b. p. 189–194°[2] (12 mm.); d^{20}_4 1.302; $n^{20}D$ 1.6110. Attempts to convert this chloride to the desired ethylene by treatment with sodium iodide in dry acetone yielded a mixture of crystalline compounds which could not be separated by repeated recrystallizations. Analysis indicated the product to be a mixture of the two pinacolones, $C_6H_5C(=O)C(C_6H_4Cl)_2$ and $ClC_6H_4C(=O)C(C_6H_5)_2$, in spite of precautions to exclude moisture. From 63 g. of *p*-chlorobenzophenone chloride and 70 g. of sodium iodide boiled under reflux in 500 cc. of dry acetone for twelve hours, 45 g. of the mixture was obtained, m. p. 126–145°. After repeated recrystallization a sample melted at 130–142°.

Anal. Calcd. for $C_{26}H_{18}Cl_2O$: C, 74.82; H, 4.35. Found: C, 75.09; H, 4.39.

The desired ethylene was obtained by boiling 5 g. of *p*-chlorobenzophenone chloride in 50 cc. of dry ether with 10 g. of pure zinc dust for one hour. The mixture was filtered, washed with dilute hydrochloric acid, alkali and water and dried over calcium chloride. The ether was evaporated and the solid residue was extracted twice with 20-cc. portions of boiling alcohol. The residue was then crystallized several times from 50 cc. of alcohol to yield 0.5 g. (12%) of *sym-p,p'-dichlorotetraphenylethylene*, m. p. 202–203°.

Anal. Calcd. for $C_{26}H_{18}Cl_2$: C, 77.81; H, 4.52. Found: C, 77.85; H, 4.56.

When 0.25 g. of the ethylene in 10 cc. of benzene and 10 cc. of absolute alcohol was treated with 1 g. of sodium, a quantitative yield of fine white needles of tetraphenylethane was obtained, m. p. 209°.[3]

Anal. Calcd. for $C_{26}H_{22}$: C, 93.37; H, 6.63. Found: C, 92.89; H, 6.80.

Reduction of 1.1 g. of the ethylene in 15 cc. of methylcyclohexane with hydrogen at 110 atm. and 100° using 2 g. of Raney nickel as a catalyst yielded a mixture of products from which 0.3 g. of fine white needles of *p*-chlorotetraphenylethylene was isolated by recrystallization from aqueous acetic acid. The product melted sharply at 168°; Bergmann and Christiani[4] report 165–166° and Norris and Tibbetts,[5] 162°.

Anal. Calcd. for $C_{26}H_{19}Cl$: C, 85.11; H, 5.22. Found: C, 85.28; H, 5.43.

(2) Overton[1] reports the boiling point as 192° (12 mm.); Morgan (THIS JOURNAL, **38**, 2100 (1916)) reports 190° (10–12 mm.); and Ingold and Wilson (*J. Chem. Soc.*, 1493 (1933)) report 191–193° (13 mm.).

dl- and *meso-*γ,γ'-Diphenyl-γ,γ'-suberodilactone

The reduction of β-benzoylpropionic acid with zinc dust in boiling 80–90% acetic acid has been found to yield γ-phenyl-γ-butyrolactone, m. p. 35–36°, in 30–40% yield accompanied by the corresponding bimolecular reduction products, the two stereoisomeric γ,γ'-diphenyl-γ,γ'-suberodilactones, in 12–17% yields. For example, 16 g. of β-benzoylpropionic acid in 75 cc. of 80% acetic acid was boiled for three and one-half hours while 25 g. of zinc dust was added in portions. The hot mixture was filtered and the cake of zinc dust was extracted with several portions of hot acetic acid to remove the high-melting dilactone. After several recrystallizations from glacial acetic acid, 1.5 g. (9%) of high melting dilactone was obtained, m. p. 267°.[1]

On cooling the filtered reaction mixture, zinc acetate crystallized. This was removed by filtration and water was added. Crystalline dilactone and oily lactone separated from solution. Filtration yielded 1 g. (6%) of low-melting dilactone. After repeated recrystallization from alcohol, various samples showed a characteristic behavior in that they melted sharply at 165° to a cloudy semi-liquid which changed to a clear liquid sharply at 175.5°.

Anal. Calcd. for $C_{20}H_{18}O_4$: C, 74.57; H, 5.63; sapn. eq., 161. Found (267°): C, 74.55; H, 5.58; sapn. eq.,[2] 162. Found (165°): C, 74.34; H, 5.65; sapn. eq.,[2] 164.

(1) Fieser ("Organic Syntheses," Vol. XV, John Wiley and Sons, Inc., New York, N. Y., 1935, p. 65) has reported the isolation of γ,γ'-diphenyl-γ,γ'-suberodilactone, m. p. 254°, as a by-product of the Clemmensen reduction of β-benzoylpropionic acid.

RECEIVED JULY 30, 1942

A Dioxanate of Iodine Pentafluoride

Iodine pentafluoride is partially soluble in dry 1,4-dioxane, addition of an excess causing colorless crystals of a dioxanate of formula $IF_5 \cdot C_4H_8O_2$ to precipitate. The crystals start to hydrolyze immediately upon contact with the atmosphere, yielding iodic acid as the only solid residue after complete hydrolysis. They are likewise hydrolyzed over sulfuric acid in a desiccator.

When placed upon a melting point block, the dioxanate melts after an interval of time as low as 84°, but on immediate contact with the block only at 112° or above. In all cases melting is accompanied by decomposition and the evolution of hydrogen fluoride and purple iodine fumes.

Analysis was conducted by a modification of the method of Prideaux[1] (samples being weighed by shaking from a weighing bottle). Calculated for $IF_5 \cdot C_4H_8O_2$: IF_5, 71.6. Found: IF_5, 69.9.

NEW BOOKS

Electrochemistry and Electrochemical Analysis. By HENRY J. S. SAND, D.Sc., Ph.D., F.I.C. Volume III, Electrical Methods Applied to Titration, Moisture Determination and *p*H Measurement. Chemical Publishing Company, Inc., 234 King Street, Brooklyn, New York, 1942. ix + 118 pp. Illustrated. 12.5 × 19 cm. Price, $2.25.

This volume is devoted primarily to potentiometric and conductometric methods. Probably a statement could have been added that activities of other radicals could have been determined by applying the same principles as in the electrometric and *p*H determinations. If the "Determination of Moisture" is to be available to chemists, it is buried in a book with this general title. Volume III seems to be written from the same point of view as Volume II and to be equally meritorious. It seems to include all workable methods up to date written in a readily understandable style.

D. J. BROWN

Polarography. Polarographic Analysis and Voltammetry. Amperometric Titrations. By I. M. KOLTHOFF, Professor and Head of the Division of Analytical Chemistry, University of Minnesota, Minneapolis, Minn., and J. J. LINGANE, Dept. of Chemistry, Harvard University. Interscience Publishers, Inc., 215 Fourth Avenue, New York, N. Y., 1941. xvi + 510 pp. 141 figs. 15.5 × 23.5 cm. Price, $6.00.

This book is an excellent, timely and comprehensive treatise that covers the essentials of the theory and practice of the polarographic method of investigation that was originated by J. Heyrovsky and his associates. This text is the most complete and systematic treatise in the field that has thus far appeared. Both authors have made numerous and significant original communications to the development of the science and art of polarography and for this reason the text has a masterful and purposeful style that could only come from long and substantial work with the subject.

The book is divided into eight parts. *Part one* is a brief and simple introduction. *Part two* contains twelve chapters which expound fully the fundamental theory of the diffusion current along the lines established by Ilkovic and amplified by MacGillavry and Rideal. The diffusion coefficient and the other factors that enter into the magnitude of the diffusion current are thoroughly and critically discussed. Many of the illustrative data are taken from the careful and exhaustive researches of the authors and their associates. Separate chapters deal with the migration current, the electrocapillary curve of mercury, the residual current and with maxima in current–voltage curves and with the inadequacy of our present knowledge of the causes of these maxima. The detailed theory of the reduction of simple metallic ions, complex ions and of organic substances is treated in the three following chapters. The authors properly lay much stress upon half-wave potentials, accurate measurement of capillary constants, and the analysis of waves by plotting log $i/i_d - i$ *versus* potential (i being the diffusion current at any point in the wave and i_d the limiting diffusion current). A very generous number of formulations of simple and complicated cases of current–voltage relations is given to aid the unfamiliar worker to set up equations for use in connection with a particular problem. The rather involved question of hydrogen discharge in various media is well reviewed. The concept of mixed potentials is introduced and briefly discussed in a short chapter.

