemann, *Z. physik. Chem.*, **A156**, 397 (1931); (b) *J. prakt. Chem.*, **140**, 97 (1934).

Experimental

I. Synthesis of 3-Fluoro-*dl*-tyrosine

***o*-Fluoroanisole.**[5,6]—To 2.60 kg. of freshly distilled *o*-anisidine in 5.2 l. of concd. hydrochloric acid was added 1.53 kg. of sodium nitrite in 2 l. of water. Throughout the above and succeeding operation the reaction mixture was stirred vigorously and the temperature was not allowed to rise above 0°. Five liters of fluoboric acid, prepared from 4.05 l. of technical 52% hydrofluoric acid and 1.86 kg. of boric acid,[7] was added to the clear solution of the diazotized amine and the mixture maintained at −10° for one hour. The precipitate was then recovered, washed successively with water, ethanol, and ether, and dried *in vacuo* over sulfuric acid. The yield of diazonium fluoborate was 2.70 kg. or 57.5% of the theoretical amount. The diazonium salt was then decomposed, in 540-g. portions, in a manner identical with that described in *Organic Syntheses*.[7] The crude fluoroanisole was taken up in ether, the ethereal solution washed successively with dilute sodium hydroxide and water and finally dried over sodium sulfate. Fractional distillation gave 820 g. of *o*-fluoroanisole, b. p. 69–70° (26 mm.), a yield of 53.5% from the diazonium fluoborate or an over-all yield of 30.8% from *o*-anisidine.

Anal. Calcd. for C_7H_7OF (126): C, 66.7; H, 5.6. Found: C, 66.8; H, 5.9.

2-Fluoro-4-nitroanisole.[5b,6]—The nitration of *o*-fluoroanisole according to the directions given by Schiemann and Miau[6b] consistently gave 39–40% of the theoretical amount of 2-fluoro-4-nitroanisole, m. p. 104.5°, instead of the 70% reported by these authors. All attempts to improve the yield by modification of the procedure with respect to temperature, duration of the reaction, and concentration of the nitric acid were without effect. In no case was the compound of m. p. 53° described by Holmes and Ingold[6a] as a 2-fluoro-4-nitro-anisole obtained.

2-Fluoro-4-aminoanisole.[5b,6b]—The reduction of 2-fluoro-4-nitroanisole with hydrochloric acid and stannous chloride as described by Schiemann and Miau[6b] gave 65–75% of the theoretical amount of 2-fluoro-4-aminoanisole, m. p. 82.0°, which confirms the observations of these authors.

2-Fluoro-4-cyanoanisole.—To 51 g. of 2-fluoro-4-aminoanisole in 110 ml. of concd. hydrochloric acid and 100 ml. of water was added 26 g. of sodium nitrite in 50 ml. of water. The diazonium salt was then added, with vigorous stirring, to a solution, maintained at 60–70°, of 105 g. of potassium cyanide and 92 g. of copper sulfate in 500 ml. of water layered with 100 ml. of benzene. The reaction product was taken up in an additional quantity of benzene and the solution dried over sodium sulfate. Fractional distillation gave 25 g. (46%) of the nitrile,

(6) (a) E. L. Holmes and C. K. Ingold, *J. Chem. Soc.*, **129** 1328 (1926); (b) G. Schiemann and T. Miau, *Ber.*, **66**, 1179 (1933).

(7) *Organic Syntheses*, **13**, 46 (1933).

b. p. 96–98° (1.5 mm.), m. p. 95–96°. After repeated recrystallization the substance melted at 96.5°.

Anal. Calcd. for C_8H_6ONF (151): N, 9.3; Found: N, 9.4.

3-Fluoroanisaldehyde.[2]—(A) To a solution of 15 g. of stannous chloride in 80 ml. of ether, previously saturated with hydrogen chloride, was added 8 g. of 2-fluoro-4-cyanoanisole in 100 ml. of ether.[8] The reaction mixture was allowed to stand overnight after hydrogen chloride had been passed through it, with stirring, for four hours. The precipitate was recovered, decomposed with warm water, the aldehyde taken up in ether and the ethereal solution dried over sodium sulfate. Fractional distillation gave 63% of the theoretical amount of 3-fluoroanisaldehyde, b. p. 93° (4.5 mm.), m. p. 29–30°.

Anal. Calcd. for $C_8H_7O_2F$ (154): C, 62.4; H, 4.5. Found: C, 62.4; H, 4.6.

(B) Twenty grams of *o*-fluoroanisole was added to 27 g. of zinc cyanide[9] suspended in 100 ml. of benzene. After the solution was saturated with hydrogen chloride, 24 g. of aluminum chloride was added and the reaction mixture was heated at 40–50° for four hours. The complex, after standing overnight, was decomposed by refluxing with 10% hydrochloric acid and the crude aldehyde was isolated as described above. Fractional distillation gave 6.5 g. of *o*-fluoroanisole and 7.0 g. of 3-fluoroanisaldehyde, m. p. 29–30°. The yield of aldehyde was therefore 29% of the theoretical amount, based on the original starting material, or 42% on the basis of *o*-fluoroanisole consumed.

4-(3′-Fluoro-4′-methoxybenzal)-2-phenyl-oxazolone-5.[2]—Six grams of 3-fluoroanisaldehyde was condensed with hippuric acid in the presence of acetic anhydride and sodium acetate,[2,10] and 11 g. (95%) of 4-(3-fluoro-4-methoxybenzal)-2-phenyl-oxazolone-5, m. p. 207° (cor.), was obtained.

3-Fluoro-*dl*-tyrosine.[2]—Thirty grams of the above azlactone gave, on reduction and hydrolysis,[2] 10.3 g. of 3-fluoro-*dl*-tyrosine, dec. p. 275–278° with rapid heating. The yield of amino acid from 3-fluoroanisaldehyde was 49% of the theoretical amount.

Anal. Calcd. for $C_9H_{10}O_3NF$ (199): C, 54.3; H, 5.0; N, 7.0. Found: C, 54.4; H, 5.2; N, 6.9.

3-Fluoro-5-iodo-*dl*-tyrosine.—To 7 g. of 3-fluorotyrosine in 8 *N* ammonium hydroxide was added 9 g. of iodine dissolved in the minimum amount of potassium iodide solution and the mixture was allowed to stand overnight. The crystalline precipitate was then recovered, dissolved in alkali and reprecipitated by the careful addition of acid. The mother liquors were concentrated *in vacuo* to remove the excess ammonia and carefully acidified, whereupon a further quantity of 3-fluoro-5-iodo-*dl*-tyrosine was obtained. After recrystallization from 50% ethanol the compound melted with decompn. at 192°. The yield was 5.4 g. or 47% of the theoretical amount.

Anal. Calcd. for $C_9H_9O_3NFI$ (324.9): C, 32.9; H, 2.8; N, 4.3. Found: C, 32.9; H, 3.1; N, 4.1.

II. Synthesis of 3,5-Difluoro-*dl*-tyrosine

3-Fluoro-4-methoxyacetophenone.—To 750 g. of *o*-fluoroanisole in 2.4 l. of carbon disulfide was added, with cooling, 1.80 kg. of aluminum chloride and 6.5 g. of acetic anhydride.[11] The reaction mixture was refluxed for one hour and then poured into ice water. The solid was recovered and recrystallized (charcoal) from ethanol. The yield of 3-fluoro-4-methoxyacetophenone, m. p. 92° was 700–800 g. or 70–80% of the theoretical amount.

Anal. Calcd. for $C_9H_9O_2F$ (168): C, 64.3; H, 5.4. Found: C, 64.1; H, 5.3.

3-Fluoro-4-methoxy-5-nitroacetophenone.—Twenty-two and one-half ml. of nitric acid, sp. gr. 1.5 in 45 ml. of concd. sulfuric acid was added, with stirring, at −10°, to 90 g. of 3-fluoro-4-methoxyacetophenone in 270 ml. of sulfuric acid. After thirty minutes the mixture was poured onto ice and the product isolated by extraction with ether and distillation *in vacuo;* 50 g. (44%) of 3-fluoro-4-methoxy-5-nitroacetophenone, b. p. 144–147° (4 mm.), was obtained. The crystalline phenylhydrazone, m. p. 160–161° dec., was prepared for analysis.

Anal. Calcd. for $C_{15}H_{14}O_3N_3F$ (303): N, 13.9. Found: N, 13.9.

3-Fluoro-5-nitroanisaldehyde.—Fourteen grams of 3-fluoroanisaldehyde was dissolved in 200 ml. of concd. sulfuric acid at −10° and while maintaining this temperature there was added 8.8 g. of nitric acid, sp. gr. 1.5. The resulting solution was allowed to stand at −10° for three hours and then poured into ice water. A white crystalline solid was recovered. This product was recrystallized from isopropyl ether, yielding 10 g. (55%) of 3-fluoro-5-nitroanisaldehyde m. p. 57–58°. Reaction of the aldehyde with hydroxylamine gave an oxime m. p. 138–139°.

Anal. Calcd. for $C_8H_7O_4N_2F$ (214): N, 13.1. Found: N, 13.1.

3-Fluoroanisic Acid.[2]—Two hundred and seventy-five grams of potassium permanganate dissolved in the minimum quantity of hot water was added to 100 g. of 3-fluoro-4-methoxyacetophenone suspended in 1 l. of water (at 80°) containing 2 g. of potassium hydroxide. After the reaction was completed the manganese dioxide was removed and the filtrate acidified with sulfuric acid. The solution was then heated to 95–98° and sufficient ethanol was added to dissolve the precipitate, 70.3 g. (70%) of 3-fluoroanisic acid, m. p. 208–210°, crystallized from this solution on standing at 0° for twenty-four hours.

Anal. Calcd. for $C_8H_7O_3F$ (170): C, 56.5; H, 4.1. Found: C, 56.6; H, 4.2.

3-Fluoro-5-nitroanisic Acid.—(A) Forty-eight grams of 3-fluoroanisic acid was added in small portions to 250 ml. of nitric acid, sp. gr. 1.5, with efficient stirring at −5°. The clear solution was allowed to stand at 0° for two hours and then poured into ice water. The 3-fluoro-5-nitroanisic acid separated as a white solid which was recovered, washed with cold water, and recrystallized from benzene, m. p. 166°. The yield was 35 g. or 57% of the theoretical amount.

Anal. Calcd. for $C_8H_6O_5NF$ (215): C, 44.7; H, 2.8; N, 6.5. Found: C, 44.7; H, 2.9; N, 6.6.

(11) C. R. Noller and R. Adams, THIS JOURNAL, **46**, 1892 (1924).

(B) Three grams of 3-fluoro-5-nitroanisaldehyde was refluxed for one hour with 25 ml. of water and 1.5 g. of potassium permanganate. The reaction product was filtered and upon acidification 2.0 g. (62%) of 3-fluoro-5-nitroanisic acid of m. p. 165° was obtained. After recrystallization the substance melted at 166°.

(C) Oxidation of 3-fluoro-4-methoxy-5-nitroacetophenone with potassium permanganate at 100° (see B above) gave 3-fluoro-5-nitroanisic acid of m p. 164–165°, recrystallized 166°. The yield was poor.

Methyl 3-Fluoro-4-methoxy-5-nitrobenzoate.—The esterification of 3-fluoro-5-nitroanisic acid was conducted in the usual manner with methanol and hydrogen chloride. From 200 g. of the acid 160 g. (80%) of the ester b. p. 128–131° (3 mm.), m. p. 50°. was obtained.

Anal. Calcd. for $C_9H_8O_5NF$ (229): N, 6.1 Found: N, 6.4.

Methyl 3-Fluoro-4-methoxy-5-aminobenozate.—One hundred and forty grams of the above nitro compound was dissolved in methanol and reduced catalytically with the aid of platinic oxide. Upon evaporation of the solvent, 110 g. (90%) of the amine, m. p. 53°, was obtained. After recrystallization from isopropyl ether the compound melted at 55°.

Anal. Calcd. for $C_9H_{10}O_3NF$ (199): N, 7.0. Found: N, 7.2.

3,5-Difluoroanisic Acid.—To 30 g. of methyl 3-fluoro-4-methoxy-5-aminobenzoate in 25 ml. of concd. hydrochloric acid was added, at −5°, 11 g. of sodium nitrite dissolved in the minimum quantity of water; 60 ml. of fluoboric acid (see above) was then added to the clear solution of the diazotized amine, still maintaining the temperature at −5°. After the reaction mixture had stood for some time at 0°, the insoluble diazonium fluoborate was recovered, washed in the usual manner and dried *in vacuo* over sulfuric acid. The yield was 38 g. or 89% of the theoretical amount. The diazonium fluoborate (38 g.) was then decomposed by dry distillation and 13 g. of methyl 3,5-difluoro-4-methoxybenzoate, was obtained. Without further purification the ester was saponified with alcoholic potassium hydroxide and upon acidification of the reaction mixture 9.0 g. (32%) of crude 3,5-difluoroanisic acid was obtained. Several recrystallizations from benzene gave 8.0 g. (28%) of pure difluoroanisic acid, m. p. 162°.

Anal. Calcd. for $C_8H_6O_3F_2$ (188): C, 51.1; H, 3.2. Found: C, 51.3; H, 3.3.

4-(3′,5′-Difluoro-4′-methoxybenzal)-2-phenyloxazolone-5.—Eight grams of 3,5-difluoroanisic acid was heated on a steam-bath for three hours with thionyl chloride. The excess reagent was removed by distillation *in vacuo* at 100° and the crude acid chloride, m. p. 15–20°, was converted into 3,5-difluoroanisaldehyde without further purification. The reduction was accomplished by refluxing a solution of the acid chloride in 25 ml. of xylene, containing 1 g. of 5% palladium barium sulfate and 45 mg. of quinoline sulfur poison,[12] while passing in hydrogen for three hours. At the end of this time no more hydrogen chloride was being evolved and the reaction mixture was filtered, extracted with a small quantity of dilute hydrochloric acid, washed with water, dried over sodium sulfate, and the xylene removed *in vacuo*. The residual liquid aldehyde was converted into the azlactone in the usual manner and from this reaction 7.0 g. (52%) of 4-(3′,5′-difluoro-4′-methoxybenzal)-2-phenyloxazolone-5, m. p. 165–169° dec., was obtained.

Anal. Calcd. for $C_{17}H_{11}O_3NF_2$ (315): N, 4.4. Found: N, 4.6.

α-N-Benzoylamino-3,5-difluoro-4-methoxycinnamic Acid.—The above azlactone was saponified with alcoholic sodium hydroxide and after acidification of the reaction mixture α-N-benzoylamino-3,5-difluoro-4-methoxycinnamic acid, m. p. 200–201°, was obtained.

Anal. Calcd. for $C_{17}H_{13}O_4NF_2$ (333): C, 61.2; H, 3.9; N 4.2. Found: C, 61.0; H, 4.2; N, 4.1.

3,5-Difluoro-*dl*-tyrosine.—Seven grams of 4-(3′,5′-difluoro-4′-methoxybenzal)-2-phenyloxazolone-5 and 7 g. of red phosphorus in 65 ml of hydriodic acid, sp. gr. 1.7, and 50 ml. of acetic anhydride, was refluxed for five hours. The reaction mixture was then worked up in the usual manner and 3.7 g. of the crude amino acid was obtained. Recrystallization from water gave 3.0 g. (62%) of 3,5-difluoro-*dl*-tyrosine, m. p. 263–265° dec.

Anal. Calcd. for $C_9H_9O_3NF_2$ (217): C, 49.8; H, 4.2; N, 6.5. Found: C, 49.7; H, 4.3; N, 6.3.

3-Fluoro-4-methoxy-5-aminobenzyl Alcohol.—(A) Four grams of 3-fluoro-5-nitroanisaldehyde in 30 ml. of ethanol was shaken with 50 mg. of platinic oxide and 0.1 ml. of 0.1 *M* ferrous chloride, in the presence of 3–4 atm. of hydrogen, for thirty minutes. After removing the catalyst and solvent the residual dark oil was distilled *in vacuo;* 0.95 g. (27%) of 3-fluoro-4-methoxy-5-aminobenzyl alcohol, b. p. 141° (2 mm.), m. p. 55°, was obtained.

Anal. Calcd. for $C_8H_{10}O_2NF$ (171): N, 8.2. Found: N, 8.2.

(B) 3-Fluoro-5-nitroanisaldehyde (6.3 g.) dissolved in 25 ml. of dry isopropyl alcohol was treated with 2 g. of aluminum isopropoxide and the mixture slowly distilled until no more acetone could be detected in the distillate. The residue was poured into water, extracted with ether and the ethereal solution dried over sodium sulfate. Fractional distillation gave 65% of the theoretical amount of 3-fluoro-4-methoxy-5-nitrobenzyl alcohol, b. p. 155–159° (3 mm.). The alcohol thus obtained was reduced quantitatively with platinic oxide and hydrogen to give 3-fluoro-4-methoxy-5-aminobenzyl alcohol, m. p. 55°.

All attempts to convert 3-fluoro-4-methoxy-5-aminobenzyl alcohol to the corresponding diazonium fluoborate, either by diazotization in the usual manner or by diazotization in fluoboric acid,[13] were unsuccessful. In a control experiment 3-amino-4-methoxybenzyl alcohol gave a 60% yield of the diazonium fluoborate.

3-Fluoro-4-methoxy-5-aminoacetophenone.—This substance was prepared by the reduction of the corresponding nitro compound in ethanol solution with platinic oxide and hydrogen. The amine, b. p. 138° (2.5 mm.), was converted into the hydrochloride which did not exhibit a true m. p. but decomposed slowly from 160–175°.

(12) K. W. Rosenmund and F. Zetsche, *Ber.*, **54**, 425 (1921).

(13) C. M. Suter, E. J. Lawson and P. G. Smith, THIS JOURNAL, **61**, 161 (1939).

Anal. Calcd. for $C_9H_{11}O_2NFCl$ (219.5): N, 6.4. Found: N, 6.5.

All attempts to prepare the diazonium fluoborate from this amine by the usual procedures were unsuccessful.

Methyl 3,5-Diamino-4-methoxybenzoate.—The methyl ester of 3,5-dinitroanisic acid[14] was reduced catalytically in an ethanol solution and a quantitative yield of the diamine, m. p. 157°, was obtained.

On tetrazotizing the diamine according to the method given by Schiemann and Pillarsky,[15] 55% of the theoretical amount of crystalline tetrazonium fluoborate separated very slowly from the reaction mixture. It was found impossible to control the decomposition of this salt so as to give a practical yield of difluoroanisic acid.

2,6-Diamino-4-nitrophenol.[16]—Hydrogen sulfide was passed into a solution of 75 g. of picric acid in 500 ml. of 28% ammonia and 500 ml. of water. Heat was evolved and cooling was necessary to prevent the temperature from rising above 75°. When the solution cleared and when heat was no longer evolved, the passage of hydrogen sulfide was stopped and the mixture evaporated *in vacuo* until the residue was practically free of ammonia. After filtration the solution was acidified, the precipitate extracted with dilute hydrochloric acid and the extract filtered. Careful addition of acid to the filtrate gave, on cooling, 45% of the theoretical amount of 2,6-diamino-4-nitrophenol, m. p. 169° dec.

Anal. Calcd. for $C_6H_7O_3N_3$ (169): N, 24.8. Found: N, 24.6.

Eight grams of the diamine heated on a steam-bath for one hour with 100 ml. of acetic acid and 9.5 g. of acetic anhydride gave a 65% yield of 2,6-diacetoamino-4-nitrophenol, m. p. 235° with decompn.

2,6-Diamino-4-nitroanisole.—Finely powdered 2,6-diacetamino-4-nitrophenol was treated, at 0° for twenty-four hours with an ethereal solution of diazomethane. A 75% yield of 2,6-diacetamino-4-nitroanisole, m. p. 211°, was obtained by recrystallizing the precipitate with ethyl acetate. 2,6-Diamino-4-nitroanisole, m. p. 180–181°, was obtained in an 85% yield from the diacetyl derivative by saponification with 5 *N* sodium hydroxide.

Anal. Calcd. for $C_7H_9O_3N_3$ (183): N, 22.9. Found: N, 23.0.

A 52% yield of the tetrazonium fluoborate was obtained from the above diamine but it was found that the salt decomposed explosively giving a very small amount of oily product.

2,6-Difluoro-4-nitroanisole.—To 2.4 g. of 2-fluoro-4-nitro-6-aminoanisole,[6b] m. p. 108°, in 3.6 ml. of concd. hydrochloric acid was added 0.9 g. of sodium nitrite in 2 ml. of water and the resulting filtered solution treated with 4 ml. of fluoboric acid. The diazonium fluoborate was obtained in a 60% yield. The decomposition of this salt was difficult to control and it was found impossible to obtain more than a 10% yield of 2,6-difluoro-4-nitroanisole, m. p. 35°.

Anal. Calcd. for $C_7H_5O_3NF_2$ (189): N, 7.4. Found: N, 7.5.

Summary

The synthesis of 3,5-difluoro- and 3-fluoro-5-iodo-*dl*-tyrosine from *o*-anisidine has been described.

dl-Threonic Acid from 3-Hydroxy-crotonic Acid

BY J. W. E. GLATTFELD AND E. C. LEE[1]

While *dl*-erythronic lactone can be prepared without difficulty and in quantity directly from 3-hydroxy-isocrotonic lactone[2] which itself is easily obtained in good yield as a by-product in the synthesis of *dl*-2,3-dihydroxybutyric acid,[3] the epimeric tetronic acid, *dl*-threonic acid, is still a rare chemical. The only synthesis of the last-named acid that is reported in the literature was accomplished by Braun.[4] Glycerol-1,3-dichlorohydrin is the starting material and this is converted into *dl*-threonic acid by a procedure consisting of six steps. While the yield in each step is good (varying from 25 to 81%) the over-all yield is only about 2% of the theoretical.[5] As none of the intermediates is available commercially, it becomes necessary to start with glyceroldichlorohydrin in each attempt to synthesize *dl*-threonic

(1) The material in this article is taken from a dissertation submitted by E. C. Lee in August, 1936, to the faculty of the Division of the Physical Sciences in the University of Chicago in partial fulfilment of the requirements for the Ph.D. degree. Dr. Lee died in June, 1939. This article has been prepared by the senior author.
(2) Braun, THIS JOURNAL, **51**, 235 (1929).
(3) Glattfeld, Leavell, Spieth and Hutton, *ibid.*, **53**, 3164 (1931).
(4) Braun, *ibid.*, **52**, 3167 (1930); **54**, 1133 (1932).

(5) Braun also prepared one of the intermediates, 2-hydroxy-3-chloro-butyronitrile from epichlorohydrin and hydrogen cyanide (Lespieau) in 65% yield as against 25% from glycerol-1,3-dichlorohydrin. This would make the over-all yield of *dl*-threonic acid from the former 6.5% as against 2% from the latter. In spite of the lower yield, Braun seems to consider the dichlorohydrin as the starting material in this procedure for he says [*ibid.*, **52**, 3168 (1930)] "Lespieau's method has the great disadvantage that the handling of anhydrous hydrogen cyanide above its boiling point is very inconvenient. The *new procedure* (italics the author's) avoids this; it involves the treatment of dichlorohydrin with sodium cyanide in aqueous suspension."

acid. This acid is a possible source of *dl*-threose, which is necessary for the study of the saccharinic acid rearrangement of the tetroses which has been undertaken in these laboratories. It is for this reason that efforts to simplify Braun's synthesis or to find a new synthesis for this substance are being continued as opportunity offers. Some improvements have been made in Braun's procedure. These will be reported in another paper. In the present article, the transformation of 3-hydroxy-crotonic acid into *dl*-threonic acid is reported.

The starting material in this synthesis is acrolein. This has been transformed into *dl*-threonic acid with an over-all yield of 4.1% of the theoretical in five steps: acrolein $\xrightarrow{(1)}$ vinylglycolic nitrile $\xrightarrow{(2)}$ ethyl vinylglycolate $\xrightarrow{(3)}$ ethyl 3-bromo-crotonate $\xrightarrow{(4)}$ 3-hydroxy-crotonic acid $\xrightarrow{(5)}$ *dl*-threonic acid.

3-Hydroxy-crotonic acid was not recorded in the literature until 1932, when its preparation was reported by Kirrman and Rambaud.[6] The first three steps in their synthesis were the same as the first three listed under the new procedure indicated above. They then transformed the ethyl 3-bromo-crotonate into ethyl 3-acetoxy-crotonate, which in turn was hydrolyzed to 3-hydroxy-crotonic acid. The entire sketchily-described procedure of Kirrman and Rambaud was repeated. From one mole of acrolein, a few grams of the hydroxy-acid was obtained, but when five moles of acrolein was used, none was obtained. The severe treatment of the 3-bromo-ester with sodium acetate in boiling acetic acid was suspected of causing rearrangement, the longer period of heating required with larger quantities affording more opportunity for this to take place. Conversion of the bromo-ester to the acetoxy-ester was therefore eliminated, the former being hydrolyzed directly to 3-hydroxy-crotonic acid in improved yield by means of aqueous potassium carbonate. Incidentally, the preparation of ethyl vinylglycolate was studied and the yield reported in the literature[7] (49% from acrolein) improved by about 10%.

Experimental Part

Preparation of Ethyl Vinylglycolate (Steps 1 and 2).—The procedure was that used by Lobry de Bruyn[8] and by Van der Sleen.[7] Although these authors give detailed descriptions of the procedure a few comments on it should be made.

The addition of hydrogen cyanide to the acrolein proceeds slowly in a perfectly dry medium. Too much water on the other hand, causes polymerization of both the acrolein and the cyanohydrin. Ether of the proper water content was obtained by washing ordinary ether with saturated salt solution, strong permanganate solution, and water consecutively, shaking up the ether with sodium sulfate, and storing it over the sulfate for fifteen hours. Instead of adding glacial acetic acid in portions to the mixture of acrolein, ether and potassium cyanide, it was found advantageous to add the cyanide (pulverized but not dried) in portions to an ether solution of acrolein and glacial acetic acid at 10° (not lower). After all of the cyanide (1.5 moles) had been added, the reaction mixture was allowed to stand for two hours (no longer) with occasional shaking. Water was then added to dissolve the salt and the extraction with ether and subsequent distillation carried out as soon and as rapidly as possible. The last of the ether was removed at reduced pressure, yielding the crude cyanohydrin as a residue. This was transformed into the ethyl ester essentially by the procedure of Van der Sleen, 2 moles of acrolein (112 g.) giving 160 g. of the ester: a 61% yield.

Preparation of Ethyl 3-Bromo-crotonate (Step 3).—To a vigorously stirred mixture of 54 g. of phosphorus tribromide and 5 cc. of pyridine[9] kept at 20°, was added dropwise a solution of 10 g. of pyridine in 65 g. (0.5 mole) of ethyl vinylglycolate over a period of one and one-half hours. The mixture was stirred an additional half-hour, and then subjected to distillation at 13 mm. until considerable fuming occurred and the distillate became orange. The entire product was redistilled twice to free it of colored material and to complete the rearrangement and then fractionated. The second portion, which distilled at 77.5–84.5° at 6 mm., weighed 49 g.; a yield of 51% on the basis of the ethyl vinylglycolate.

Preparation of 3-Hydroxy-crotonic Acid (Step 4).—A mixture of 49 g. (0.25 mole) of the ester and 83 g. (0.5 mole) of hydrated potassium carbonate in 200 cc. of water kept at 80° was vigorously stirred for four hours at the end of which time it was cooled to 10°. Under vigorous stirring, 75 cc. of concentrated hydrochloric acid was added. Troublesome foaming due to escaping carbon dioxide was controlled by the occasional addition of a small amount of ether. The solution after filtration to remove a small amount of dark oil was concentrated under reduced pressure at 60°. The slightly-colored crystalline residue was heated with 57 cc. of acetone, the solution filtered while hot, and the material on the filter paper washed with three 25-cc. portions of acetone. The combined filtrates were filtered once more and then reduced in volume as completely as possible in vacuum at 45°. The warm residue, partly crystalline, was dissolved in 23 cc. of hot ethyl acetate. The solution was allowed to stand in an ice–salt mixture for an hour. The crystals were separated, washed with a minimum of ethyl acetate, and then recrystallized from 11 cc. of ethyl acetate. The product was dried, first in the air on a porous plate, and then in a desic-

(8) Lobry de Bruyn, *ibid.*, **4**, 221 (1885).

(9) Bouis, *Ann. chim.*, **9**, 411 (1928).

cator over concentrated sulfuric acid. It weighed 7.1 g.; a yield of 27.8% on the basis of the bromo-ester. The product melted at 108°, the recorded melting point of 3-hydroxy-crotonic acid.

Preparation of *dl*-Threonic Acid (Step 5).—To 10.2 g. (0.1 mole) of 3-hydroxy-crotonic acid in 500 cc. of water and 2.5 cc. of a 1% aqueous solution of osmic acid was added 6.4 g. (0.033 mole) of silver chlorate in two portions separated by an interval of twenty-four hours. After forty-eight hours the silver chloride was removed by filtration, and the filtrate reduced in volume as completely as possible in vacuum at 60° and 15 mm. The sirupy residue was dissolved in 30 cc. of acetone, the solution filtered from a small amount of dark material, and most of the acetone evaporated from a crystallizing dish on the steam-bath. The material was then stored in a vacuum desiccator over concentrated sulfuric acid until bubbling ceased. The partly crystalline mass was then dissolved in 10 cc. of ethyl acetate and the solution chilled in an ice–salt bath. The crystals were separated and washed with a mimimum of ethyl acetate. The product, which melted at 97°, weighed 6.5 g.; a yield of 48% based on the hydroxy acid. A small portion of the product was recrystallized from the same solvent. This material melted at 99°. It showed no depression of the melting point when mixed with a sample of *dl*-threonic acid which had been prepared by Braun.

Summary

The work of Kirrman and Rambaud on the preparation of 3-hydroxy-crotonic acid was successfully repeated. The yield, however, was very low.

Their procedure has been modified so that 3-hydroxy-crotonic acid can now be obtained in four steps from acrolein in 8.6% yield.

3-Hydroxy-crotonic acid has been oxidized to *dl*-threonic acid with silver chlorate and osmic acid in 48% yield. The over-all yield of threonic acid, from acrolein in five steps, (4.1%) compares favorably with that obtained by Braun (2.5%) in six steps from glycerol-1,3-dichlorohydrin.

Keto-cyclol Tautomerism of 1,6-Diketones. 1,4-Dibromo-1,4-dibenzoylbutane*

BY TSI-YU KAO

In seeking for a direct method for the preparation of 1,2-dibenzoylcyclobutane (IV) the action of molecular silver on 1,4-dibromo-1,4-dibenzoylbutane was tried. Since silver is a monovalent element it appeared altogether unlikely that it would lead to a Reformatsky condensation such as that reported by Fuson and Farlow.[1] These authors treated 1,4-dibromo-1,4-dibenzoylbutane with zinc and obtained besides 1,4-dibenzoylbutane (III) three other compounds: 2-phenyl-3-benzoylcyclopentanone, 1-phenyl-5-benzoyl-1-cyclopentene (IX), and its oxide (VIII).

Molecular silver actually gave a small yield of the desired cyclobutane derivative, but the chief product was 1-phenyl-5-benzoyl-1-cyclopentene oxide (VIII). The formation of this substance is explained adequately by the keto-cyclol tautomerism of 1,6-diketones. This mechanism explains equally well the formation of the cyclopentene derivatives from the dibromo compound (I) by the action of zinc dust.

While the cyclol forms of simple 1,6-diketones have not been isolated, there is considerable evidence that their existence is possible. For example, Baeyer and Liebig[2] obtained 1-cyclopentenealdehyde as well as adipaldehyde by oxidation of α,α'-dihydroxysuberic acid. Marshall and Perkin[3] showed that 1,4-diacetylbutane when distilled or boiled with alcoholic potash gave 1-acetyl-2-methyl-1-cyclopentene. By the action of sodamide on 1,4-dibenzoylbutane Bauer[4] obtained two isomeric cyclopentene derivatives: 2-phenyl-3-benzoyl-1-cyclopentene and 1-phenyl-2-benzoyl-1-cyclopentene. The latter was prepared by Skraup and Guggenheimer[5] by heating 1,4-dibenzoylbutane at 300–310°. Similarly, 2,4,5-triphenyl-1-benzoyl-1-cyclopentene results when 1,4-dibenzoyl-2,3-diphenylbutane is treated with sodium ethylate.[6] All of these transformations can be explained as due to the elimination of water from the cyclol form of the diketone or diacid.

Still more striking evidence for the existence of the cyclol forms has been furnished by Vogel,[7] who showed that 2,2,3,3-tetramethyl-1,4-diacetylbutane exists only in the cyclol form.

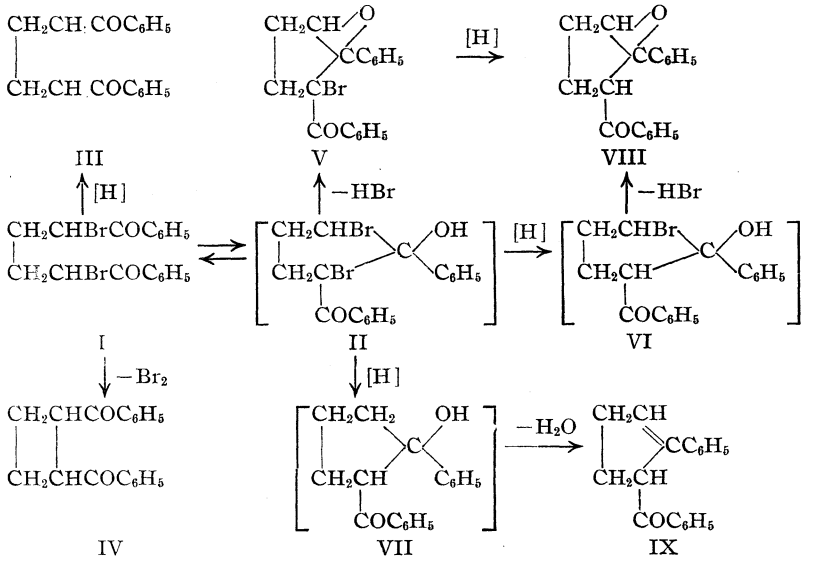
The results presently reported can be explained similarly by assuming 1,4-dibromo-1,4-dibenzoylbutane to exist in both the keto (I) and the cyclol (II) forms. Removal of bromine from the keto form by the action of molecular silver yields 1,2-dibenzoylcyclobutane, and elimination of hydrogen bromide and one bromine atom from the cyclo form gives rise to the cyclopentene oxide (VIII). The probable course of these reactions is represented by the diagram



Debromination of I and II yields, respectively, 1,4-dibenzoylbutane and the cyclopentene (IX), presumably formed from the cyclol, VII. The oxide (VIII) could be formed either by elimination of hydrogen bromide from the cyclol, VI, or by debromination of the bromo oxide (V).

The latter method of formation has been shown to be possible. The bromo oxide (V) is formed when the dibromide (I) is treated with sodium cyanide,[8] diethylamine or sodium acetate. The sodium derivative of ethyl malonate produces the same change. When the bromo compound (V) is treated with zinc dust and sodium iodide in acetone it gives the oxide (VIII). This reaction serves also to establish the structure of the bromo oxide (V).

Experimental

Action of Molecular Silver on 1,4-Dibromo-1,4-dibenzoylbutane.—A mixture of 15 g. of the dibromide, 32 g. of sodium iodide and 15 g. of molecular silver (prepared by the method of Gomberg and Cone[9]) was covered with acetone and heated for eight hours under reflux. The mixture was filtered while hot and the filtrate allowed to run into a large volume of water. The residue was washed two or three times with hot acetone and finally extracted with acetone in a Soxhlet apparatus. The acetone solution obtained in this way was also poured into water. It usually contained very little organic material.

The water–acetone mixture was heated to remove the acetone and the product separated by filtration and dried. The filtrate, which was always turbid, was extracted twice with benzene to make sure that no material was lost; very little was recovered, however. The yellow product was first extracted with petroleum ether (b. p. 40–60°) in a Soxhlet apparatus for four hours and then with ethyl alcohol (in portions) until all of the organic compounds were removed. This usually required about twenty-four hours.

From the petroleum ether was obtained a solid melting at 115–140°. Fractional crystallization from alcohol gave *cis*-1,2-dibenzoylcyclobutane (m. p. 121–122°) and 1-phenyl-5-benzoyl-1-cyclopentene oxide (m. p. 169.5–170.5°) in yields of 13 and 37%, respectively. Both compounds were identified by the method of mixed melting points. The former was the more soluble and was contained in the mother liquors from which the latter had crystallized. A small amount of 1,4-dibenzoylbutane also was isolated.

1-Phenyl-5-bromo-5-benzoyl-1-cyclopentene Oxide.—A mixture of 4.2 g. of 1,4-dibromo-1,4-dibenzoylbutane, 17 g. of diethylamine and 30 cc. of dry benzene was refluxed for about thirty minutes. The bromo compound dissolved to give a wine-red solution. The mixture was filtered to remove the crystals of diethylamine hydrobromide which were then washed with benzene. The washings were added to the filtrate and the solvent was distilled under diminished pressure. The clear, viscous oily residue was dissolved in ether and the solution washed successively with hydrochloric acid and water. After the solution was dried the solvent was removed and the residue crystallized from alcohol: yield, 2 g. (59%); m. p. 138–139°.