Part three deals with technique and equipment. A list of typical equipment is given with photographs of some commercially available instruments. The section on technique, though brief, is adequate and contains some very useful ideas not available in other books on the subject.

Part four attempts to summarize in rather brief space the fundamental facts about the polarographic behavior of the various inorganic ions. This section gives a very good summary of the facts that were known at the time the manuscript was prepared. There still remains a great need for systematic practical measurements in many instances. A few actual polarograms giving unusual forms of waves might be of some service to the worker. A final chapter in this part gives a few practical applications to the analysis of alloys and other substances.

Part five deals with the polarographic estimation of organic substances. This is a rapidly expanding field of work and the authors have made a careful study and summary of the published data. The information is well classified and systematically treated.

Part six is a very brief survey of the biological applications of the method. Here again the book gives a rather brief introduction to a rapidly growing body of literature.

Part seven treats briefly the measurement of current–voltage curves with micro-platinum electrodes. A large proportion of this work has come from the researches of the senior author and his associates. This line of study is still fragmentary but the results thus far obtained suggest that such electrodes may extend the application of the method to certain cases where the use of the dropping mercury electrode is impractical.

Part eight deals with polarometric or amperometric titrations. A beginning of the application of the polarized mercury electrode system to titrations was made by various associates of Heyrovsky, notably V. Majer, Strubl and others. The senior author and his collaborators have systematized and extended this field of work and have introduced improved techniques. The essentials of the theory and practice are briefly and clearly given.

The appendix gives tables of the potentials of reference electrodes and of the half-wave values for inorganic ions, and a chart for the latter in various media. The indices appear to be adequate and accurate.

The book as a whole is attractively arranged and reflects well the skill and care that have been used by both authors and publishers in its composition and production. Anyone

who has worked even briefly in this interesting field can appreciate the meticulous care that the authors have used in the preparation of the manuscript and the proper emphasis that they have placed upon the fundamentals of theory and practice. The book can be recommended without reservation to anyone who is interested in the theory or the practical application of the methods.

N. HOWELL FURMAN

Principles and Practice of Chromatography. By L. ZECHMEISTER, California Institute of Technology, and L. CHOLNOKY, University of Pecs. Translated from the second and enlarged German edition by A. L. Bacharach and F. A. Robinson. Foreword by I. M. Heilbron. John Wiley and Sons, Inc., 440 Fourth Ave., New York, N. Y., 1941. xviii + 362 pp. 74 figs. 14 × 22 cm. Price, $5.00.

The second edition of this invaluable pioneering book appeared only a year and a half after the first. The revision has kept pace with the rapid progress in the field and results in a larger volume of wider scope, with many new illustrations and 200 new references to the literature.

Chromatographic analysis (use of Tswett adsorption columns) is offered as a means of testing for homogeneity, establishing the possible identity of two substances, of concentration from great dilution, separating mixtures, and of purification. Some isomers have been separated by this method.

Since the book is both text and laboratory manual (in a general rather than detailed way) there is much helpful discussion of adsorption powders, solvents, eluents, development and extrusion. Micro-chromatography is included. The original technique of Tswett was applied to plant pigments and other colored substances, but Zechmeister and Cholnoky review the modern applications to separation of colorless substances, as by the use of ultraviolet light, indicators, color reactions, etc. The important triumphs of chromatographic separations in the fields of chlorophylls, porphyrins, bile pigments, carotenoids, flavins, anthocyanins, pigments, dyestuffs, alkaloids, vitamins, sterols, hormones, enzymes and even with inorganic cations and anions are well presented.

This book is most stimulating to biochemists, organic chemists and botanists, but many other scientists will find it extremely useful.

HARRY N. HOLMES

An Outline of Organic Nitrogen Compounds. By ED. F. DEGERING, CARL BORDENCA and B. H. GWYNN and collaborators. John S. Swift Co., 5 E. Third St., Cincinnati, Ohio, 1942. Prev. editions 1938, 1940. 381 pp. 16 × 23.5 cm. Price, $2.00 and $3.00.

This is a planographed edition of extensive chemistry notes accumulated by the senior author during his teaching career in dealing with a special Course on Organic Nitrogen Compounds offered for graduate students in Purdue University during the past twelve years. Acknowledgment is made of abstraction of much of the material presented in the book from several standard texts on organic chemistry including "Recent Advances in Organic Chemistry" by Stewart; "Organic Chemistry" by Gilman; Sidgwick's "Organic Chemistry of Nitrogen" by Taylor and Baker; and "Syntheses of Nitrogen Ring Compounds" by Hollins.

The edition is devoted chiefly to a concise and intelligible presentation of the chemistry of the ammonia system of organic compounds. Fundamental reactions illustrating the transformations of type compounds in both the aliphatic and aromatic series are reviewed.

The general concepts of organic structure and reaction mechanisms are explained according to the modern electronic theory of chemical change, but the authors have restricted the use of electronic formulas in the major text for the following reasons: "It must be apparent that the continuous use of electronic formulas and equations throughout the book would make its price prohibitive."

A short chapter is devoted to a condensed review of the chemical nature of alkaloidal substances, and one to the review of nitrogen heterocyclic chemistry. The latter is practically limited, however, to the chemistry and review of nitrogen ring compounds containing only one nitrogen atom as—dimethyleneimines, trimethyleneimines, pyrrols, pyrrolines, pyrrolidines, pyrrolidones, indols, pyridine, quinoline, isoquinoline and related condensed nitrogen ring compounds.

Cyclic ureide chemistry is illustrated briefly by reference to barbituric acid and its relationship to uric acid, and the naturally occurring purines—theobromine, theophylline and caffeine.

Comprehensive references to the original literature enhance the practical value of the book.

TREAT B. JOHNSON

Micromethods of Quantitative Organic Analysis. By JOSEPH B. NIEDERL, PH.D., Associate Professor of Chemistry, and VICTOR NIEDERL, Teaching Fellow, New York University, Washington Square College. Second edition. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1942. xiii + 347 pp. 62 figs. 15.5 × 23.5 cm. Price, $3.50.

The following statements, taken from the Introduction, indicate the scope of changes introduced into the second edition of this successful text. "In the present edition the chapters on balances and weighing have been enlarged to include the use of ordinary analytical balances of proper sensitivity and precision. Additional paragraphs treating the calibration of weights, the determination of the zero reading and the determination of the sensitivity and precision of microanalytical as well as the ordinary analytical balance have also been included." "To the changes in the carbon and hydrogen determination as given in the first edition, . . . , have been added several types of combustion-tube fillings," and the manometric method of D. D. Van Slyke and J. Folch has been described. "The determinations of halogen and sulfur have been improved" and "the standard solutions have been unified in a single chapter." "To the ebullioscopic, cryoscopic and vaporimetric molecular-weight has been added an iso-thermic method." "Liberal time estimates have been given for all the more important determinations in order to facilitate the planning of a day's working or teaching schedule."

A valuable feature of this edition, as well as the earlier one, is the literature survey, which has been brought up to 1941. The citations number well above a thousand references.

The present edition maintains the same high standard set by its predecessor.

W. M. LAUER

Volumetric Analysis. By I. M. KOLTHOFF, Professor and Head of Division of Analytical Chemistry, University of Minnesota, and V. A. STENGER, Analytical Research Chemist, The Dow Chemical Company. Second Revised Edition, 1942. Vol. I. Theoretical Fundamentals. Interscience Publishers, Inc. 215 Fourth Ave., New York, N. Y. xv + 309 pp. 31 illus. 23.5 × 15.5 cm. Price, $4.50.