The same compound was obtained by using sodium cyanide or sodium acetate instead of diethylamine but yields were low.

Action of the Sodium Derivative of Ethyl Malonate on 1,4-Dibromo-1,4-dibenzoylbutane.—This experiment was originally carried out with the intention of making ethyl 2,5-dibenzoyl-1,1-cyclopentanedicarboxylate. The product, however, was identical with the bromo compound of Kao and Fuson and proved to be 1-phenyl-5-benzoyl-5-bromo-1-cyclopentene oxide (V).

To a solution of 1.2 g. of metallic sodium in 50 cc. of absolute ethyl alcohol was added first 4.2 g. of ethyl malonate and then a solution of 10 g. of the dibromide in 100 cc. of dry benzene. The stopper of the reaction flask was secured with a wire and the vessel was placed in a water-

(8) Kao and Fuson, THIS JOURNAL, **54**, 313 (1932).
(9) Gomberg and Cone, *Ber.*, **39**, 3286 (1906).

bath which was heated to boiling and kept at that temperature for five hours. The contents were evaporated nearly to dryness and the residue crystallized from ethyl acetate. The bromo compound melted at 138–139°; yield, 64% of the theoretical amount.

Debromination of 1-Phenyl-5-bromo-5-benzoyl-1-cyclopentene Oxide.—A mixture of 7 g. of the bromo oxide, 7 g. of zinc dust, 10 g. of sodium iodide and 100 cc. of dry acetone was refluxed for eight hours. The mixture was filtered and the residue washed several times with hot acetone. The acetone solution was poured into a large volume of water and the precipitated oxide purified by recrystallization. It melted at 169–170° and was identified by the mixed melting point method as 1-phenyl-5-benzoyl-1-cyclopentene oxide. The yield was 0.7 g.

Summary

Treatment with molecular silver converts 1,4-dibromo-1,4-dibenzoylbutane into a mixture of 1,4-dibenzoylbutane, 1,2-dibenzoylcyclobutane and 1-phenyl-5-benzoyl-1-cyclopentene oxide. With the sodium derivative of ethyl malonate the dibromide yields 1-phenyl-5-benzoyl-5-bromo-1-cyclopentene oxide. The latter is also formed from the dibromide by the action of diethylamine Treatment of the oxide with zinc dust and sodium iodide in acetone converts it to the bromine-free cyclopentene oxide.

These transformations are interpreted on the assumption that the dibromide exists in tautomeric keto and cyclol forms.

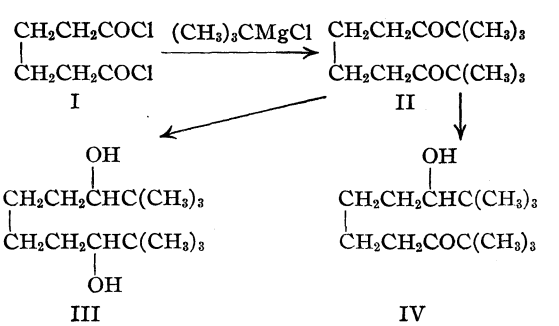
1,4-Dibromo-1,4-dipivalylbutane

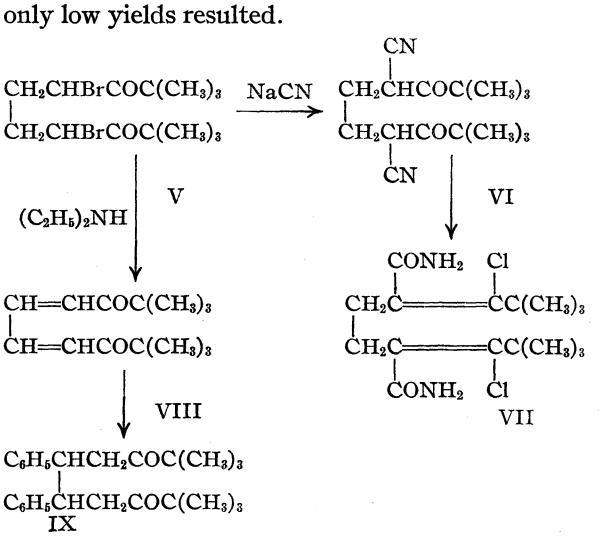
BY REYNOLD C. FUSON AND JOHN W. ROBINSON, JR.

1,4-Dibromo-1,4-dipivalylbutane (V) has been synthesized for use in connection with a general study of ring closures of 1,4-dihalogen compounds. The primary problem from the synthetic point of view was that of making the parent diketone, 1,4-dipivalylbutane (II). This compound was obtained in yields of 25% by treatment of adipyl chloride with *t*-butylmagnesium chloride. An excess of the Grignard reagent must be avoided at all times to minimize reduction of the diketone. Incomplete reaction gave δ-pivalylvaleric acid [$(CH_3)_3CCO(CH_2)_4CO_2H$]. It was impossible to



eliminate completely the formation of this by-product; the average yield of this substance was about 20%.

The use of an excess of *t*-butylmagnesium chloride gave an oil which evidently contained the diol (III) or the hydroxy ketone (IV) or both. An attempt was made to obtain the desired diketone by oxidation of the oil with chromic acid but only low yields resulted.



The dibromide (V) was formed without difficulty but only one of the two possible stereoisomeric forms was isolated. Its structure was proved by cleavage to pivalic acid by the action of alkali on the pyridinium salt.

Treatment of the dibromide with sodium cyanide was found to give the corresponding dinitrile (VI) together with a liquid which had the composition of the cyanocyclobutane derivative which might be expected by analogy with the behavior of

dibromoadipic esters.[1] On the other hand, the conversion of 1,4-dibromo-1,4-diaroylbutanes to dihydro-1,4-pyrans under these conditions[2] suggests that the liquid might be the dihydro-1,4-pyran, isomeric with the cyclobutane derivative. The data at hand do not permit a decision between these two possibilities.

Treatment with diethylamine dehydrohalogenated the dibromide (V) giving 1,4-dipivalyl-1,3-butadiene (VIII). This compound failed to condense with maleic anhydride, but reacted with phenylmagnesium bromide to yield 1,4-dipivalyl-2,3-diphenylbutane (IX). Catalytic hydrogenation converted the diene to the saturated diketone (II).

The dicyano diketone (VI) gave two moles of gas in the Grignard machine,[3] but attempts to alkylate it and to effect ring closure through the disodium derivative were fruitless. The cyano groups showed extraordinary resistance to the action of hydrolytic agents. Long heating with aqueous sodium hydroxide, for example, did not alter the compound. However, heating with concentrated hydrochloric acid in a closed tube produced a remarkable transformation. The product proved to be a chloro amide which probably has the structure VII. This is a novel type of reaction for β-keto nitriles; presumably its realization in this instance is to be ascribed to the steric hindrance afforded by the *t*-butyl radical.

Experimental

Synthesis of 1,4-Dipivalylbutane

A. By Condensation of Adipyl Chloride with *t*-Butylmagnesium Chloride.—To an ice cold solution of 0.136 mole of adipyl chloride in 400 cc. of absolute ether was added gradually over a two-hour period 0.30 mole of *t*-butylmagnesium chloride in 500 cc. of absolute ether. Vigorous stirring was used during the addition and the temperature of the reaction mixture maintained at 0°. Stirring was continued for three hours after the addition was complete.

The mixture was decomposed at 0° with ammonium chloride and worked up in the usual way. The ether solution was washed with aqueous sodium carbonate solution and dried. Evaporation of the ether left an oil which could be crystallized from low-boiling petroleum ether. In this way 6.5 to 8.5 g. of 1,4-dipivalylbutane was obtained melting at 52–52.5°.

Anal. Calcd. for $C_{14}H_{26}O_2$: C, 74.28; H, 11.58. Found: C, 74.19; H, 11.40.

The di-2,4-dinitrophenylhydrazone when purified by repeated crystallization from chloroform melted at 251–252° (uncor.).

Anal. Calcd. for $C_{26}H_{34}N_8O_8$: C, 53.23; H, 5.84; N 19.09. Found: C, 52.87; H, 5.97; N, 18.81.

Distillation of the filtrate from the crystallization of 1,4-dipivalylbutane gave 5 g. of a neutral oil boiling at 119–124° (3.5 mm.). It appeared to be impure 2,2,9,9-tetramethyl-3,8-decanediol (III).

Anal. Calcd. for $C_{14}H_{30}O_2$: C, 72.98; H, 13.12. Found: C, 71.56; H, 11.12.

The sodium carbonate solution was acidified with hydrochloric acid and extracted with ether. In this way there was obtained 5 g. of δ-pivalylvaleric acid boiling at 151–153° (2 mm.) and melting at 45–47°.

Anal. Calcd. for $C_{10}H_{18}O_3$: C, 64.48; H, 9.74. Found: C, 64.53; H, 9.61.

B. By Oxidation of the Neutral Oil.—One gram of the neutral oil boiling at 119–124° (3.5 mm.) was treated with 1 g. of chromic acid in glacial acetic acid solution. Only a small amount of the diketone could be isolated.

1,4-Dibromo-1,4-dipivalylbutane.—The bromination of 1,4-dipivalylbutane in warm carbon tetrachloride proceeded rapidly to give a 90% yield of the dibromide. The product crystallized from an ether–petroleum ether mixture, m. p. 119.5–120°.

Anal. Calcd. for $C_{14}H_{24}O_2Br_2$: C, 43.77; H, 6.30. Found: C, 43.67; H, 6.29.

Cleavage to pivalic acid was effected by the following procedure. One gram of the dibromide was dissolved in 10 cc. of ethyl acetate, 5 g. of pyridine was added and the mixture allowed to stand for twenty-four hours. The solid which formed was removed by filtration and the filtrate heated nearly to boiling; an additional quantity of the solid resulted. The solid was dissolved in 10 cc. of water and treated with cold 5% sodium hydroxide solution. An intense red color developed. The solution was acidified with dilute sulfuric acid and extracted five times with ether. In this way pivalic acid was isolated, m. p. 34–35°.

1,4-Dipivalyl-1,3-butadiene.—A solution of 4 g. of 1,4-dibromo-1,4-dipivalylbutane and 20 g. of diethylamine in 100 cc. of dry benzene was boiled under reflux for fourteen hours. The diethylamine hydrobromide was removed by filtration and the filtrate concentrated to about 15 cc. under reduced pressure. Cooling the benzene solution to 0° caused the butadiene to separate in white cotton-like crystals. These were recrystallized from methanol, m. p. 145–146°. The yield was 21% of the theoretical.

Anal. Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97. Found: C, 75.90; H, 10.22.

The di-2,4-dinitrophenylhydrazone melted at 280–282°.

Anal. Calcd. for $C_{26}H_{30}N_8O_8$: C, 53.60; H, 5.19. Found: C, 53.32; H, 5.19.

Reduction was carried out in two ways.

A. With Sodium Hydrosulfite.—This method gave a solid melting at 70–72° which decolorized solutions of permanganate in acetone and discharged the color of carbon tetrachloride solutions of bromine without evolution of hydrogen bromide. The compound was not studied further.

(1) Fuson and Kao, THIS JOURNAL, **51**, 1536 (1929); Fuson, Kreimeier and Nimmo, *ibid.*, **52**, 4074 (1930).

(2) Fuson, Kuykendall and Wilhelm, *ibid.*, **53**, 4187 (1931).

(3) Kohler, Fuson and Stone, *ibid.*, **49**, 3181 (1927).

B. With Hydrogen.—Raney nickel was used as the catalyst. The product had a melting point of 52–53° which was not depressed by the addition of 1,4-dipivalylbutane.

Reaction of the Butadiene with Phenylmagnesium Bromide.—This reaction was carried out in the usual manner. A solid was isolated melting at 206–207° which is the melting point given for 2,3-diphenyl-1,4-dipivalylbutane.[4]

1,4-Dicyano-1,4-dipivalylbutane.—A mixture of 8 g. of 1,4-dibromo-1,4-dipivalylbutane, 4 g. of powdered sodium cyanide, 120 cc. of absolute alcohol and 120 cc. of dry ethyl acetate was refluxed for forty hours. Removal of the solvents left a dark brown residue to which was added 150 cc. of water. The aqueous solution was extracted with four 50-cc. portions of ether. The resulting solution was evaporated to dryness and the residue crystallized from alcohol. The dinitrile was obtained in yields of 1.4 to 1.7 g., m. p. 92–93°.

Anal. Calcd. for $C_{16}H_{24}N_2O_2$: C, 69.53; H, 8.75; N, 10.13. Found: C, 69.75; H, 8.72; N, 10.17.

Reaction of the Dinitrile with Hydrochloric Acid.—A mixture of 0.5 g. of the dinitrile and 10 cc. of concentrated hydrochloric acid was heated in a closed tube (capacity about 30 cc.) for two hours at 140–150°. A solid was obtained which after recrystallization from benzene melted at 198–200°. The yield was 0.33 g.

Anal. Calcd. for $C_{16}H_{26}Cl_2N_2O_2$: C, 55.02; H, 7.50; N, 8.02; Cl, 20.30; mol. wt., 349. Found: C, 55.18; H, 7.43; N, 7.46; Cl, 20.70; mol. wt., 330.

(4) Hill and Susselman, THIS JOURNAL, **53**, 4424 (1931).

The alcoholic filtrate left after the separation of the dicyano compound was found to contain a neutral oil boiling at 163–168° (6 mm.); $n^{20}D$ 1.4722.

The 2,4-dinitrophenylhydrazone was crystallized from alcohol, m. p. 225–227°.

Anal. Calcd. for $C_{21}H_{27}N_5O_5$: C, 58.76; H, 6.34; N, 16.30. Found: C, 58.30; H, 6.49; N, 16.45.

An **oxime** was formed by heating a mixture of 1 g. of the oil, 1.5 g. of hydroxylamine hydrochloride, 3 g. of potassium acetate and 10 cc. of water. It was crystallized from alcohol, m. p. 183–185°.

Anal. Calcd. for $C_{15}H_{24}N_2O_2$: C, 68.15; H, 9.15. Found: C, 68.28; H, 8.96.

Repetition of the foregoing test using sodium hydroxide in place of potassium acetate gave an **isomeric oxime** melting at 146–148°.

Anal. Calcd. for $C_{16}H_{24}N_2O_2$: C, 68.15; H, 9.15; N, 10.59. Found: C, 68.23; H, 9.14; N, 10.47.

Summary

1,4-Dipivalylbutane (II) has been prepared by the action of *t*-butylmagnesium chloride on adipyl chloride.

1,4-Dibromo-1,4-dipivalylbutane (V) has been converted to the corresponding dicyano compound (VI) and to 1,4-dipivalyl-1,3-butadiene (VIII).

The 1,2,4-Trimesityl 1,4-Diketones and Related Compounds, Including the Stereoisomeric Mono and Dienols[1]

BY ROBERT E. LUTZ AND CHARLES J. KIBLER

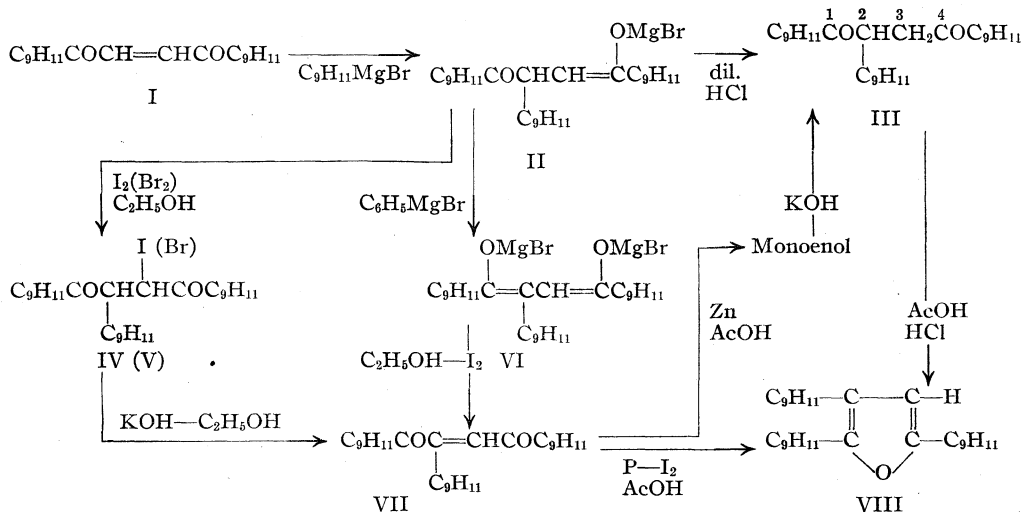
The preparation of this series of compounds was undertaken in order to extend the study of the hindering effect of mesityl groups. It was expected that here the damping of the keto–enol shift and the consequent increase in the persistence of enolic forms would make it possible to prepare some of the stereoisomeric mono and dienols or, at least, to obtain evidence of their existence. Furthermore, it was hoped that new information might be obtained concerning the properties of highly hindered enolic groups and the mechanism of certain reactions which supposedly proceed through enolic intermediates, particularly furan ring closure.[2] This report deals with a preliminary investigation in which these objectives were in a degree accomplished.

(1) This paper was presented at the Boston meeting of the American Chemical Society, September 14, 1939.

(2) Lutz and Reveley, THIS JOURNAL, **61**, 1854 (1939).

The Saturated 1,4-Diketone (III).—The starting point in the synthesis of these compounds was di-(trimethylbenzoyl)-ethylene (I). Addition of mesitylmagnesium bromide at 20° gave the monoenolate II by 1,4-addition, the reaction proceeding quickly but stopping at this point. When the reaction mixture was hydrolyzed by means of dilute hydrochloric or acetic acid, the saturated diketone III was produced in good yield; the free monoenol could not be isolated and was quite mobile, ketonizing quickly to the saturated diketone even when dilute acetic acid under mild conditions was used.

That the reaction between mesitylmagnesium bromide and di-(trimethylbenzoyl)-ethylene actually stopped at the stage of the monoenolate, II, was demonstrated (a) by conversion of the product with alcoholic iodine or bromine into the



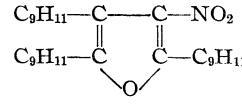
monohalogeno saturated diketones IV and V, (b) by the failure of the product to undergo oxidation to the unsaturated diketone VII when hydrolyzed in the presence of iodine or quinone, a reaction characteristic[2] of dienolates of the type of VI, and (c) by actual enolization upon more drastic treatment with the Grignard reagent to the true dienolate VI which was readily oxidizable to the unsaturated diketone when treated in the usual way with alcoholic iodine.

From these results it appears that the newly introduced mesityl group in the 1,4-addition product II definitely hinders enolization at the adjacent carbonyl. This effect is to be contrasted with the absence of any such marked hindrance in the case of the reactions between phenyl[2,3] and mesityl[4] magnesium bromides and dibenzoylethylene, and between phenylmagnesium bromide and di-(trimethylbenzoyl)-ethylene,[3] where even under mild conditions dienolates corresponding to VI are obtained.

The Unsaturated 1,4-Diketone (VII).—The trimesityl unsaturated 1,4-diketone of this series can be made in either of two ways: (a) through elimination of halogen acid from the halogeno saturated diketones IV and V by means of alcoholic potassium hydroxide, or (b) by hydrolysis under oxidizing conditions with alcoholic iodine, of the dienolates obtained by the action of a Grignard reagent on suitable compounds in this series such as the monoenolate II, the halogeno saturated diketones IV and V, or the saturated diketone III.

The unsaturated diketone VII is distinctly less reactive than the other compounds of this type which have been studied, as would be expected in view of the extreme hindrance offered by the three mesityl groups. It is reduced by zinc and boiling acetic acid through a 1,6-mechanism to a monoenol (to be described later) which is easily ketonized to the saturated diketone III; and the phosphorus–iodine–acetic acid reagent converts it directly into trimesitylfuran, VIII. Attempts to convert it into trimesitylacetoxyfuran by means of acetic anhydride and sulfuric acid failed.

2,3,5-Trimesitylfuran (VIII).—Trimesitylfuran (VIII) was obtained from the saturated diketone III in excellent yield by the prolonged action of boiling acetic acid saturated with dry hydrogen chloride. Furanization was effected also, although less efficiently, by the action of hydriodic acid at 170° and by the phosphorus–iodine–acetic acid reagent.



IX

The action of nitric–acetic acid mixtures on the furan produces a mononitro derivative without disrupting the furan nucleus. The nitro group presumably is located in the β-position as formulated in IX.[5] The resistance of the furan nucleus here toward oxidative ring fission constitutes another illustration of the striking stabilizing influence of two mesityl groups in the 2,5-positions, an effect which is presumably due to the hindrance of the mesityl groups toward addition of the reagents at the ends of the diene system.

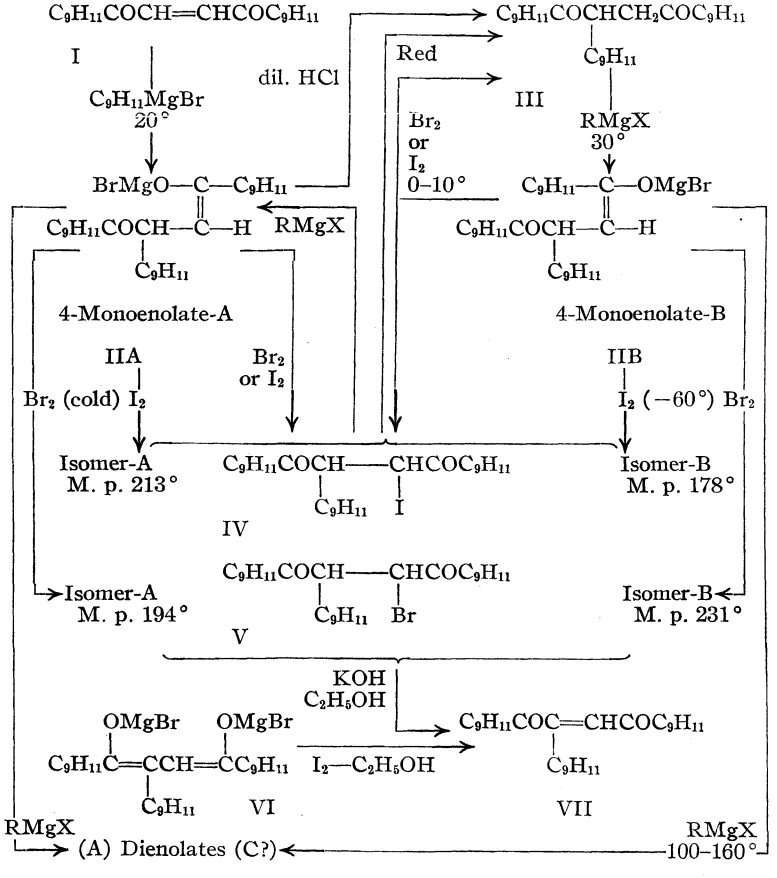
(5) The β-position is the reactive one in all of the analogous compounds studied. (Lutz and Kibler, a study of 2,5-dimesitylfurans to be published shortly.)

The Halogeno Saturated 1,4-Diketones, IV and V.—The halogeno trimesityl 1,4-diketones IV and V are of special interest because of their ready conversion into one of the two possible stereoisomeric 4-monoenolates (II) by the action of Grignard reagents, and also because of the various stereochemical relationships involved. The bromo and the iodo compounds exist each in two stable diastereoisomeric forms. These are prepared by the action of the appropriate halogen on one or the other of the isomeric (*cis-trans*) 4-monoenolates IIA and B which will be described separately below. The reactions are illustrated in the second diagram where the configurations and stereochemical relationships have been indicated as far as they have been determined. In order to simplify the naming of these various compounds, particularly the different types of enolates, the chain has consistently been numbered as in formula III.

The structures of the halides, given as IV and V, follow from the formation of both pairs of isomers



in the same reaction, namely, the halogenation of the 4-monoenolate-A (IIA) in which the position of the enolic group is known from the mode of preparation through 1,4-addition of mesitylmagnesium bromide to di-(trimethylbenzoyl)-ethylene (I). The stereoisomeric halides of the type A are best obtained in quantity by the action of the appropriate halogen on this 4-monoenolate-A and are obtained almost exclusively under controlled conditions. The B-isomers are obtained almost exclusively by halogenation at −60° of the stereoisomeric 4-monoenolate-B which is obtained by direct partial enolization of the saturated diketone III (to be described below).

The existence of these stereoisomeric halides is somewhat surprising in view of the instability of di-(trimethylbenzoyl)-bromo[5] and chloro[6]-ethanes, $C_9H_{11}COCH_2CH(Br \text{ or } Cl)COC_9H_{11}$, which lose hydrogen halide even during crystallization under relatively mild conditions. The halides in this series withstand the prolonged action of sodium acetate in boiling alcohol. Hydrogen halide is eliminated only by the action of the more powerful reagent, potassium hydroxide, with the formation of the unsaturated diketone VII.

On the other hand, the halogens are very easily eliminated from these compounds by reduction with zinc and acetic acid and also with sodium bisulfite or potassium iodide in acetic acid. The latter two reductions are of a type characteristic for α-halogeno ketones, and particularly halogen derivatives of β-diketones. The iodides, of course, are much more easily reduced than the bromides, and liberate iodine from potassium iodide in acetic acid at room temperature, whereas the bromides react thus only at elevated temperature. The product of reduction in all cases is the saturated diketone III.

The 4-Monoenolate-A (IIA).—The monoenolate obtained by the 1,4-addition of mesitylmagnesium bromide to di-(trimethylbenzoyl)-ethylene is designated as the 4-monoenolate-A. It is obtained also by the action of a Grignard reagent on any one of the halogeno satu-

(6) Lutz and Wood, THIS JOURNAL, **60**, 229 (1938).

rated diketones IV or V. It is characterized by the reactions with bromine and iodine. When it is brominated a mixture of two stereoisomeric halides A and B results with the isomer-A in the larger proportion; at lower temperatures the bromide of type A is obtained as the chief product. In iodination chiefly the iodo diketone-A is obtained even at room temperature, and only very small amounts of the isomer-B can be detected; at low temperature the iodide-A appears to be formed exclusively.

The direction of enolization in the 4-monoenolate-A indicated in formula IIA is certain from the mode of formation by the addition of mesitylmagnesium bromide to di-(trimethylbenzoyl)-ethylene (I).

The 4-Monoenolate-B (IIB).—The existence of the stereoisomeric 4-monoenolate, designated as isomer-B, was discovered in studying the direct enolization of the saturated diketone III by means of different Grignard reagents. Methylmagnesium iodide reacts rapidly with evolution of *one* molecule of methane, but the secondary reaction involving enolization of the other carbonyl group, with evolution of the second molecule of methane and the formation of a dienol, takes place very slowly and only at elevated temperatures. In respect to this secondary enolization the 4-monoenolate-B is distinctly different from the 4-monoenolate-A which undergoes this reaction easily at a moderate temperature and gives the dienolate-A quickly and in good yield. The rigorous proof of the existence of the 4-monoenolate-B and its stereoisomerism with the isomer-A is the halogenation with iodine or bromine at a lowered temperature with the formation of the iodo and bromo diketones-B consistently and almost exclusively in good yield.

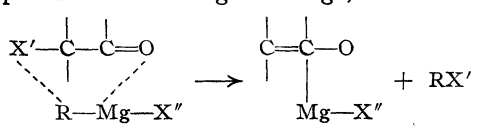
In some of the first experiments in which the reaction between iodine and the 4-monoenolate-B was carried out at room temperature or at 10°, largely the saturated diketone III was obtained and the full extent of the presence of the 4-monoenolate-B was overlooked; this result was found to be due to the high rate of ketonization of the 4-monoenolate-B at ordinary temperatures, which apparently is greater than in the case of the 4-monoenolate-A, and which under the conditions of this experiment enables ketonization to compete on favorable terms with iodination. When the halogenation was carried out at −60° the ketonization was relatively slow and became negligible, and at the same time the stereochemical mode of reaction was much more sharply defined.

The Configurations at the 4-Enolic Group.—There exists a basis for assignment of configurations at the 4-enol group in the striking fact that the configuration greatly influences the ease of the secondary enolization at the hindered 1-carbonyl. It seems reasonable to assume that the configuration offering the greater resistance to this secondary enolization will be that with the 4-mesityl group in the *cis* position with respect to the rest of the chain since this arrangement should involve the greater degree of steric hindrance. Thus the 4-monoenolate-B which undergoes the secondary enolization with great difficulty should have the configuration indicated in formula IIB, and the 4-monoenolate-A which is very easily converted into a dienolate should have the structure IIA. This argument is strengthened by the fact that the relative rates of ketonization at the 4-enolic group are consistent with the conclusion. Assuming that the ketonization of a free 4-enolic group would be hindered to the greater degree when the enolic hydroxyl group is *cis* with respect to the residue of the chain, and to the lesser degree when *cis* with respect to the hydrogen atom, then again, the 4-monoenolate-A must have the configuration indicated in IIA and the 4-monoenolate-B the structure IIB.

Stereochemical Relationships and Mechanism of Reaction.—It is clear from the foregoing discussion that the *cis* and *trans* isomeric 4-monoenolates IIA and B actually exist and are stable, and that halogenation of these isomers occurs in a consistent stereochemical manner. Whether the reaction is *cis* or *trans*, however, is not known because no information is available concerning the actual configurations of the halides produced.

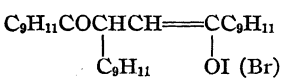
The halides IV and V, both the A and B-isomers, react readily with the Grignard reagent, the first stage of the reaction proceeding very rapidly in the cold with the formation of one and the same 4-monoenolate, isomer-A. Since the two 4-monoenolates, A and B, appear to be stable once formed, it may safely be assumed that the reaction is not guided or influenced by the configuration of the starting material as is the addition of halogen to the two monoenolates. This result would be expected because it is not easy to conceive of a marked stereochemical guiding influence emanating from the kind of configurational difference (diastereoisomerism) involved in the two types of halides.

In the formation of the 4-monoenolate by the two different methods, namely, the direct enolization of the saturated diketone III and the interaction of a Grignard reagent and the halogeno diketones A or B (IV or V), opposite stereochemical results are obtained. This is not surprising because the two reactions differ sharply in that α-hydrogen is involved in the one case and α-halogens in the other, with the elimination, respectively, of hydrocarbon and alkyl halide. This does not necessarily indicate different mechanisms in the two reactions, however. Probably, the mechanism of the reaction in the case of the halides is a simple 1,4-reaction between alkyl-magnesium halide and the conjugated system of carbonyl group and carbon–halogen linkage, as follows:



The enolizing action of the Grignard reagent on the saturated diketone may possibly follow a similar path but with opposite stereochemical results.

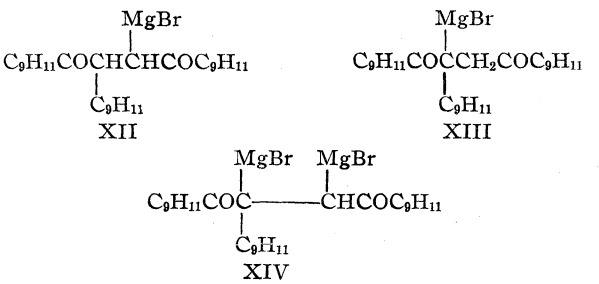
Alternative Formulations.—The hypohalite structures for the halogeno diketones IV and V (namely, X and XI), although perhaps not excluded, are highly improbable. On the basis of these formulations, which involve *cis–trans* rather than diastereoisomerism, each type of isomer should react with the Grignard reagent to give a different stereoisomeric 4-monoenolate since the 4-monoenolates-A and B are known to be stable under these conditions; actually, however, this is not the case.



X (XI)

cis and *trans*

The various mono and dienolates described in this paper may of course be formulated as true Grignard reagents, namely, XII, XIII and XIV[7]; no stereoisomerism is possible with XIII, but XII and XIV would involve diastereoisomerism instead of *cis–trans* isomerism. In view of the possibility that the whole conjugated system of the enolate group, namely, C=C—O or C=C—O—Mg, may function in reaction as a unit, and that conversely the system O=C—C—Mg might also react as a unit with one addend going to oxygen, it may not be possible from the reactions of the various compounds to decide conclusively as to which type of structure is correct. However, the true enolate formulations have been assumed here because they seem best to account for all of the reactions studied so far, particularly hydrolysis which leads to definite mono and dienols, and the existence of two isomeric 1-monoenols (described below) which would be impossible on the basis of formula XIII alone.



The Stereoisomeric 1-Monoenolates and the Dienolates.—In the foregoing discussion the question of enolization exclusively at the end of the molecule carrying the 2-mesityl group has not entered. Just as with the 4-monoenolates, the 1-monoenolates should exist in *cis* and *trans* forms, but due to the hindrance of the extra mesityl group these monoenolates should be harder to form, and the free 1-monoenols, once formed, should be extraordinarily persistent. Since the saturated diketone III enolizes first at the 4-carbonyl, it was necessary to go to the dienolates and then, avoiding oxidation to the unsaturated diketone, to allow the dienol to ketonize partially, the mobile 4-enol group ketonizing first and leaving the more persistent 1-enol. One of the two possible 1-monoenols has thus been obtained and in this case it was isolated as a metastable crystalline solid; also, there is definite evidence for the existence of the stereoisomer. These two 1-monoenols are best considered along with the stereoisomeric dienolates of which four are possible; of the latter, the existence of at least two has been demonstrated; furthermore, one free dienol has been isolated crystalline. The study of these dienolates, of course, is handicapped by the sensitivity of the free dienols toward oxygen, and the mobility of the free 4-enol group.

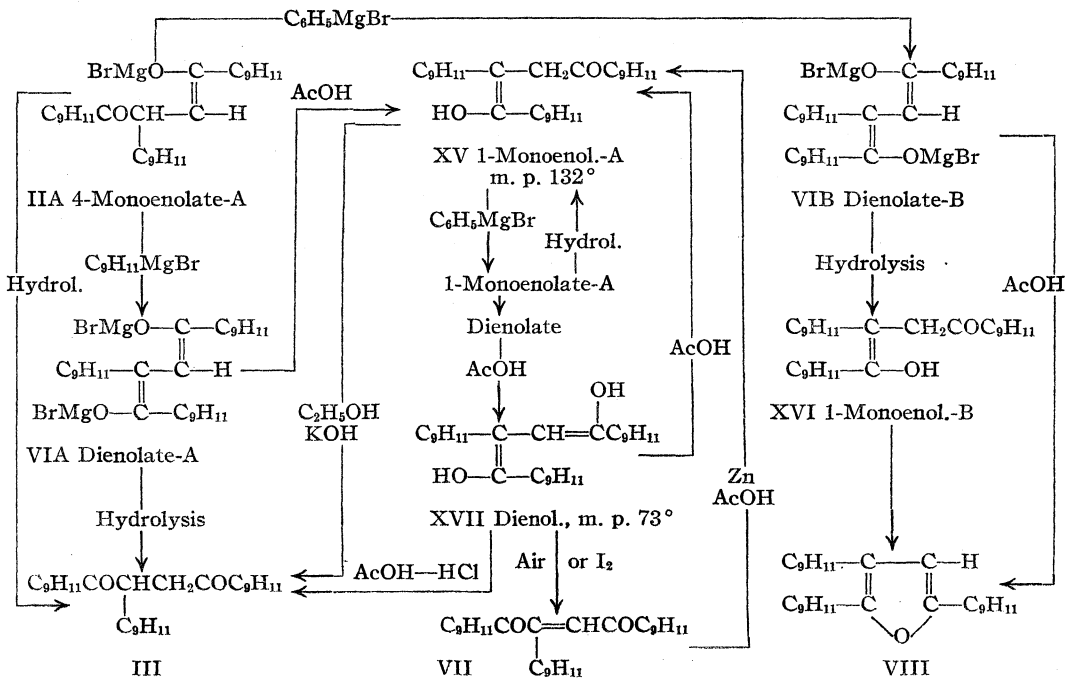
The Dienolate-A (VIA).—The dienolate VIA, arbitrarily named isomer-A, has been obtained from the 4-monoenolate-A by the enolizing action of mesitylmagnesium bromide. The preparation of this dienolate is most conveniently carried out by allowing an excess of mesitylmagnesium bromide to react either with di-(trimethylbenzoyl)-ethylene (I) or the halides IV or V, followed by

(7) *Cf.* Fuson, Fugate and Fisher, THIS JOURNAL, **61**, 2362 (1939).

heating for a short time to enolize the remaining and hindered 1-carbonyl group. That a dienolate was actually present was shown by hydrolysis in alcoholic iodine solution with resulting oxidation to the unsaturated diketone VII.