The reviewer believes that the first edition of this book has become so well known that a detailed enumeration of the contents of this revision is not necessary. Such an omission seems further justified because, although this edition appears to have been quite completely rewritten, there has been no radical change in either contents or arrangement.

The number of chapters remains the same. An introductory chapter has been added and the chapter on the "Stability of Solutions" has been eliminated and is to be included in the second volume; with these exceptions the chapter headings and order are essentially as before. A much more liberal use of references to the original literature adds substantially to the value of the book. The chapters on "Reaction Velocity" and on "Adsorption and Coprecipitation Phenomena" have been extensively revised and there has been added to Chapter X a discussion of amperometric titrations.

The present first chapter, which contains considerable material previously found in Chapter X, affords a more logical introduction to the book. It contains various definitions, a classification of volumetric methods, and a general introductory discussion of ionization and oxidation–reduction principles. The Brönsted definition of acids and bases is presented briefly but thereafter the treatment of neutralization methods and hydrolysis effects is along conventional lines.

The reviewer obtained the impression that the present edition has been held to a slightly more elementary level than the former one: this may account for the change on the title page from "Theoretical Principles" to "Theoretical Fundamentals." Also, there seems in some cases a lack of consistency in the extent to which certain topics are treated. Hydrogen ion indicators are presented as organic compounds behaving as weak acids or bases with no discussion of their structures or of the theory of their color change, while thirty pages are given to potential indicators with fifty or more detailed structural formulas being shown.

In some few cases it seems unfortunate that topics should be discussed without reference to more recent work. Thus in the discussion of the permanganate–oxalate reaction the only reference is to the work of Skrabal (1904). Also in the very interesting chapter on "Volumetric Methods of Organic Chemistry" it would seem that the behavior of the double bond could have been more explicitly discussed in the terms of modern organic theory rather than by resorting to the "partial valence" and "complete affinity quantity" of Thiele (1899, 1901).

The above are minor criticisms of a very valuable book which should be available to everyone seriously interested in the theory and development of volumetric methods of analytical chemistry.

VOLUME 64 DECEMBER 23, 1942 NUMBER 12

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE OHIO STATE UNIVERSITY]

The Synthesis of 5-D-Glucosido-D-arabinose

BY NORMAN S. MAC DONALD AND WM. LLOYD EVANS[1]

The disaccharide, 5-D-glucosido-D-arabinose, is of much scientific interest. In the first place, this compound is a possible intermediate in the alkaline degradation of the 6-hexosido-hexose type[2] of carbohydrate. Furthermore, the acetylated 5-D-glucosido-D-arabinose would possess both the pyranoid ring in the hexose section of the molecule and the furanoid ring in the pentose section. So far as the authors are aware, a carbohydrate of this type has not been synthesized hitherto.

The purpose of the present work was to prepare this disaccharide and characterize it. After trying to obtain the compound by several of the well known degradative and synthetic procedures, its preparation was finally achieved by the Wohl technique for the degradation of sugar oximes, as modified by Zemplén.[3]

The 5-D-glucosido-D-arabinose heptaacetate was characterized by an elementary analysis, determination of acetyl number, and by an estimation of the pentose content.

Deacetylation of the acetate gave a white amorphous hygroscopic powder whose aqueous solution exhibited mutarotatory power. The deacetylated sugar failed to give an aldehyde reaction with Schiff reagent, a fact which when coupled with that of mutarotation indicates the presence of a ring in the reducing section of this new disaccharide. Since the point of biosidic linkage of the reducing section is carbon atom five, it therefore follows that the lactal ring of the arabinose section is of the furanoid type. Treatment of this water solution with phenylhydrazine led to a phenylosazone.

The acetylation of the free sugar was carried out with hot acetic anhydride–sodium acetate and, therefore, it seems likely that the crystalline material is the β-isomer.

Upon working up the mother liquors of the degradation, a small amount of a different crystalline substance was isolated. An insufficient quantity of this compound prevented complete characterization. It is suggested, however, that this lower melting, higher rotating compound is the α-isomer.

Experimental Part

Preparation of Gentiobiose Oxime.—To a solution of 17.5 g. of gentiobiose, obtained by the deacetylation of β-gentiobiose octaacetate[4] with NaOMe, was added an alcoholic solution of hydroxylamine. The latter was made by adding 2.6 g. sodium in 65 cc. of absolute ethanol to 8.9 g. of hydroxylamine hydrochloride (98% pure) in 6 cc. of hot water, cooling, and filtering the precipitated sodium chloride. The hydroxylamine hydrochloride used is 150% in excess while the sodium is 90% of the amount required to neutralize the hydrochloric acid completely. After the dropwise addition of the hydroxylamine to the sugar solution, 10 g. of powdered calcium carbonate was added to neutralize any possible acidity which might hydrolyze the biosidic link. The temperature was then raised to 55° and kept at that point for two hours. Without removing the calcium carbonate, the solution was

(1) Abstracted from a Thesis presented by N. S. MacDonald to the Graduate School of The Ohio State University in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(2) (a) W. L. Evans and R. C. Hockett, THIS JOURNAL, **53**, 4384 (1931); (b) W. L. Evans, *Chem. Revs.*, **6**, 281 (1929).

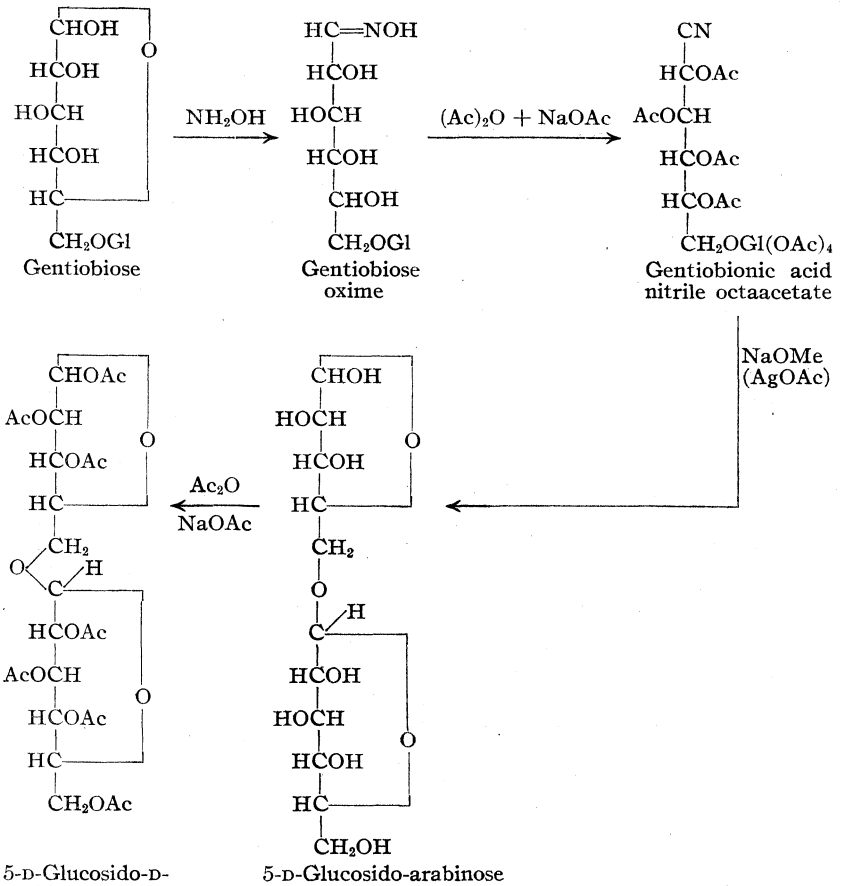
(4) D. D. Reynolds and Wm. Lloyd Evans, THIS JOURNAL, **60**, 2559 (1938).



concentrated to dryness *in vacuo*. Twenty-five cc. of absolute ethanol was then added, and the solution again evaporated to dryness. The residue was dissolved in 20 cc. of water, decolorized with carboraffin, and evaporated several times with absolute alcohol in order to dry it completely. The powder so obtained could not be crystallized and hence it was used directly in the next step.

Preparation of Gentiobionic Acid Nitrile Octaacetate.—Twenty grams of freshly fused sodium acetate was added to 145 cc. of acetic anhydride in a 250-cc. Erlenmeyer flask and the mixture heated to 110° in an oil-bath. To this was added 17.9 g. of dry, powdered gentiobiose oxime in such small portions that the temperature neither rose above 120° nor fell below 105°. This operation required about one-half hour. After the temperature was kept at 110–115° for an hour longer the deep brown solution was allowed to cool to 80°. It was then poured into 750 cc. of cold water and stirred for one hour. The crumbly material which appeared was stirred with fresh water, filtered, dissolved in ethanol and decolorized with carboraffin. Dilution of the resulting solution with water led to the separation of sirups. These sirups were each subjected to fractional precipitation from ethanol–water and, after some time, nuclei were obtained. Upon inoculating the sirups with these nuclei, crystals became readily available. The long needles are very soluble in chloroform and ethyl acetate, moderately soluble in methanol and ethanol, very slightly soluble in ligroin and water; m. p. 108–109° (cor.); yield 14.5 g. (35%); $[\alpha]^{25}D$ +8.60°, ($CHCl_3$, c = 2.5). It may be noted here that the sign of the optical rotation is in accord with that predicted by the Hudson–Levene hydrazide rule, as extended to sugar acid nitriles.[5] This empirical generalization states that if the hydroxyl group on carbon two lies on the right side in the straight chain structural formula, the acetylated nitrile of the sugar acid will be dextrorotatory.

Anal. Calcd. for $C_{27}H_{37}O_{18}CN$: C, 49.78; H, 5.48; N, 2.07. Found: C, 49.73, 49.77; H, 5.51, 5.57; N, 2.38, 2.57.

The compound gives a positive qualitative test for —CN (addition of sodium hydroxide and ferrous sulfate followed by acidification gives the characteristic prussian blue precipitate).

Quantitative Determination of —CN Group.—The weighed sample (0.1156 g.) was dissolved in 25 cc. of absolute methanol and a solution of 0.3 g. of silver nitrate in 4 cc. of water added. After adding 10 cc. of methanol saturated with ammonia, the flask was stoppered and allowed to stand at room temperature for ten hours. The clear solution was then acidified with dilute nitric acid and allowed to stand for three hours in a dark place. The precipitated silver cyanide was filtered into a weighed Gooch crucible, washed, dried at 100° and weighed. Calcd.: —CN, 3.85. Found: —CN, 3.60.

Degradation of Gentiobionic Acid Nitrile Octaacetate to 5-D-Glucosido-D-arabinose Heptaacetates.—Four grams of the nitrile was dissolved in 10 cc. of dry chloroform and a solution of 0.2 g. of sodium in 15 cc. of absolute methanol added, after cooling both in ice-water. The mixture gelatinized in one minute, but was allowed to stand in the bath for an additional five minutes. The gel was shaken with 15 cc. of water and immediately acidified with 5 cc. of acetic acid. After diluting with 15 cc. of water, the solution was extracted with 25 cc. of chloroform. A suspension of 5 g. of silver acetate in 10 cc. of glacial acetic acid was added to the water layer, with shaking. After ten minutes, the silver cyanide and excess silver acetate were removed by filtration, the filtrate giving no precipitate with a drop of fresh silver acetate solution. The filtrate was then warmed and dilute hydrochloric acid added dropwise to precipitate the Ag^+. After filtration, the colorless solution was treated with a small amount of sodium bicarbonate to reduce the acidity, then concentrated to a sirup *in vacuo*. This sirup was dried by repeatedly evaporating to dryness with absolute ethanol. To the dried sirup was added 20 cc. of acetic anhydride and 3 g. of freshly fused

(5) V. Deulofeu, *Nature*, **131**, 548 (1933).

sodium acetate, the mixture placed in a boiling water-bath and kept at that temperature for one hour. The dark solution was then poured into 125 cc. of cold water and stirred for one hour. The granular material was filtered off and dissolved in chloroform, dried over anhydrous sodium sulfate and treated with carboraffin. Upon concentrating *in vacuo*, a yellow sirup was obtained, which was subjected to fractional precipitation from ethanol–water. Two products were finally obtained in the crystalline state: I, (less alcohol-soluble fraction), rhombohedra, m. p. 161–162° (cor.); $[\alpha]^{25}D$ −14.4° ($CHCl_3$, c = 4.2); yield 1.2 g. (32%).

Anal. Calcd. for $C_{25}H_{34}O_{17}$: C, 49.50; H, 5.61; acetyl, 11.6.[6] Found: C, 49.51, 49.25; H, 5.56, 5.67; acetyl, 11.7, 11.7.

II. (More alcohol-soluble fraction), needles; m. p. 132–133° (cor.); $[\alpha]^{25}D$ +23.1° ($CHCl_3$, c = 3.8.)

Anal. Calcd. for $C_{25}H_{34}O_{17}$: C, 49.50; H, 5.61. Found: C, 49.51, 49.40; H, 5.88, 5.82.

Such a small amount of this material was obtained that a satisfactory acetyl number could not be determined.

Preparation of 5-D-Glucosido-D-arabinose.—The free sugar was prepared in an amorphous condition by deacetylation of the heptaacetate I. To a cooled solution of 0.78 g. of the acetate in 30 cc. of absolute methanol was added 0.05 g. of sodium in 5 cc. of absolute methanol. After standing in the ice-box for two hours, and concentrating to a volume of 15 cc., a precipitate appeared. This material was filtered rapidly and washed with cold absolute methanol. The amorphous powder reduces Fehling's solution and is very hygroscopic; yield 0.25 g.; equilibrium rotation $[\alpha]^{30}D$ −3.14° (H_2O, c = 4.1).

Phenylosazone of 5-D-Glucosido-D-arabinose.—To the water solution of the free sugar, used for the determination of the optical rotation, was added a mixture of 0.3 g. of phenylhydrazine and 8 cc. of glacial acetic acid. After warming on the water-bath for forty-five minutes, the dark solution was diluted with 20 cc. of water and allowed to stand overnight. The crude material so precipitated was recrystallized by dissolving in the smallest possible amount of pyridine, diluting with a ten-fold volume of acetone, and adding ligroin to turbidity. A crop of yellow needles was obtained; m. p. 209–210° (cor.); mixed m. p. with glucose phenylosazone 198–200°.

Anal. Calcd. for $C_{23}H_{30}O_8N_4$: N, 11.43. Found: N, 11.17, 11.02.

Estimation of Pentose in 5-D-Glucosido-D-arabinose Heptaacetate.—The method used was a modification of the standard procedure for pentose determination[7] as developed by Tollens. Sixty-eight milligrams of the material (I) was transferred to a 20-cc. distilling flask equipped with a 25-cc. dropping funnel in the neck and a short water jacket for the arm. The acetate was dissolved in 8 cc. of absolute methanol and 1.0 cc. of a sodium methylate solution (1%) added. It was found that unless the material was deacetylated and thus rendered water soluble, before the acid distillation, results were not reproducible. After three minutes, 10 cc. of 12% hydrochloric acid was added, boiling stones dropped in and the distillation begun gently. After 10 cc. had come over, the distillate gave a red color to paper moistened with aniline acetate, a positive test for the presence of furfural. The distillate was allowed to drop through a filter into a graduated cylinder and 100 cc. was collected, fresh 12% hydrochloric acid being added to maintain a constant level in the distilling flask. To the colorless distillate was added a solution of 0.05 g. of phloroglucinol in 10 cc. of warm 12% hydrochloric acid. A yellow color developed immediately, which darkened rapidly. Within ten minutes, a blue-black precipitate appeared. The mixture was diluted to 150 cc. with water and allowed to stand twelve hours at room temperature, after which it was filtered into a weighed Gooch crucible, dried and weighed. By applying empirical correction factors,[7] the weight of pentose is calculated from the weight of furfural-phloroglucide obtained: weight of arabinose calcd., 0.017 g.; weight of pentose found, 0.016 g.