The configuration at the 4-enol group is undoubtedly the same as that in the 4-monoenolate-A because this group was already formed and possessed the configuration indicated before enolization at the 1-carbonyl took place (inversion appears to be unlikely under the conditions).

and acetic acid reduction of the unsaturated diketone VII. The structure XV follows for this monoenol since it is distinctly different from the two 4-monoenols-A and B and since the partial ketonization of the dienol would be expected to occur far more rapidly at the more mobile 4-enol group. The configuration is obviously similar to that of the corresponding 1-enol group in the dienolate-A, with the 1 and 2-mesityl groups *trans* to each other as indicated in formula XV. This configuration is assigned on the basis of the ready



The dienolate-A was characterized by its behavior upon hydrolysis; treatment with acetic acid gave the 1-monoenol-A and the use of the stronger acid, dilute hydrochloric acid, produced the saturated diketone III. The end result is in sharp contrast with that obtained on hydrolysis of the 1-monoenolate-B and the dienolate-B (described below) where trimesitylfuran (VIII) is formed exclusively under comparable conditions. The inability of the dienolate-A to go to the furan has been used as the basis for assignment of the configuration at the 1-enol group. The complete configuration is given in formula VIA.

The 1-Monoenolate-A (XV).—When the hydrolysis of the dienolate-A was carried out cautiously using acetic acid, the 1-monoenol-A was produced. It was isolated in crystalline form and characterized. It was obtained also by the zinc ketonization exclusively to the saturated diketone III and the absence of furanization which is the sole result when the isomeric 1-monoenolate-B XVI and the dienolate-B (VIB) are hydrolyzed under comparable conditions.

The 1-monoenol-A is rearranged readily to the saturated diketone III; however, it does not react with ferric chloride, bromine or diazomethane although it reacts instantly with methylmagnesium iodide with evolution of one molecule of methane. The failure of these typical enol tests must be attributed to the combined hindering effects of the two mesityl groups. The failure of the ferric chloride test might be expected, however, since it is known that another mesityl ketone,[8] $(C_6H_5)_2$-$CHCH{=}C(OH)C_9H_{11}$, does not give the color test although it reacts normally with bromine. It is

(8) Kohler and Thompson, THIS JOURNAL, 59, 888 (1937).

evident then that the dimesityl enol group, $C_9H_{11}\overset{|}{C}=C(OH)C_9H_{11}$, has none of the usual enol properties except some of those due to the active hydrogen.

Because of the inability of the enolic group of the 1-monoenol-A to react normally, the proof that it is really an enol should be examined. The evidence is as follows: the compound is isomeric with the saturated diketone and must be the enol by difference; it has an active hydrogen atom, is metastable and is convertible into the saturated diketone by the catalytic action of acids or bases.

In this connection, because of the difficulty of distinguishing between the keto and the 1-monoenol forms in this series, it was necessary to consider the saturated diketone III and the evidence that it is not itself an enol form. The saturated diketone does not react with bromine or iodine and is stable toward alkali or acid as catalysts for ketonization. It is enolized rapidly by methylmagnesium iodide with evolution of only *one* molecule of methane, and the resulting 4-monoenolate-B is shown to be the monoenolate by its reaction with one molecule of halogen to give the B-halides IV and V. From these facts then there can be no question that the saturated diketone is correctly formulated.

Reduction of the unsaturated diketone VII with zinc and boiling acetic acid, as mentioned above, proceeds slowly with the formation of the 1-monoenol-A. Reduction undoubtedly is 1,6, with the 4-enol group of the resulting dienol quickly ketonizing under these conditions.

A Crystalline Dienol.—The crystalline dienol XVII was isolated in one of the reactions studied. The 1-monoenol-A XV was treated with an excess of phenylmagnesium bromide and the resulting dienolate (probably A) was decomposed cautiously in dilute alcohol acidified with acetic acid, the free dienol separating in crystalline form. A purified sample absorbed oxygen from the air and was completely oxidized in the solid state within one week in contact with air, and reacted immediately with one equivalent of iodine; it gave in both cases the unsaturated diketone VII in approximately quantitative yields. It reacted instantly with methylmagnesium iodide with evolution quantitatively of two molecules of methane. Treatment with acetic acid caused partial ketonization to the 1-monoenol-A. Thus the configuration at the 1-enol group must correspond to that of the 1-monoenol-A as indicated in formula XVII. The configuration at the 4-enol group has not yet been ascertained.

The Dienolate-B (VIB).—As described above, the 4-monoenolate-A (IIA) reacts further with mesitylmagnesium bromide to give the dienolate-A (VIA). However, if *phenyl*magnesium bromide is used instead to bring about enolization of the hindered carbonyl group, a dienolate of distinctly different properties is obtained. The new dienolate is designated as the isomer-B (formula VIB). That this new product is actually a dienolate is shown by hydrolysis and oxidation by means of alcoholic iodine to the unsaturated diketone VII.

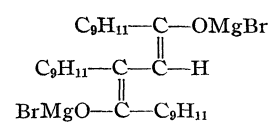
The new dienolate-B is characterized by hydrolysis. Under the usual conditions trimesitylfuran is produced exclusively, a result entirely different from that in the case of the dienolate-A where only the saturated 1,4-diketone is obtained under similar conditions. On the basis of this fact and the mode of preparation, the formula VIB has been assigned.

The 1-Monoenol-B (XVI).—Decomposition of the dienolate-B in acetic acid gave an oil which evidently was not the dienol since it did not undergo oxidation to the unsaturated diketone VII. The oil was distillable in the vacuum oven but resisted attempts at crystallization. On standing it slowly and spontaneously changed to the furan VIII which was not immediately isolable at the beginning. Under no conditions could it be converted into the saturated diketone III. It is evident that this oil contains the fourth monoenol which is therefore designated as the 1-monoenol-B XVI. In view of the ease of furan ring closure here, coupled with the fact that the 1-monoenol-A does not undergo furanization except under drastic conditions capable of dehydrating any of the compounds in the series, it is possible with reasonable assurance to assign a definite configuration at the 1-enol group both in the dienolate-B and in the 1-monoenol-B, with the 1- and the 2-mesityl groups *cis* to each other, as indicated in formulas XVI and VIB.

In the formation of the dienolate-B from the 4-monoenol-A, it is probable that the 4-enolate group remains unchanged in configuration, and in consequence it seems likely that both the dienolates-A and -B and the 4-monoenolate-A are identical in respect to the 4-enolic group, as formulated in the diagram. The new dienolate-B, then, presumably differs from the dienolate-A only in the

configuration at the 1-enol group. Whether or not this be true, it is noteworthy that the enolization at the 1-carbonyl of the 4-monoenolate-A goes in different ways with mesityl and phenylmagnesium bromides to produce configurationally opposite arrangements at the 1-enolic grouping.

The Possible Existence of a Third Dienolate (C).—The saturated diketone III when enolized by the action of the Grignard reagent gives first the 4-monoenolate-B, as described above. When the secondary enolization is forced under drastic conditions a second molecule of methane is evolved, but some decomposition occurs and the result is not of quantitative significance. The formation of some dienolate was demonstrated by oxidation with iodine to the unsaturated diketone, but the yield was poor. If no rearrangement at the 4-enol group took place, then this must be a third dienolate, C (formula XVIII), with the 4-enol group corresponding in configuration to that of the 4-monoenolate-B, and differing in this respect from the dienolates-A and -B; and since no furan was obtained from the reactions the configuration at the 1-enol must correspond to that of the 1-monoenol-A (as indicated). However, in view of the poor yields, the production of a mixture of products, and the possibility of rearrangement at the 4-enol group under the drastic conditions involved, and in the absence of any definite characterizing reaction, this question must be regarded as unsettled. It is conceivable that the configuration of the 4-monoenolate-B may actually inhibit enolization at the 1-carbonyl with rearrangement necessarily preceding the secondary enolization, and in such a case the dienolate formed here would be either A or B (VIA or B). Unfortunately, attempts to test these points were not successful.



XVIII

Dienolate—C (?)

The Bearing of the Results on the Mechanism of Furan Ring Closure.—The foregoing results are entirely consistent with the probable mechanism of furan formation[2] involving addition of an enolic hydroxyl to a γ-carbonyl followed by loss of a molecule of water. According to this theory the dienols should not be capable of giving the furan directly. The two stereoisomeric dienols which are known with certainty (IVA and B) do not do so (one of them gives the furan but only after partial ketonization and consequent destruction of the dienol system). It is hoped that the two remaining theoretically possible dienols can be isolated and tested in this connection since it is conceivable that one of them might undergo direct furanization, even though the dienol form has now been shown to be unnecessary to this reaction in at least one instance.[9]

If the suggested mechanism of furanization is correct, then in cases of unsymmetrical compounds where the enol groups, as here, can exist in four forms (two *cis–trans* pairs), two of the isomers with the enolic hydroxyl and chain in the *cis* relationship could theoretically give the furan.[10] However, if one of the two γ-carbonyl groups is unreactive due to great steric hindrance (as in the case of the 1-carbonyl group in this series), then only one of these two isomers of favorable configuration would be at all likely to undergo furanization. In the trimesityl series under discussion, neither of the two stereoisomeric 4-monoenols IIA and B gives the furan. One of these, of course, would have a favorable configuration but in this case furanization would not be expected because of the enormous and undoubtedly prohibitive steric hindrance at the γ-carbonyl coupled with the mobility and speed of ketonization of the 4-enolic group. Of the two 1-monoenols the A-isomer XV cannot be furanized under ordinary conditions and undergoes ketonization exclusively, but the B-isomer XVI gives the furan directly and spontaneously and is the only compound in the series to do so. Here then is a definite case of spontaneous furanization through a monoenol where the dienol certainly cannot be involved, and where there evidently exists the only possible combination of factors which would be favorable to this reaction, namely, the *cis* configuration with respect to the enolic hydroxyl and the chain bearing the γ-carbonyl, a marked persistence of the

(9) *Cf.* also the supposed monoenol of 1,4-diphenyl-2-mesitylbutanedione-1,4 (Ref. 4).

(10) Kleinfeller and Trommsdorff [*Ber.*, **72**, 257 (1939)] have made the suggestion that the failure of their substituted saturated 1,4-diketone to undergo dehydration to the furan was not because of any difficulty of enolization but rather because of enolization in one-half of the molecule to an enolic group of unfavorable configuration. Presumably, these authors in referring to the "enolform" involved in dehydration mean the dienol since they state that only one of the four possible stereoisomers would have a configuration favorable for ring closure. If the monoenols were meant, then of the four possible isomers (two *cis–trans* pairs), two would have configurations favorable to ring closure, assuming, of course, a mechanism of reaction such as has been suggested in Ref. 2 According to this theory of the mechanism, however, there is no obvious explanation of the failure of this saturated 1,4-diketone to undergo dehydration (perhaps it will do so if suitable conditions are found).

enol group due to hindrance by the substituted mesityl groups, and a γ-carbonyl with a minimum of hindrance and capable of reaction, given time to do so.

The inconsistency in the ease of furanization of various saturated 1,4-dimesityl 1,4-diketones is understandable in terms of some resultant of the various factors which have been discussed.[11]

Continuation of the work on this series of compounds with extension to tetraaryl types is in progress.

Experimental Part

1,2,4-Trimesitylbutanedione-1,4, III.—In a typical experiment 5.7 g. of finely powdered di-(trimethylbenzoyl)-ethylene was added in half-gram portions to a thoroughly stirred solution of four equivalents of mesitylmagnesium bromide in 45 cc. of absolute ether. The temperature was held at 20° as the immediate and vigorous reaction proceeded. The resulting clear brown solution was stirred for fifteen minutes, cooled to 0° and poured into ice water acidified with dilute hydrochloric acid. The product was extracted by means of ether, the solution on concentration depositing 5.3 g. of triphenylbutanedione. After repeated crystallization from acetone it was obtained as slender needles melting at 147–147.5°.[12] It is very soluble in acetone, butanone, ethyl acetate and ligroin but difficultly soluble in methanol and ethanol.

Anal. Calcd. for $C_{31}H_{36}O_2$: C, 84.5; H, 8.2. Found: C, 84.5; H, 8.2.

Bromination in chloroform solution did not give a crystalline product.

Reaction with methylmagnesium iodide at room temperature according to the Zerewitinoff method in isoamyl ether gave a precipitate and showed evolution quantitatively of one molecule of methane; further evolution of methane did not occur even on long standing. At 100°, fifteen hours were required for a half of a molecule more of methane to form. On hydrolysis of the products in alcoholic iodine and working up in the usual way, some unsaturated as well as saturated diketone was isolated. A yield of 20% of unsaturated diketone was isolated upon hydrolysis in alcoholic iodine.

2,3,5-Trimesitylfuran, VIII.—Dehydration of the saturated 1,4-diketone (III) with acetic anhydride and sulfuric acid in the usual way failed. The effective procedures developed are described below, the best one being (a).

(a) A solution of 0.5 g. of III in 15 cc. of concd. acetic acid containing 0.6 cc. of water was refluxed gently for thirty hours with a continuous stream of dry hydrogen chloride passing through at the rate of about 20 bubbles per minute. The solution on cooling deposited 0.41 g. of nearly pure furan and 0.13 g. more was recovered from the filtrate. On repeated crystallization from concd. acetic acid or ethanol, it melted at 106.5°. It crystallizes slowly.

Anal. Calcd. for $C_{31}H_{34}O$: C, 88.1; H, 8.1. Found: C, 87.84; H, 7.9.

(b) A mixture of 0.2 g. of III and 1 cc. of hydriodic acid (sp. gr. 1.7, protected with hypophosphorous acid) was heated in a sealed tube at 160–170° for one hour. The product upon standing for several days in ethanol deposited the furan in 50% yield.

(c) A mixture of 0.2 g. of III, 8 cc. of concd. acetic acid, 6 drops of hydriodic acid (sp. gr. 1.7) and 0.1 g. each of red phosphorus and of iodine, was refluxed for one hour (the peculiar conditions here used were chosen for a control experiment). When the mixture was poured into water and worked up in the usual way, 0.13 g. of the furan was isolated.

Bromination of the furan with phosphorus pentabromide at 90° for half an hour gave an amorphous solid melting at 120–150°. Analysis indicated it to be a tetrabromide.

Anal. Calcd. for $C_{31}H_{30}OBr_4$: Br, 43.4. Found: Br, 41.7.

4(?)-Nitro-2,3,5-trimesitylfuran, IX.—A suspension of 0.2 g. of VIII in 2 cc. of concd. acetic acid at 15° was treated with 0.4 cc. of a 1–3 mixture of concd. nitric and acetic acids. On standing for thirty minutes the suspended solid dissolved, and scratching and seeding caused deposition of 0.12 g. of the mononitro derivative which on repeated crystallization from isopropanol was obtained as rhombic prisms melting at 206.5–207°.

Anal. Calcd. for $C_{31}H_{33}O_3N$: C, 79.6; H, 7.1; N, 3.0. Found: C, 79.9; H, 7.1; N, 3.2.

3-Iodo-1,2,4-trimesitylbutanedione-1,4-A, IV.—The solution of magnesium 4-monoenolate-A, prepared from 20 g. of di-(trimethylbenzoyl)-ethylene and 90 cc. of an ether solution of two equivalents of mesitylmagnesium bromide, was decomposed by adding it slowly to a vigorously stirred solution of 20 g. of iodine in 400 cc. of ethanol cooled in an ice-bath, the temperature varying between 0 and 10°. The product crystallized directly from the ethanol solution. After standing for half an hour at 0° with stirring to ensure complete precipitation, enough concd. hydrochloric acid was added to dissolve the magnesium hydroxide, and the product was filtered off; yield 26.5 g. of practically pure material. The yields in different runs varied from 74–79%. After repeated crystallization from concd. acetic acid and from ethyl acetate it was obtained as colorless rectangular plates melting at 213° with decomposition and liberation of iodine.

Anal. Calcd. for $C_{31}H_{35}O_2I$: C, 65.7; H, 6.2. Found: C, 65.8; H, 6.2.

Small amounts of the isomeric iodo compound B were obtainable by fractional crystallization of the residues from this experiment.

Reduction was brought about in four ways as follows:

(a) A sample of the iodo compound reacted with potassium iodide in concd. acetic acid at room temperature with liberation of approximately one equivalent of iodine (titrated) and formation of trimesitylbutanedione III in quantitative yield.

(11) 1,4-Dimesitylbutanedione-1,4, $C_9H_{11}COCH_2CH_2COC_9H_{11}$ [Lutz, Johnson and Wood, THIS JOURNAL, **60**, 716 (1938)] and the saturated diketone of this series, III, for example, are dehydrated only with considerable difficulty, whereas 2,3-dimethyl-1,4-dimesitylbutanedione-1,4, $C_9H_{11}COCH(CH_3)CH(CH_3)COC_9H_{11}$ [Lutz and Taylor, *ibid.*, **55**, 1593 (1933)] is converted into the corresponding furan with extraordinary ease.

(12) Melting points of all analytical samples are corrected.

(b) The action of zinc dust in boiling concd. acetic acid (three min.) gave III.

(c) Refluxing for one hour in 60% ethanol with an excess of sodium bisulfite gave III.

(d) Hydrogenation in ethyl acetate using platinum oxide catalyst liberated iodine and gave III in good yield.

Alcoholic potassium hydroxide, refluxed for one hour, converted the iodo compound into the unsaturated diketone VII. Refluxing with an excess of anhydrous sodium acetate in ethanol for eight hours was without effect.

3-Iodo-1,2,4-trimesitylbutanedione-1,4-B, IV.—Solutions of the magnesium 4-monoenolate-B from the action of an excess of phenyl, ethyl or methylmagnesium halide at room temperature on trimesitylbutanedione, III, were poured into excess of cooled alcoholic iodine. From 0.4 g. of III, upon decomposition in alcoholic iodine at −10 to −15°, 0.25 g. of IVB was obtained, and from the mother liquors 0.15 g. of unchanged material (III). The iodide was not pure, however, and contained a little of the higher melting isomer-A. When the decomposition in alcoholic iodine was carried out at −60° the yield of the iodo compound-B was about the same but it was practically pure. Exhaustive crystallization from ethyl acetate and from concd. acetic acid gave a product of constant melting point of 178° (elongated hexagonal plates). It did not give a mixture melting point depression with the higher melting isomer-A but did with the bromo compound, isomer-A.

Anal. Calcd. for $C_{31}H_{35}O_2I$: C, 65.7; H, 6.2. Found: C, 65.5; H, 6.1.

Examination of the mother liquors of the above experiment failed to reveal the presence of even small amounts of the unsaturated diketone VII which would be expected as a result of oxidation of small amounts of dienolate by the iodine.

Reaction with the Grignard Reagent.—A sample (0.1 g.) of IVB was added to 1 cc. of ether containing two equivalents of ethylmagnesium bromide at 20° and the resulting mixture immediately was poured into 15 cc. of boiling concd. acetic acid. On diluting with water and crystallizing from ethanol 0.05 g. of the saturated diketone III was obtained.

In a similar experiment in which the ether solution was heated for five minutes and then poured into boiling acetic acid, a mixture of about equal parts of the saturated and unsaturated diketones III and VII was obtained, indicating that part of the material had been enolized at both of the carbonyls. Phenylmagnesium bromide, used instead of ethylmagnesium bromide, caused complete enolization to the dienolate under these conditions.

Reduction with sodium bisulfite in boiling 60% ethanol (thirty minutes) gave a quantitative yield of III.

The action of potassium hydroxide in excess in boiling ethanol (one hour) converted the iodide in good yield into the unsaturated diketone VII.

3-Bromo-1,2,4-trimesitylbutanedione-1,4-A, V.—A solution of the 4-monoenolate-A (II) and 12 cc. of an ether solution of two equivalents of ethylmagnesium bromide at 20° was cooled immediately to 0° and added to 25 cc. of ethanol solution containing 1.5 g. of bromine also at 20°. The product crystallized and was filtered off (2.4 g.). Fractional crystallization from acetone and from isopropanol gave 1.35 g. of nearly pure bromo diketone VA and 0.1 g. of the stereoisomer (B). The isomer-A was purified by repeated crystallization from isopropanol and melted at 192.5–193.5°.

Anal. Calcd. for $C_{31}H_{35}O_2Br$: C, 71.7; H, 6.8. Found: C, 71.7, 71.9; H, 6.9, 6.8.

When the 4-monoenolate-A solution was decomposed in alcoholic bromine at higher temperatures (10°) a difficultly separable mixture of the bromodiketones A and B was obtained.

Ethylmagnesium bromide at 20° enolized the bromodiketone-A quickly and when the mixture was decomposed in alcoholic iodine at 10° the iododiketone-A (IV) was obtained exclusively and in good yield.

The bromodiketone-A was not affected by the prolonged action of boiling ethanolic sodium acetate (twelve hours), but when refluxed for thirty minutes with a 95% methanolic solution of an excess of potassium hydroxide, the unsaturated diketone VII was obtained.

Reduction with sodium bisulfite in 60% ethanol (refluxing for four hours) gave the saturated diketone III.

3-Bromo-1,2,4-trimesitylbutanedione-1,4-B, V.—A solution of the 4-monoenolate-B, prepared by the action of phenyl, methyl or ethylmagnesium halide on III, was decomposed in alcoholic bromine. In a typical experiment starting with 0.2 g. of III, decomposing in alcoholic bromine at −60°, 0.2 g. of nearly pure bromodiketone-B was obtained (80%). Repeated crystallization from acetone gave a pure product melting at 230–231°.

Anal. Calcd. for $C_{31}H_{35}O_2Br$: C, 71.7; H, 6.8; Br, 15.4. Found: C, 71.5; H, 7.1; Br, 15.5.

When in several different experiments the solution of the 4-monoenolate-A was decomposed in alcoholic bromine at temperatures ranging from 0 to −15°, a mixture of the isomers A and B was obtained.

Ethylmagnesium bromide at 20° reacted rapidly with the bromodiketone-B. On decomposition in alcoholic iodine at 10°, the iododiketone-A was obtained exclusively in good yield.

Reduction in the usual way with zinc dust and concd. acetic acid gave III.

Sodium acetate in boiling ethanol (two hours) was without effect, but refluxing for two hours in 95% ethanol containing an excess of potassium hydroxide gave the unsaturated diketone in nearly quantitative yield.

1,2,4-Trimesityl-2-butenedione-1,4, VII.—A suspension of 4 g. of the iododiketone IVA in 125 cc. of ethanol and 3 g. of potassium hydroxide was refluxed for one hour, giving a dark red solution which was diluted with water cautiously as it cooled, the product separating in 90% yield. On repeated crystallization from methanol, ethanol or ligroin it was obtained as colorless needles which melted at 142–144°, turning yellow as it melted. It became colorless on solidification. Its solutions in common solvents are yellow.

Anal. Calcd. for $C_{31}H_{34}O_2$: C, 84.9; H, 7.8. Found: C, 85.1; H, 7.6.

The unsaturated diketone VII is obtainable similarly as described from the other halides IVB and V (A and B). Methanol may be substituted for ethanol as the solvent but it is not as satisfactory due to the difficult solubility of the halides.

Various attempts to make the acetoxyfuran by means of acetic anhydride and concd. sulfuric acid failed, no reaction occurring even at boiling temperature.

The unsaturated diketone was not changed on exposure to sunlight in ethanol or in chloroform containing iodine.

Reduction.—Zinc dust and concd. acetic acid produced the 1-monoenol-A (see this compound). Sodium hydrosulfite in dilute ethanol as medium did not bring about reduction. The combination 8 cc. of concd. acetic acid, 4 drops of water, 0.1 g. of iodine and 0.1 g. of red phosphorus, refluxed for one hour, gave the furan VIII in good yield.

1,2,4-Trimesitylbutane-1,4-dione-4-enolate-A, IIA.—A solution of this enolate is obtained by the action of mesitylmagnesium bromide on the saturated 1,4-diketone III as already described. Since neither it nor the free enol could be isolated, this compound was characterized by its reactions as follows:

(a) The reaction with iodine and bromine leads to the iodo and bromodiketones IVA and VA.

(b) Decomposition in an alcoholic solution of quinone or ferricyanide produced only the saturated diketone III and no unsaturated diketone VII, showing that significant amounts of the dienolate were absent.

(c) When decomposed in dilute hydrochloric acid the saturated diketone III was formed exclusively.

(d) Decomposition by dropping the ether solution slowly into boiling concd. acetic acid in an apparatus arranged to collect the ether boiled off, gave the saturated diketone III exclusively and in good yield.

(e) Mesitylmagnesium bromide in isopropyl ether with refluxing for two hours under an atmosphere of nitrogen converts it into the dienolate-A (see this compound). When ethyl ether was used and the mixture refluxed for two hours and decomposed in alcoholic iodine in the usual way, only the iododiketone-A was obtained, showing that the higher temperature obtainable in boiling isopropyl ether is required to produce the dienolate.

(f) Phenylmagnesium bromide converted it readily into the dienolate-B (see this compound), the reaction proceeding upon five minutes of refluxing with ethyl ether as solvent.

Preparation of the 4-Monoenolate-A from the Iododiketone IVA.—This method is the most convenient and the product is obtainable thus free from tarry secondary products which are formed in the reaction between mesitylmagnesium bromide and di-(trimethylbenzoyl)-ethylene. The general procedure was to add the sample of iododiketone to 3–4 equivalents of phenylmagnesium bromide in ether, controlling the temperature by means of an ice-bath to 20°, and allowing the solution to stand not more than two to three minutes before use. The other three halogeno diketones can be used in the same experiment and ethyl or mesitylmagnesium bromides can be used with equal success.

The 4-monoenolate-A from the iododiketone-A was characterized by application of the tests (a), (d) and (f) listed under the first preparation described above. The products from the iododiketone-B and from the bromodiketones A and B were characterized by application of (a) with conversion into the iododiketone-A.

An attempt was made to isolate the 4-monoenolate-A under mild conditions by hydrolysis in ice water acidified with dilute acetic acid, extraction by ether, and evaporation at room temperature. An oil was obtained which crystallized promptly from ethanol as the saturated diketone III. Similarly a solution of the 4-monoenolate-A was decomposed in ice water and extracted with ether without acidification, separated, the ether layer dried over anhydrous sodium sulfate for a few minutes, and added to an ether solution of an excess of diazomethane. Only the saturated diketone was recovered.

1,2,4-Trimesitylbutane-1,4-dione-4-monoenolate-B, IIB.—The action of phenyl, ethyl or methylmagnesium halide in ether on trimesitylbutanedione III at room temperature gives the 4-monoenolate-B. The reaction was carried out under a variety of conditions, in some cases with refluxing, but heating proved to be unnecessary and introduced some dienolate. The enolization of the second and hindered carbonyl here is much more difficult to bring about than in the case of the 4-monoenolate-A. The solutions of the 4-monoenolate-B on decomposition in alcoholic bromine or iodine gave the B-halides IV and V when the temperature was lowered. At temperatures from 0–25° mixtures of the bromides (largely B) were obtained, but with iodine ketonization took place so rapidly that the saturated diketone III was obtained in large amounts (over 75% in one case) along with smaller amounts of the iododiketone IVB.

Characterization of the 4-monoenolate-B was best made by halogenation at lowered temperature (−60°). Hydrolysis of a sample in boiling concd. acetic acid gave only the saturated diketone III, and careful examination of the products failed to reveal the presence of trimesitylfuran. The 4-monoenolate-B was decomposed in a cooled (10°) solution of quinone in ethanol, but only the saturated diketone could be isolated, showing that there was little dienolate present in the sample. Unsuccessful attempts were made to isolate the free 4-monoenol-B by hydrolysis of the enolate in ice water acidified with acetic acid and extraction with ether. The oil obtained crystallized quickly at room temperature when triturated with isopropanol, giving the saturated diketone.

1,2,4-Trimesitylbutane-1,4-dione-1-monoenol-A, XV.—A mixture of 8 g. of the unsaturated diketone VII, 20 g. of zinc dust, and 125 cc. of concd. acetic acid was refluxed with mechanical stirring for one hour. On filtration and dilution with ice water the product coagulated and was filtered, dried and recrystallized from ligroin. The yields averaged 60%. On repeated crystallization from ligroin it was obtained as cubic prisms melting at 131–131.5°.

Anal. Calcd. for $C_{31}H_{36}O_2$: C, 84.5; H, 8.2. Found: C, 84.3; H, 8.2.

The 1-monoenol-A was obtained also from the hydrolysis of the dienolate-A (see that compound). It crystallized from ethanol with water of crystallization and melted with effervescence at 95–100°, solidified and remelted at 130°. On standing the hydrate loses its solvent of crystallization and reverts to the anhydrous form. It does not give a color reaction with alcoholic ferric chloride nor does it react at all readily with alcoholic bromine or with diazomethane (in ether for eighteen hours). In a quantitative test it reacted with methylmagnesium iodide at room temperature under nitrogen with evolution of 0.93

molecule of methane. Phenylmagnesium bromide at 20° gives the monoenolate also as was shown by decomposition in alcoholic iodine and recovery of the 1-monoenol-A unchanged, with little or no oxidation to the unsaturated 1,4-diketone. Under more drastic conditions the monoenol reacts with phenylmagnesium bromide to give the dienolate-A (see that compound).

The 1-monoenol-A, when heated with iodine, red phosphorus and concd. acetic acid for one hour, gave trimesitylfuran. The saturated diketone III is furanized under these conditions also.

The action of potassium hydroxide in 95% ethanol (refluxed for one hour) produced the saturated diketone.

1,2,4-Trimesitylbutanedione-1,4 Dienolate-A, VIA.—The dienolate-A was obtained as an ether insoluble powder by adding di-(trimethylbenzoyl)-ethylene to mesitylmagnesium bromide in isopropyl ether (giving first the 4-monoenolate-A) followed by refluxing for two hours under an atmosphere of nitrogen. A dienolate which was presumably the same was obtained by adding the 1-monoenol-A, XV, to an ether solution of an excess of phenylmagnesium bromide and refluxing for thirty minutes. These dienolates from the two sources appeared to be identical since they gave similar results when tested in the following experiments carried out independently on samples prepared in the two ways.

(a) The suspension of product was poured into an ethanol solution of an excess of iodine (10°), and the mixture was then diluted with water containing sodium bisulfite (acidified) to destroy the excess of iodine. The resulting oil was crystallized from ethanol and a good yield of the unsaturated diketone VII was obtained.

(b) Decomposition in boiling acetic acid andre fluxing for one hour after expulsion of all of the ether, gave an oil from which only the saturated diketone III could be isolated. No furan was detected. The presence of the magnesium salts evidently was responsible for ketonization of the 1-monoenol-A in this reaction.

(c) When the ether solution of the dienolate was poured into concd. acetic acid magnesium salts crystallized and were filtered off. The ether was then boiled off; the remaining solution in concd. acetic acid was then refluxed for one hour and diluted with water. Extraction with ether and concentration gave the 1-monoenol-A, XV, which was crystallized from ligroin or isopropanol and identified.

While the identity of the two samples with respect to configuration at the 1-enol group is certain, the identity of configurations at the 4-enol group is not rigorously proved because in one case (dienolate-A) the group was formed before and in the other case after enolization at the 1-enol group, and because the tests listed do not distinguish between the 4-monoenolate configurations. Attempts to prove the point by converting both samples of dienolate to the same crystalline dienol were unsuccessful. The dienol (described below) was isolated only in the second case when the dienolate was prepared from the 1-monoenol-A. The failure to isolate the dienol from the first preparation (dienolate-A) is of no significance in view of the experimental difficulties involved, particularly the difficulty of crystallizing, the presence of mesitylene from excess Grignard reagent, and the sensitivity of the dienol itself. It is hoped that in the further investigations under way derivatives may be obtained which will throw light on this question.

1,2,4-Trimesitylbutanedione-1,4 Dienol, XVII.—Two-tenths gram of the 1-monoenol-A (XV) was added to 4 cc. of phenylmagnesium bromide solution in ether (concn. 0.001 mole per g.) and the mixture was refluxed for thirty minutes, the dienolate precipitating. On cooling to 0° and adding 20 cc. of 80% ethanol containing 2 cc. of concd. acetic acid, followed quickly by 50 cc. of water, a white solid separated and was filtered quickly and crystallized from ethanol. The first crop of crystals melted low and successive crops of material were then obtained (rectangular plates) which melted sharply at 70–71°. In another run a sample melting at 72–73° was obtained. The yield was 0.1 g. The compound in the solid state was oxidized by air and after standing for a week was converted quantitatively into the unsaturated diketone VII. The change proceeded rapidly when the material was treated with iodine in ethanol, and in a quantitative experiment where the excess of iodine was estimated by titration with sodium thiosulfate, one molecule of iodine was used up with the formation of the unsaturated diketone in quantitative yield. In the Zerewitinoff apparatus with methylmagnesium iodide at room temperature 1.89 molecules of methane was liberated with the formation of a white precipitate.[13]

Rearrangement to the saturated diketone III was brought about by heating a solution of the dienol in concd. acetic acid containing a small amount of concd. hydrochloric acid for fifteen minutes. Rearrangement to the 1-monoenol-A (without isolating the dienol from the magnesium dienolate) was described under the preparation of this compound.

While the configuration at the 1-enol group is certain the configuration at the 4-enol group has not been established relative to the 4-monoenolates-A and B.

1,2,4-Trimesitylbutanedione-1,4 Dienolate-B, VIB.—The dienolate-B is obtained in two ways: (1) by the enolization of the 4-monoenolate-A in diethyl ether after its preparation from di-(trimethylbenzoyl)-ethylene and mesitylmagnesium bromide; this was done by adding *phenyl*-magnesium bromide to the mixture and refluxing for thirty minutes; and (2) by the action of phenylmagnesium bromide on the iododiketone IVA in ethyl ether, with refluxing for five minutes.

The dienolate-B differs from the A-isomer by its solubility in ether. The probable identity of the materials from the two sources was established by the following experiments carried out on each sample separately.

(a) Samples were decomposed in alcoholic iodine solution at 10° and worked up in the usual way, giving the unsaturated diketone VII and showing that they actually contained the dienolate.

(b) Solutions were decomposed by adding them slowly to boiling concd. acetic acid in an apparatus arranged to collect the ether which volatilized, the solution then being

(13) Unfortunately before carbon and hydrogen analyses could be carried out on the above described sample, oxidation to VII had occurred. New samples prepared subsequently were not as good and analyses were unsatisfactory (carbon was low). It did not seem worth while to delay publication further, however, and the formulation of the dienol is therefore based on the quantitative data described.

refluxed for one hour, diluted with water and extracted with ether. Crystallization of the resulting oil from isopropanol gave trimesitylfuran VIII exclusively, no saturated diketone being detected.

In one experiment the dienolate-B was decomposed in cold dilute acetic acid and only traces of the furan were isolable from the oily product which could be distilled in the vacuum oven. This oil is very evidently the **1-monoenolate-B.**

From the fact that the two samples of the dienolate-B give the furan rather than the saturated diketone, it is certain that they both have the same configuration at the 1-enol group as indicated in formula VIB. Both samples, of course, must have the same configuration at the 4-enol group (corresponding to that of the 4-monoenolate-A) since this group was formed in both experiments before enolization occurred at the 1-carbonyl group.

Summary

1,2,4-Trimesitylbutanedione-1,4 was obtained as the result of 1,4-addition of mesitylmagnesium bromide to di-(trimethylbenzoyl)-ethylene. The 4-monoenolate-A was first formed (proved by halogenation) and was further enolized to the dienolate (proved by oxidation).

1,2,4-Trimesityl-2-butenedione-1,4 was obtained by oxidation of the dienols and by elimination of halogen acid from the 3-halogeno-1,2,4-trimesitylbutane-1,4-diones.

2,3,5-Trimesitylfuran and its mononitro derivative are described.

The 3-halogeno-1,2,4-trimesityl-1,4-butanediones have been obtained each in diastereoisomeric forms.

The existence of two 4-monoenolates, A and B, was demonstrated: A was formed by the addition of mesitylmagnesium bromide to di-(trimethylbenzoyl)-ethylene or by the action of any Grignard reagent on the 3-halogeno-1,2,4-trimesitylbutane-1,4-diones, and B by the enolization of the saturated 1,4-diketone. They were characterized by halogenation to the stereoisomeric halogeno diketones. A basis for assignment of configurations is discussed.

The 1-monoenol-A (m. p. 145°) was obtained by partial ketonization of the dienolate. It lacked most of the usual enolic properties. Ketonization gave the saturated diketone. Enolization gave a crystalline dienol which was metastable and easily oxidized to the unsaturated 1,4-diketone.

The existence of two dienolates, A and B, was demonstrated. A was obtained from the 4-monoenolate-A by enolization with mesitylmagnesium bromide, and was converted by hydrolysis and ketonization to the saturated diketone. B was obtained by the action of phenylmagnesium bromide on the 4-monoenolate-A and was characterized by hydrolysis with spontaneous formation of trimesitylfuran.

Configurations at the 1-enol group are assigned on the basis of the relative ease of furan formation and ketonization.

The mechanism of furan ring closure is discussed in the light of this work.

Sulfanilamide Derivatives. V. Constitution and Properties of 2-Sulfanilamidopyridine[1]

BY M. L. CROSSLEY, E. H. NORTHEY AND MARTIN E. HULTQUIST

Although 2-sulfanilamidopyridine[2] (now named "sulfapyridine" by the American Medical Association) has received wide publicity as a result of its use in the treatment of pneumonia,[3] attention has been drawn to the fact that practically nothing has been published on its physical and chemical properties, and no evidence has been given in support of the assigned structure.[4]

We had independently synthesized this compound as part of our program on N^1-substituted sulfanilamides and had made a pharmacological study, but the announcements from England were made before we were prepared to publish our information. We offer the following evidence on constitution as well as data on the properties of the carefully purified compound.