Control.—A mixture of 0.036 g. of D-arabinose tetraacetate and 0.052 g. of D-glucose pentaacetate was treated in exactly the same manner: weight of arabinose calcd., 0.017 g.; weight of pentose found, 0.016 g. In order to make sure that hydroxymethylfurfural, obtainable from the glucose section, did not interfere, 0.05 g. of gentiobiose octaacetate was subjected to exactly the same treatment. No coloration of aniline acetate and no precipitate with phloroglucinol were obtained under these conditions.

(7) "Allen's Commercial Organic Analysis," 5th ed., Vol. I, p. 498.

Summary

1. Crystalline gentiobionic acid nitrile octaacetate was prepared by the removal of the elements of water from amorphous gentiobiose oxime. The sign of its optical rotation agrees with that predicted from the Hudson–Levene hydrazide rule, as extended to sugar acid nitriles by Deulofeu.

2. 5-D-Glucosido-D-arabinose heptaacetate was prepared by the degradation of gentiobionic acid nitrile octaacetate with sodium methoxide and the acetylation of the resulting compound.

3. Since the free sugar is mutarotatory in aqueous solution and shows no reaction with Schiff reagent, it is concluded that the arabinose section of this compound contains the furan ring.

4. The presence of arabinose was established by the detection of furfural in the products of the acid hydrolysis of the disaccharide.

5. The phenylosazone of 5-D-glucosido-D-arabinose was prepared from the amorphous free sugar.

6. It is suggested that the two acetylated compounds obtained from the degradation constitute an α,β-isomeric pair.

Basic Amino Acids in Strains of Tobacco Mosaic Virus

BY C. A. KNIGHT

It was shown in a recent communication from this Laboratory that the Holmes ribgrass strain of tobacco mosaic virus differs strikingly from ordinary tobacco mosaic virus in aromatic amino acid content.[1] It was also shown that cucumber viruses 3 and 4, which are related to tobacco mosaic virus, possess the same amount of tyrosine as the latter but contain distinctly different amounts of tryptophane and phenylalanine. These results demonstrated clearly for the first time the nature of some of the chemical differences between strains of tobacco mosaic virus. However, no distinctive difference was detected between the aromatic amino acid composition of ordinary tobacco mosaic virus and that of the yellow aucuba, green aucuba, J14D1, or masked strains of the virus. These strains are serologically, and in certain other respects, much more closely related to the common tobacco mosaic virus than are the other strains mentioned above. It seemed desirable, therefore, to extend the original investigation to include other amino acids, in order to determine whether there are demonstrable chemical differences between tobacco mosaic virus and some of its more closely related strains. The present report deals with analyses of the 8 previously described strains of tobacco mosaic virus[1] for arginine and histidine.

Experimental

Preparations of the viruses were made by purely physical methods involving filtration and differential centrifugation of the juices from infected Turkish tobacco plants, or from cucumber plants in the cases of cucumber viruses 3 and 4. Highly purified solutions of each virus in distilled water were frozen, dried *in vacuo*, and then further dried to constant weight at 110° in a drying oven. The white fluffy material thus obtained was used for amino acid analyses.

Arginine.—Arginine was determined by a colorimetric procedure based on the Sakaguchi reaction and by a gravimetric method involving precipitation of arginine as the flavianate.[2,3]

For the colorimetric test, 15 to 20 mg. of virus was hydrolyzed in 1 ml. of concentrated hydrochloric acid in a sealed tube in an oven at 110° for twenty hours. The hydrolysate thus obtained was transferred quantitatively to a 100 ml. volumetric flask, the solution was made to volume with distilled water, and 1 ml. aliquots were taken for analysis. The Sakaguchi reaction was carried out essentially as described by Thomas and co-workers,[2] with the exception that readings were made with a Klett-Summerson photoelectric colorimeter using Green Filter 54. The method used for the gravimetric determination of arginine involved a preliminary isolation of the basic amino acids by the electrolytic procedure of Albanese.[3]

The arginine content of tobacco mosaic virus was found by colorimetric and gravimetric methods to be 9.2 ± 0.1%. As may be observed in Table I, the arginine values obtained by the two different methods agreed remarkably well for all of the strains. Four of the 8 strains were found to contain about 9.2% arginine. On the other hand, cucumber viruses 3 and 4 were found to contain significantly less arginine than ordinary tobacco mosaic virus, while the green and yellow aucuba viruses were found to contain significantly more arginine than the type strain.

TABLE I

ARGININE AND HISTIDINE IN STRAINS OF TOBACCO MOSAIC VIRUS

Virus	Arginine: No. of preparations	Arginine: Sakaguchi method, %[a]	Arginine: No. of preparations	Arginine: Flavianate method, %[a]	Histidine, %
Tobacco mosaic	7	9.2	8	9.2	None
Yellow aucuba	7	10.0	2	10.0	None
Green aucuba	7	10.0	1	10.0	None
Holmes' ribgrass	4	9.1	1	9.2	0.55
Holmes' masked	2	9.2	1	9.0	None
J14D1	2	9.2	1	9.2	None
Cucumber virus 4	5	8.7	2	8.7	None
Cucumber virus 3	1	8.7	1	8.8	None

[a] The results of individual analyses for arginine showed a maximum deviation from the averages listed of ±0.2% for the Sakaguchi method and ±0.1% for the flavianate method.

Histidine.—Ross was unable to detect histidine in ordinary tobacco mosaic virus upon examination of whole hydrolysates of the virus or portions of hydrolysates obtained by chemical fractionation, although an amount of histidine equivalent to less than 0.1% of the virus could be recovered when added to various fractions.[4] Hence, it was concluded that histidine is not present in the tobacco mosaic virus molecule. The present experiments confirm this conclusion.

The Albanese technique for the estimation of histidine[3] was found to be quite unreliable for the determination of very small amounts of histidine in mixtures which contained large amounts of arginine. On the other hand, the conditions required in the Jorpes modification of the Pauly reaction[5] seemed admirably suited to such analyses and

particularly adaptable to the determination of small amounts of histidine in the histidine–lysine fraction obtained from tobacco mosaic virus by the electrolytic method. In the present investigation, the Jorpes procedure was slightly modified by substituting for the Zeiss photometer a Klett–Summerson photoelectric colorimeter with Green Filter 54. Results of tests with a standard solution of histidine showed that a true proportionality was obtained between the colorimeter reading and the amount of histidine present in the range 0.005 to 0.05 mg. per ml.

Application of the Pauly test to the histidine–lysine fractions of the strains indicated the absence of histidine from all except the ribgrass strain (Table I). Analyses on 2 different preparations of the ribgrass virus gave histidine values of 0.39 and 0.43%.

It has been suggested that the presence of carbohydrate may result in the destruction of histidine during the acid hydrolysis of proteins.[6] In order to evaluate fairly the apparent absence of histidine from all except one of the strains, the destructive effect of the virus carbohydrate was tested in two ways. In the first, small amounts of histidine were added to tobacco mosaic virus during hydrolysis and the recovery of histidine was noted, and, in the second, nucleic acid was removed from tobacco mosaic and the ribgrass viruses before hydrolysis and the effect on the histidine analyses was observed. In two trials in which small amounts of histidine were added to tobacco mosaic virus during hydrolysis, recoveries of 36 and 64% were made. In the other approach, tobacco mosaic and the ribgrass viruses were freed from nucleic acid by treatment with alkali. Negative phosphorus and carbohydrate tests on 25- to 30-mg. portions of the proteins indicated that essentially all of the nucleic acid had been removed. Five hundred and ten mg. of nucleic acid-free tobacco mosaic virus protein and 470 mg. of the corresponding preparation of ribgrass virus protein were then hydrolyzed as usual and the basic amino acids were isolated by the electrolytic procedure. No histidine could be demonstrated in the histidine–lysine fraction of the tobacco mosaic virus protein by the Pauly reaction, but 0.55% of histidine (calculated on the basis of the intact virus) was detected by the same method in a similar fraction of the ribgrass virus protein.