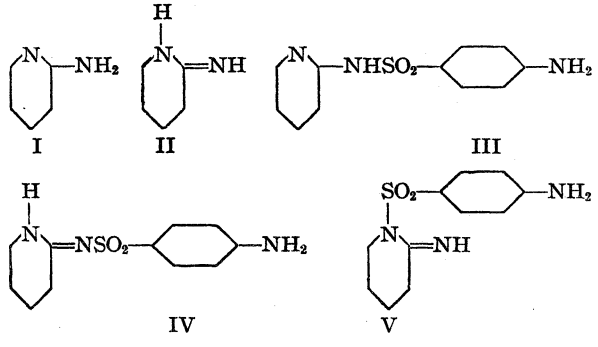
(1) Presented in part before the Division of Medicinal Chemistry, A. C. S. Meeting, Baltimore, Md., April, 1939.

(2) See Sulfanilamide Derivatives I, THIS JOURNAL, **60**, 2217 (1938), for nomenclature.

(3) Whitby, *Lancet*, **1**, 1210 (1938); synthesized by J. A. Ewins and M. A. Phillips.

(4) Marshall, *J. Am. Med. Assoc.*, **112**, 352 (1939).

2-Sulfanilamidopyridine was synthesized by reaction of N-acetylsulfanilyl chloride with 2-aminopyridine, followed by hydrolysis of the acetyl group. 2-Aminopyridine is a well-known compound, but can exist in tautomeric forms having the structures I and II, so that it is necessary to decide which form represents the structure of its sulfanilyl derivative. Structures III, IV and V represent the possibilities through replacement of a hydrogen attached to nitrogen in formulas I and II. 2-Aminopyridine derivatives



having structure II undergo hydrolysis on boiling in sodium hydroxide solution with evolution of ammonia and production of pyridone.[5]

Actually, no hydrolysis of 2-sulfanilamidopyridine occurred on boiling with 50% sodium hydroxide, or weaker strengths. When hydrolyzed by boiling with 36% hydrochloric acid, practically quantitative yields of sulfanilic acid and 2-aminopyridine were obtained. This evidence supports structure III and is against IV and V.

Further evidence in support of III is that the compound forms a monosodium salt which hydrolyzes in water to give a *p*H of 10 to 11. This is characteristic of all sulfonamides of the structure —SO_2NH—.[6] While structures IV and V might conceivably give rise to monosodium salts, it would be predicted from the behavior of the sodium salt of 2-aminopyridine that these would be more highly hydrolyzed in water and would give rise to higher *p*H values than those found.

These facts and deductions lead one to the conclusion that structure III is correct and justify the name 2-sulfanilamidopyridine.

Physical Properties of 2-Sulfanilamidopyridine.—2-Sulfanilamidopyridine is soluble to the extent of approximately 1.05 g./100 cc. in water at 100°; 0.11 g./100 cc. at 40°; 0.05 g./100 cc. at 20°.

It melts with slight decomposition in a capillary tube, over the range: 190.4 (first shrinking)—190.9 (first meniscus)—191.5° (complete melting). On the Dennis block a value of 192.8° was obtained on warming from room temperature, and the same value was obtained by placing the material in contact with the hot bar.

The compound crystallizes from alcohol in small, glistening rhombs. It is white, odorless and tasteless.

Chemical Properties.—2-Sulfanilamidopyridine dissolves readily in strong hydrochloric acid, presumably forming a hydrochloride or dihydrochloride. Potentiometric titration on addition of hydrochloric acid, however, gives a smooth curve without indication of salt formation, so that it is evident that the hydrochloride is highly dissociated. 2-Sulfanilamidopyridine forms a sodium salt which may be isolated and purified.[7]

The solution in hydrochloric acid may be titrated quantitatively by diazotization with sodium nitrite. The reaction is in equimolecular proportions and involves only the amino group of the sulfanilamide part of the molecule.

On heating a sample of the material in a test-tube to about 220° decomposition occurs with development of a brown color and evolution of sulfur dioxide and aniline (a similar but slower decomposition occurs at the melting point and explains the wide range). This is in contrast to sulfanilamide, which develops a blue or violet color and evolves ammonia and aniline.

Purified 2-sulfanilamidopyridine had the following microanalysis[8]: Calcd. for $C_{11}H_{11}O_2N_3S$: C, 52.99; H, 4.45; N, 16.86; S, 12.86. Found: C, 53.02, 53.06; H, 4.66, 4.55; N, 16.72, 16.72; S, 12.76, 12.93.

When assayed by titration with 0.1 *N* sodium nitrite to an end-point on starch iodide paste, the results were 100.2, 100.0. Molecular weight determinations using *m*-dinitrobenzene (K_f 12.49, setting point 89.70°) gave: 251.5, 251.5, 251.0, 248.0. Calcd. 249.29.

Experimental Part

2-(N^4-Acetylsulfanilamido)-pyridine.—18.8 g. (0.2 mole) of 2-aminopyridine (purified by double vacuum fractionation and three recrystallizations from 1 part benzene and 2 parts hexane; melting range 57.0–58.0°; setting point 57.90°) was dissolved in 75 cc. of anhydrous dioxane; 23.5 g. (0.1 mole) of N-acetylsulfanilyl chloride (recrystallized twice from toluene and once from chloroform; m. p. 148.5–149.5°) was added. The mixture was warmed to 95° and held fifteen min. On cooling and stirring, the oily layer crystallized. The crystals were filtered and washed with 25 cc. of dioxane, then 25 cc. of alcohol, and finally with 150 cc. of water. The dry weight was 27 g. or 92.8% based on N-acetylsulfanilyl chloride.

The crude 2-(N^4-acetylsulfanilamido)-pyridine was recrystallized from 200 cc. of dioxane and 125 cc. of water with use of activated charcoal and the crystals were washed with dilute dioxane. On drying, the material partially melted and changed crystalline form indicating loss of

(8) Purification and determination of physical constants were carried out by W. J. Mader. Microanalyses were made under the direction of G. L. Royer.

dioxane of crystallization. After two recrystallizations from 70% alcohol, the melting range was 225.2° (first softening), 226.6° (first meniscus), 228.1° (final melting). This value was unchanged by recrystallization from 30% acetic acid, diacetone alcohol, and 70% alcohol. On the Dennis block, the material melted at 230.5° when placed on the hot bar or at 229.0° when warmed from room temperature. When a sample was heated at 230° for five minutes, then remelted, the range was 190.0–227.5°, indicating thermal decomposition.

Anal. Calcd. for $C_{13}H_{13}O_3N_3S$: C, 53.59; H, 4.50; N, 14.43; S, 11.00. Found: C, 53.47; H, 4.56; N, 14.53; S, 10.95.

The condensation was also run in pyridine in which case equimolecular amounts of 2-aminopyridine and N-acetylsulfanilyl chloride were used. The crude product so obtained contained a yellow impurity which was difficult to remove.

2-Sulfanilamidopyridine.—The acetyl derivative was hydrolyzed by boiling 29.1 g. (0.1 mole) with 10 g. (0.25 mole) of sodium hydroxide and 150 cc. of water for two hours. The excess sodium hydroxide was neutralized to *p*H 11, activated charcoal was added, and the hot mixture clarified, giving a colorless solution. On acidifying to *p*H 6, 23.1 g. of colorless crystals was obtained equal to 92.5%.

After two recrystallizations from 70% alcohol, the compound had the properties noted above, which remained unchanged on further recrystallizations from alcohol and chlorobenzene.

Hydrolysis of 2-Sulfanilamidopyridine.—Seventy-five grams (0.3 mole) of 2-sulfanilamidopyridine was boiled with 300 cc. of concentrated hydrochloric acid for one hour. After twenty min. crystals started to separate. The mixture was cooled to 15°, the crystals filtered, and washed with a little cold water; weight of crystals: 46.7 g. Titration by nitrite gave 100.2% purity, calculated as sulfanilic acid. The material decomposed gradually above 300°.

The mother liquor was evaporated to 50 cc. and a little more sulfanilic acid removed. Sodium hydroxide was then added in great excess and the oil layer separated. The aqueous layer was extracted with toluene. The toluene extract combined with the oil was dried over solid sodium hydroxide and distilled. The cut from 205 to 212° amounted to 21.0 g., with 2.0 g. of forerun and 1.3 g. of still residue; the total was 24.3 g. or 86% calculated as 2-aminopyridine. The setting point of the main cut was 57.9°, unchanged by admixture with 2-aminopyridine. The material did not resemble ordinary 2-aminopyridine in odor when freshly distilled, but on standing in the air for twenty-four hours the normal odor returned.

The aqueous mother liquors were titrated with sodium nitrite and accounted for 2.7 g. calculated as sulfanilic acid. Total recovery was 49.4 g. or 95.4%.

Melting Range Behavior.—Capillary melting ranges were determined by immersing the tube in a bath preheated to 180°. The values given are corrected. No difference was noted in melting range through use of sealed tubes filled with nitrogen. Some decomposition occurred on melting, as shown by heating a sample at 193° for five minutes in air and in nitrogen. The resulting melting ranges then were: sample melted in air, 154.0–184.5–189.9°; sample melted in nitrogen, 165.0–186.0–190.5°. This would indicate that decomposition on melting was both thermal and oxidative.

Summary

1. The preparation of 2-sulfanilamidopyridine and its physical and chemical properties are described.

2. Evidence in favor of the accepted formula for this compound is given.

X-Ray and Optical Properties of Built-up Films

BY SEYMOUR BERNSTEIN

The discrepancy of about 3.6% between X-ray and optical measurements of the thickness per layer of barium–copper stearate films has been reported by C. Holley and S. Bernstein[1] and by C. Holley.[2] Investigations of refraction corrections in the X-ray measurements and possible phase change corrections in the optical measurements show that these cannot account for the discrepancy. Further investigation indicates that the discrepancy must be explained in terms of the structure of the films.

(2) C. Holley, *ibid.*, **53**, 534 (1938).

Phase Changes on Reflection

The film thicknesses were measured optically by measuring the fringe displacement between a step of 100 layers to 1000 or more layers of film deposited on an optical flat, as described by Mr. Holley.[2] In order to determine whether the phase change on reflection from the surface of the 100 layer portion was different from the phase change on reflection from the surface of the thicker portion of the films, a 1900-100 layer film was coated with aluminum by evaporation. Before having been covered with aluminum the

TABLE I

OPTICAL AND X-RAY MEASUREMENTS OF FILM THICKNESS

Film no.	Type	No. of layers	Average $\delta \times 10^6$	d_0, Å.	d_r, Å.	$d_0 - d_r$, Å.
1	Ba-Cu stearate	1100-100	5.1	48.57	50.45	−1.88
2	Ba-Cu stearate	1100-100	4.3	48.44	50.25	−1.81

displacement between the 100 layer and the 1900 layer portion was an integral number of fringes, that is, the fringes were continuous across the boundary between the two portions. The fringes were continuous also after the film had been covered with aluminum. Since the total displacement was sixteen whole fringes, to account for the discrepancy of 3.6% the fringes from the thick and thin portions of the film should have shifted relative to each other by more than half a fringe. If the assumption is made that the thickness of aluminum on the thick and thin portions of the film was the same, then the fact that no shift of fringes was observed indicates that the discrepancy could not be due to phase changes on reflection.

Optical and X-Ray Measurements

The results of the film measurements are given in Table I. All of the films of Table I were kindly built for the writer by Dr. Katharine B. Blodgett of the General Electric Company. In Table I, d_0 denotes the thickness of a double layer as determined optically. All of the films of less than 1000 layers in thickness were measured[3] by Dr. Blodgett with an optical spectrometer. Films 1 and 2 were measured optically by C. Holley with the interferometer method described by him.[2] Films 4 and 5 were measured optically with the interferometer by the author. All of the X-ray measurements given in Table I were also made by the author. The symbol d_r used in Table I denotes the grating-space of the films, corrected for refraction and based upon the ruled grating wave length scale.

The X-ray apparatus used has been described by Mr. C. Holley.[2] The X-ray measurements were made by two methods. (1) The X-ray lines were reflected on both sides of the direct beam and the glancing angles determined from the distance between two corresponding orders and the distance from the axis of rotation to the photographic plate. (2) X-Ray reflections from the film were matched against those from a gypsum crystal. With the film used as the crystal, a photograph was taken of the fifth-order tungsten $L\alpha_1$ line, for example. The film was then replaced by a gypsum crystal and a photograph taken of the first order tungsten $L\gamma_1$ line. The photographic plate remained in the same position during the two exposures. The glancing angle of the $L\alpha_1$ line from the film was then determined from the known glancing angle of the reference line reflected from gypsum, by use of the distance between the lines, measured on the photographic plate and the distance from the plate to the axis of rotation of the crystal. The time of exposure for both methods was about three hours per order.

The index of refraction of the films for X-rays was determined from the absolute measurements of the first method by use of the apparent grating-spaces in the different orders according to the method of Stenstrom.[4]

The experimentally determined value of the unit decrement, δ, for all of the films was found to be more than 1.5 times as great as the value 3.4×10^{-6} calculated by Lorentz dispersion theory from the density measurements of barium–copper stearate films determined by R. W. Mattoon. This discrepancy between the observed and calculated index of refraction cannot account for the discrepancy between X-ray and optical measurements of the grating-space because the entire correction for refraction in the fifth order of the tungsten $L\alpha_1$ line amounts to only 0.3%.

The optical measurement given in Table I for Film 4 is the result of 200 measurements of the fractional part of a fringe, made before the film was exposed to X-rays. The measurement shown for Film 5 is the result of two sets of 200 measure-

(3) K. B. Blodgett, THIS JOURNAL, 57, 1007 (1935).

(4) Compton and Allison, "X-Rays in Theory and Experiment," p. 280.

ments of the fractional part of a fringe, one set of 200 measurements having been taken before, and one set after, exposing the film to X-rays. The average of one set of measurements was the same as the average of the other set to 0.01 fringe. The total number of fringes for Films 3 and 4 was eight.

From Table I, the following conclusions can be made. (1) The X-ray grating-space is greater than the optically measured thickness of a double-layer for barium–stearate and barium–copper stearate films; for copper stearate films the optical measurement is the greater. (2) For barium stearate and barium–copper stearate films the difference between the X-ray and optical measurements is about 3.5%; for copper stearate films this difference is about 0.7%.

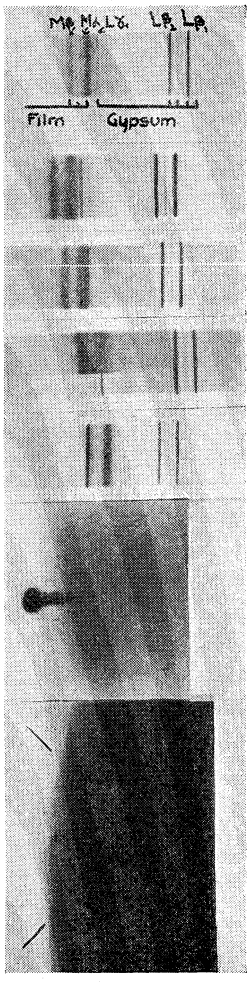

Fig. 1.—Barium stearate.

Fig. 2.—Barium stearate.

Fig. 3.—Barium–copper stearate.

Fig. 4.—Barium–copper stearate.

Fig. 5.—Copper stearate.

Fig. 6.—Rotation photograph of metal stearate film.

Fig. 7.—Rotation photograph of ethyl stearate film.

Variation of Measurements with Film Composition.—Measurements of a set of films of varying proportions of barium stearate and copper stearate show that although a change in film thickness measured optically is accompanied by a change in X-ray measured thickness of the same sign, there is no close correspondence between the magnitudes of changes in the optical and X-ray measurements of film thickness.

TABLE II

Fig.	Film no.	Barium acetate, *M*	$KHCO_3$, *M*	Copper acetate, *M*	KCN, *M*
1	7	10^{-4}	....	.....	....
2	10	10^{-4}	2×10^{-4}	.....	5×10^{-4}
3	11	10^{-4}	2×10^{-4}	3.5×10^{-6}	....
4	12	0.3×10^{-4}	2×10^{-4}	3.5×10^{-6}	....
5	3	.....	....	10^{-4}	....

The variation of X-ray grating-space with film composition can be observed in Figs. 1, 2, 3, 4, and 5. The solutions used by Dr. Blodgett in building the films with which these photographs were taken are given in Table II. Corresponding optical and X-ray measurements were made for Film 7 of Fig. 1 and Film 3 of Fig. 5. In going from the pure barium stearate film of Fig. 1 to the pure copper stearate film of Fig. 5, the X-ray grating-space decreases from 49.92 to 47.20 Å., a difference of 5.5%; while the optical measurement of the thickness of a double layer decreases from 48.52 to 47.82 Å., a decrease of approximately 1.5%. The X-ray and optically measured thicknesses both decrease with increasing copper content and with simultaneously decreasing barium content, but the X-ray grating-space decreases at a much greater rate.

Skeletonized Films.—Dr. Blodgett and Dr. Irving Langmuir have described the process of skeletonizing a film.[5] After a film is built it is dipped into benzene. That portion of the film which consists of pure stearic acid is dissolved by the benzene; the portion which consists of metal stearate remains on the slide. If the proportion of stearic acid in the film is too high the film collapses. If the proportion of stearic acid is not too high the optically measured film thickness changes by only 1 or 2%.

X-Ray measurements were made of a skeletonized and an unskeletonized film of lead arachidate. The two films were built by Dr. Blodgett at the same time from the same solution, after which one of them was dipped into benzene for one minute. According to Dr. Blodgett a test film made from the same solution showed that 40% of the material had been removed by soaking

(5) K. B. Blodgett and I. Langmuir, *Phys. Rev.*, **51**, 980 (1937).

the film in benzene for one minute and that a change in thickness of 1 or 2% had taken place. The X-ray measurements for the two films are given in Table III. These measurements show that the grating-spaces of the skeletonized and unskeletonized films are the same within experimental error. The relative intensities of the first three orders for the two films were also the same.

TABLE III

COMPARISON OF GRATING-SPACES OF A SKELETONIZED AND AN UNSKELETONIZED FILM

	Distances in cm.		
	1R to 1L	2R to 2L	3R to 3L
Unskeletonized film	3.207	6.285	9.382
Skeletonized film	3.204	6.287	9.387
Difference, %	−0.1	+0.04	+0.05

In Table III, the values given are the distances measured on the plate from a given order of WLα_1 line on one side of the direct beam to the same order on the opposite side of the direct beam. Thus 1R to 1L denotes the distance from the first order Lα_1 line on one side of the beam to the first order Lα_1 line on the opposite side of the direct beam.

This identity of the grating-spaces of the skeletonized and unskeletonized films seems to indicate that the X-ray photographs give a measure of the grating-space of crystals of metal stearate contained within the films, and that such a measurement should not be compared with an optical measurement of the film thickness.

Rotation Photographs of Metal Stearate Films.—The zero layer-line reflections from which the grating-space measurements of Table I were made have shown that the films have a regular arrangement of molecules in a direction perpendicular to the surface upon which they are built. The question arises as to whether or not the films have regular arrangements of molecules in planes parallel to the surface on which they are built.

Figure 6 is a rotation photograph taken with one of the barium–copper stearate films. Only the zero layer-line reflections appear. The background is badly fogged because of scattering from the glass plate upon which the films were built. However, it may be concluded that either reflections on layer-lines other than the zero layer-line are very much weaker than the zero layer-line reflections or that they do not appear at all. The fact that they do not appear would indicate that the films do not have a regular arrangement over an appreciable area in planes inclined at an angle to the surface of the slides upon which the films are built or in planes parallel to these surfaces. Every one of several other films of barium–copper stearate, copper stearate, and barium stearate also showed only zero layer-line reflections.

Suggested Structure of Metal Stearate Films.—The following film structure is suggested as one which is consistent with the results described above.

The film consists of many small crystals of metal stearate embedded in a matrix of amorphous stearic acid or stearic acid crystals. These crystals of metal stearate all have the same, or nearly the same, orientation in a direction perpendicular to the slide upon which the film is built but have a random arrangement in planes parallel to the foundation surface. The X-ray measurements are a measure of the grating-space of the metal stearate crystals. The optical measurements are a statistical average of the thickness per layer.

The similarity in the X-ray photographs taken with X and Y films[6,7] indicates that the film structure is independent of the type of deposition.

The suggested film structure is also consistent with Dr. Langmuir's interpretation[8] of the contact potential measurements of Porter and Wyman.[9]

Films of Ethyl Stearate.—Stenhagen reported[10] the use of ethyl stearate, along with a number of other substances, in building films. These films differ from stearate films in that there is no question of degree of saturation. In the case of stearate films, the stearic acid on the water surface is partly changed to metal stearate by the metal ions in solution. In the case of ethyl stearate, if the *p*H of the water is not too low or too high, the ethyl stearate placed on the water surface is transferred unchanged to the slide.

Stenhagen found the following X-ray and optical values for ethyl stearate films: X-ray grating-space, 25.7 Å.; optical measurement of the thickness per layer, 28.0 ± 0.5 Å. The writer built several films of Eastman Kodak Company ethyl stearate and found the apparent X-ray grating-space in the second order to be 25.2 Å. Stenhagen, in his optical measurement, assumed that the index of refraction for ethyl stearate films is

(6) C. Holley and S. Bernstein, *Phys. Rev.*, **49**, 403 (1936).
(7) S. Bernstein, THIS JOURNAL, **60**, 1511 (1938).
(8) I. Langmuir, *ibid.*, **60**, 1190 (1938).

(10) E. Stenhagen, *Trans. Faraday Soc.*, **34**, 1328 (1938).

the same as the index for barium–copper stearate films. The average of the two X-ray measurements is about 9% less than the optical measurement. This difference cannot be due to Stenhagen's assumption of the equality of index of refraction of barium–copper stearate and ethyl stearate films.

The available evidence, then, seems to indicate that the discrepancy found for metal stearate films persists in the case of ethyl stearate films.

A rotation photograph taken with an ethyl stearate film differed from those of the metal stearate films in that reflections other than those of the zero layer-line appeared for the ethyl stearate film. The rotation photograph is shown in Fig. 7. The presence of these reflections indicates that in the case of ethyl stearate films all of the small crystals have the same orientation.

The suggestion that many small crystals form of themselves within the films is indicated also by the fact that the average of the two X-ray grating-space values for ethyl stearate is the same as the value for one of the natural crystalline forms of ethyl stearate found by T. Malkin.[11] Also, as Stenhagen already has pointed out,[10] these tiny crystals can be seen in the ethyl stearate films under a microscope.

The writer is greatly indebted to the following people for their help: To Dr. Katharine B. Blodgett of the General Electric Company for her coöperation. In addition to building many of the films and making optical measurements of some of them, Dr. Blodgett gave freely of her time to the discussion of the many problems which arose in the course of the investigation. To Professor Arthur H. Compton and Dr. Elmer Dershem for their careful guidance. To the Charles A. Coffin Foundation of the General Electric Company for the grant of a fellowship which enabled him to continue with the work.

(11) T. Malkin, *J. Chem. Soc.*, 2796 (1931).

Summary

X-Ray refraction corrections and possible optical phase change corrections fail to account for the discrepancy between X-ray and optical measurements of the thickness of built-up stearate films. The results indicate that the discrepancy must be explained in terms of the film structure. X-Ray measured thicknesses of barium–copper stearate and barium stearate films are greater than the corresponding optical measurements; X-ray measured thicknesses of copper stearate films are less than the corresponding optically measured thicknesses. Measurements of a set of barium–copper stearate films of varying proportions of barium stearate and copper stearate show that the film thickness varies greatly with film composition and that a change in X-ray measured thickness is not accompanied by a change in optically measured thickness of the same magnitude. Skeletonized and unskeletonized films of the same original composition were found to have the same X-ray grating-space. Metal stearate films give only zero layer-line reflections. An ethyl stearate film showed other than zero layer line reflections in addition to those of the zero layer line. A film structure is suggested which is consistent with the X-ray and optical measurements and with reported contact potential measurements.

The Catalytic Decomposition of Azodicarbonate Ion

BY CECIL V. KING

In his attempts to make diimide HN=NH, Thiele[1] prepared the potassium salt of azodicarbonic acid, by alkaline hydrolysis of azodicarbonamide. He found this salt fairly stable in alkaline solution in the cold, though it decomposes in a few minutes on heating. It is very soluble in water, but decomposes rapidly and is all gone in one to two minutes. In acid solutions the decomposition is even more rapid. Thiele found quantitative formation of nitrogen and hydrazine; the reaction takes place as follows

Alkaline solution

$$2\ \begin{matrix}\mathrm{N{-}COO^-}\\ \|\\ \mathrm{N{-}COO}\end{matrix} + 4OH^- \longrightarrow N_2 + N_2H_4 + 4CO_3^= \quad (1)$$

Faintly alkaline solution

$$2\ \begin{matrix}\mathrm{N{-}COO^-}\\ \|\\ \mathrm{N{-}COO}\end{matrix} + 4H_2O \longrightarrow N_2 + N_2H_4 + 4HCO_3^- \quad (2)$$

Acid solution

$$2\ \begin{matrix}\mathrm{N{-}COO^-}\\ \|\\ \mathrm{N{-}COO}\end{matrix} + 4H^+ \longrightarrow N_2 + N_2H_4 + 4CO_2 \quad (3)$$

Obviously these equations do not represent the mechanism of the decomposition; Thiele suggested the intermediate formation of diimide, which instantly gives nitrogen and hydrazine

$$2N_2H_2 \longrightarrow N_2 + N_2H_4$$

The rapid decomposition in acid solution and greater stability in basic solution suggest an acid catalyzed reaction. Preliminary study in alkaline buffers showed great sensitivity to general acid catalysis. The rate was found to be measurable in solutions of sodium hydroxide from 0.01 *M* to 0.10 *M*.

Experimental

Materials, Apparatus and Procedure

Sodium azodicarbonate was made by the method described by Thiele[1] for the potassium salt. Three preparations evolved 94, 95 and 90%, respectively, of the theoretical amount of nitrogen from acid solution. Microanalyses indicated little if any carbonate impurity, but rather some other nitrogen-containing compound.

Sodium hydroxide stock solutions free from carbonate were prepared; distilled water was not freed from carbonate since carbonate is formed in the decomposition. **Sodium acetate** buffers were made by neutralizing samples of acetic acid and adding excess sodium hydroxide. **Acetoxime** was made and purified by redistillation. Other chemicals were the best commercial grade available.

Nitrogen evolution was followed in an apparatus similar to that described by Brönsted and Duus.[2] The reaction flasks were of 100 cc. capacity and 60 cc. of solution was used for each measurement. The thermostat temperature was kept at 24.9 ± 0.02°. Since the manometers were not thermostated, the room temperature was kept constant to ±0.5° during any one experiment. In most of the experiments 73-mg. samples of azodicarbonate were used, making this concentration 0.0075 *M*. In all except salt effect experiments the ionic strength of the solution was kept at $\mu = 0.1225$ by addition of sodium chloride as an inert salt if necessary.

Hydrogen Ion and Water Catalysis.—In sodium hydroxide solutions, the previous considerations suggest the rate equation:

$$dx/dt = k_1 C_{N_2(COO)_2^=} C_{H_3O^+} + k_2 C_{N_2(COO)_2^=} C_{H_2O} \quad (4)$$

In all solutions used equation (1) is valid for the decomposition, *i. e.*, only carbonate ion is produced during at least the first quarter of the reaction. Also

$$C_{H_2O^+} = K_w/C_{OH^-}$$

where K_w is the ion product of water at the ionic strength in question. Neglecting the water catalysis and the change in ionic strength during reaction

$$dx/dt = kC_{N_2(COO)_2^=} \times K_w/C_{OH^-}$$

where dx/dt = moles decomposing per minute. Since two hydroxyl ions are used for each azodicarbonate ion

$$\frac{dx}{dt} = kK_w \frac{a - x}{b - 2x}$$

where a and b are initial moles of azodicarbonate and hydroxyl ion, respectively. This may be integrated to give

$$\frac{kK_w t}{2.3(b - 2a)} = \log \frac{a}{a - x} + \frac{2x}{2.3(b - 2a)} \quad (5)$$

Omission of the water catalysis term of equation (4) was found to be justified in practice. In the faster experiments it is too small to change the form of the rate equation appreciably, and in the slower experiments at higher hydroxyl ion concentrations the last term of equation (5) becomes small and the entire rate almost of the unimolecular form.

(1) Thiele, *Ann.*, **271**, 127 (1892).

(2) Brönsted and Duus, *Z. physik. Chem.*, **117**, 299 (1925).

Rate constants were evaluated by plotting log $(a-x) - 2x/2.3\ (b - 2a)$ *vs.* t (in minutes). The negative slope of the straight line obtained, multiplied by $2.3(b - 2a)$, gives kK_w. Typical plots are shown in Fig. 1. Deviations from linearity occur for solutions of low hydroxyl ion concentration, where bicarbonate ion is formed and equation (1) is valid only near the beginning of the reaction. In this case the rate constant is obtained from the first few readings. In the special case where $b = 2a$, the rate equation becomes $kK_w = 2x/t$ and a plot of x *vs.* t should be linear. This was found true for the first few readings.

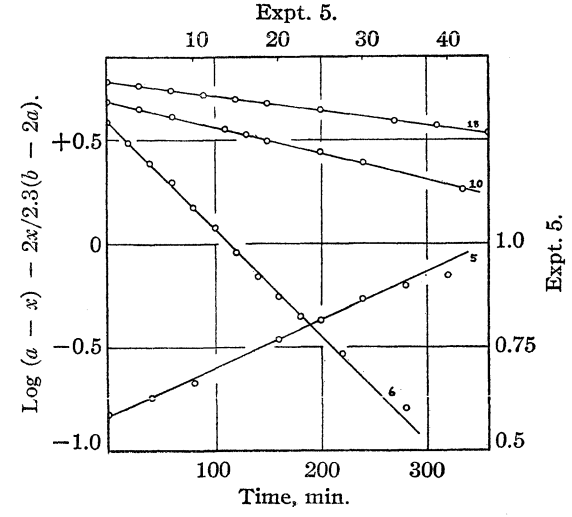

Fig. 1.—Determination of rate constants: expt. 6—divide time scale by 2, expt. 5—$(b - 2a)$ is negative.

It is evident that correct initial pressure readings must be obtained to evaluate equation (5). The azodicarbonate dissolves rapidly when dropped into the solution, and in the slower experiments no correction was necessary for slow attainment of pressure equilibrium. In the faster experiments pressure readings were taken at frequent intervals for several minutes, and an extrapolation made to an initial pressure in agreement with the rate curve.

The rate constants obtained in sodium hydroxide, with sodium chloride added to maintain a constant total ionic strength of 0.1225, are given in Table I. The increasing values of kK_w with increasing hydroxyl ion concentration are obviously due to the increasing proportion of catalysis by water. Division by the initial hydroxyl ion concentration of each experiment gives "constants," kK_w/b, which are comparable dimensionally with the unimolecular rate constants ob-

tained in similar reactions in which the pH remains unchanged during the reaction. These values, which we shall call k', are given in Table I and plotted *vs.* hydrogen ion concentration in Fig. 2. The value of K_w used to calculate the hydrogen ion concentration was 1.665×10^{-14}, taken for $\mu = 0.1225$ from the data of Harned and Mannweiler for sodium chloride solutions.[3] This assumes K_w to be the same in sodium hydroxide and sodium chloride solutions, and also to be unaffected by the small amount of bivalent ion present.

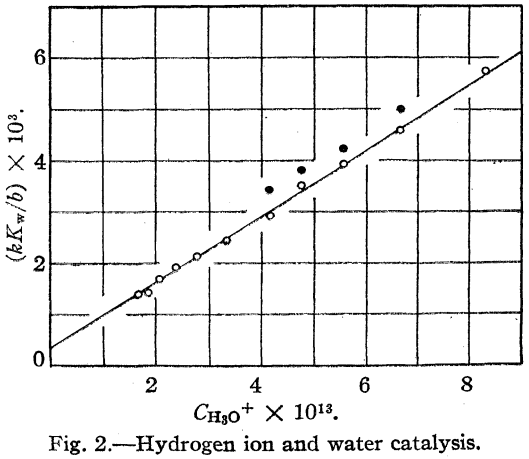

Fig. 2.—Hydrogen ion and water catalysis.

The position of the straight line of Fig. 2 was determined by the method of least squares. Its equation is

$$k' = (3.287 \times 10^{-4}) + (6.388 \times 10^9\ C_{H_3O^+}) \quad (6)$$

(3) Harned and Mannweiler, THIS JOURNAL, **57**, 1873 (1935).

The slope is the molar hydrogen ion catalytic constant, $k_m(H_3O^+) = 6.39 \times 10^9$, and the intercept g ves the water catalysis constant, $k_{H_2O} = 3.29 \times 10^{-4}$. The latter value divided by the water concentration gives the molar water constant, $k_m(H_2O) = 5.92 \times 10^{-6}$.

Salt Effect.—Experiments 15, 16, 19 and 20 (Fig. 2) were run with 0.015 *M* sodium azodicarbonate instead of 0.0075 *M* as in all other experiments, while the ionic strength remained 0.1225 as before. That the higher values of k' are due to specific salt effects rather than lack of validity of equation (5) is indicated by the experiments of Table II, in which 0.02 *M* sodium hydroxide was used throughout and sodium chloride and sodium sulfate added to increase the ionic strength. Values of k' are plotted in Fig. 3 *vs.* ionic strength; bivalent ions apparently exert a smaller negative salt effect than univalent ions. The type and magnitude of the salt effect are in agreement with the Brönsted theory, but the smaller effect of bivalent ions must be ascribed to the peculiarities of this particular case.

Catalysis by Acetic Acid.—Rate constants in solutions of sodium hydroxide and sodium acetate were found to be appreciably higher than in sodium hydroxide and sodium chloride of the same ionic strength. If we assume no change in K_w and the same primary salt effect, the increase may be ascribed to catalysis by molecular acetic acid. Several experiments are detailed in Table III. The acetic acid concentration (C_{HAc}) was calculated from the equation

$$C_{HAc} = \frac{K_w}{K_{HAc}} \frac{C_{Ac^-}}{C_{OH^-}}$$

where $K_w = 1.665 \times 10^{-14}$ ($\mu = 0.1225$) and

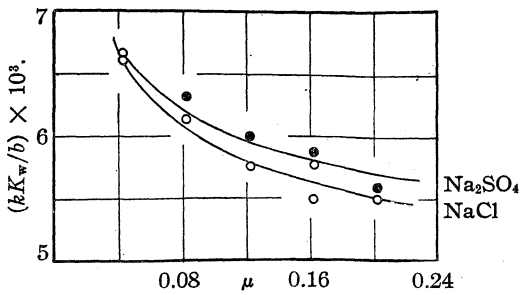

Fig. 3.—Salt effect.

$K_{HAc} = 2.87 \times 10^{-5}$ at this ionic strength.[4] Values of the hydrogen ion and water catalysis calculated from equation (6) are subtracted from k' to give $\Delta k'$.

Since the acetate ion concentration remains sensibly constant during the decomposition when hydroxyl ion is present in excess, the rate equation for these solutions has the same form as equation (5). The molar catalytic constants obtained are not very accurate or even consistent, largely because the entire error of each determination is included in the relatively small increase in rate. The average value of Table III, k_m (HAc) $= 1.9 \times 10^5$, may be regarded as an approximation for the acetic acid catalysis.

Ammonium Ion Catalysis.—Catalysis by ammonium ion was measured similarly by adding ammonia to sodium hydroxide solutions and noting the increase in rate. Assuming that the ammonia present does not affect the ionization of water or the primary salt effect, this increase may be ascribed to the ammonium ion. Since the ammonia concentration is little changed during the decomposition if excess hydroxyl ion is present, the rate equation again has the same form as equation (5). The ammonium ion concentration can be calculated from $C_{NH_4^+} = K_{NH_3}C_{NH_3}/C_{OH^-}$, using $K_{NH_3} = 3.95 \times 10^{-5}$ at this ionic strength.[5]

(4) Harned and Hickey, THIS JOURNAL, **59**, 1284 (1937).
(5) Harned and Robinson, *ibid.*, **50**, 3157 (1928).

The rates obtained are given in Table IV. Again the rate increases are erratic since the entire error falls on the increase. The average value k_m (NH_4^+) = 7.3 is taken as the molar catalytic constant.

Catalysis by Acetoxime.—The molar catalysis by an acid as weak as acetoxime should be much smaller than that by acetic acid or ammonium ion, but on the other hand higher concentrations of molecular acid (HA) can be maintained in the alkaline solutions necessary. Equation (5) is unusable in this case, since both hydroxyl ion and the weak acid anion decrease in concentration as the reaction proceeds. The correct rate equation

$$dx/dt = C_{N_2(COO)_2^-}(k_1C_{H_3O^+} + k_2C_{H_2O} + k_3C_{HA})$$

cannot easily be transformed into usable form even if the water catalysis be neglected. Fortunately this equation approaches the unimolecular form; it can be seen from the expression

$$C_{HA} = \frac{K_w}{K_{HA}} \frac{C_{A^-}}{C_{OH^-}}$$

that since both C_{A^-} and C_{OH^-} are diminishing, C_{HA} remains relatively constant and $C_{H_3O^+}$ increases less than in the preceding cases. Satisfactory "unimolecular" rate constants can be obtained by plotting log $(a - x)$ *vs. t;* in some cases the plot is perfectly linear over two-thirds of the reaction and in other cases the slope near the beginning of the reaction can be used.