The histidine–lysine fraction of the nucleic acid-free ribgrass virus protein was also analyzed for histidine by the nitranilic acid gravimetric procedure as described by Block.[6] After allowance was made for the 6% nucleic acid in the ribgrass virus, a histidine value of 0.57% was obtained, in good agreement with the 0.55% found by the colorimetric procedure, and both figures are almost one-third greater than the highest value obtained on whole virus.

In general, the results of the above experiments appear to confirm earlier observations regarding the destruction of histidine in the presence of carbohydrate during acid hydrolysis of proteins. In particular, the data emphasize the absence of histidine from tobacco mosaic virus and its presence in the ribgrass virus. This is the first demonstration of the presence in a strain of tobacco mosaic virus of a constituent which is apparently entirely lacking in the common strain.

(6) R. J. Block, *J. Biol. Chem.*, **133**, 67 (1940).

Lysine.—If the amino nitrogen of the intact virus[7] is attributed to epsilon amino groups of lysine, tobacco mosaic virus contains about 1.35% of lysine. However, the experiments of Ross[8,9] have led him to conclude that tobacco mosaic virus contains very little, if any, lysine. In the present investigation, analyses of the electrolytically obtained lysine fractions of eight strains of tobacco mosaic virus indicated the presence of amino nitrogen which was unattributable to known constituents of the virus and which might therefore represent lysine. The amounts of this nitrogen were too small to permit the confirmatory isolation of lysine derivatives, but attempts to isolate such derivatives starting with considerably larger samples of virus are now in progress and will be described in detail in a later communication.

Discussion

Analysis of eight strains of tobacco mosaic virus indicated that each strain possesses a characteristic and constant amount of arginine. Thus, in seven preparations of tobacco mosaic virus obtained from different groups of diseased tobacco plants over a period of two to four years, the arginine content was found to be 9.2 ± 0.1%. On the other hand, seven preparations of green aucuba virus and seven of yellow aucuba virus obtained over a similar period of time were found to contain 10.0 ± 0.1% of arginine. The difference between the compositions of the aucuba viruses and ordinary tobacco mosaic virus is particularly striking in view of the very close relationship of these strains. For example, it is almost impossible to distinguish between the symptoms produced by ordinary tobacco mosaic virus and the green aucuba strain in diseased Turkish tobacco plants. It is generally necessary to inoculate to *Nicotiana sylvestris* Spegaz. and Comes to differentiate between the two strains. The green aucuba strain produces local lesions on *N. sylvestris*, whereas the ordinary strain does not. It is now possible, on the basis of arginine content, to distinguish definitely between these strains with considerably less than the amount of virus obtained from a single diseased plant. The significantly lower amounts of arginine found in cucumber viruses 3 and 4 than in ordinary tobacco mosaic virus are somewhat less surprising because the relation of the cucumber strains to the latter is less close.

In general, the data from the basic amino acid analyses of the virus strains support and extend the observations resulting from the aromatic

amino acid analyses.[1,10] It is quite clear that the protein components of strains of tobacco mosaic virus differ in their amino acid compositions. Whether or not these differences are responsible for the different biological properties of the various strains remains to be shown. In any case, they must be considered when sufficient data have been gathered to permit an intelligent correlation of biological properties with chemical structure. The nucleic acid components of the viruses cannot, of course, be entirely neglected. There is no unequivocal evidence at present that the nucleic acids of various strains of tobacco mosaic virus differ either quantitatively or qualitatively. On the other hand, the results of phosphorus analyses indicate that 8 of the strains contain essentially the same amount of nucleic acid, and colorimetric tests show that all of these 8 strains contain ribose nucleic acid.[1] Nevertheless, it will not be certain that the nucleic acids of strains of tobacco mosaic virus are identical until thorough analytical studies have been completed.

The discovery of the presence of histidine in the ribgrass virus is especially interesting, for it represents the first case in which one strain of tobacco mosaic virus has been found to contain a constituent apparently lacking in another. The ribgrass virus has not yet been obtained directly by mutation of ordinary tobacco mosaic virus, as have certain yellow strains[11,12] and the Holmes masked strain.[13] Thus, the ribgrass strain may represent a stable product resulting from many variations rather than from one. However, if the ribgrass strain developed originally from ordinary tobacco mosaic virus, it is necessary to assume that at one stage some histidine was added to a virus molecule which previously contained none. Unless it can be established experimentally that direct changes of this type can occur in completely formed virus molecules, it seems reasonable to assume that the introduction of a new amino acid occurred as a result of a departure from the usual pattern of the synthetic process of virus multiplication. On this basis the phenomena of virus multiplication and virus variation become directly related, the latter representing simply a modification of the former.

The author is indebted to Dr. W. M. Stanley for his interest and encouragement during the course of this investigation.

Summary

Eight strains of tobacco mosaic virus were analyzed for arginine and histidine. Analyses by two methods of seven different preparations of tobacco mosaic virus indicated that this virus contains 9.2 ± 0.1% of arginine. A similar amount of arginine was found in the Holmes masked, Holmes ribgrass, and J14D1 strains. On the other hand, the green and yellow aucuba strains were found to contain 10.0% of arginine and the cucumber viruses 3 and 4, 8.7% of arginine. No histidine could be detected in seven of eight strains, but about 0.55% of histidine was found in the ribgrass strain. Indirect analyses indicated that the eight strains contain a small amount of lysine, but this finding has not yet been verified by isolation methods.

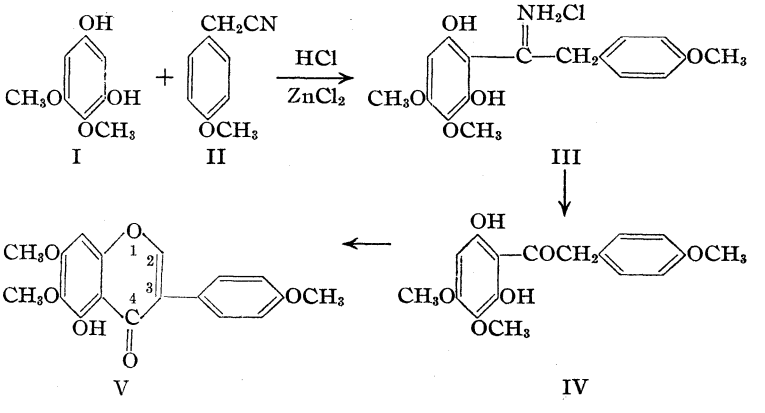
Synthesis of Tectorigenin Dimethyl Ether

BY R. L. SHRINER AND R. W. STEPHENSON

An isoflavone structure has been suggested for tectorigenin, the aglucone of the naturally occurring glucoside, tectoridin. This structure was deduced from its degradation products,[1] absorption spectra[2] and general chemical properties.[2,3] Two other possible substituted coumaran structures were shown to be quite different from the natural aglucone.[4] The present paper reports the synthesis of the dimethyl ether of tectorigenin (V).

The starting materials are 4,5-dimethoxyresorcinol (I) and homoanisonitrile (II). The first was prepared by the sequence: guaiacol → 4,6-dinitroguaiacol → 3,5-dinitroveratrole → 3,5-diaminoveratrole → 4,5-dimethoxyresorcinol, according to the directions of Baker and Robinson.[5] Homoanisonitrile has been synthesized repeatedly by a number of methods; for instance, recently by Julian and Sturgis, and by Lapine.[6] The direct chloromethylation of anisole to *p*-methoxybenzyl chloride[7] followed by reaction with sodium cyanide[8] in the presence of an emulsifying agent to promote rapid reaction of the chloride with the cyanide was found to be a time saving procedure, although the yields were low (29%).