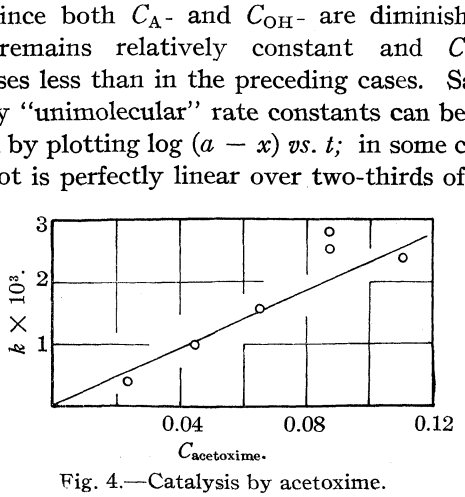

Fig. 4.—Catalysis by acetoxime.

TABLE V

CATALYSIS BY ACETOXIME: $C_{N_2(COO)^-}$ = 0.0075 *M*, μ = 0.1225, 24.9°, K_{HA} = 6.0 × 10^{-13}

.05	.15	.0100	.1100	.01346	.01108	.00238

Rate constants obtained in this manner are given in Table V. Hydroxyl ion and unneutralized acetoxime concentrations were calculated using K_{HA} = 6.0 × 10^{-13}, a value calculated by Scudder[6] for 25° from measurements of Lundén on the rate of ethyl acetate hydrolysis in barium hydroxide partly neutralized by acetoxime.[7] Values of *k'*, called $k_{H_3O^+, H_2O}$ in Table V, were calculated for these hydroxyl ion concentrations from equation (6). The acetoxime constants, k_{HA}, are plotted *vs.* C_{HA} in Fig. 4, and the slope of the straight line is taken as the molar catalytic constant, k_m (HA) = 0.023.

It is doubtful whether the value K_{HA} = 6.0 × 10^{-13} is correct under the experimental conditions here, or whether a more satisfactory value could be calculated from Lundén's experimental results. Use of a smaller value for K_{HA} and a larger value for K_w leads to a somewhat better linear relation in Fig. 4, but due to lack of more precise rate measurements and probable complications of a type to be described later, it seems better to accept the above value as approximately correct.

Catalysis by Maltose.—In solutions containing maltose the rate is also approximately of the unimolecular form. Some difficulty arose from slow decomposition of the maltose; while it was usually unnecessary to take pressure readings for more than sixty minutes, over a period of several hours the solutions turned brown, and final pressure readings were one to five millimeters higher than usual. Since this led to rate constants that were evidently too low, new values of the rate constants were calculated using for the total pressure rise the average for preceding experiments in which the same azodicarbonate sample was used. This gives fairly consistent results, but of course introduces some error.

In calculating the values of Table VI, the dissociation constant of maltose was taken as 1.4 × 10^{-12}. This is somewhat lower than the value determined by Michaelis and Rona[8] at 18°, namely, 1.8 × 10^{-12}. Use of the latter value changes the position of the catalytic constants so that, in Fig. 5, no satisfactory straight line can be drawn through them and through the origin. In general too high values of the dissociation constant lead to a curve which is concave downward, too low values to a curve concave upward. The change is not sensitive enough for accurate estimation of the dissociation constant.

Catalysis by Sucrose.—In mixtures of sodium hydroxide and sucrose, the rate is again "unimolecular" over the first portion of the decomposition. Three series of experiments were run: (a) various concentrations of sucrose were added to 0.03 *M* sodium hydroxide, thus maintaining the total base concentration (C_{OH^-} + C_{S^-}) constant; (b) solutions were made up at nearly constant hydroxyl ion concentration (or *p*H) with varying sucrose concentrations; and (c) the total base concentration was kept at 0.06 *M*. In each case the ionic strength was kept at 0.1225 by addition of sodium chloride where necessary. Details are given in Table VII, where hydroxyl ion and unneutralized sucrose concentrations are given, then rate constants, hydrogen ion and water catalysis calculated from equation (6), and finally the portion of the total catalysis due to sucrose. Hydroxyl ion concentrations were calculated using K_{HS} = 2.4 × 10^{-13} for the sucrose dissociation constant, a value determined by Michaelis and Rona[8] by hydrogen electrode measurements in sodium hydroxide–sucrose mixtures with an ionic strength about 0.1 at 18°. This is based on a value of K_w = approximately 10^{-14}, and is larger than the older value found for 25° by Madsen[9] from the rate of ethyl acetate hydrolysis in such mixtures at an ionic strength of 0.0245 and again based on K_w = 10^{-14}. Experiments under way in this Laboratory show that this constant is at least as high as 2.4 × 10^{-13} at μ = 0.1225; and smaller values lead to unreasonably high values for the molar catalysis constant of sucrose.

effect of sucrose seeming to approach a limiting upper value in series (b). A plot of the molar constants (slopes of solid and broken straight lines of Fig. 6) *vs.* the reciprocal of the sucrate ion concentration is not linear, and probably extrapolates to zero at infinite base concentration.

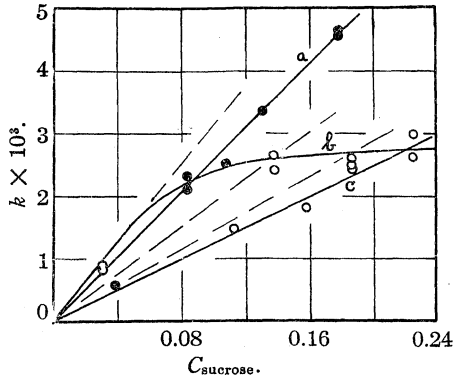

Fig. 6.—Catalysis by sucrose: (a) $C_{OH^-} + C_{S^-} = 0.03\ M$, (b) C_{OH^-} nearly constant, (c) $C_{OH^-} + C_{S^-} = 0.06\ M$.

The abnormalities of this catalysis are similar to those in the acid catalysis of diazoacetate ion decomposition[10] and in the nitramide decomposition in *m*-cresol.[11] Similar abnormalities would probably appear in the catalysis by maltose, acetoxime and the other acids if they were studied in more detail. Due to lack of accurate dissociation constants for these very weak acids and the relative inaccuracy of rate constant measurements, it seems impractical to make a more detailed study at this time.

For the present purpose we shall use as the molar catalytic constant for sucrose the value obtained with 0.06 *M* sodium hydroxide solutions, k_m (HS) = 0.0125.

Comparison of Rate Constants with Acid Strengths.—In Fig. 7 values of log k_m/p are plotted *vs.* log $(q/p\ K_A^0)$, where p and q are used as suggested by Pedersen and K_A^0 is the acid dissociation constant at zero ionic strength (where this is known) (see ref. 10). In this case p and q are always 1, except for acetic acid, where q is 2.

TABLE VIII

THE RELATION BETWEEN VELOCITY CONSTANTS AND ACID STRENGTH

Acid	k_m	K_A^0
H_3O^+	6.39×10^9	55.5

(11) Brönsted, Nicholson and Delbanco, *Z. physik. Chem.*, **A169**, 379 (1934).

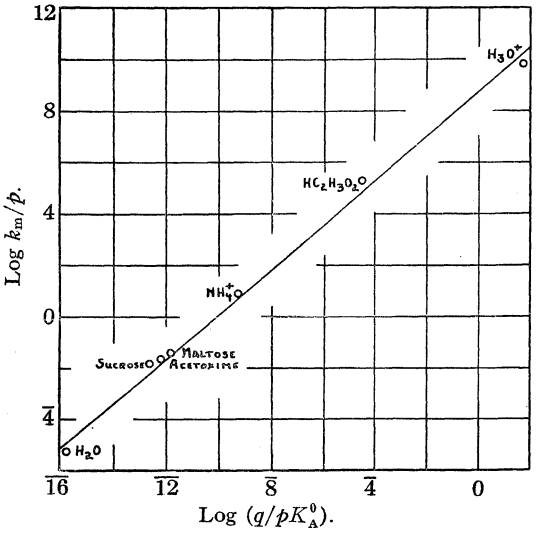

Fig. 7.—The relation between rate constants and acid dissociation constants.

The rates show satisfactory agreement with the Brönsted theory for general acid catalysis. Points on the straight line of Fig. 7 are represented by the equation

$$k_m/p = 7.40 \times 10^8 (q/pK_A^0)^{0.86}$$

Discussion.—This reaction is more sensitive to acid catalysis than any previously studied. The water catalysis is six times as great and the hydrogen ion catalysis eighteen times as great as in the diazoacetate ion catalysis.[10] The value of the constant G in the Brönsted equation (7.40×10^8) is thirty-nine times as great. On the other hand, the exponent, 0.86, is similar to the value found in several other cases.

This high sensitivity is probably largely due to the double negative charge of the azodicarbonate ion, which increases its ability to capture a proton from the catalyzing acid. While little definite evidence is available, one should expect the nitrogen–carbon bond of the azodicarbonate to be inherently more stable than that of the diazoacetate, from a comparison of the spacial relationships in the two ions, for example. The azodicarbonate is more thermostable: the diazoacetate explodes vigorously on heating or even with friction in the cold; the azodicarbonate decomposes less vigorously on heating to a somewhat higher temperature. Further, the diazoacetate poly-

merizes readily in solution, probably through rupture of a nitrogen–carbon bond, while this behavior is not shown by the azodicarbonate.

Consequently the actual increase in sensitivity to acid catalysis due to the double negative charge may well be much greater than shown by simple comparison of these two cases. It is significant that the positively charged hydrogen ion shows three times as great an increase in catalytic effect as the neutral water molecule. The effect of the charge of the catalyzing acid has been discussed in detail by Pedersen.[12]

The strength of azodicarbonic acid cannot be estimated easily, because of its instability and the nature of the decomposition products. It is almost certainly too strong to allow appreciable amounts of the acid ion or molecular acid to exist in the alkaline solutions used here. The general acid catalysis excludes spontaneous decomposition of traces of acid or acid ion as the mechanism of the reaction; but spontaneous decomposition of small amounts of equimolecular ion-acid compounds in equilibrium with the components would be indistinguishable from the bimolecular mechanism postulated. Neither mechanism accounts for the depressing effect of bases on the molar acid catalysis, found here for sucrose and in the diazoacetate decomposition for other acids.

(12) Pedersen, *J. Phys. Chem.*, **38**, 581 (1934).

The author is indebted to Mr. Lewis Appleton, who carried out some of the experimental work reported here.

Summary

The decomposition of azodicarbonate ion to give nitrogen, hydrazine and carbon dioxide or carbonate ion, has been found to be extremely sensitive to general acid catalysis. It is catalyzed by water, hydrogen ion and other acids in accordance with the equation $dx/dt = C_{N_2(COO)_2}(k_1C_{H_3O^+} + k_2C_{H_2O} + k_3C_{HA} + \ldots)$. That this equation does not completely explain the mechanism is shown by the fact that the molar catalysis by sucrose (and probably by other weak acids) is diminished by bases (hydroxyl ion, sucrate ion, etc.).

The molar catalysis constants as evaluated show good agreement with the Brönsted equation $k_m/p = G(q/pK_A^0)^x$ where $G = 7.40 \times 10^8$ and $x = 0.86$. This value of G is the highest yet found for acid catalysis; the value of x is similar to that found in several other cases.

The Photochemical Oxidation of Hydrogen[1]

BY HILTON A. SMITH AND A. NAPRAVNIK

There have been reported three earlier studies[2,3,4] of the photochemical oxidation of hydrogen by light of wave length 1719–1725 Å. The first of these papers dealt with the over-all temperature coefficient of the reaction, while the other two resulted from studies of the individual products obtained, and the quantum yields of these products at room temperatures. The present paper reports the quantum yields of the individual products at elevated temperatures as well as additional room temperature data.

Experimental

In the last of the papers mentioned above, it was demonstrated that the reaction products were ozone, hydrogen peroxide, and water. Analysis of this mixture was carried out by pumping the exit gases from the reaction cell through an analyzing bubbler, after which they were dried and returned to the cell. Three successive runs were made on each hydrogen–oxygen mixture. During the first run the bubbler contained titanium sulfate solution. The hydrogen peroxide formed was absorbed in this solution and determined colorimetrically. During the second run the bubbler contained neutral potassium iodide solution. This absorbed both hydrogen peroxide and ozone. The bubbler liquid subsequently was acidified and the liberated iodine titrated with sodium thiosulfate. The yield of ozone was calculated by subtracting from this result the yield of hydrogen peroxide determined in the first run. Finally, a much longer run was made, again using potassium

iodide in the bubbler. The pressure drop found during this run was corrected for ozone and hydrogen peroxide absorbed in the bubbler, and the water yields subsequently calculated.

A critical study of these procedures was undertaken. As a result it was possible to show that while either ozone or hydrogen peroxide may be determined individually by absorption in neutral potassium iodide, and subsequent titration of the iodine liberated in the acidified solution,[5] the two cannot be analyzed by simultaneous absorption in such a solution. In the presence of each other they are evidently catalytically decomposed.[6] It was shown that under conditions such that both ozone and hydrogen peroxide are formed in appreciable quantities, the apparent yield of ozone plus hydrogen peroxide was much less than that of hydrogen peroxide alone. For example, the yield of hydrogen peroxide obtained by passing a gas mixture of 50 mm. of oxygen and 710 mm. of hydrogen before the light source used in this research was 8.66×10^{-7} mole per minute. In this mixture the yield of ozone is approximately equal to that of peroxide. When the products obtained using this same mixture were passed through a bubbler containing neutral potassium iodide (2.5% solution), the yield of ozone plus hydrogen peroxide was only 1.95×10^{-7} mole per minute, a value less than one-fourth that of either product.

Further experiments established the fact that, if the mixture of ozone and peroxide were first passed through a bubbler containing titanium sulfate solution and then through neutral potassium iodide, the hydrogen peroxide was removed by the first bubbler, while the ozone was removed by the second. The passage of ozone through the titanium sulfate solution affects neither the ozone yields nor those of peroxide. This method of analysis was used in the work reported here.

The experimental set-up was similar to that previously employed.[4] The light source consisted of a condensed spark operating in a nitrogen atmosphere between two slowly revolving aluminum disks.[7,8] The gases to be illuminated were circulated at a velocity of 700 ml. per minute through a thin-walled quartz vessel of approximately 1 ml. volume (this time of light exposure was too short to cause photochemical decomposition of the products), and then through the two ice-cooled absorption bubblers. After the ozone and hydrogen peroxide had been removed, the gases were dried by means of a dehydrite tube, and returned to the cell through an all-glass circulating pump. This pump was a modification of the type described by Balsbaugh, Larsen, and Lyon.[9] It had two barrels, and the solenoids around these barrels were connected in quarter phase to the same motor. Thus, pumping action occurred four times per cycle. The pump operated at a speed of 80 cycles per minute. A section of capillary tubing between the pump and the cell evened out the gas flow so that it was quite regular when exposed to the light source. The whole circulating system was connected through a capillary tube to a constant-volume manometer.

The oxygen and hydrogen used were generated by the electrolysis of a solution of sodium hydroxide. Air or tank nitrogen was used in experiments dealing with nitrogen–oxygen mixtures.

The procedure employed in making a run was as follows. After the system was filled with the desired pressures of hydrogen and oxygen, the circulating pump was allowed to run for about fifteen minutes in order to assure temperature equilibrium with the surroundings. The pressure and temperature of the system were then taken. The pump was again allowed to run for a few minutes, and pressure readings repeated. This was continued until constant readings were obtained. Next, the gases passing through the reaction cell were exposed to the light source for a definite length of time, generally thirty minutes. After the illumination, the temperature was adjusted to its pre-run value, and pressure readings taken as before. The two bubblers were subsequently removed from the system, and ozone and peroxide yields determined. The pressure drop occurring during the run was corrected for the amounts of these products formed, and the water yield then calculated.

For runs at elevated temperatures, the thin-faced quartz cell was equipped with a thermocouple well which entered the cell from the gas-entrance side to a point just before that at which the reaction took place. Preceding the cell, and connected to it by a quartz to pyrex graded seal, was a short grill made from approximately four feet of pyrex tubing. The grill and cell were enclosed in a pyrex jacket to which was attached a long side arm, allowing entrance of the nitrogen into the cell jacket at a point behind the grill. The nitrogen emerged from the cell jacket through a round hole slightly less than one centimeter in diameter, this opening being directly between the thin face of the reaction cell and the spark. The cell jacket was insulated by placing it in a box packed with loose asbestos fibers, the front of the jacket emerging from the box for a distance of about one centimeter.

The side arm through which the nitrogen entered the cell jacket was wound with nichrome resistance wire. Heated nitrogen was blown over the pyrex grill at a rate of eight liters per minute, thus heating the gases passing into the reaction cell. Temperature equilibrium was established in the heat exchanger, and the temperature of the gases just before exposure to the light source was read by means of a copper–constantan thermocouple connected

to a Leeds and Northrup potentiometer. During a run the temperature was kept constant to ±1°. Runs were made in the same manner as those performed at room conditions.

At the highest temperatures a number of experiments were tried without exposure to the light source. No dark reaction was detected.

As in earlier research,[4] each run with hydrogen–oxygen mixtures was preceded and followed by control runs made with air at atmospheric pressure in the system. The amounts of all products obtained were reduced to constant incident light intensity by means of these control runs. Since for experiments at elevated temperatures it was not feasible to cool the cell to room temperatures for the air runs, these were made under the same conditions as those of the corresponding hydrogen–oxygen runs.

A series of measurements of ozone yields in air at one atmosphere pressure and varying temperatures was made in order to study the effect of increased temperature on the yields of ozone. The results are given in Table I. They indicate clearly that in the mixture under consideration the amount of ozone formed is constant over the temperature range studied, and thus, that the control runs could be used without correction. This result is expected, since under the conditions of the runs, sufficient oxygen is present to absorb all of the light entering the cell. (Lyman[10] states that an air column one centimeter long completely absorbs the strong aluminum spark lines in the neighborhood of 1720 Å.)

Results

The quantum yields of the several products of each run were calculated by dividing such yields by the yield of ozone found in a mixture of nitrogen and oxygen containing the same partial pressure of oxygen as that of the hydrogen–oxygen run, and multiplying the resultant figure by two.[11] It has been demonstrated previously that neither reduction of total pressure nor dilution with nitrogen affects the quantum yield of ozone in the nitrogen–oxygen mixtures.[4] Table I indicates that the temperatures used in this research do not seriously alter its value.

TABLE I

EFFECT OF TEMPERATURE ON OZONE YIELDS IN AIR

T, °C.	Yields O_3 moles/min. × 10^6
25	3.14
100	2.95
150	3.16
200	2.97
240	3.13
280	2.98

Quantum yields of ozone, hydrogen peroxide and water obtained at room temperatures using hydrogen–oxygen mixtures of total pressures varying from 1140 to 95 millimeters are given in the first five figures. In the case of runs made at 95 mm. pressure, it was difficult to obtain reproducible results, but the general trend of the curves is certainly correct.

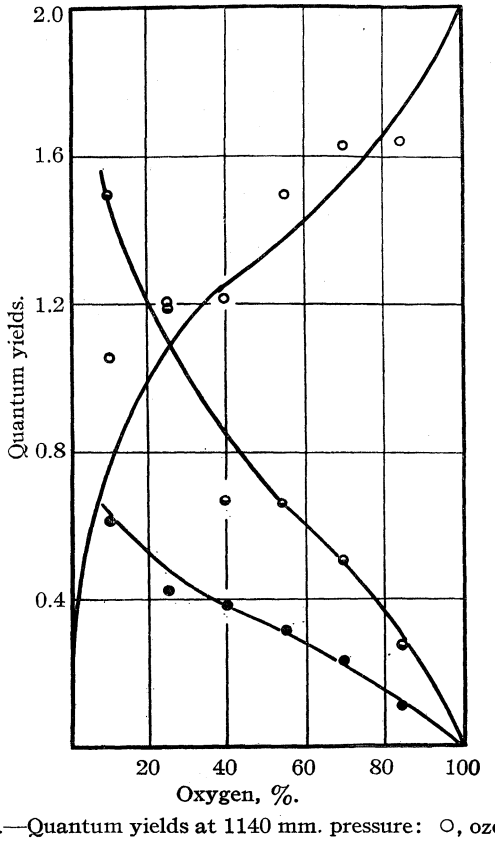

Fig. 1.—Quantum yields at 1140 mm. pressure: ○, ozone; ⊖, water; ●, hydrogen peroxide.

The quantum yields were not corrected for reaction due to absorbed light of wave lengths 1854–1862 Å., these corrections having been shown to be small in the case of a cell of the type used in this research.[4] This is particularly true at low pressures.

An examination of the figures shows the following:

1. With increasing oxygen content, the quantum yields of ozone increase, rapidly at first, and then more slowly, to a maximum value of two. The yields of water and hydrogen peroxide decrease quite regularly, the water yields always being greater than those of peroxide.

2. Pressure change from 1140 to 380 mm. has the following effect on the quantum yields of the three reaction products. The yields of both water and hydrogen peroxide increase, while that of ozone is decreased. These changes are minor

at high pressures, but become more pronounced at low pressures, as the results at 190 and 95 mm. total pressure indicate. The increase in water yields is much greater than that of peroxide yields, values as great as 14 having been found for water at 95 mm.

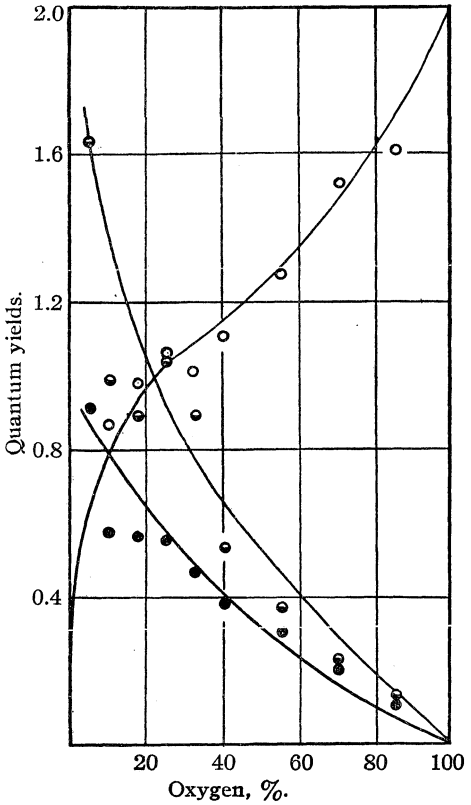

Fig. 2.—Quantum yields at 760 mm. pressure: ○, ozone; ◒, water; ●, hydrogen peroxide.

The results found using hydrogen–oxygen mixtures of 190 mm. total pressure and temperatures from 25 to 280° are given in Figs. 6, 7, and 8. They indicate that the quantum yields of ozone fall off with increasing temperature until this product becomes undetectable at temperatures as low as 150° for mixtures containing 10% oxygen, and higher temperatures for mixtures containing larger percentages.

In the case of water and hydrogen peroxide, the quantum yields are greatly increased with rise in temperature, the increase being relatively small at first, but subsequently becoming very rapid. The hydrogen peroxide yields are always much smaller than those of water, but the changes in the curves parallel each other very closely.

Similar results were obtained at higher total pressures, although the region of rapid rise in the quantum yields of water and peroxide was not found in the temperature range studied.

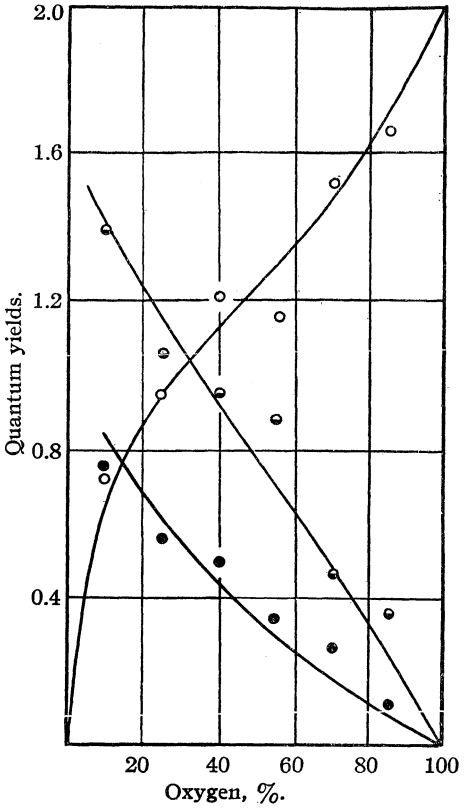

Fig. 3.—Quantum yields at 380 mm. pressure: ○, ozone ◒, water; ●, hydrogen peroxide.

Discussion

In general, the above results are explainable through a rather simple mechanism. The primary reaction is unquestionably that of rupture of an oxygen molecule to form two oxygen atoms.[12]

$$O_2 + h\nu \longrightarrow 2O \qquad 2I_{abs.} \quad (1)$$

This is followed by interaction of the atoms formed with molecules of oxygen and hydrogen. There is good evidence[13] that the oxygen atom will react with oxygen molecules to form ozone on triple collisions only.

$$O + O_2 + M \longrightarrow O_3 + M \qquad k_2 \quad (2)$$

As to its reaction with hydrogen, two possibilities exist. The first is that the oxygen atom may combine with hydrogen in a triple collision to form water.

$$O + H_2 + M \longrightarrow H_2O + M \qquad (3a)$$

In order to explain the experimental results it is

(12) Herzberg, *Z. physik. Chem.*, **4B**, 223 (1929).

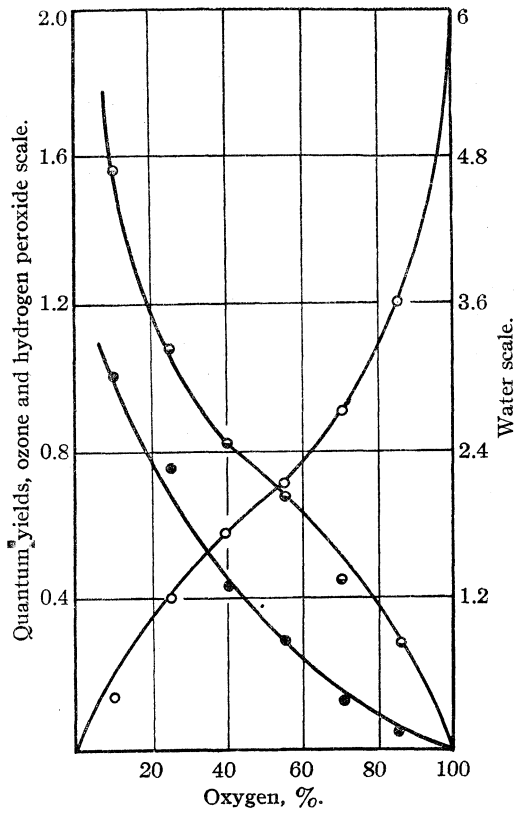

Fig. 4.—Quantum yields at 190 mm. pressure: ○, ozone; ◒, water; ●, hydrogen peroxide.

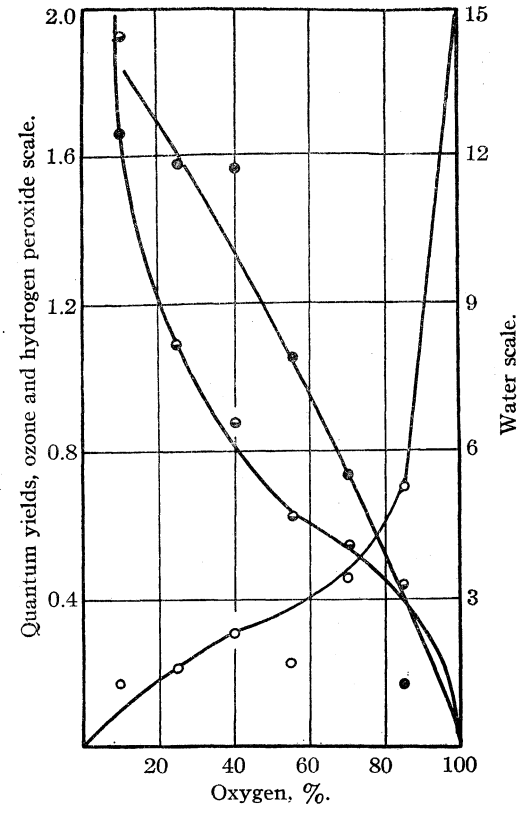

Fig. 5.—Quantum yields at 95 mm. pressure: ○, ozone; ◒, water; ●, hydrogen peroxide.

necessary to assume that in this reaction the third body is an oxygen molecule rather than a hydrogen molecule. However, it will be pointed out farther on that the possibility of hydrogen as the third body is not excluded.

$$O + H_2 + O_2 \longrightarrow H_2O + O_2 \qquad k_3 \quad (3)$$

The oxygen atoms may also react with the hydrogen molecules through a bimolecular collision.

$$O + H_2 \longrightarrow OH + H \qquad k_4 \quad (4)$$

The probability of this reaction is low,[14,15] but because other reactions require three-body collisions, the reaction is important, particularly at low pressures. The only logical fate of the OH radical is a reaction with hydrogen to form water and a hydrogen atom.

$$OH + H_2 \longrightarrow H_2O + H \qquad (5)$$

Finally, there is rather conclusive evidence that the sole result of the action of hydrogen atoms on a mixture of hydrogen and oxygen at room temperature and ordinary pressures is the formation of hydrogen peroxide.[16,17] The first step is the formation of the complex HO_2, which must take place by a triple collision mechanism.[18]

$$H + O_2 + M \longrightarrow HO_2 + M \qquad (6)$$

In order to explain the results of the mercury-sensitized reaction, Bates[19] postulated that HO_2 may react with hydrogen to form hydrogen peroxide and hydrogen atoms.

$$HO_2 + H_2 \longrightarrow H_2O_2 + H \qquad (7a)$$

This reaction is, however, energetically improbable at room temperatures. The logical fate of this radical is its reaction with another HO_2 either in the gas phase or on the walls to form hydrogen peroxide and oxygen; such a reaction was proposed by Bray[6] for the reaction in solution, and was also included in Bates' mechanism.

$$HO_2 + HO_2 \longrightarrow H_2O_2 + O_2 \qquad (7)$$

It should be noted, however, that the particular method by which hydrogen atoms react with the

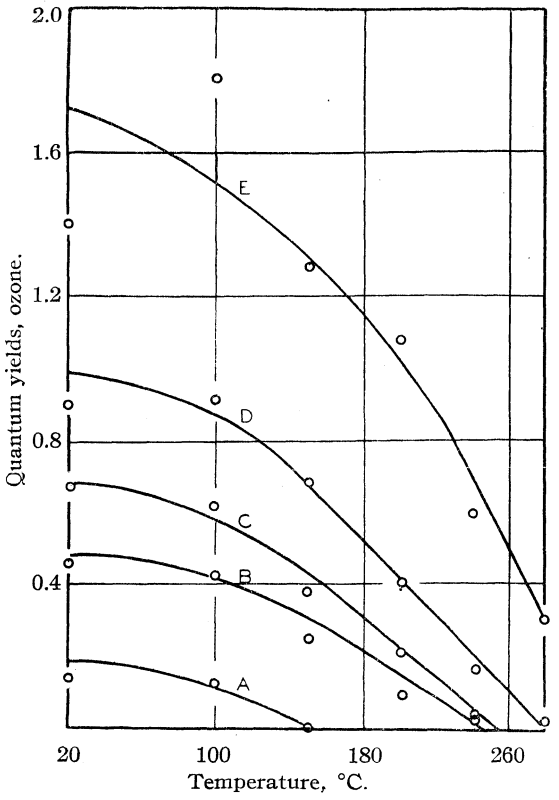

Fig. 6.—Quantum yields of ozone as a function of temperature, total pressure $H_2 + O_2 = 190$ mm.: A, 10% O_2; B, 30% O_2; C, 50% O_2; D, 70% O_2; E, 90% O_2.

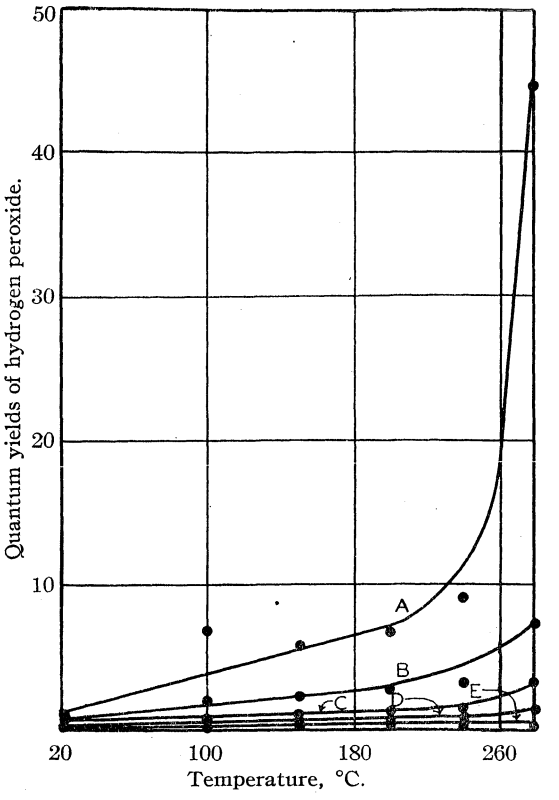

Fig. 7.—Quantum yields of hydrogen peroxide as a function of temperature, total pressure $H_2 + O_2 = 190$ mm.: A, 10% O_2; B, 30% O_2; C, 50% O_2; D, 70% O_2; E, 90% O_2.

gas mixture to form hydrogen peroxide may be altered without seriously affecting the resulting calculations.

Expressions for the quantum yields of the three products as calculated from the reaction mechanism given above are as follows

$$\Phi_{O_3} = \frac{2}{1 + k_3(H_2)/k_2(M) + k_4(H_2)/k_3(O_2)(M)}$$

$$\Phi_{H_2O_2} = \frac{2}{1 + k_3(O_2)/k_4 + k_2(O_2)(M)/k_4(H_2)}$$

$$\Phi_{H_2O} = \frac{8(O_2)/(M) + 2}{1 + k_3(O_2)/k_4 + k_2(O_2)(M)/k_4(H_2)}$$

Assuming that at one atmosphere total pressure $k_2 = k_3$ and $k_3(M) = 4k_4$, the above equations become

$$\Phi_{O_3} = \frac{2}{1 + (H_2)/(M) + (H_2)/4(O_2)}$$

$$\Phi_{H_2O_2} = \frac{2}{1 + 4(O_2)/(M) + 4(O_2)/(H_2)}$$

$$\Phi_{H_2O} = \frac{8(O_2)/(M) + 2}{1 + 4(O_2)/(M) + 4(O_2)/(H_2)}$$

Corresponding equations are easily derived for quantum yields at other pressures by introducing the appropriate factor into the ratio $k_4/k_3(M)$.

The values obtained from such equations fit the experimental results quite well, except in the case of water at low pressures. Here it is clear that the high quantum yields can be accounted for only by the introduction of a chain mechanism which is negligible at higher pressures. In the preceding mechanism, the only reasonable change which will result in such increased water yields is a change in the reactions representing the formation of hydrogen peroxide from hydrogen atoms. One might suspect that the reaction

$$H + O_2 \longrightarrow OH + O \qquad (8)$$

is responsible for the low pressure results were it not for its high activation energy, and also for the fact that if it were sufficiently prominent to cause the increased water yields, the quantum yields of both ozone and hydrogen peroxide should be much larger than those actually observed.

Another possibility is the reaction

$$HO_2 + H_2 \longrightarrow H_2O + OH \qquad (9)$$

which might well compete with (7) at low pressures since it involves the reaction of HO_2 with a

primary material rather than with another HO_2. This reaction followed by (5) and (6) readily accounts for increased water yields without affecting the yields of ozone or hydrogen peroxide, since the reaction of HO_2 by the chain of (9), (5), and (6) results in the formation of two molecules of water plus another HO_2 complex, and does not involve oxygen atoms. The chain would be broken by the formation of hydrogen peroxide.

Evidently there is some activation energy associated with (4), thus accounting for its probability of only 10^{-7} or 10^{-8}. As the temperature is increased, more molecules become sufficiently activated to react by (4), and this uses up oxygen atoms at the expense of (2) and also probably (3). While the yields of water and hydrogen peroxide do increase some as the ozone yields decrease, the sudden rapid rise in the formation of these two does not occur until a temperature considerably greater than that corresponding to the disappearance of ozone is reached. For instance, in a 10% H_2–90% O_2 mixture the formation of ozone is undetectable at 150°. The rapid rise in the water and peroxide yields does not occur until a temperature of some 220° is reached. Clearly, the disappearance of ozone is in no way connected with the appearance of long chains leading to water formation. Until the sudden rise in the water and hydrogen peroxide formation occurs, the course of the reaction is reasonably well described by the mechanism already outlined.

These sudden increases are probably due to the fact that the activation energy of (8) is overcome, allowing it to compete with (6). The result of the operation of this reaction is to cause a branching of the chain, forming two new chains of the type postulated in the room temperature mechanism. The new chains thus formed will be broken by the formation of hydrogen peroxide, and thus the simultaneous increase in water and peroxide yields is accounted for. Since the temperature at which chain branching becomes prominent is well above that at which (2) becomes negligible, no difficulty is offered by the fact that (8) does not cause increased ozone formation.

In order to check experimentally the fact that the results observed at elevated temperatures are caused by primary reactions rather than by the interaction of hydrogen and ozone, a run was made under the following conditions. A grill fashioned from 15 inches (38 cm.) of 6-mm. pyrex

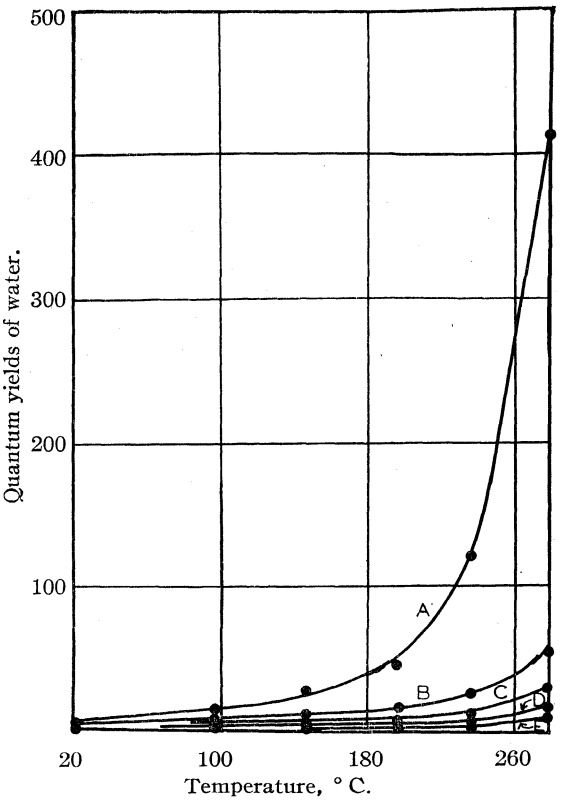

Fig. 8.—Quantum yields of water as a function of temperature, total pressure $H_2 + O_2 = 190$ mm.: A, 10% O_2; B, 30% O_2; C, 50% O_2; D, 70% O_2; E, 90% O_2.

tubing and surrounded by a pyrex jacket was placed between the reaction cell and the absorption bubblers. A resistance wound side arm allowed admission into the jacket of air at any desired temperature. The grill was equipped with a thermocouple well for measuring the temperature attained by the reaction gases after passing through two-thirds of the pyrex tubing. The volume between the thermocouple and the gas exit approximated that of the reaction cell between the light source and the exit of the gases from the heated jacket.

A 30–70 oxygen–hydrogen mixture at 190 mm. total pressure was exposed to the light source. The quartz cell was kept at room conditions while the air passing around the grill between the reaction cell and the absorption bubblers was maintained at such a temperature that the thermocouple reading corresponded to 260°. Thus the reaction products were kept at a temperature above 260° for as long a period as in a regular run. Under these conditions in the regular cell, no ozone was found, while quantum yields of approximately 5 and 40 were found for hydrogen

peroxide and water, respectively. On the other hand, in the room temperature runs the quantum yields were as follows: ozone, 0.5; hydrogen peroxide, 0.6; water, 2.8. The approximate quantum yields found with the cell at room conditions and the grill at 260° were: ozone, 0.1; hydrogen peroxide, 0.1; water, 3.5.

In order to bring the gas inside the grill to 260° the reaction products were necessarily exposed to more and hotter surface than in the regular runs. As a result, one would naturally expect some decomposition of the ozone and hydrogen peroxide on the walls of the grill. This accounts for the reduced yields of these products. The slight increase in the water yields is also readily attributed to decomposition of the peroxide. The fact that some ozone is still found after this treatment, while water and peroxide formation in no way compares to that found when the quartz cell was heated, indicates quite clearly that the reaction of hydrogen and ozone does not account for the results already presented.

Three objections may be raised to the proposed mechanism. The first of these lies in the fact that when the third body in (2) is a hydrogen molecule, reactions (2) and (3) involve identical reactants. If (2) takes place on nearly every triple collision as stated by Schumacher,[13] reaction (3) also must do so since $k_2 = k_3$. Accordingly, the theoretical yields of ozone must be decreased by an amount equal to the yields of water formed by (3). On the other hand, if only a small fraction of the triple collisions indicated by (2) are effective, this objection disappears. The probability of reaction (4) is estimated by Harteck and Kopsch[14] as 10^{-7}, and by Rodebush, Wende, and Campbell as 10^{-8}.[15] If these estimates are correct, reaction (2) cannot take place on nearly every triple collision, or else (4) could not compete with it, and no peroxide would be found.

A second objection results from the apparent exclusion of the hydrogen molecule as stabilizer in reaction (3). Actually this possibility is included in the proposed mechanism. If one combines (4) and (5) the result is

$$O + H_2 + H_2 \longrightarrow H_2O + H + H \qquad (10)$$

Since the reaction of an oxygen atom with a hydrogen molecule to form water is exothermic by some 117 kcal., while the heat of dissociation of the hydrogen molecule is only 102 kcal., it is readily understandable that reaction (10) might occur when a hydrogen molecule is the stabilizing body in the formation of water.

Finally, the absorption of light in the 1720 Å. region should produce a normal (^3P) and an excited (^1D) oxygen atom. No differentiation has been made between the two. Since the fastest possible reaction is evidently a three-body affair, it seems highly probable that collisional deactivation of the excited atom will take place before chemical reaction occurs.

Relation to the Mercury Sensitized Reaction.—The temperature coefficient of the mercury sensitized hydrogen–oxygen reaction was studied by Taylor and Salley.[20] These authors compared their results with those obtained for the direct photochemical reaction (2), and concluded as follows:

"The temperature coefficients of the mercury sensitized and the direct photochemical reactions of hydrogen and oxygen are shown to be comparable over the whole temperature range. It is suggested that the chain mechanism is the same whether initiated by atomic oxygen or atomic hydrogen."

The mechanism here proposed for the direct photochemical reaction would lead one to expect the complete similarity to the mercury sensitized reaction found by Taylor and Salley. The reaction responsible in both cases for the sudden rise in the temperature coefficient occurring at about 500° and approximately atmospheric pressure is reaction (8) which leads to chain branching.

Relation to the Explosion Reaction.—There is probably little doubt that the chains giving rise to large water yields in the photochemical reaction are the same as those involved in the explosion of oxy-hydrogen mixtures. For this reason it is of interest to examine mechanisms which have been presented in explaining the latter.

A rather satisfactory explanation of the explosive reaction is that proposed by Kassel and Storch[21] and modified by Lewis and von Elbe.[22] The present work would indicate that the explosion should follow reactions (4), (5), (6), and (9) for simple chain carrying reactions. However, (6) may result in chain breaking whenever (7) is more predominant than (9). Chain branching occurs by (8). The reaction as outlined by Kassel[23] includes four of the five equa-

(20) Taylor and Salley, THIS JOURNAL, **55**, 96 (1933).
(21) Kassel and Storch, *ibid.*, **57**, 672 (1935).
(22) Von Elbe and Lewis, *ibid.*, **59**, 656 (1937).
(23) Kassel, *Chem. Rev.*, **21**, 331 (1937).

tions given above. In place of (9), however, he gives the reaction (7a). The arguments given by Kassel seem to apply equally well if (9) is substituted. If (7a) were important at elevated temperatures, the yields of hydrogen peroxide should not parallel the water yields as was found for the photochemical reaction, but should depend primarily on the activation energy of (7a).

The modification proposed by von Elbe and Lewis[22] is identical with that proposed here, except that it admits the possibility of (7a) as well as (9), and also includes a reaction

$$H + O_2 + H_2 \longrightarrow H_2O_2 + H \qquad (11)$$

in order to explain the explosion limits. The present work gives no indication that such a reaction is of importance.

Acknowledgment.—The authors are grateful to the Roy R. Hornor Fund of Lehigh University for financial aid.

Summary

The photochemical oxidation of hydrogen has been studied by exposing mixtures of hydrogen and oxygen at room temperature to light of wave length 1719–1725 Å. The total pressure of the reaction mixture was varied from 1140 to 95 mm.

In general, with increasing oxygen content, the quantum yields of ozone increase while those of hydrogen peroxide and water decrease. Lowering of the total pressure tends to increase the water and peroxide yields, apparently at the expense of the ozone. At pressures of 190 mm. and less, the formation of water shows chain characteristics.

The temperature coefficients for the formation of the individual products have also been studied over the range 25 to 280°. The formation of ozone has a negative temperature coefficient while those of water and hydrogen peroxide are positive. At total pressures of 190 millimeters and in a 10–90% oxygen–hydrogen mixture, the temperature coefficients of water and hydrogen peroxide formation increase with great rapidity at temperatures above 230°.

A mechanism has been offered which explains satisfactorily the experimental results.

The relation of the direct photochemical reaction to the mercury sensitized and the explosive reactions has been discussed.

Thermodynamic Properties of Substances. III. Vapor Volumes as Functions of Reduced Temperature Alone

BY HAROLD A. FALES AND CLARA S. SHAPIRO

In a previous article[1] we have shown that vapor volumes of chemically different substances can be expressed as a function of liquid volume and reduced temperature:

$$V_g = V_l e^{k(1-\tau^2)^m/\tau^n} \qquad (1)$$

The same type of function was found to give correct values for vapor pressures of thirty liquids, including water, the parameters k', m', n', being very close in value to those of the above equation.[2,3]

$$P_s = P_{cr}\, e^{-k'(1-\tau^2)^{m'}/\tau^{n'}} \qquad (2)$$

An attempt was made[3] further to express vapor volumes as a function of reduced temperature alone by an analogous equation

$$V_g = V_{cr} e^{k''(1-\tau^2)^{m''}/\tau^{n''}} \qquad (3)$$

This equation was applied to water vapor and was found to hold for almost the entire saturation line (60–360°) with an average deviation under 0.2 volume per cent.

In view of the fact that equations (1), (2) and (3) represent the behavior of water and equations (1) and (2) apply to the various other substances as well, it seems reasonable to presuppose that equation (3) would also apply to the other substances; actual tests confirm this supposition in every one of the cases, as will be shown in detail in the following pages.[4]

(1) H. A. Fales and C. S. Shapiro, THIS JOURNAL, **58**, 2418 (1936).
(2) H. A. Fales and C. S. Shapiro, *ibid.*, **60**, 794 (1938).
(3) H. A. Fales and C. S. Shapiro, *ibid.*, **60**, 784 (1938).

(4) After completing the test of equation (3) on all the various substances, we tried out (on water) the more general form

$$V_g/V_{cr} = \exp.\ k''[(1+\tau)^{s''}(1-\tau)^{m''}/\tau^{n''}] \qquad (4)$$

as was done previously for the vapor pressure of water.[3] This was done in the hope that it would improve the agreement at both extremes of the saturation line, namely, near the melting point and near the critical point. We found that both forms (4) and (3) fit water volumes equally well at every point in the interval 60–360°,

The substances selected for the present study are the same as before, except that argon has been replaced by krypton. The latter was chosen because its densities were recently measured by the Leiden Laboratories and checked by them up to highest coexistence temperatures against their new, very accurate mean diameter equation.[5]

In accordance with our earlier procedure, we have first made a graphical intercomparison of the observed vapor volume curves, which enabled us to answer two separate questions: (a) what is the shape and relative order of vapor volume curves of different liquids? (b) how are the three thermodynamic properties (vapor volume, vapor pressure and volume ratio) of any single substance related among themselves in the coördinate system?

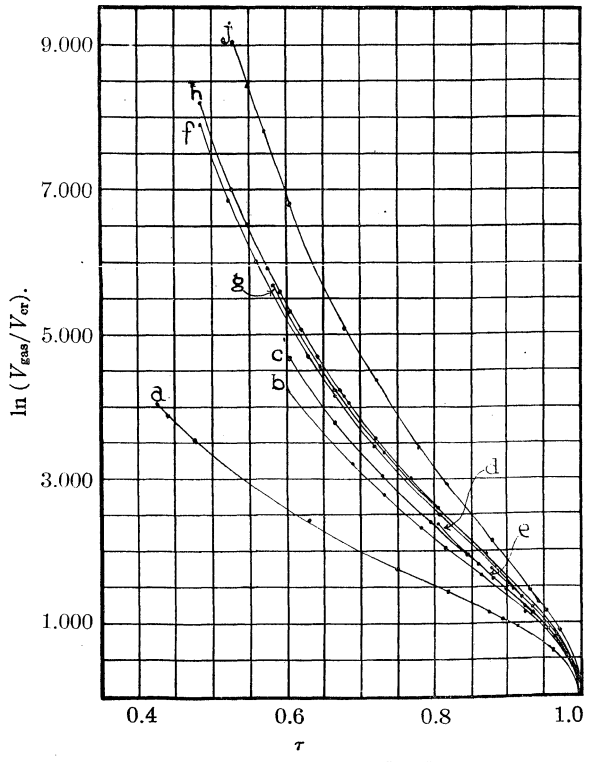

Fig. 1.—ln $(V_g/V_{cr}) = k''(1 - \tau^2)^{m''}/\tau^{n''}$: a, helium; b, krypton; c, ethane; d, acetylene; e, carbon monoxide; f, benzene; g, *n*-pentane; h, ammonia; j, ethyl alcohol.

the average deviation being: ΔV_g = 0.18 and 0.17%, respectively. At lower temperatures (0–40°) equation (4) deviates a trifle more than eq. (3).

As to the parameters, we find that both forms have practically equal values of k'', m'', n''; moreover, the constant s'' of eq. (4) is almost identical with its constant m'' (0.4708 and 0.4713). Since equation (4) did not show any appreciable improvement over eq. (3) in the case of water, there did not seem to be sufficient reason for investigating it any further.

(5) Literature on the new Leiden equation and on krypton densities is given below in Table V (bibliography).

For this purpose we have plotted the values ln V_g/V_{cr} obsd. against reduced temperature and have compared the ordinates of different curves at $\tau = 0.6000$ with each other as well as with the corresponding ordinates ln P_{cr}/P_s obsd., and ln V_g/V_{liq} obsd. of each substance.

We find here, as in the previous studies, that the ln of reduced vapor volume is represented by a family of curves, each of a form similar to that given earlier for water,[3] and very similar in shape to the curves ln V_g/V_{liq}. We see further that the order of the vapor volume curves, which is given herewith, is very close to that of the vapor pressures and is almost identical with the sequence of volume ratios[2,1]

1 Helium	16 Benzene
2 Hydrogen	17 *i*-Pentane
3 Neon	18 *n*-Pentane
4 Krypton	19 Ammonia
5 Oxygen	20 Monofluorobenzene
6 Carbon monoxide	21 Methyl formate
7 Nitrogen	22 Ethyl ether
8 Ethylene	23 *n*-Hexane
9 Ethane	24 Water
10 Hydrogen chloride	25 Acetic acid
11 Nitrous oxide	26 Ethyl propionate
12 Acetylene	27 Sulfur trioxide
13 Methyl ether	28 Methyl alcohol
14 Carbon dioxide	29 Ethyl alcohol
15 Carbon tetrachloride	30 Nitrogen tetroxide

As to the relative position of the above thermodynamic properties, we find that for every substance listed here their ascending order is the same as that shown for water:[3] ln P_{cr}/P_s; ln V_g/V_{cr}; ln V_g/V_{liq}.

An illustration of interrelation of different vapor volume curves is shown in Fig. 1, in which nine representative substances are plotted

(a) Helium	(f) Benzene
(b) Krypton	(g) *n*-Pentane
(c) Ethane	(h) Ammonia
(d) Acetylene	(j) Ethyl alcohol
(e) Carbon dioxide	

For graphical comparison of different properties of a single substance the reader is referred to the article on water.[3]

Accuracy of the Proposed Equation.—The tolerance of the vapor volume equation for water was estimated earlier.[3,1] It was found to be affected by two sources of error: (a) errors in T_{cr} and (b) errors in vapor volume. The deviations in the critical volume were assumed negligible due to the precise method of extrapolation used by Keyes and his collaborators.[6] Hence the total accuracy of equation (3) for water was found

(6) For corresponding literature see Table V below.

exactly equal to that of the volume ratio equation (1). In applying eq. (3) to other substances for which the critical densities are less accurately known, we can no longer neglect the effect of deviations in d_{cr} because for the majority of them the critical density is uncertain by at least 1–2% and for some liquids it may be in error by as much as 5–10%.[1]

The question of errors in critical density was discussed recently by Mathias and Crommelin of Leiden in connection with their new four-term diameter equation[5]

$$d_m = a + bT + cT^2 + dT^3 \qquad (5)$$

These authors have shown that the critical densities of krypton and carbon monoxide calculated from eq. (5) are about 1% higher than the d_{cr} values obtained from the rectilinear diameter formula

$$d_m = a + bt \qquad (6)$$

It seems to follow that many other substances for which the critical densities were extrapolated from the linear eq. (6) will be in error by about 1–2%.

Such will be the case with noble and permanent gases as well as with some organic and inorganic compounds. As to the reduced mean density formulas used by the "Int. Crit. Tables"

$$d_m = d_{cr}[1 + \gamma(1 - \tau) + \kappa(1 - \tau)^2] \qquad (7)$$

$$d_m = d_{cr}[1 + \gamma(1 - \tau)] \qquad (8)$$

it is obvious that they are less accurate than eq. (5) above, hence the critical densities given in Vol. III of these Tables may also deviate from true values by several per cent.

This situation raises a question: to what extent does an error of 1–5% in the critical density affect the total accuracy of the vapor volume equation?

To test this influence we have taken an actual case (carbon monoxide) and have made two sets of calculations using first the new and then the old d_{cr} values. In both sets of calculations the same reference points were used for evaluating the constants k'', m'', n''. A careful comparison of the results showed that, although the two sets of parameters I and II are different, the respective values of d_{gas} calcd. I and II are equal to each other at every temperature. In other words, a difference of 1% in d_{cr} produced no change in the calculations. Three other substances were tested similarly; these are krypton, ethyl ether, and ethane, with errors in d_{cr}, respectively, of 1, 1 and 5%. In each case we have found the two sets of calculated densities to be identical within 0.05%, which is a further proof that errors in d_{cr} of 1–5% have no effect whatsoever on the accuracy of the proposed equation.

In Table I we give the details of our calculations on carbon monoxide. This substance was chosen because of its long coexistence range (0.5–1.0 T_{cr}), and because its vapor densities are very accurately measured up to within 2° from the critical temperature. This affords an opportunity to test the proposed equation in the critical region (0.97–1.0 T_{cr}).

Table I is divided in two parts: the upper illustrates the agreement between experiment and the proposed equation. The lower part shows the effect of change in d_{cr} on the calculated values of d_{gas}. Here the calculations are given in detail for several temperatures and will be discussed first.

In columns 2 and 3 of the bottom part are given the two sets of observed ln V_g/V_{cr} data, the respective values of d_{cr} being 0.305 and 0.301. In columns 4 and 5 are given the corresponding sets of calculated ln V_g/V_{cr} values. In column 6 are shown the differences in per cent. between the observed ln values ($\Delta \ln$ % obsd. I–II); in column 7 are given the corresponding differences between the two sets of calculated ln values ($\Delta \ln$ % calcd. I–II). Examination of columns 6 and 7 shows clearly that at every temperature $\Delta \ln$ % obsd. I–II is equal to $\Delta \ln$ % calcd. I–II. From this fact it obviously follows that at each temperature the difference between observed and calculated ln values is the same for each set. This is very clearly demonstrated in the last two columns of the bottom part which contain the deviations $\Delta \ln$ % obsd. − calcd. I and $\Delta \ln$ % obsd. − calcd. II. We see that these are practically equal at every point both in sign and in value, averaging $\Delta \ln \phi = 0.62\%$ and 0.64%, respectively.

In the upper half of Table I are given: the Leiden data for vapor densities of carbon monoxide together with the two sets of calculated d_{gas} values I and II. At the very top of the table are given the corresponding two sets of parameters k'', m'', n''. In the last three columns are shown the two sets of deviations Δd_g % I and II, together with the corresponding deviations of the Leiden mean diameter equation (5). In examining this part of Table I we see again that the deviations Δd_g % obsd. − calcd. I and II are nearly identical at all temperatures. This shows that correct values for vapor densities can be obtained

from the proposed equation even when the critical density is only approximately known.

As to the agreement between experiment and calculation, we see that it is quite satisfactory. The estimated tolerance of equation (3) for carbon monoxide is $\Delta \ln$ est. $= 0.95\%$ while the average deviation actually found is $\Delta \ln \phi = 0.62\%$. Considering the volumes themselves we see that the deviations $\Delta d_g\,\%$ are rather small and regularly distributed even in the critical range where the maximum is $\Delta d_g = 1.2\%$ at $\tau = 0.988$ (0.5° below T_{cr}). Here, as in the case of water,[3] we see that in the critical neighborhood (0.97–1.0 T_{cr}) the vapor densities deviate much less than

TABLE I

							average $\Delta \ln$ % (0.55–0.96 T_{cr})	

Comparison of equations

Average differences:
Tolerance of equations (1) and (3), $\Delta \ln$ % est. = 0.95%
Average deviation of equation (3), $\Delta \ln V_g/V_{cr} = 0.62\%$
Average deviation of equation (1), $\Delta \ln V_g/V_{liq} = 0.58\%$

do the corresponding logs; this fact makes the equation applicable at these extreme temperatures.

In order to see how the proposed equation compares with other test equations, we have checked the above results against the Leiden eq. (5), which at very high temperatures can be used for evaluating vapor densities. We see that in the interval 0.9–0.98 T_{cr} the individual deviations are of the same order of magnitude for both eqs. (3) and (5), but at still higher temperatures the Leiden formula fits experimental data much better. On the whole we find that the proposed equation is valid in a long range 0.55–1.0 T_{cr} with an average accuracy $\Delta V_g = 0.9\%$. The Leiden eq. (5) applies to a short interval 0.9–1.0 T_{cr} within $\Delta V_g = 0.35\%$.

We have next proceeded to test other substances in a manner entirely similar to that described above. In each case we have compared the proposed equation with other vapor volume formulas. The intercomparison was done by a graphical method. For every substance the deviations of each equation from one and the same set of experimental data were calculated and plotted to the same scale so that the regional distribution and the average value of each set of deviations could be compared among themselves.

In Table II, which is similar in construction to Tables II of earlier articles,[1,2] we give the results of our calculations for the same nine typical substances portrayed in Fig. 1. The deviations are given up to the highest volumes known and are recorded in volume per cent. Average deviations are also given. In examining Table II we find certain points of interest with regard to individual substances which will be mentioned briefly.

Helium.—Its densities between 0.45–0.75 T_{cr} were evaluated from the latest form of the Leiden eq. of state[6]; the densities between 0.85–0.90 T_{cr} have been measured directly, while the value at 0.96 T_{cr} evidently has been calculated from the rectilinear diameter equation (6).[5] Examining our calculations we see that the proposed equation is in agreement with both the observed and calculated Leiden data, except at 0.96 T_{cr}. The average deviation $\Delta V_g = 0.5\%$ (0.45–0.92 T_{cr}) is much smaller than could be expected, as is evident from the fact that the tolerance for helium is Δ ln % estd. = 4.0%,[1] while the actually found deviation is $\Delta \ln \phi = 0.3\%$.

Contrasting the proposed equation with other formulas, we find that the volume ratio equation (1), when recalculated on the basis of the latest density data,[6] gives excellent agreement. At every point it runs parallel to the proposed equation and its average deviation is exactly the same as for the latter: $\Delta V_g = 0.5\%$. (In evaluating the averages the large discrepancies at 0.96 T_{cr} were omitted.) We have further checked our results against the standard Clapeyron equation for helium (available only between melting and boiling points) and against Meyers' equation (given for helium only at the high temperatures 0.8–0.9 T_{cr}).

Meyers' equation was discussed previously.[1,7] It is in good agreement with observed data of many liquids in the range melting point to 0.9 T_{cr}. At higher temperatures it is not valid. For helium its average deviation is $\Delta V_g = 1\%$ (0.8–0.9 T_{cr}). The Clapeyron equation has an equivalent accuracy at lower temperatures. We conclude from above that both the proposed and the volume ratio functions represent the helium data more closely and in a longer range than either the Clapeyron or Meyers' equation, the shortcoming of the former undoubtedly being due to inaccuracies in the data for latent heat of helium.

Krypton.—Its densities have been measured at Leiden up to 1° of T_{cr}. One value, however, for $\tau = 0.6000$, was calculated by them from their equation of state.[6] Contrary to the case of helium, we find that for this particular value the proposed and the volume ratio equations deviate enormously from the Leiden equation of state, while they fit remarkably well the other (observed) data for this substance. Both equations average $\Delta V_g = 0.23\%$ between 0.65–0.98 T_{cr}. The mean density equation (5) is equivalent to the other two between 0.85–0.98 T_{cr} ($\Delta V_g = 0.21\%$ on the average). In the immediate vicinity of the critical point the latter is definitely superior (average $\Delta V_g = 0.9\%$ as against 3.0% and 2.8%).

Ethane.—Its vapor densities between 0.65–0.90 T_{cr} are taken from the "Int. Crit. Tables" and are based on the experiments of Porter. The data at high temperatures (0.90–0.995 T_{cr}), as well as the critical constants, are from the new measurements of Sage, Webster and Lacey.[6] In our calculations the first two reference points were taken from the "Int. Crit. Tables" data and the third one from the data of Sage and co-workers. This was done purposely in order to test the consistency of the two sets of measurements. In fact we find exceptionally close agreement between the proposed equation and the experimental values of Porter and of Sage. With the exception of one value at 0.9 T_{cr}, the deviations in the range 0.65–0.96 T_{cr} are all under 0.2% and average 0.09 volume per cent. Even in the critical region (0.96–1.0 T_{cr}) the average $\Delta V_g = 0.6\%$. Comparing these results with the reduced diameter eq. (7), used by "Int. Crit. Tables," we see that the latter is much inferior, since its average is $\Delta V_g = 0.7\%$ (0.8–1.0 T_{cr}).[8]

As to the volume ratio equation, we find that calculations based on the new data of Sage, Webster and Lacey are less accurate than those based on the "Int. Crit. Tables" values alone. The average deviation is $\Delta V_g = 0.8\%$, as compared with 0.5% obtained previously.[1,9]

The only explanation seems to be that the liquid densi-

(7) C. H. Meyers, *Bur. Standards J. Research*, **11**, 691 (1933).

(8) We also notice that the "Int. Crit. Tables" diameter eq. (7), leads to a d_{cr} value which is 5% higher than that obtained by Sage and co-workers, or that selected by Pickering (see table of best critical data: "Int. Crit. Tables," Vol. III, 248 (1928)).

(9) Through oversight the critical temperature, the estimated tolerance and the actual and per cent. log deviations of the volume ratio eq. (1) for ethane were incorrectly given in the article on Orthobaric Densities.[1] These should be: $T_{cr} = 305.3°$ K.; Δ ln % estd. = 0.5%; $\Delta \ln \rho = 0.0045$ (actual) = 0.25%.

ties of Sage and collaborators are not quite consistent with the measurements of earlier observers recorded in the "Int. Crit. Tables." However, we find that the parameters of the recalculated volume ratio equation are of the same order of magnitude as before[1,9]: $K_{cr} = 3.638$ (Sage's critical data); $k = 3.681$; $m = 0.4175$; $n = 1.199$.

Acetylene.—In the case of this substance the question arises as to the correct value of the critical temperature. The different observed values range from 37.05° by Ansdell (1879) and by Mathias (1909) to 35.4° by Cardozo and Baumé (1912). In the "Int. Crit. Tables" the value 36.0° is used as the best average of the above. The vapor densities of acetylene are given in the "Int. Crit. Tables" to two significant figures only. The data for high temperatures are based on the experiments of Mathias (Leiden). The values at lower temperatures are evidently calculated from the reduced rectilinear diameter eq. (8). This equation is in agreement with Mathias' observed densities between −23° and +29° and leads to his value of d_{cr}, but in the interval +29° to +36.0° the discrepancy amounts to 2–3%. Remembering that the diameter equation is usually quite accurate in the critical region, one may ask whether the value 36.0° accepted as T_{cr} by "Int. Crit. Tables," might not be in error. In order to investigate this point we have turned to the original paper of Mathias.[6] It appears that his density values are much more consistent with the value $T_{cr} = 37.05°$, since the equation $d_m = a + bt°$ referred to this temperature agrees with his observations within 0.5% up to the highest temperatures.

In Table II we have applied the proposed equation both to the "Int. Crit. Tables" data and to Mathias' data for acetylene. For comparison we give the diameter equations (8), and (6), used by "Int. Crit. Tables" and Mathias, respectively. Examining the respective four sets of deviations, we notice that the densities of the "Int. Crit. Tables" cannot be represented by the proposed equation. The discrepancies amount to several volume per cent. and are especially large between 0.85–0.95 T_{cr}, which indicates the possibility of an error in T_{cr} greater than 0.5°.[1]

On the other hand, when referred to $T_{cr} = 37.05°$ and compared with the original d_{gas} values of Mathias, the proposed equation gives very good agreement. In the interval 0.9–0.98 T_{cr} it is slightly superior to Mathias' diameter eq. (6), ($\Delta V_g = 0.3\%$ against 0.5%). In the critical interval the reverse is true, the respective differences being $\Delta V_g = 1.5\%$ and 0.6%. We might add that the constants k'', m'', n'', obtained from Mathias' data, are quite in line with those of other substances.

Carbon Dioxide.—For this substance two sets of measurements are available, both in the short interval 0.9–1.0 T_{cr}. Those of Lowry and Ericson are checked against the cubic vapor density equation originally suggested by Jüptner.[6,12] The more recent measurements of Michels, Blaisse and Michels[6] are checked against the rectilinear diameter eq. (6). These authors have also given new critical constants for carbon dioxide, which are in good agreement with those of other observers. In our calculations we have used the critical data of Michels and collaborators, but the reference points were taken from the d_{gas} values of Lowry and Ericson, since we were interested in the numerical test of the cubic density equation. Our results show that both the proposed and the volume ratio equations deviate by less than 1% from the experimental densities of either observer, thereby indicating the high consistency of the two sets of measurements. On the other hand both equations are quite comparable to the cubic formula, the respective average deviations being $\Delta V_g = 0.8\%$, 0.8%, and 0.7% (0.9–0.99 T_{cr}). The rectilinear diameter eq. is much more accurate in this interval (average $\Delta V_g = 0.25\%$).

The remaining four substances: benzene, *n*-pentane, ammonia and ethyl alcohol are all checked in Table II against Meyers' equation discussed above. We find that **ammonia** shows excellent agreement both with the proposed and with Meyers' equations, the latter being superior at very low temperatures. In our calculations the three reference points were taken from the Bureau of Standards data. The deviations from these data are very small, averaging $\Delta V_g = 0.15\%$ and 0.04%, respectively (0.5–0.8 T_{cr}). The deviations from the d_{gas} values obtained from the Beattie and Lawrence equation of state[6] are larger: $\Delta V_g = 0.3$ and 0.4% on the average (0.8–0.9 T_{cr}). As to ***n*-pentane,** we see that Meyers' equation excels over the proposed equation at low and moderately high temperatures. ($\Delta V_g = 0.4\%$ as against 0.8% between 0.65–0.97 T_{cr}.) In the critical neighborhood Meyers' equation is not expected to hold and, accordingly, we find its deviation to rise to 15% at $\tau = 0.995$, where the proposed equation differs as little as 0.6% from observed value.

Ethyl alcohol is represented much more accurately by the proposed equation than by that of Meyers. We see that the former follows Young's data all along the line with an average $\Delta V_g = 0.5\%$ (0.6–0.96 T_{cr}). The latter deviates unevenly at different temperatures, averaging $\Delta V_g = 1.5\%$ between 0.5–0.8 T_{cr} and $\Delta V_g = 3\%$ between 0.8–0.99 T_{cr}. Substitution of the vapor densities evaluated by the Bureau of Standards (0–130°)[6] makes the agreement definitely worse for either formula, which suggests a lack of consistency between the two sets of d_{gas} data. **Benzene** shows a similar lack of consistency between Young's measured densities and those calculated by the Bureau of Standards from the latent heat (0–130°).[6] Since Young's values are extrapolated at low temperatures, we have used the Bureau of Standards values for the first reference point. We find that the proposed equation deviates from the calculations of the Bureau of Standards by $\Delta V_g = 1.5\%$ (0.6–0.8 T_{cr}). On the contrary, the densities measured by Young are in close agreement with our calculations, the deviations averaging $\Delta V_g = 0.5\%$ (0.8–0.97 T_{cr}). The equation of Meyers shows a reverse picture: it fits the Bureau of Standards values within $\Delta V_g = 0.1\%$ and differs from those of Young by $\Delta V_g = 2\%$ on the average.

The inspection of the foregoing nine typical substances shows that the proposed equation expresses vapor densities of different liquids very accurately (within one volume per cent. or less) in the range boiling point to 0.97 T_{cr}. Near the critical temperature the majority of substances show larger differences, but only a few give as much as 5–6% deviation even at those very high

temperatures. When compared with other formulas, the proposed equation is found equivalent to the volume ratio function, as regards precision. It is also found comparable and in some cases superior to other vapor volume equations recorded in the literature. Only in the critical region it is less accurate than the mean density formulas (5)–(8) of Cailletet and Mathias.

In Table III we give, as in previous papers, a brief summary of our calculations on thirty liquids. The table is constructed in the same way as before.[1,2] The arrangement of liquids is in the order of ascending ln V_g/V_{cr} values at $\tau = 0.6000$.

In part 1, column 3 of this table we give numbers to literature references, which are listed in Table V below. The fourth column gives values of critical densities which in all cases, except that of ethyl ether, were obtained by extrapolation from mean density equations. The critical density of ethyl ether was obtained by direct measurement (Schröer[6]). In column 5 are given the observed values of ln V_g/V_{cr} which were read directly from the graph at $\tau = 0.6000$. In the last three columns we compare the average deviations of the proposed equation ($\Delta \ln \phi$ %) with the estimated tolerances ($\Delta \ln$ % estd.) and with the corresponding average deviations of the volume ratio equation ($\Delta \ln \rho$ %). The figures in the columns ($\Delta \ln$ % estd. and $\Delta \ln \rho$ %) are the same as in the article on orthobaric densities[1] with few corrections, namely: two new substances, krypton and carbon dioxide, have been added and three old ones, helium, ethane and acetylene, have been recalculated on the basis of more reliable data.

TABLE III

SUMMARY OF RESULTS

Substances in the table are arranged in the ascending order of curves

[a] The numbers in column 3 indicate the corresponding references on observed vapor densities and critical densities listed in Table V. [b] The critical densities are all extrapolated from corresponding equations, except that of ethyl ether which is the value actually measured by Schröer. [c] The per cent. deviations given in the last three columns refer to the range of reliable densities (0.6–0.95 T_{cr}) with the following exceptions: helium, hydrogen, ethylene (0.45–0.95); oxygen and sulfur trioxide (0.75–0.95); acetylene and carbon dioxide (0.90–0.99); and nitrogen tetroxide (0.65–0.75). [d] The average deviations of the volume ratio equation, $\Delta \ln \rho$ %, for helium, ethane, carbon dioxide and acetylene are recalculated in accordance with the new data for these substances (see Tables II and V for details). [e] The tolerances of the proposed equation, $\Delta \ln$ % estd., for acetylene and carbon dioxide refer to the range 0.9–0.95 T_{cr} and are evaluated according to the method given in the article on orthobaric densities.[1] [f] The average deviations $\Delta \ln \rho$ % for benzene and ammonia were evaluated from Young's, respectively, Bureau of Standards data only.

TABLE III (*Concluded*)

Proposed equation: $\ln V_g/V_{cr} = k''(1 - \tau^2)^{m''}/\tau^{n''}$ V_g = vapor volume (cc./g.)

[a] The critical coefficient $K_{cr} = (RT_{cr})/(P_{cr}V_{cr})$ is given for comparison. The values are the same as in the previous papers, except those of ethane, carbon dioxide, acetylene, ethyl ether. For these substances K_{cr} was recalculated in accordance with the new values for the critical constants (see Table V). [b] The values of k'', m'', n'', in brackets are not reliable, the range of known densities being too short, or the data at the reference points being uncertain. [c] The average deviations for the proposed equation and the volume ratio equation refer in general to the range: 0.6–0.97 T_{cr}. Exceptions: see footnote *c* in the first half of Table III. The average deviations for Meyers' equation refer to the range 0.6–0.9 T_{cr}. Exceptions: helium (0.8–0.92 T_{cr}); water (0.42–0.95 T_{cr}); ammonia (0.5–0.9 T_{cr}); benzene (0.7–0.95 T_{cr}); methyl and ethyl alcohols (0.55–0.97 T_{cr}). The average deviations for the mean density equation refer in general to the range: 0.85–1.0 T_{cr}. Exceptions: helium, ethyl ether, *n*-hexane, methyl formate (0.75–1.0 T_{cr}); hydrogen, ethane, hydrogen chloride, benzene (0.7–1.0 T_{cr}); neon; nitrous oxide, methyl ether (0.6–1.0 T_{cr}); Acetylene and carbon dioxide (0.9–1.0 T_{cr}) (for literature see Table V). [d] The equation for carbon dioxide in column 9 is that of Jüptner and used by Lowry and Ericson (0.9–0.97 T_{cr}). [e] The equation for water in column 10 is that by Keyes, Smith and Gerry (0.45–0.95 T_{cr}).