Condensation of 4,5-dimethoxyresorcinol (I) with homoanisonitrile (II) was effected by means of hydrogen chloride and zinc chloride. Hydrolysis of the intermediate iminohydrochloride (III) yielded the substituted desoxybenzoin (IV). A Claisen condensation of the latter compound with ethyl formate and sodium followed by acidification yielded 5-hydroxy-4′,6,7-trimethoxyisoflavone (V). This compound melted at the same temperature as dimethyltectorigenin[4] and a melting point of a mixture of the two samples showed no depression. The acetyl derivative of the synthetic isoflavone (V) was identical with the acetate prepared from the methylated tectorigenin.[4]

In the first step in the above synthesis, the Hoesch reaction is shown taking place in the 2-position of 4,5-dimethoxyresorcinol (I) rather than the 6-position. The reactivity of the 2-position in substituted resorcinols of this type has been previously pointed out by Baker and Robinson[5] who have shown that 3,4,5-trimethoxyphenylacetonitrile condenses in the 2-position. Methoxyacetonitrile also reacted with the 2-position of 4,5-dimethoxyresorcinol.[9] Hence it seems very probable that the condensation with homoanisonitrile also takes place in the 2-position especially since the properties of the isoflavone (V) indicate an hydroxyl group in the 5-position.[4]

The second step in the synthesis of tectorigenin dimethyl ether involves the Claisen condensation with ethyl formate and ring closure with the 6-hydroxyl of the substituted desoxybenzoin (IV) and not with the 2-hydroxyl. The fact that ring closure in compounds of this type always appears to involve the unhindered 6-hydroxyl group has been well established by previous work by Baker and Robinson,[5] Bargellini[10] and Chapman, Perkin and Robinson.[11]

The present synthesis of tectorigenin dimethyl

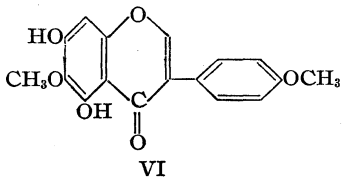
ether coupled with the fact that iretol (2,4,6-trihydroxyanisole) is one of the degradation products of tectorigenin[1] shows that tectorigenin possesses the isoflavone structure (VI).



VI

Experimental

Homoanisonitrile.—One hundred fifty grams of anisole, 150 g. of 40% formalin, 15 cc. of petroleum ether, and 15 g. of zinc chloride were placed in a three-necked flask equipped with a mercury-sealed stirrer. The flask was placed in an ice-bath, and hydrogen chloride gas was added with stirring at such a rate that the temperature remained at 15°. After one hour and fifteen minutes the gas addition was stopped, and 30 g. of cracked ice was added. The stirring was continued for five minutes. After stopping the stirring, an oily layer rose to the top of the solution. This layer was separated, dissolved in 200 cc. of benzene, and washed with 100 cc. of 10% sodium carbonate. The benzene solution was then washed once with 100 cc. of water and added to a solution of 70 g. of sodium cyanide in 180 cc. of water. One gram of sodium laurylsulfate (Dupanol WA) was added and stirring and heating were started. The benzene was distilled out by steam developed in the flask. After the distillation of the benzene was complete the condenser, which had been set downward for distillation, was raised to a vertical position and the solution heated at the boiling point until the solution had boiled with stirring, a total of three and one-half hours. After cooling, the solution was extracted with 800 cc. of ether in three portions. The ether solution was dried with sodium sulfate, and the ether was distilled off. The residue was distilled under diminished pressure. The first fraction (26 g.) was anisole b. p. 53–55° at 20 mm. The second fraction was homoanisonitrile b. p. 154–56° at 20 mm. Sixty grams (29%) of the nitrile was obtained.

The first step in this synthesis must be carried out quickly. The chloromethylanisole must be freed from hydrogen chloride and added to the sodium cyanide as quickly as possible. Otherwise polymerization or hydrolysis of the chloromethylanisole to methoxybenzyl alcohol occurs.

2,6-Dihydroxy-3,4-dimethoxy-α-(*p*-methoxyphenyl)-acetophenone (IV).—A 1.45-g. quantity of 4,5-dimethoxyresorcinol, 1.8 g. of homoanisonitrile, and 0.5 g. of anhydrous zinc chloride were dissolved in 60 cc. of dry ether. Dry hydrogen chloride gas was passed into the solution at 0°. The hydrogen chloride was added rapidly for one hour, then slowly for two hours. The flask was then stoppered and allowed to stand overnight. After the flask had stood for twenty hours, 100 cc. of dry ether was added and the flask again allowed to stand overnight. The ether was then poured off the viscous oil and the oil washed with dry ether. Approximately 100 cc. of 10% hydrochloric acid was added to the oil and the solution boiled under reflux for one-half hour. After cooling, the solution was extracted with ether and the ether solution dried with anhydrous sodium sulfate. Removal of the ether left a red oil which became crystalline upon the addition of methyl alcohol. Recrystallization from methyl alcohol gave 0.8 g. (29%) of white crystals melting at 116.5°.

Anal. Calcd. for $C_{17}H_{18}O_6$: C, 64.15; H, 5.66. Found: C, 64.32; H, 5.99.

Dimethyltectorigenin.—To 0.20 g. of powdered sodium at 0° was added 0.28 g. of 2,6-dihydroxy-3,4-dimethoxy-α-(*p*-methoxyphenyl)-acetophenone in 4.5 cc. of redistilled ethyl formate. The mixture was stirred for four and one-half hours at 0°. Then about 10 g. of crushed ice was added, and the stirring was continued for three hours. After the solution had stood overnight without stirring so that the ethyl formate had evaporated, the solid was filtered off. This solid was dissolved in pyridine and precipitated with water. Repeated precipitation gave 0.04 g. (14%) of light tan colored microscopic needles m. p. 186°. Recrystallization of this material from methanol gave silvery white needles melting at 188°. A mixed melting point of this material with a sample of dimethyltectorigenin prepared by Matson[4] (from natural tectorigenin) gave no alteration in melting point.

Anal. Calcd. for $C_{18}H_{16}O_6$: C, 65.85; H, 4.87. Found: C, 65.69; H, 5.06.

Dimethyltectorigenin Acetate.—In 0.6 cc. of dry pyridine was dissolved 0.026 g. of dimethyltectorigenin and 0.26 cc. of acetic anhydride. The stoppered tube was allowed to stand at room temperature for three days. Then 5 cc. of water was added to the mixture. After standing several hours light tan crystals had formed. These were purified by dissolving in pyridine and precipitating with water. After several crystallizations silvery-white crystals melting at 213° were obtained. A mixed melting point of this material with a sample of dimethyltectorigenin acetate, prepared by Matson[4] (from natural tectorigenin) gave no alteration in melting point.

Anal. Calcd. for $C_{20}H_{18}O_7$: C, 64.86; H, 4.86. Found: C, 65.00; H, 4.95.

In order to establish the validity of the use of melting points of mixtures in the isoflavone field, five different synthetic isoflavones were found to exhibit depressions in melting point when any two of them were mixed together.

Summary

A synthesis of tectorigenin dimethyl ether has been carried out which provides additional evidence that tectorigenin possesses the isoflavone structure.

Refractive Indices and Densities of Normal Saturated Fatty Acids in the Liquid State

BY A. DORINSON, M. R. MCCORKLE AND A. W. RALSTON

Few systematic studies of the refractive indices of the saturated fatty acids are found in the literature; there is the classical work of Eijkman,[1] the investigation of Scheij[2] on the naturally occurring fatty acids, and the more modern work of Waterman and Bertram.[3] Determinations were made at arbitrary and scattered temperatures; only the work of Falk[4] on butyric acid embraces a large number of determinations over a wide range of temperature. We have measured the refractive indices of the normal saturated fatty acids in the liquid state, from caproic to stearic inclusive, at a sufficient number of temperatures between 20 and 80° to enable us to plot the variation of refractive index with temperature for each acid, as shown in Fig. 1. In addition, the densities of these acids were determined at 80° and these data were used to calculate the molar volume and the molar refractivity of each acid at that temperature. The refractive indices are listed in Table I and the densities in Table II. The values listed in Table I have not been corrected for the effect of temperature on the refractometer prism, since we feel that less confusion will arise among investigators using these figures if they are left uncorrected. Whenever we shall have occasion here to treat the refractive indices as functions of the homologous series, a correction given by

$$0.00006\ (t - 20) \qquad (1)$$

where t is the temperature at which the refractive index was determined, will be added. This is the correction for the refractometer prism only. A correction should also be applied for the effect of temperature on the compensating prisms in the refractometer, but since their temperature could be estimated only crudely, this correction will be omitted. Since the compensating prisms do not deviate the sodium D line, the correction is probably very small.