Examining the three sets of deviations, we see that in all cases, except that of carbon dioxide, the $\Delta \ln \phi$ % of the proposed equation are smaller than the estimated tolerances and are very close to the $\Delta \ln \rho$ % of the volume ratios.

We conclude that the proposed equation holds with required accuracy in twenty-nine cases out of thirty and that it has the same reliability as the volume ratio equation.

In part 2 of Table III we give the constants k'', m'', n'' of the proposed equation together with the critical coefficients (for the purpose of comparison). The latter values are the same as given before, except a few new data: the K_{cr} of ethane, carbon dioxide, acetylene and ethyl ether. In the last four columns the precision of the proposed equation is compared with the precision of other vapor volume functions, the deviations V_g obsd. $- V_g$ calcd. being in volume per cent.[10] The literature references on the different equations are given under individual substances in Table V below.

(10) The ΔV_g % of the volume ratio equation are taken from the article on orthobaric densities; ref. 1, Table III$_2$, column 6. To obtain the volume per cent. deviations the actual log differences were multiplied by 100.

In examining individual liquids with regard to the accuracy of the proposed equation, we notice, as in the case of pressures, that the best agreement with experiment is found for those substances recently measured, the average deviations being between 0.09–0.6%. These are: water, ammonia, krypton, carbon dioxide, helium and ethane. Of the substances measured by Young, *i*-pentane, monofluorobenzene, ethyl ether, ethyl propionate and ethyl alcohol fall in the same category, while *n*-pentane, *n*-hexane, carbon tetrachloride, methyl formate, methyl alcohol, acetic acid and benzene deviate from experiment by about 1% on the average. Of the substances listed in the "Int. Crit. Tables," only one, acetylene, has a set of adjusted vapor densities less consistent than the original data (of Mathias). In all other instances, methyl ether, hydrogen chloride, sulfur trioxide and nitrous oxide, the adjusted vapor densities of "Int. Crit. Tables" were found in close agreement with the proposed equation, the average deviations ranging between 0.5–1.0 volume per cent., while the original data of the respective observers were found inconsistent with both the "Int. Crit. Tables" data and with our calculations.[11]

Comparison of the Constants k'', m'', n'' of the Proposed Vapor Volume Equation.—These constants possess the same general characteristics as the corresponding parameters for vapor pressures and for volume ratios.[2,1] Thus we find that helium and nitrogen tetroxide have extreme values of k'', m'' and n''. We also notice that the parameters change but little from substance to substance, the limits being: k'', from 1.89 (He) to 4.32 (N_2O_4); m'', from 0.4062 (O_2) to 0.5568 (SO_3); and n'', from 0.8809 (SO_3) to 1.744 (C_2H_5OH). Where two substances are located on adjacent curves, their parameters become very close, as was found for other properties. For instance: ethyl ether and *n*-hexane have $k'' =$ 2.9216 and 3.0012; $m'' =$ 0.4522 and 0.4627; $n'' =$ 1.622 and 1.595; similarly water and acetic acid have $k'' =$ 3.281 and 3.196; $m'' =$ 0.4717 and 0.4740; and $n'' =$ 1.519 and 1.568; etc.

We notice further (as before) that the constant k'' varies more than m'' or n''. The increase of the constant k'' from substance to substance is parallel to the rise of the critical coefficient and to the order of curves $\ln V_g/V_{cr}$. For each substance it stands in almost constant ratio to its critical coefficient, the values K_{cr}/k'' lying within narrow limits, 1.14–1.39. Since the same parallelism was observed with regard to the curves $\ln P_{cr}/P_s$ and $\ln V_g/V_{liq.}$, we conclude that the critical coefficients exert a directing influence on the arrangement of the above three thermodynamic properties. To what extent this influence is alike for all of them can be seen by comparing Table III of the present paper with Tables III of the earlier articles.[1,2] We find that the first eighteen and last three of the vapor volume curves (helium to *n*-pentane and methyl alcohol to nitrogen tetroxide) have identical positions with the volume ratio curves. Carbon dioxide is placed just below carbon tetrachloride, which is different from its position in the pressure table; this, however, is provisional inasmuch as accurate measurements of its densities at low temperatures are not available. Krypton is placed just below oxygen in all three tables. The nine remaining substances exhibit slight shifts in their position: for instance, monofluorobenzene is removed from benzene even further than in the volume ratio table, ammonia entering between it and *n*-pentane. Acetic acid, ethyl propionate and sulfur trioxide follow each other as in the volume ratio table. Water, on the contrary, occupies the same place as in the pressure table, just above *n*-hexane.

In summarizing we can say that the three properties, vapor pressures, vapor volumes and volume ratios of different substances show almost identical behavior for the equilibrium liquid–vapor, as demonstrated by the relative succession of their curves and by the close correspondence of their k and n parameters. As appropriate examples we can cite in addition to that of water[3] two other substances, nitrogen tetroxide and carbon monoxide. The former has respective k values 5.4, 4.33, 4.0, while its n values are 1.24, 1.31, 1.22; the latter has k values 2.77, 2.51, 3.25, and n values 1.48, 1.52, 1.32.

(11) The case of nitrous oxide is typical in this regard. Its densities and critical data have been measured many times, but with little concordance. Only recently Quinn and Wernimont[6] have carried out new measurements over a long temperature range. On checking these data against the cubic equation of Jüptner (same as used for carbon dioxide by Lowry and Ericson), they have found complete lack of agreement, the deviations ranging from 2–50% and averaging 17%.[6] The proposed equation fits their values much closer than that of Jüptner, since the average deviation is only 5.5%; however, this cannot be considered a satisfactory agreement, especially since the constants of k'', m'', n'' acquire abnormal values. The agreement of the proposed equation with the adjusted vapor densities of nitrous oxide and with the "Int. Crit. Tables" diameter equation is within $\Delta V_g = 0.8\%$ in the range 0.6–0.97 T_{cr}. Accordingly, the parameter values obtained are in line with those of other substances, suggesting high consistence of the "Int. Crit. Tables" d_{gas} data for nitrous oxide.

TABLE IV

Ratio average		Per cent. deviations number of substances: 0%		0.2–5.0%		6–10%		11–15%		20–100%	
		Δa	Δu	Δa	Δu	Δa	Δu	Δa	Δu	Δa	Δu
k'/k''	1.076	0	0	25	7	0	15	3	3	1	4
m'/m''	2.087	0	0	21	20	5	6	1	0	2	3
n'/n''	0.9816	0	0	26	25	0	1	1	1	2	2

In closing this discussion we wish to point out that the parameters k'' and n'' for vapor volume are in no instance exactly equal to the constants k' and n' for pressure, although at first sight the ratios k'/k'' and n'/n'' appear to be close to unity. Similarly, the ratios m'/m'' are never exactly equal to the integer 2. In order to make this clear, we have computed the averages for the ratios k'/k'', m'/m'', n'/n'', on the basis of all the liquids studied, except those with bracketed parameters. In Table IV we show how many substances deviate from those averages (Δa), as well as from the integral ratio values (Δu). On the top of the table we mark per cent. deviations divided into groups. In the vertical columns marked Δa and Δu we give the number of substances contained in each one of these groups:

Table IV shows that the deviation from unity or from 2 is never zero, but for the majority of substances the difference is small. It is also clear that for nearly all thirty liquids the constant k' for pressure is slightly larger than k'' for volume; the reverse is true for the constant n, with but few exceptions; the constant m'' for volume is almost half that of pressure. This regularity is followed by the majority of liquids within 5% or less.

It must be added that of thirty substances only one, sulfur trioxide, has very abnormal ratios k'/k'', m'/m'', and n'/n'' which equal 0.657, 1.54 and 2.67, respectively. The cause of this abnormality lies in the pressure constants which form a very peculiar set of values.[2] The volume parameters of sulfur trioxide are quite within the range of normal values.

Intercomparison of Different Vapor Volume Equations.—Historically there appear to be only four original attempts to express vapor density as function of temperature alone. Cailletet and Mathias observed many years ago that at high temperatures the densities of nitrous oxide, sulfur dioxide and other substances can be expressed by a parabolic equation, which in ordinary and in reduced units is[6,12]

$$d_{gas} = a - bt - c\sqrt{t_{cr} - t} = d_{cr}[1 + B(1 - \tau) - C\sqrt{1 - \tau}] \text{ range: 0.8–1.0 } T_{cr} \quad (9)$$

Later van Laar and also Jüptner developed on the basis of respective theoretical considerations the relationships

$$d_{gas} = f(-\sqrt{1 - \tau}) = d_{cr}[1 - \alpha(1 - \tau)^{0.5} + \gamma(1 - \tau) - \phi(1 - \tau)^{1.5} + \kappa(1 - \tau)^{2.0} - \nu(1 - \tau)^{2.5} + \ldots] \quad (10)$$

$$d_{gas} = F(-\sqrt[3]{1 - \tau};\ 1 + \tau) = d_{cr}[1 - \omega(1 - \tau)^{1/3} + \beta(1 - \tau)^{2/3} - \left(\frac{\delta}{1 + \epsilon\tau} - 1\right)(1 - \tau)] \quad (11)$$

These were found, however, to be in complete disagreement with experiment.[12]

Finally, Jüptner offered an empirical cubic equation, which was considered by van Laar an artificial relationship,[12] yet was found to give good results at high temperatures[6,12]

$$d_{gas} = d_{cr} + b'(t_{cr} - t) - c'\sqrt[3]{t_{cr} - t} = d_{cr}[1 + B'(1 - \tau) - C'\sqrt[3]{1 - \tau}] \text{ range: 0.8–0.95 } T_{cr} \quad (12)$$

In this equation the constants B' and C' are characteristic for each substance.

All other vapor density formulas recorded in the literature and used here for comparison, express d_{gas} in terms of two or more variables. To the category $d_{gas} = f(d_{liq}, t)$ belong, besides the volume ratio eq. (1), the different modifications of the mean density equation (5)–(8). Recently two formulas of the type: $V_{gas} = f(p, t)$ were

(12) We give the literature on variation of vapor density with temperature: (a) parabolic d_{gas} equations, Cailletet and Mathias, *J. phys.*, **5**, 549 (1886). Further elaboration of same: Mathias, *ibid.*, **1**, 53 (1892). (b) Van Laar's equation of state and the function: $d_{gas} = f(-\sqrt{1 - \tau})$; expansion of it into series and numerical tests, showing disagreement: van Laar; "Die Zustandgleichung," Leipzig, 1924, pp. 132–139, 327–328, 332–333, 344–345. (c) Jüptner's vapor pressure equation and the function: $d_{gas} = F(-\sqrt[3]{1 - \tau}, 1 + \tau)$ also numerical test on fluorobenzene (Young's data), showing poor results: Jüptner, *Z. physik. Chem.*, **63**, 355, 360 (1908); **73**, 173 (1910). (d) Cubic d_{gas} equation: Jüptner, *ibid.*, **80**, 299, 307–311 (1912); numerical test on fluorobenzene showing poor agreement when $C' = 2$ is a universal constant: *ibid.*, pp. 309–310; discussion of the cubic equation (assuming B' and C' to be characteristic constants), van Laar, "Die Zustandgleichung," pp. 345–348; numerical tests on carbon dioxide showing good results when equation is applied to high temperatures only and the constants have characteristic values: Lowry and Ericson, THIS JOURNAL, **49**, 2729 (1927). Numerical tests on nitrous oxide showing disagreement when equation is applied to the whole saturation line: Quinn and Wernimont, *ibid.*, **51**, 2002 (1929). (e) Modification of the cubic equation, assuming the coefficient $C' = f(1 - \tau)$; also numerical test on fluorobenzene, showing no improvement over $C' = 2$: Jüptner, *Z. physik. Chem.*, **80**, 299, 309 (1912). Further modification of cubic equation, assuming the first term, unity, to be replaced by T/T_{cr} and the constants B' and C' to be equal to each other: $d_{gas} = d_{cr}[B''(1 - \tau) - B''(1 - \tau)^{1/3} + \tau]$; no direct numerical tests are given here, Jüptner, *Z. physik. Chem.*, **85**, 1, 55–57 (1913).

TABLE V

BIBLIOGRAPHY ON EXPERIMENTAL DATA FOR VAPOR VOLUMES AND CRITICAL PROPERTIES; INCLUDING EMPIRICAL TEST EQUATIONS USED BY DIFFERENT OBSERVERS

(1) The new scale of temperature: (Absolute zero = −273.144°C.); improved equation for mean diameter (in ordinary and reduced units); corrected critical temperatures, critical densities and critical coefficients for: helium, hydrogen, neon, oxygen, nitrogen, carbon monoxide, and ethylene (Mathias and Crommelin, *Ann. phys.*, **5**, 137, 143, 144 (1936)); for krypton (Mathias, Crommelin and Meihuizen, *ibid.*, **8**, 467 (1937)); improved equation of state (Leiden), "Leiden Lab. Comm. No. 234e."

(2) Substances observed at the Leiden Laboratories: Helium and carbon monoxide; vapor densities calcd. (eq. of state) and observed; also the corresponding mean diameter equations, *Ann. phys.*, **5**, 137, 143 (1936).

Helium: vapor density at 5°K. (0.96 T_{cr}), also Clapeyron eq. (melting to boiling point), "Leiden Lab. Comm. No. 179c."

Hydrogen, oxygen, nitrogen: vapor densities calcd. (eq. of state) and observed; also corresponding rectilinear diameter equations, *Ann. phys.*, **17**, 416 (1922).

Neon: same, *ibid.*, **19**, 231 (1923).

Ethylene: same, *ibid.*, **11**, 344 (1929).

Krypton: vapor densities calcd. (eq. of state) and observed: *ibid.*, **8**, 467 (1937).

Acetylene: vapor densities observed (−23.75° to t_{cr}); t_{cr} = 37°.05; also the rectilinear diameter equation, Mathias, *Compt. rend.*, **148**, 1102 (1909). Critical density: "International Critical Tables," Vol. III, 230 (1928). Adjusted vapor densities (normal b. p. to t_{cr}); t_{cr} = 36.0°; also the reduced rectilinear diameter equation: *ibid.*, "Int. Crit. Tables," III, 230 (1928).

(3) Ethane: adjusted vapor densities (from Porter) between: normal b. p. and +10° also at +20 and +30°, together with the reduced mean diameter equation of second degree: "Int. Crit. Tables," Vol. III, 230 (1928); observed vapor densities (from isotherms) between +17.6° and t_{cr}; also all critical data, Sage, Webster and Lacey, *Ind. Eng. Chem.*, **29**, 658 (1937).

(4) Carbon dioxide: vapor densities observed (−5.8 to +22.9°); also the cubic equation for d_{gas} as function of temperature alone: Lowry and Ericson, THIS JOURNAL, **49**, 2729 (1927). Vapor densities (from isotherms) between +2.8° and t_{cr}; also all critical data and the rectilinear diameter equation: Michels, Blaisse and Michels, *Proc. Roy. Soc.*, **A160**, 358 (1937).

(5) Substances recorded in the "International Critical Tables" (1928). Hydrogen chloride, methyl ether, sulfur trioxide: adjusted vapor densities (normal b. p. to t_{cr}); all critical data; mean diameter eq.; *ibid.*, Vol. III, p. 228–236. Nitrous oxide: adjusted vapor densities (normal b. p. to t_{cr}); reduced rectilinear diameter equation; all critical data, "International Critical Tables," Vol. III, p. 228 (1928). Original observed vapor densities; corresponding T_{cr} values and test equations: (a) Cailletet and Mathias, *J. phys. radium*, **5**, 549 (1886); (b) Villard, *Compt. rend.*, **118**, 1096 (1894); (c) Quinn and Wernimont, THIS JOURNAL, **51**, 2002 (1929).

(6) Substances observed by Young: *n*-hexane, carbon tetrachloride, monofluorobenzene, methyl formate, ethyl propionate, acetic acid, ethyl alcohol, methyl alcohol: vapor densities observed (0° to t_{cr}); also all critical data and corresponding mean density equations; Young, *Proc. Roy. Dublin Soc.*, **12**, 374 (1910). The cubic equation applied to fluorobenzene; Jüptner, *Z. physik. Chem.*, **80**, 309, 310 (1912).

Ethyl and methyl alcohols: vapor densities calculated from the Clapeyron equation (0–130°); *Bur. Standards J. Research*, **6**, 881 (1931).

Benzene: vapor densities calculated from the Clapeyron equation between 0 and +130°; Fiock, Ginnings and Holton, *Bur. Standards J. Research*, **6**, 881 (1931). Vapor densities observed between +140° and t_{cr}; also all critical data and mean diameter equation of second degree: Young, *Proc. Roy. Dublin Soc.*, **12**, 374 (1910).

i-Pentane and *n*-pentane: vapor densities observed (0° − t_{cr}); also all critical data; Young, *Proc. Roy. Dublin Soc.*, **12**, 374 (1910). Mean density equations of second degree (same range): Timmermans, *ibid.*, **13**, 310 (1912).

Ethyl ether: vapor densities observed (0° − t_{cr}); also t_{cr}; P_{cr}; and the mean diameter eq. of second degree; Young, *ibid.*, **12**, 374 (1910). Critical density (observed): Schröer, *Z. physik. Chem.*, **129**, 79 (1927); **140**, 241 (1929).

(7) Ammonia: vapor volumes observed between −77.5 and +60°; also all critical data and an empirical test equation: (a) Circular Bur. Standards, No. 142, (1923); and (b) the ammonia table in the article by Meyers, *Bur. Standards J. Research*, **11**, 699 (1933). Vapor densities calculated from the eq. of state of Beattie and Lawrence between +60° and +95.6°; ammonia table in the article of Meyers, *ibid.*; equation of state; Beattie and Lawrence, THIS JOURNAL, **52**, 6 (1930). (Vapor densities calculated from the Clapeyron equation between −50 and +50°: *Bur. Standards* Sci. Papers, No. 18, 707 (1923).)

(8) Water: vapor volumes calculated from the empirical equation for water at saturation between 0–340°: Keyes, Smith and Gerry, *Proc. Am. Acad. Arts and Sci.*, **70**, 319 (1936). Vapor volumes between 340° − t_{cr}, calculated by the Clapeyron equation (Bureau of Standards data) *ibid.*, table of saturated volumes. Values of T_{cr} and d_{cr}: Smith and Keyes, *ibid.*, **69**, 285 (1934). Vapor volumes calculated from the Clapeyron eq. between 0–360° (details). Preliminary report, *Bur. Standards;* Osborn, Stimson and Fiock, *Mech. Eng.*, **57**, 162 (1935).

(9) Nitrogen tetroxide: vapor densities observed between +3 and +55°: Mittasch, Kuss and Schleuter, *Z. anorg. Chem.*, **159**, 29 (1927). Vapor densities observed between +60° − t_{cr}; also T_{cr} and d_{cr}; (also mean rectilinear diameter eq. in this interval): Bennewitz and Windish, *Z. physik. Chem.*, **A166**, 401 (1933).

(10) Meyers' equation: C. H. Meyers, *Bur. Standards J. Research*, **11**, 691 (1933).

suggested for water and ammonia by Keyes and collaborators and by the Bureau of Standards, respectively. The Clapeyron equation gives vapor volume as a function of V_{liq}, dp/dT and T; while Meyers' equation

$$\log_{10}(1 - pv_{gas}/RT)(1 - pv_{liq}/RT) = A \log_{10} p/p_{cr} \; 2.718 \text{ (range: } 0.5\text{–}0.9\ T_{cr}) \quad (13)$$

expresses vapor volume in terms of V_{liq}, P_{sat} and T.

In the last two columns of Table III are given the summarized results on intercomparison of the proposed equation with the several volume functions listed above. For every one of the thirty substances the average deviations of each equation were evaluated (in volume per cent.) by a graphical method, as described under Table II.

Examining the equations (9)–(12) of the type $d_{gas} = f(\tau)$, we see that only two, the first and the last, have any applicability, and this over a limited range. The proposed equation was found to be superior to each of them, inasmuch as it expresses correctly the whole saturation line rather than a portion of it, with an accuracy equal to or better than that of equations (9) or (12).

Comparing the deviations of the proposed equation with those of the volume ratios, we find that twenty-three out of thirty liquids have smaller or equal average deviations. The seven substances which show inferior results are: *n*-pentane, *n*-hexane, carbon tetrachloride, ethyl propionate, methyl formate, acetic acid and methyl alcohol. As to the distribution of deviations, they run for most liquids parallel in both equations. Water, sulfur trioxide, hydrogen and a few organic liquids are exceptions, but here the difference is not so great as to be of importance. On the whole we feel justified to conclude that the proposed and the volume ratio equations are entirely equivalent as regards accuracy, range of validity and extent of applicability to different substances.

Considering the different modifications of the mean density equation, we see that they are of no practical value at lower temperatures, but in the region 0.9–1.0 T_{cr} they are invariably superior to the proposed equation (ethane and methyl alcohol being the only exceptions so far encountered).

The functions $V_{gas} = f(p, T)$ of Keyes and coworkers and of the Bureau of Standards are extremely accurate (V_{gas} = 0.03% and 0.1%). On the other hand, they are very cumbersome in form (7 or 8 constants), and seem to be of specific rather than general applicability.

Meyers' equation was tested on eight liquids. At low and moderate temperatures it was found equivalent or slightly better than the proposed equation in all cases except that of ethyl alcohol. The fact that it does not hold above 0.9 T_{cr}, as well as the large number of independent variables necessary for its evaluation make this relationship inferior to the proposed equation. However, at temperatures below the boiling point it is most reliable.

Clapeyron's equation was contrasted with the proposed equation on ammonia, water[3] and helium. Both equations apply about equally well to the first two substances (ΔV_g = 0.1–0.2%). The inferior accuracy of the Clapeyron equation for helium is subject to revision, pending more accurate data for the latent heat of helium.

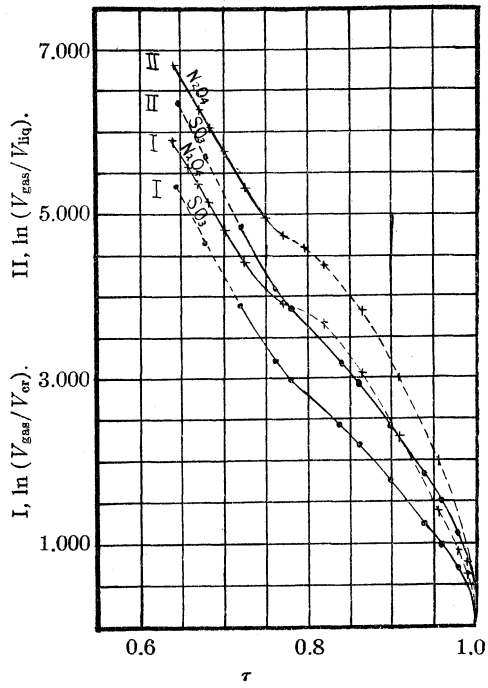

Fig. 2.—Curves I give ln (V_g/V_{cr}), obsd. Curves II give ln (V_g/V_{liq}), obsd. ———— Parts of experimental curves I and II which follow the equations; - - - - - - - - - parts of experimental curves I and II which deviate from the equations. ●, SO_3; +, N_2O_5.

As the result of the above comparative study of equations, we can say that both the proposed and the volume ratio functions have a definite advantage over the other vapor volume expressions here discussed, because, having equivalent or, sometimes, better accuracy, they fit a larger variety of liquids over a longer temperature interval than any of the others. In addition, we see

that the proposed equation is the only rather satisfactory attempt to express V_{gas} in terms of a single independent variable, reduced temperature.

Before leaving the subject we wish to add a few words regarding sulfur trioxide and nitrogen tetroxide. Both were previously found to have abnormally shaped experimental curves ln V_{gas}/V_{liq}.[1] The deviating portion of either curve was found in disagreement with the volume ratio equation, while the portion regularly shaped was found to follow this equation within expected limits. A corresponding behavior is to be noted for the vapor volume curves of these substances. In Fig. 2, the observed curves ln V_g/V_{cr} of SO_3 and N_2O_4 are plotted alongside the observed values of their ratios, ln V_g/V_{liq}. We see that for either substance the two functions have deviating portions (dotted lines) very similar both in direction and in length of temperature interval. As to the proposed equation, we find that it follows the experiment in the normal region of the vapor volume curves ($\Delta V_g = 0.6\%$ and 1.0% for SO_3 and N_2O_4, respectively). On the other hand, in the abnormal section of these curves the vapor volume equation deviates enormously from observed data, and this behavior is in accordance with that observed for the volume ratio.[1]

Summary

1. The reduced vapor volume of chemically different substances is found to be an exponential function of reduced temperature alone. The form of this function is identical with those for vapor pressure and for volume ratio

$$\ln V_g/V_{cr} = k''(1 - \tau^2)^{m''}/\tau^{n''} = x \qquad (14)$$

$$V_{gas} = V_{cr} \cdot e^x \qquad (15)$$

2. The accuracy of this equation is well within experimental limits; it is in good agreement with vapor volume equations of other investigators.

3. When compared with the volume ratio equation it is found to give analogous results as regards average and regional accuracy and range of application. Its advantage lies in the fact that V_{gas} is expressed as a function of one independent variable only.

4. The parameters k'', m'', n'' of this equation have the same characteristics as the constants of the vapor pressure and of the volume ratio equations; they vary only slightly with chemical properties of substances; the constant k'' increases in the same order as the critical coefficient and the heights of ordinates ln V_g/V_{cr}, but there is no simple mathematical relationship between K_{cr} and k''.

5. The three properties, vapor pressure, vapor volume and volume ratio, exhibit striking similarity along the whole saturation line, since not only the mathematical expressions of these functions are identical, but the respective parameters are of the same order of magnitude; further, the geometrical shape of the curves ln P_{cr}/P_s, ln V_g/V_{cr}, ln V_g/V_{liq} is similar and their relative order to each other is identical for every substance here studied; finally, for each one of these properties the successive order of liquids in the coördinate system is the same with but few exceptions.

6. The constants k'' and n'' for vapor volume are nearly equal to the respective constants for pressure and the constants m'' are nearly half the others. However, in no case have the ratios k'/k'', n'/n'', m'/m'' assumed the integral values 1, or 2. Their averages for 30 liquids are respectively: 1.08; 0.98; and 2.09.

An Empirical Relation between Solubility of Slightly Soluble Electrolytes and Dielectric Constant of the Solvent

BY J. E. RICCI AND T. W. DAVIS

The solubilities of an electrolyte in two media of different dielectric constant are related, on the basis of the Born theory of ion–solvent interaction,[1] and ignoring ion–ion interactions, by the equation[2]

$$\log S_2 = \log S_1 - C\frac{z_+z_-}{2r}\left(\frac{1}{D_2} - \frac{1}{D_1}\right) \qquad (1)$$

If the interionic effects are taken into account, by introducing the Debye–Hückel expression for the mean ionic activity coefficients of the electrolyte in each medium, the solubility being sufficiently low in each, the equation is modified as follows

$$\log S_2 = \log S_1 - C\frac{z_+z_-}{2r}\left(\frac{1}{D_2} - \frac{1}{D_1}\right) + \frac{\frac{B}{D_1^{3/2}} z_+z_- \sqrt{\mu_1}}{1 + \frac{A}{D_1^{1/2}} a\sqrt{\mu_1}} - \frac{\frac{B}{D_2^{3/2}} z_+z_- \sqrt{\mu_2}}{1 + \frac{A}{D_2^{1/2}} a\sqrt{\mu_2}} \qquad (2)$$

where A, B and C are constants at any given temperature, S the solubility, D the dielectric constant, the z's represent ionic valences, both considered as positive numbers, μ the ionic strength, r the ionic radius in the Born sense, and a the distance of closest approach of the ions in the Debye–Hückel sense. The subscripts refer to the two different media.[3] Equations 1 and 2, both, require previous knowledge of the ion size a, and in the absence of such information the equations cannot be used.

In connection with studies of the solubilities of salts in dioxane–water mixtures,[2] we have noted that the activity coefficient of an electrolyte in saturated solution is in many cases practically constant and independent of the nature of the solvent. Several examples of this empirical regularity are found in the literature although no especial significance has hitherto been laid upon it. Thus Walden[4] reported tetraethylammonium iodide to be about 48% dissociated in saturated solution in many solvents. The quantity $-\log f_\pm$, for thallous iodate, calculated from its solubility in alcohol–water solvents, on the basis of the limiting law of Debye and Hückel, by La Mer and Goldman,[5] is practically a constant. The mean activity coefficient, $f_\pm$, of a number of uni-univalent electrolytes in pure methanol was determined by Brönsted, Delbanco and Volqvartz,[6] on the basis of solvent effects of added salts, and was noted to be practically the same as that in saturated aqueous solutions; although this fact was specifically mentioned by these authors, no further notice was taken of it, or of any possibility of applying the relation.

From the measurements of Brönsted and Williams[7] on the solubility of complex cobalt ammines in the presence of added salts, the activity coefficient of croceo tetranitro-diammino cobaltiate (a uni-univalent electrolyte) is calculated to be 0.981 at saturation both in pure water (D = 81.1) and in water saturated with ether (D = 74.5), at 18°; and that of the luteo salt (a 3:1 type), 0.916 and 0.907, respectively, in the same solvents. Similar measurements by Hansen and Williams[8] give the following values for $f_\pm$ at saturation, for the croceo cobaltiate at 25°

(a) in water (D = 78.5), 0.978
(b) in 20 mole % ethanol (D = 54.0), 0.969
(c) in 40 mole % ethanol (D = 41.4), 0.969
(d) in 60 mole % ethanol (D = 33.8), 0.974

The values for the croceo sulfate (a 1:2 salt) are 0.805, 0.929 and 0.952 in (a), (b) and (c), respectively, and for the luteo iodate (3:1), 0.537, 0.756 and 0.857, respectively, in the same solvents. We see here a substantial constancy at least in the case of the simpler types.

Table I shows the mean activity coefficients for silver acetate in its pure saturated solutions in various solvents, as determined by the usual method of solvent salt effects. The approximate constancy of f is evident.

TABLE I

ACTIVITY COEFFICIENT OF SILVER ACETATE IN PURE SATURATED SOLUTION, AT 25°

Solvent	Dielectric constant	$f_\pm$
Water[9]	78.55	0.800
Alcohol[9] 10%	72.9	.797
20%	67.1	.803
30%	61.2	.802
Acetone[10] 10%	73.0	.804
20%	67.0	.805
30%	61.0	.798
Dioxane[2] 10%	69.7	.786
20%	60.8	.771

If this observation should be found to apply generally even though approximately, it offers a simple way of predicting solubilities in any medium from a knowledge of the value in one, inasmuch as the logarithm of the activity coefficient at saturation is related directly to the ionic strength (and hence to the saturation concentration for a pure solution if complete dissociation is assumed), by means of the familiar Debye–Hückel equations.

If the activity coefficient of an electrolyte, at saturation, is a constant, independent of the dielectric constant of the medium, the solubilities in two media will be related, where the Debye–Hückel limiting law holds, by the equations:

$$-\log f_1 = -\log f_2 \qquad (3)$$

$$\frac{1.8123 \times 10^6 (z_+z_-)^{3/2}\nu^{1/2}\sqrt{S_1}}{D_1^{3/2}\,T^{3/2}\sqrt{2}} = \frac{1.8123 \times 10^6 (z_+z_-)^{3/2}\nu^{1/2}\sqrt{S_2}}{D_2^{3/2}\,T^{3/2}\sqrt{2}} \qquad (4)$$

where T is the temperature and ν is the total number of ions formed by the complete ionization of one molecule of the electrolyte, and the other symbols have the meanings previously noted.

If the Debye–Hückel expression for the activity coefficient is modified to take into account the effect of the ionic size, then the equation takes the form

$$\frac{\frac{B}{D_1^{3/2}\,T^{3/2}}\sqrt{S_1}}{1+\frac{A}{D_1^{1/2}\,T^{1/2}}a\sqrt{S_1}} = \frac{\frac{B}{D_2^{3/2}\,T^{3/2}}\sqrt{S_2}}{1+\frac{A}{D_2^{1/2}\,T^{1/2}}a\sqrt{S_2}} \qquad (5)$$

where $B = 1.8123 \times 10^6 (z_+z_-)^{3/2}\nu^{1/2}/\sqrt{2}$, and $A = 50.288 (z_+z_-)^{1/2}\nu^{1/2}\sqrt{2}$, a being in Ångström units.

In either case the solubility in any dielectric can be calculated from that in any one reference medium. In equation 4 the variation of the solubility with D is seen to be independent of the valence type of the electrolyte since the valence factors cancel out of the equation. In equation 5, the valence factors again cancel except those involved in the definition of the ionic strength in the denominators, so that the effect of the valence type is only very slight.

Neglecting effects of ionic size, and using, therefore, equation 4, the solubility in the second medium is related to that in the first or reference medium at the same temperature, by the equation

$$S_1^{1/2}/D_1^{3/2} = S_2^{1/2}/D_2^{3/2} \qquad (6)$$

or

$$\log S_2 = \log S_1 + 3(\log D_2 - \log D_1) \qquad (7)$$

so that a plot of the logarithm of the solubility against the logarithm of D would give a straight line with a slope of 3. The solubility according to equation 5 can be written in the form

$$\log S_2 = \log\left(\frac{2K^2}{\nu z_+z_-}\right) + \log D_2 + \log T - 2\log\left[\frac{1.8123 \times 10^6 z_+z_-}{D\,T} - 50.288\,K\,a\right] \qquad (8)$$

where K is the negative logarithm of the activity coefficient in the first medium.

In order to determine the extent to which this empirical rule of constant activity coefficient may be applicable, and to test its possible usefulness in correlating known solubilities and hence in predicting unknown solubilities, we have examined much of the published data on solubilities of slightly soluble electrolytes in non-aqueous solvents and in mixtures of water and organic liquids. For comparison between the calculated and the observed solubilities ($S_{\text{obsd.}}$), the calculations were made, from the solubility in water, according to the various principles: thus, S_f represents the solubility calculated by means of the simplest equation, namely, eq. 7; S_{fa}, that according to equation 8; and S_{Born}, according to equation 1. The latter two calculations of course could be made only where suitable values of the ion diameters could be found. The values of a used in the various cases were taken from reports in the literature on aqueous solutions, some determined by solubilities, some by e. m. f.'s. The dielectric constants for the various solvents were taken from the literature, principally from the data of Åkerlöf.[11]

As an example and to facilitate comparison, the data and calculations for the solubility of barium iodate monohydrate in dioxane–water solvents,[2] presented in Table II, are shown graphically also in Fig. 1, where log S has been plotted against log D. The predictions of the constant activity coefficient rule, as can be seen both from the table and from the curves, are at least in moderate agreement with the observed values over the whole range, while the Born equation very quickly predicts much too small solubility. Since S_{fa} differs so little from S_f in this case, values of S_{fa} have not been calculated for the other salts reported, even where values of a were available.

The degree of usefulness of the principle of constant activity coefficient at saturation, in predicting at least the order of magnitude for solubilities in organic solvents from the known solubility in water, is best judged by means of the ratio, $S_f/S_{obsd.}$, especially if this is compared with the same ratio for the solubility calculated from the Born equation. Thus in the case of barium iodate monohydrate, the ratio, $S_f/S_{obsd.}$, is correct throughout as far as the order of magnitude is concerned, within a maximum factor of only 2.6, while the ratio $S_{Born}/S_{obsd.}$, becomes extremely low especially in the high dioxane mixtures.

The results of the comparison of observed and calculated solubilities for a number of uni-univalent electrolytes in various solvents are shown in Tables III, IV and V. Table III lists the results for silver acetate in dioxane–water solvents; here the ratio, $S_f/S_{obsd.}$, is, throughout the very wide range of D covered, again satisfactory in respect to the order of magnitude of the calculated solubility, the factor being $^1/_6$ at worst. Table

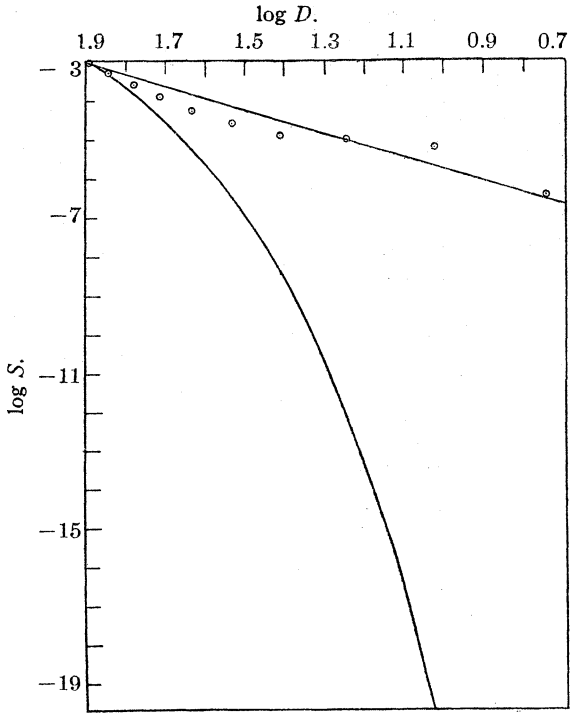

Fig. 1.—Solubility of $Ba(IO_3)_2 \cdot H_2O$ in dioxane–water mixtures: the straight line, as predicted on constant activity coefficient; the curve, as predicted by the Born equation; the points, as observed, ⊙.

IV gives the ratio, $S_f/S_{obsd.}$, for a number of 1:1 electrolytes in mixtures of water with various organic substances. The value of the ratio is seen to be such, throughout, as to predict at least roughly the solubility in the various media. The dielectric constants represented in this group vary from 112.4 in the case of silver chloride in glycine solutions, to that of ethanol at 40°, 22.2; a variation of temperature, between 14 and 40°, is also included, in the data for the perchlorates in ethanol–water mixtures. Table V gives

[a] A very different value (0.565×10^{-3}) for this solubility is given by R. P. Seward and W. C. Schumb, THIS JOURNAL, **52**, 3692 (1930).

Some results on higher type electrolytes are given in Tables VI and VII. The ratio $S_f/S_{obsd.}$ for silver sulfate in dioxane–water solvents (Table VI) again shows that the order of magnitude of the solubility can be predicted down to 90% dioxane ($D = 5.6$), in great contrast to the calculation based on the Born equation. From the ratios obtained for the salts listed in Table VII it is again seen that the solubility is predicted, roughly in most cases, at least in respect to the order of magnitude. Only one experimental point has been omitted in the preparation of this table, namely, the solubility of potassium chloroplatinate

in 95% ethanol at 14°; for this point, the ratio $S_f/S_{obsd.}$ was 19.

The solubility according to the Born equation, S_{Born}, also was calculated for several of the salts reported in Tables IV and VII, such as silver chloride, silver acetate and lead chloride. On the whole the calculated S_{Born} was in poorer agreement with the observed than the calculated S_f, except in the case of lead chloride, where it was just slightly better throughout. Although, therefore, the solubility according to the Born equation (where dependable values of a are available) is occasionally better than that predicted by the simpler calculation on the basis of the constant activity coefficient, the latter is on the whole at least as good as the Born calculation; the Born calculation, moreover, fails completely in the high dioxane range, while the correct order of solubility is still given by the constant activity coefficient rule.

The solubilities for the three potassium compounds in Table VII are interesting from the point of view of analytical chemistry, inasmuch as the simple rule of constant activity coefficient has at least a rough degree of usefulness in predicting the order of magnitude of the solubilities in various mixtures of alcohol and water; and in the absence of knowledge of the ionic diameter, no other estimate of the solubilities would be possible.

The solubilities of a series of complex cobalt ammines, in water and in pure methanol (at 20°), were determined by Brönsted, Delbanco and Volqvartz.[6] On calculating the solubility in methanol according to the rule of constant activity coefficient, from the observed solubility in water, S_w, the ratio of the calculated to the observed solubility in methanol, or S_f/S_M, was found to be 0.3 to 7.6 (averaging 1.9) for twenty-two 1:1 electrolytes (the croceo iodate and the croceo iodoacetate being exceptions, with ratios of 22 and 19, respectively); for seventeen cases of 2:1 electrolytes the agreement between calculated and observed solubilities was much poorer, the average ratio being 12. It is to be pointed out, however, that the application of Born's equation to this same series of forty-one electrolytes cannot be expected to give better agreement than this. If we assume a value of a approximately the same for all these very similar electrolytes, then the ratio of S_w to S_M at 20° (substituting an average value of 2.5 Å. for a in Born's equation) should be $10^{\frac{246}{2.5}\left(\frac{1}{31}-\frac{1}{81.3}\right)}$, or about 89.6, for the 1:1 electrolytes. The actual ratio for this group however, varies from about 5 to about 400, which would correspond to a change in the Born parameter from 7 to 1.8 Å. We may say that the calculation on the simple idea of a constant activity coefficient is at least as useful as the Born calculation and can be used to predict roughly approximate solubilities in different media.

Table VIII (part A) lists certain interesting measurements by K. Volqvartz[6] on the solubility of the uni-univalent electrolyte, flavo tetranitrodiammino cobaltiate, in various pure solvents with dielectric constants varying from 20.8 (for acetone) to 84.7 (for formamide); part B of this table gives the solubility of the croceo salt in sugar solutions, determined by Brönsted and Williams.[7] The ratio of calculated to observed solubility (the calculated being on the basis of the water solubility as reference) shows considerable scattering. The important point, however, is that the observed variation of solubility in this group of measurements is of such a nature that no simple theory, obviously, can account for them. The solubility of the croceo salt in sugar solution, for example, rises as D decreases. The same is true for the solubility of the luteo tetranitrodiammino cobaltiate (3:1 type) in 0.877 *M* sugar solution,[7] and for the nitro-rhodanotetrammine picrate in methanol,[6] as compared to the solubility in water. Moreover, taking the solubility in water as reference, the solubility of the flavo salt in two media such as acetonitrile and nitrobenzene with almost identical dielectric constants, *viz.*, 35.7 and 37.0, respectively, should

be the same, as long as there is attributed to the electrolyte in question an ionic diameter characteristic of the electrolyte itself. There are obviously, in other words, factors of a highly specific nature entering here, so that uniform theories based on physical variables such as ionic radii and dielectric properties (which are the only variables in the Debye–Hückel, the Born and the Bjerrum ion association[19] theories) cannot be expected to work satisfactorily throughout. The Debye effect[20] of non-uniform distribution of solvents around the charged ions, moreover, depending as it does on a designation of definite molecular weight to the solvent, may be significant, but the molecular weight, of course, remains in doubt. Finally, also, the ions may be differently solvated in the various media, but this may be regarded as just another way of referring to the Debye dielectric distribution effect.

Conclusion

Inasmuch as the observed solubilities can be interrelated, for different media, about as well, with the simple rule of constant activity coefficient, as on the basis of the Born equation utilizing the elusive parameter, the "ionic diameter," it is interesting to speculate as to any possible theoretical foundation that can be suggested for the validity of the assumption of at least an approximately constant activity coefficient at saturation. Consideration of the Born equation, modified for interionic effects according to the Debye–Hückel theory, *i. e.*, eq. 2, shows that the activity coefficients for a given electrolyte at saturation in two media of different D will be equal at a given temperature for certain values of a relative to D.

Although the two activity coefficient terms in equation 2 are small and generally negligible compared to the Born term itself, so that the difference between them, $\log f_2 - \log f_1$, will be expected in general to be close to zero, it does not follow that we can in general expect the ratio, $\log f_2/\log f_1$, to equal unity, especially when the activity coefficients are themselves close to one. The principle on which the present calculations are made, that $\log f_2/\log f_1 = 1$, remains then essentially an assumption, and we can only examine the general equation to determine under what conditions the principle can be expected to apply.

For a uni-univalent electrolyte, for which $z_+z_- = 1$, and for which the ionic strength, μ, = the solubility, S, the solubility S_M compared with the solubility in water, S_{H_2O}, is given approximately, at 25°, by

$$\log S_M = \log S_{H_2O} - \frac{242}{a}\left(\frac{1}{D_M} - \frac{1}{D_{H_2O}}\right) \qquad (9)$$

Now substituting in the familiar Debye–Hückel limiting expression for $\log f$ the above value of S_M for μ_M and S_{H_2O} for μ_{H_2O}, we find by setting the two $\log f$ terms equal to each other, that

$$\frac{342.6}{D_M^{3/2}}\sqrt{S_{H_2O} \times 10^{(-242/a)[(1/D_M) - (1/D_{H_2O})]}} = \frac{342.6}{D_{H_2O}^{3/2}}\sqrt{S_{H_2O}} \qquad (10)$$

and the condition for equality is

$$a = \frac{3.083 - (242/D_M)}{3 \log D_M - 5.684} \qquad (11)$$

Table IX shows corresponding values of a and D, satisfying equation 11. This table shows the value of D at which an electrolyte having one of the a values listed in the first column would exhibit an activity coefficient at saturation equal to that of its saturated aqueous solution.

TABLE IX

a	D	a	D
2.10	100	3.38	40
2.32	80	3.98	30
All values	78.5	5.06	20
2.51	70	7.87	10
2.75	60	12.6	5
2.99	50		

The divergence from equality, for an electrolyte, for example with an a equal to 2.75 Å., would increase on both sides of $D = 60$, but while the divergence would increase continuously in lower D, it would disappear with increasing D to give equality, of course, again at $D = 78.5$. Since the a for many electrolytes appears to fall in the range 2 to 3 Å., we might expect, therefore, an approximate equality of $\log f$'s in solutions with dielectric constants between 80 and 40.

If these arguments are repeated on the basis of the more extended form of the Debye–Hückel expression for the activity coefficient, as shown in eq. 2, it is found that the range over which agreement may be expected is somewhat but almost negligibly widened.

In conclusion, we may say that whether or not there is any theoretical meaning in the principle, the assumption of a constant mean ionic activity coefficient for an electrolyte at saturation,

independent of dielectric, is useful in at least an approximate way to predict solubilities in other media from the known solubility in water, without knowledge of the parameter a required for the Born equation. And some of these predictions may be of practical value in analytical and preparative chemistry requiring recrystallizations.

Summary

1. The activity coefficient of a salt in saturated solution has been noted in many cases to be practically constant and independent of the dielectric constant of the medium.

2. This observation leads to an empirical relation between the solubility of a slightly soluble electrolyte and the dielectric constant of the solvent which makes it possible to predict the solubility of a salt in other media from the solubility in water without knowledge of ionic diameters.

3. Calculated and observed solubilities are compared; the agreement is found in general to be satisfactory at least as to the order of magnitude and to be on the whole as good as that obtained by the Born equation where ionic diameters have been estimated.

α,ω-Di-p-hydroxyphenyl Alkanes

By Edwin M. Richardson[1] and E. Emmet Reid

It has been observed that introduction of alkyl groups into phenols increases their bactericidal power and decreases their toxicity. Harden and Reid[2] showed that rather potent bactericides are produced by joining two phenols through a carbon having a side chain of varying length, giving compounds of the type  where R is H or an alkyl group.

This paper reports the preparation of a series of α,ω-di-p-hydroxyphenyl alkanes  paralleling the above series.

The solubilities in oil and in water of the compounds are given in Table I along with the partition coefficients calculated from them. The solubilities are plotted in Fig. 1. There is a marked alternation with increasing chain length. The partition coefficients and the maximum killing dilution are plotted in Fig. 2; both increase rapidly with the length of the intervening carbon chain. The two curves show a definite similarity. Unfortunately the low solubility of these compounds made extensive testing impossible. All tests were run in 20% alcohol using 20% alcohol as control. The organism used was *Staphylococcus aureus* strain #209 and the technique was a modified F. D. A. We are greatly indebted to Hynson, Westcott and Dunning for their kindness in carrying out these tests. The α,ω-derivatives here described are much less soluble than the corresponding α,α-derivatives described by Harden and Reid[2]; however, the maximum killing dilu-

Experimental

Hydrogenation of ethylenic double bonds was carried out using the Adams[3] PtO_2 catalyst. Ketones were re-

(3) Adams, Voorhees and Shriner, *Org. Syntheses*, Vol. VIII, 1928, p. 92.

duced in all cases by the Clemmensen reduction or Martin's[4] modification of it. Demethylation was accomplished in all cases by refluxing 0.1 mole with a mixture of 130 g. of glacial acetic acid and 50 g. of constant boiling hydrobromic acid.

1,2-Di-*p*-hydroxyphenylethane.—Anisoin was reduced by the Martin modification of the Clemmensen reduction giving 1,2-dianisylethane which on demethylation gave 1,2-di-*p*-hydroxyphenylethane.

1,3-Di-*p*-hydroxyphenylpropane.—*p*-Acetylanisole prepared according to Baranger[5] was condensed with anisaldehyde to give 1-anisyl-2-anisoylethylene. This on reduction and demethylation gave 1,3-di-*p*-hydroxyphenylpropane.

1,4-Di-*p*-hydroxyphenylbutane.—γ-Anisylbutyric acid was prepared by reduction of the *p*-anisoylpropionic acid obtained by condensing succinic anhydride and anisole according to Rosenmund and Shapiro.[6] The acid chloride prepared using thionyl chloride was condensed with anisole and the crude ketone obtained was reduced and demethylated to give 1,4-di-*p*-hydroxyphenylbutane.

1,5-Di-*p*-hydroxyphenylpentane.—Dianisalacetone prepared from anisaldehyde and acetone by the method of Conard and Dolliver[7] was reduced and demethylated to give 1,5-di-*p*-hydroxyphenylpentane, previously prepared by Borsche.[8]

1,6-Di-*p*-hydroxyphenylhexane.—One mole of adipoyl chloride was condensed with two moles of anisole using 2.25 moles of anhydrous aluminum chloride in 500 cc. of carbon disulfide. The diketone was reduced and demethylated to give 1,6-di-*p*-hydroxyphenylhexane. Oxidation of the diketone with alkaline potassium permanganate gave *p*-anisic acid, showing that condensation took place *para* to the methoxyl group.

1,10-Di-*p*-hydroxyphenyldecane.—Sebacoyl chloride and anisole were condensed as in the case of adipoyl chloride, and the diketone reduced and demethylated to give 1,10-di-*p*-hydroxyphenyldecane.

The solubilities in water were determined by the usual method. Solubilities in olive oil were determined by the method of Dunning, Dunning and Reid.[9]

BALTIMORE, MD. RECEIVED DECEMBER 1, 1939

Summary

1. A series of α,ω-di-*p*-hydroxyphenyl alkanes has been prepared having 2, 3, 4, 5, 6 and 10 methylene groups between the benzene rings.

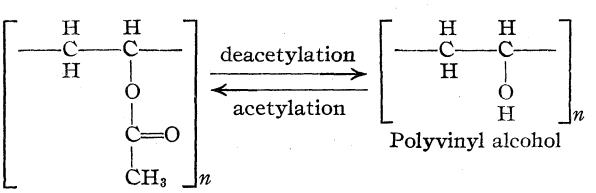
2. The lower members of the series have decided bactericidal properties but are too insoluble in water to prove useful as antiseptics.

[COMMUNICATION NO. 741 FROM THE KODAK RESEARCH LABORATORIES]

Some Relationships between Polyvinyl Acetates and Polyvinyl Alcohols*

BY W. H. MCDOWELL AND W. O. KENYON

By analogy to the simple organic esters such as ethyl acetate, polyvinyl acetate would be expected to yield the corresponding polyvinyl alcohol by deacetylation and, conversely, polyvinyl acetate would be expected from the acetylation of polyvinyl alcohol as indicated in the formulas:



Polyvinyl acetate — Polyvinyl alcohol

These reactions have been described by Staudinger and his co-workers,[1,2] by Herrmann and Haehnel[3] and by others.

The present investigations were undertaken to determine whether polyvinyl acetates could be transformed into polyvinyl alcohols and whether the alcohols could be reacetylated to produce polyvinyl acetates which are similar to the original acetates. Because of the polymeric nature of the polyvinyl alcohols and acetates, comparisons are made on the basis of the degree of polymerization as determined by viscosity measurements.

Experimental

Two different series of polyvinyl acetates of various viscosities were used. One series, composed of commercial samples, was used without further purification. The second series was prepared by the following method.

Monomeric vinyl acetate (practical grade) was distilled in an all-glass apparatus and the fraction boiling between 72.2 and 72.8° used for polymerization. Samples of the monomer were placed in all-glass reflux apparatus with the amounts of benzoyl peroxide catalyst (Eastman grade) shown in Table I and heated overnight on steam-baths.

* Presented before the Paint and Varnish Division of the American Chemical Society at the Boston Meeting, September 11–15, 1939.
(1) Staudinger, *Ber.*, **59**, 3019 (1926).
(2) Staudinger and Schwalbach, *Ann.*, **488**, 8–56 (1931).
(3) Herrmann and Haehnel, *Ber.*, **60**, 1658–1663 (1927).

The polymers obtained were dispersed in acetone, and the dopes were poured into water. The cakes of precipitated resins were steamed to remove excess monomer and decomposition products of the catalyst, cut into small pieces, and dried between 80 and 100° *in vacuo*. The specific viscosities of the polyvinyl acetates obtained are given in Table I.

TABLE I

III	0.75	.115
IV	.30	.209

acetates were measured in acetone and the polyvinyl alcohols in water. The average degrees of polymerization were calculated from the relationship

$$\text{Average degree of polymerization } (D.\ P.) = \frac{\eta_{sp}}{K_m}$$

where η_{sp} is the determined specific viscosity and K_m is the Staudinger constant. The degrees of polymerization of the polyvinyl alcohols and acetates were calculated,[4] using a value of $K_m = 2.6 \times 10^{-4}$.

Average molecular weight polyvinyl alcohol = $D.\ P. \times 44$
Average molecular weight polyvinyl acetate = $D.\ P. \times 86$

In Table II the properties of the various polyvinyl acetates and alcohols are tabulated and compared.

[a] Determined in formic acid, 0.1 g. of resin/100 cc. of solution. [b] Determined in benzene, 0.1 g. of resin/100 cc. of solution. The specific viscosities in benzene are comparable with those determined in acetone.

The polyvinyl acetates were converted to polyvinyl alcohols by the following method. Samples of resins were dissolved in methanol (about 6 cc. of solvent per gram of resin), and 4% of the theoretical amount of alcoholic potassium hydroxide necessary to react with the acetyl groups was added. On standing overnight at room temperature, a practically colorless, tough gel of polyvinyl alcohol formed. A liquid phase of excess methanol, methyl acetate, potassium acetate, and possibly acetic acid separated by syneresis. This was decanted and the polyvinyl alcohol was dispersed in water. When the aqueous dispersion was stirred into acetone, the white, fibrous polyvinyl alcohol separated. It was soaked in acetone with occasional agitation, separated and freed from acetone *in vacuo*.

The polyvinyl alcohols were reacetylated by the following method. One part of the alcohol was heated on the steam-bath for four hours with ten parts of a 2:1 (vol.) mixture of pyridine and acetic anhydride. The resulting polyvinyl acetate dissolved in the reaction mixture to form a homogeneous dope. The ester was precipitated in water, washed with water, and dried at 80 to 100° *in vacuo*. Acetyl determinations of representative samples indicated that the reacetylated materials possessed acetyl contents equal to those of the original acetates. Specific viscosities were determined in an Ostwald viscometer at 25°, using a solution of 0.1 g. of resin in 100 cc. of solution. Unless otherwise specified, the polyvinyl

Because of the decrease in molecular weight observed when polyvinyl acetates were deacetylated and reacetylated, a sample of polyvinyl acetate prepared in the laboratory was carried through two of these cycles to ascertain whether or not a further decrease would be observed in the second cycle. The results are shown in Table III.

TABLE III

Polymer	Specific viscosity	Degree of polymerization	Mol. wt.
(1) Original polyvinyl acetate	0.295	1135	97,600
(2) Polyvinyl alcohol from (1)	.175[a]	672	29,600
(3) Polyvinyl acetate by reacetylation of (2)	.086	330	28,400
(4) Polyvinyl alcohol from (3)	.180[a]	691	30,400
(5) Polyvinyl acetate by reacetylation of (4)	.090	346	29,800

[a] These specific viscosities were determined in formic acid solution, using 0.1 g. of resin per 100 cc. of solution.

The results indicate that a decrease in the degree of polymerization occurred in the first cycle but not in the second, since the values for acetates 3 and 5 are in good agreement. The *D. P.* values

(4) We wish to thank Dr. Newsome and Mr. Wagner of these Laboratories for these measurements.

for the alcohols 2 and 4 in formic acid corroborate this but are twice as great as expected. The use of a K_m value of 5.2×10^{-4} when calculating the *D. P.* values from measurements in formic acid solution would have given values for the alcohols in agreement with those of the corresponding acetates.

The polyvinyl acetates prepared in the laboratory (I to IV, Table II) underwent degradation during de-esterification to produce polyvinyl alcohols with average chain lengths about one half as great as those of the original acetates. The corresponding acetates produced by reacetylation possessed the same chain lengths, within experimental error, as those of the corresponding alcohols. Experiments with commercial polyvinyl acetates (V to X, Table II) yielded opposite results. The change in the degree of polymerization occurred principally during reacetylation, and the degrees of polymerization of the resulting acetates were about one-half those of the corresponding alcohols. There appeared to be some decrease during deacetylation, especially with the acetates of higher viscosities, though the decrease was slight when compared to that which occurred during reacetylation. The specific viscosity of the polyvinyl alcohol of experiment XI (Table II) was determined in formic acid and cannot be employed in such comparisons.

As indicated by the structural formulas previously given, polyvinyl acetate and polyvinyl alcohol are usually assumed to consist of chains of carbon atoms having hydrogen atoms, acetoxy groups and hydroxyl groups attached. The average chain lengths or degrees of polymerization as calculated from specific viscosity measurements are assumed to be proportional to the number of monomeric units comprising the chains. The conditions of deacetylation and reacetylation are mild and would not be expected to rupture the carbon chains since they do not cause breakage of carbon to carbon linkages of simpler esters. However, if it is assumed that these conditions are sufficient to rupture the carbon chains of high molecular weight compounds, a further rupture might be expected when a reacetylated ester is carried through a second cycle, for the reacetylated compounds still possess large molecular weights (Table II). A sample of polyvinyl acetate prepared in the laboratory was carried through two cycles without decrease of the degree of polymerization during the second cycle (Table III). This suggests that the viscosity decrease is not due to rupture of the carbon chains but is caused by the presence of other, less stable, linkages in the chain which are broken under the experimental conditions. If a limited number of such less stable links are present in the original esters and are broken during the first cycle, no further change would be expected in the second cycle.

While no conclusions concerning the nature of such unstable linkages can be drawn from the present data, we wish to suggest the possibility of oxygen atoms from peroxide catalyst or acetaldehyde from the vinyl acetate entering into the polymer to produce a small number of such linkages. This concept of the inclusion of oxygen in the linear chain of a polymer is not novel. Staudinger and Schwalbach[2] suggest attachment of oxygen to a vinyl acetate molecule to produce an activated addition product from which chain growth proceeds. However, it appears that the effect of such linkages on the properties of the polymers has not been considered previously. An examination of other resins produced by polymerization of ethylenic bonds in the presence of peroxide catalysts might throw additional light on this question.[5]

Summary

1. Polyvinyl acetates of various degrees of polymerization have been deacetylated to polyvinyl alcohols and the latter reacetylated to polyvinyl acetates.

2. The polyvinyl acetates obtained by reacetylation possessed degrees of polymerization, as calculated from specific viscosity measurements, which were less than those of the corresponding original polyvinyl acetates.

3. It is suggested that this decrease of the average chain lengths may be due to rupture of unstable linkages present in the linear molecule.

ROCHESTER, NEW YORK RECEIVED OCTOBER 13, 1939

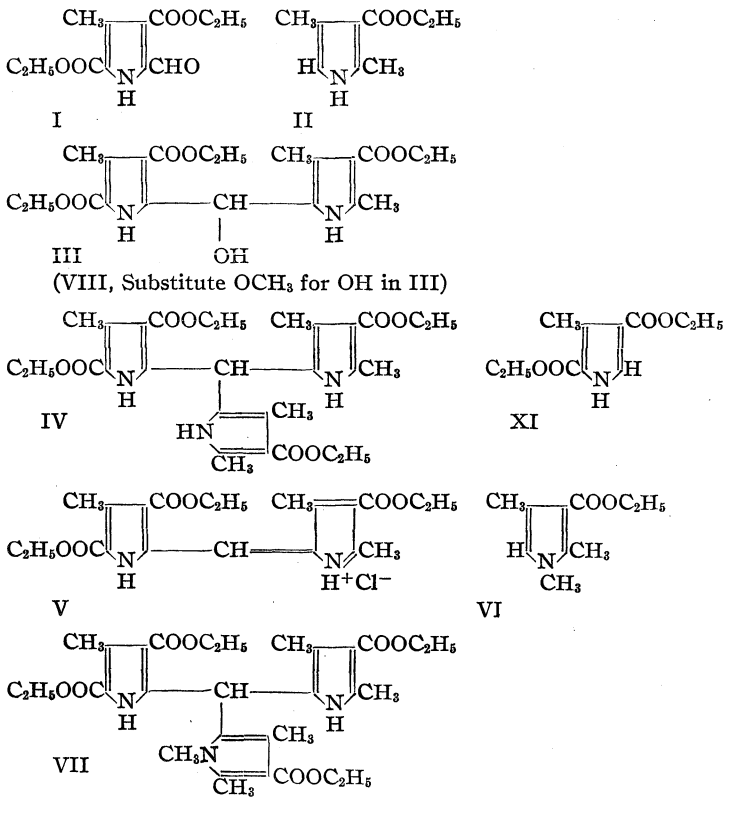
Studies in the Pyrrole Series. IV. A Dipyrrylmethene which is a True Intermediate in its own Formation[1]

BY JOSEPH H. PADEN,[2] ALSOPH H. CORWIN AND WILLIAM A. BAILEY, JR.[3]

In the preceding communication[4a] it was demonstrated that a stepwise synthesis of 3,5,4′-tricarbethoxy-4,3′,5′-trimethyldipyrrylmethene hydrochloride (compound V, Chart I) could be achieved in which a tripyrrylmethane (compound IV) was an intermediate if two moles of the alpha-free pyrrole II were used to one mole of the pyrryl aldehyde I and the resulting tripyrrylmethane cleaved subsequently by the addition of another mole of aldehyde as in scheme (1):

$$\text{I} + 2\text{II} \longrightarrow \text{IV};\ \text{IV} + \text{I} + 2\text{HCl} \longrightarrow 2\text{V} \qquad (1)$$

CHART I



The data then current did not permit a decision as to the course of the reaction when equimolar quantities of the pyrrole II and the aldehyde I were used. As an alternative to the tripyrrylmethane mechanism given in scheme (1), direct formation of methene from carbinol may be formulated:

$$\text{I} + \text{II} \longrightarrow \text{III} + \text{HCl} \longrightarrow \text{V} \qquad (2)$$

The present paper summarizes a group of experiments on the relative velocities of the reactions concerned which permits a decision between these possibilities.

In previous communications on the mechanism of the aldehyde synthesis of dipyrrylmethenes, it has been assumed arbitrarily that dipyrrylcarbinols are intermediates in the various cleavages.[4b,5] While it still seems necessary to retain the assumption of a carbinol as the first reaction product of aldehyde and alpha-free pyrrole, it is now unnecessary to assume any chemical intermediate between tripyrrylmethanes and dipyrrylmethenes, either in cleavage or in recombination, since it can be demonstrated that the methenes themselves are capable of combining with alpha-free pyrroles to form tripyrrylmethanes. This new condensation bears a superficial resemblance to the Diels–Alder reaction. In certain cases the tendency to reaction is so strong that the free base of the methene condenses spontaneously with the alpha-free pyrrole; in other cases it is necessary to use acid catalysts such as potassium acid sulfate or hydrogen chloride or to use the hydrochloride of the methene as one of the reagents. With the aid of this reaction it is possible to make the direct measurements of velocity necessary to an understanding of the course of the methene synthesis.

By the application of this new condensation, direct confirmation of our conclusion[4b] with respect to the hindering influence of an N-methyl group upon condensation is now available and is obtained by a comparison of the following two reactions:

$$\text{V (base)} + \text{II} \longrightarrow \text{IV} \qquad (3)$$
$$\text{V (base)} + \text{VI} \longrightarrow \text{VII} \qquad (4)$$

(1) Presented at the Milwaukee meeting of the American Chemical Society, September, 1938.

(4) (a) Corwin and Andrews, THIS JOURNAL, **59**, 1974 (1937); (b) **59**, 1975 (1937); (c) **59**, 1979 (1937); (d) **59**, 1976 (1937).

(5) Corwin and Andrews, *ibid.*, **58**, 1987 (1936).

In the absence of added catalyst, reaction (3) is complete in fifty seconds. Under the same conditions reaction (4) has not proceeded appreciably after one hundred minutes. In the presence of potassium acid sulfate reaction (4) is incomplete after one minute but complete in three and one-half minutes. Reaction (3) is complete in thirty seconds. Thus the N-methyl group on an alpha-free pyrrole decreases its speed of combination with a methene.

A close scrutiny of the course of the reaction between a carbinol methyl ether (compound VIII) and an alpha-free pyrrole, or alternatively between a methene base (IV free base) and an alpha-free pyrrole, both reactions in the presence of hydrogen chloride, leads to the conclusion that the reaction to form methene hydrochloride (reaction a, scheme (5) and that to form tripyrrylmethane (reaction b) are not competing reactions but are consecutive as in reaction c.[6]

$$\begin{array}{l} \text{VIII (or V base)} + \text{II} + \text{HCl} \xrightarrow{a} \text{V} + \text{II} \\ \qquad\qquad\qquad\quad \downarrow b \qquad\quad \downarrow c \\ \qquad\qquad\qquad\quad \text{IV} + \text{HCl} \end{array} \qquad (5)$$

When the mixture of carbinol–ether VIII and pyrrole II in ether or dioxane is treated with hydrogen chloride, a transient precipitate of methene hydrochloride V is formed. This immediately reacts with the pyrrole to give tripyrrylmethane IV. When the pyrrole is added after the precipitation, the reaction follows the same course. It thus becomes necessary to assume that the salt of the methene is itself able to react with alpha-free pyrroles to form tripyrrylmethanes. In the case of the N-methyl alpha-free pyrrole VI, the reaction is slow enough to permit the simultaneous isolation of methene salt V and tripyrrylmethane VII although the amount of the methene salt decreases with increasing reaction time. These observations show that the methene hydrochloride is an intermediate in the formation of tripyrrylmethane from carbinol methyl ether in the presence of hydrogen chloride and from them it is inferred that the *methene hydrochloride is an intermediate in the formation of tripyrrylmethane from free carbinol*, a material which has so far resisted all our attempts at isolation.[7]

(6) It may possibly be more accurate to say that carbinol-ether, methene base and methene hydrochloride are all equally capable of forming the same kinetic intermediate under the conditions of the various reactions. Decision upon this point would have to await a more precise and detailed kinetic analysis.

(7) Superficially, it might appear that the formation of N-methyl tripyrrylmethane VII from methene hydrochloride V and pyrrole VI (reaction 4), mentioned in the preceding paragraph, and the reverse of this reaction, namely, the cleavage of the same tripyrrylmethane to form methene hydrochloride V, reported in the preceding paper,[4b] were mutually contradictory experiments. These experiments appear to show that each side of the reaction is more stable than the other side. The apparent contradiction disappears, however, when it is remembered that hydrogen chloride is a reagent in this reaction as well as a catalyst. Presence of excess hydrogen chloride reverses the condensation reaction and causes cleavage of the tripyrrylmethane.

In the preceding paper[4a] it was stated that a decision as to whether or not tripyrrylmethane IV is an intermediate in the synthesis of methene V depends upon the determination of the relative velocities of formation of tripyrrylmethane and dipyrrylmethene.

$$\begin{array}{l} \text{I} + \text{II} + \text{V} + \text{HCl} \xrightarrow{d} 2\text{V} \\ \qquad\qquad\quad \downarrow e \qquad\quad \uparrow f \\ \qquad\qquad\quad \text{IV} + \text{I} + 2\text{HCl} \end{array} \qquad (6)$$

If aldehyde I reacts with pyrrole II faster than methene V reacts with the pyrrole (that is, if reaction d, scheme 6, is faster than reaction e), tripyrrylmethane will not be formed in appreciable quantity because of the removal of one of the reagents essential to its formation. If, on the other hand, methene V reacts with pyrrole II faster than aldehyde I reacts with it (that is, if reaction e is faster than reaction d), tripyrrylmethane formation will remove the pyrrole from the solution preferentially, and methene formation will finally take place only after subsequent cleavage of tripyrrylmethane IV by aldehyde I, a reaction demonstrated in the preceding paper.

The determination of these relative velocities has now been accomplished. In order to slow down all velocities to a measurable rate, potassium acid sulfate was used as a catalyst instead of hydrogen chloride.

$$\text{I} + \text{II} \xrightarrow{g} \text{V (base)} \qquad \text{V (base)} + \text{II} \xrightarrow{h} \text{IV}$$

$$\text{IV} + \text{I} \xrightarrow{j} 2\,\text{V(base)} \qquad (7)$$

Under these conditions the reaction of the free base of methene V with pyrrole II (reaction h, scheme 7) is complete in fifteen seconds while that of aldehyde I (reaction g) is not complete in an hour. Under the same conditions no appreciable cleavage of tripyrrylmethane IV by aldehyde I (reaction j) took place even when the mixture was refluxed for half an hour. This demonstrates that reaction g is faster than reaction j. A qualitative confirmation of these velocity relationships may be obtained from the minimum acid strength necessary to initiate the various reactions. Reaction h proceeds in the absence of

added catalyst; reaction g proceeds only when potassium acid sulfate is added; reaction f proceeds only when hydrogen chloride is added. It must be pointed out, however, that the addition of hydrogen chloride stabilizes the forward direction of reaction f by its mass action effect, so these relationships are not uncomplicated velocity relationships.

The most convincing confirmation that the relative velocities in the presence of hydrogen chloride, the standard reaction conditions for methene formation, are the same as those in the presence of potassium acid sulfate is obtained by the following experiment: as the solution of aldehyde I and pyrrole II used for the synthesis of methene V in the presence of hydrogen chloride becomes increasingly dilute the time of initial appearance of a precipitate of the methene is progressively delayed, as is the time required for obtaining the maximum yield. Under these conditions it is possible to stop the reaction well before the appearance of methene and to isolate the chemical intermediates in the reaction. When equimolar quantities of aldehyde and pyrrole are used, the intermediates isolated are equivalent quantities of unreacted aldehyde I and tripyrrylmethane IV. *This demonstrates that the tripyrrylmethane is an intermediate in the formation of the methene hydrochloride.* Since the methene hydrochloride is an intermediate in the formation of tripyrrylmethane from carbinol, which is the most probable primary product of the condensation of aldehyde and pyrrole, it follows that *the methene hydrochloride is an intermediate in its own formation.* These relationships are summarized in scheme (8).

$$2I + 2II + 2HCl \longrightarrow III + I + II + 2HCl \longrightarrow V + I + II + HCl + H_2O \longrightarrow IV + I + 2HCl + H_2O \longrightarrow 2V + 2H_2O \quad (8)$$

A number of "stable" tripyrrylmethanes of the type of methane IV have been prepared.[8] Their apparent stability would have constituted a strong argument against the adoption of a condensation to tripyrrylmethanes as a general scheme for the synthesis of methenes from aldehydes. This objection has now been removed by the proof that the case which appears to be the most unfavorable to the tripyrrylmethane mechanism is one in which the demonstration of the reality of this mechanism is relatively simple. The reaction in which a satisfactory experimental determination of mechanism will be most difficult is that in which cleavage of the tripyrrylmethane is rapid.

It is of interest to inquire into the mechanism of the last step of scheme (8). One possibility is that tripyrrylmethane IV and aldehyde I combine to form a compound which cleaves to give methene V. All our attempts to prepare such a compound have met with failure. A second possibility is that cleavage to give methene V does not take place until a molecule of aldehyde I and methane IV collide in a preferred orientation or with a sufficiently activated collision. This possibility might be explored by suitable kinetic measurements. There exists the further possibility that the reaction of formation of the tripyrrylmethane is reversible[9] and that the formation of methene is due to the slow displacement of the process toward a more stable product. In the preceding paper[4a] considerable evidence was presented to show that the reaction is actually reversible. For this reason we incline to the third scheme for the course of the cleavage. According to this scheme the rate determining step in the reaction is the combination of aldehyde I with pyrrole II. This slow step intervenes twice, the first time in the presence of excess pyrrole II which favors the reaction by its mass action effect, the second time in the presence of traces of the pyrrole, formed by cleavage of tripyrrylmethane IV. It is the slowness of this reaction combined with the rapidity of the recombination of pyrrole II with methene V which permits the isolation of tripyrrylmethane IV as an intermediate.

A corollary consistent with the preceding argument would be that the formation of readily cleavable tripyrrylmethanes from methenes and alpha-free pyrroles should be a slower process than the formation of "stable" tripyrrylmethanes. This argument already has been explored, scheme (5), for a case in which the methene remains constant and the pyrrole is varied and was found to be true in that case. The complementary case is now reported (Chart II).

Methene IX combines with pyrrole II in the presence of potassium acid sulfate to form tripyrrylmethane X. This reaction is slower in the

(8) Fischer and Ernst, *Ann.*, **447**, 139 (1926).

(9) The word *reversible* is used here in the usual sense of the organic chemist to signify a process proceeding in both directions. It does not imply that the process is energetically reversible in the thermodynamic sense. In fact, if one were to devise an electrode system to measure the free energy of such a reaction, the electrode behavior would undoubtedly be erratic and the physical chemist would say that he was dealing with an irreversible system.