Experimental

The acids used were carefully purified; their preparation is described in another communication from this Laboratory.[5] Refractive indices were measured with an Abbe type refractometer, the temperature of whose prisms could be held constant to ±0.05. A calibrated thermometer was used. Densities were determined in a modified Ostwald pycnometer at 80 ± 0.05°. Weighings were corrected for the buoyancy of air.

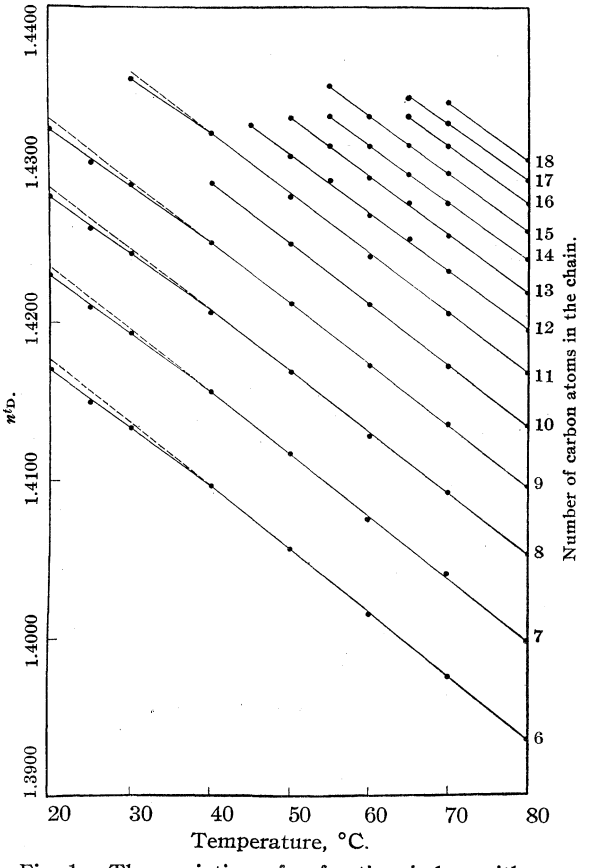

Fig. 1.—The variation of refractive index with temperature. Change of slope is shown by comparison with the extrapolation from the curve at higher temperatures. Extrapolation is represented by a dotted line.

Discussion

Molar Volumes.—The molar volumes at 80° of the acids from caproic through stearic were calculated from the densities determined in this work. By taking advantage of the fact that the densities of the straight chain saturated acids are linear functions of temperature, we were able to

Lauric	.8477		

convert data already in the literature[2,4,6–11] to the proper temperature and to extend this series of calculations at 80° down to acetic acid, and also to make a series of calculations from formic acid to pelargonic acid at 20° (see Table III). At 20° the molar volumes from acetic acid to pelargonic acid are adequately expressed by

$$V_m = 16.89n + 23.62 \qquad (2)$$

where n is the number of carbon atoms in the chain. At 80° the equation

$$V_m = 17.25n + 28.88 \qquad (3)$$

holds for butyric and higher acids. The deviation of the first three members of the series from linearity is quite sharp and the addition of a term of the form k/n does not extend the validity of the equation to include these three members. The molar volumes of the normal saturated acids, arranged serially, do not show as much deviation from a linear relation as noticed by Huggins[12] for the normal saturated hydrocarbons, nor does this deviation extend as far up the series for the acids as for the hydrocarbons.

[a] Calculated from densities obtained from references 2, 4, 6–11. [b] Calculated from equation (2). [c] Calculated from equation (3). [d] This figure and subsequent figures in this column were computed from densities in Table II.

Refractivities.—In Fig. 1 we have plotted the refractive indices of the acids, corrected according to equation (1), against temperature. The refractive indices for each acid fall upon a straight line between 40 and 80°. Below this temperature a change of direction is observed. A plausible explanation of this phenomenon can be found in the theory of molecular refractivity and in current viewpoints on the structure of liquids consisting of polar molecules. To begin with, the molar refraction for visible light, calculated by the Lorentz–Lorenz equation, is equal to the electron polarization. A collection of molecules which are inherent dipoles, such as the molecules of a fatty acid, act on each other to cause more or less orien-

tation, even in the liquid state, and consequently produce an electric field within the body of the liquid. Onsager[13] has published a theoretical treatment of this effect on the determination of dipole moments of polar substances by means of an external electrical field. It is beyond the scope of this paper to attempt a quantitative treatment of the effect of the internal electric field on the bonding electrons in the relatively non-polar part of the fatty acid chain, and hence on the refractivity, but qualitatively we would expect the electron polarization of a substance such as a fatty acid to depend on the statistical orientation of the individual molecules within the body of the liquid. On the other hand, the thermal motions of these molecules will tend to produce disorder, and at some temperature they should be vigorous enough to completely overcome the restraints caused by dipole interaction. The molecules within the liquid will then exhibit a perfectly random configuration and the net field there will be zero. On these grounds we would expect to find a temperature for each acid above which the molar refractivity will be constant and below which it will depend on temperature. We have taken the data of Falk[4] for butyric acid and instead of smoothing out the values of the refractive index, we have calculated the molar refractivities from the data as they stand. This examination shows that the molar refractivity is practically constant above 42° and a linear function of the temperature below this point. This is the only fatty acid reported for which a sufficient number of molecular refractivities could be calculated from the original data over a wide temperature range.

To eliminate the possibility that the discontinuities in the plot of the refractive indices of the acids might be due to some systematic defect in the refractometer or in the calibration of the thermometer, the refractive index of *n*-heptane was determined between 20 and 50°. The data so obtained lie on a straight line and the data of Shepard, Henne and Midgley[14] also lie on this line in full agreement with ours.

If a plot of the molar refractivity of a normal fatty acid shows discontinuity with temperature, it can be shown that a plot of the refractive indices will also exhibit discontinuity. The densities of the fatty acids are continuous linear functions of the temperature from zero to at least 80°. The density factor, then, will produce no discontinuity in the molar refractivity as calculated from the Lorentz–Lorenz formula

$$\frac{n^2 - 1}{n^2 + 2}\frac{M}{d}$$

but any discontinuity in the temperature variation of n will show up in the molar refractivity and *vice versa*, since it is impossible to eliminate n from the ratio $n^2 - 1/n^2 + 2$.

The molar refractivities of the normal saturated fatty acids, from caproic to stearic inclusive, can be expressed as a function of the number of carbon atoms in the chain by

$$R_m = 4.654n + 3.83 \qquad (4)$$

The observed values and those calculated from this formula are listed in Table IV.

TABLE IV

MOLAR REFRACTIVITIES OF NORMAL SATURATED FATTY ACIDS AT 80°

Acid	R_m (exptl.)[a]	R_m (calcd.)[b]
Caproic	31.70	31.75
Enanthic	36.34	36.40
Caprylic	41.08	41.06
Pelargonic	45.66	45.71
Capric	50.36	50.37
Hendecanoic	55.02	55.02
Lauric	59.73	59.68
Tridecanoic	64.35	64.33
Myristic	69.00	68.99
Pentadecanoic	73.65	73.64
Palmitic	78.30	78.30
Margaric	83.01	82.95
Stearic	87.59	87.61

[a] Computed from the formula $R_m = \frac{n^2 - 1}{n^2 + 2}\frac{M}{d}$, refractive indices corrected. [b] Calcd. from equation (4).

Summary

1. The refractive indices of the normal saturated fatty acids from caproic to stearic inclusive have been determined at a number of temperatures between 20 and 80°. For each acid the refractive indices are straight line functions of the temperature with an abrupt change of a slope at 40°.

2. An explanation of this change of slope has been presented.

3. The densities of these acids at 80° have also been determined. Molar volumes and molar refractivities for the homologous series have been computed and shown to be linear with respect to the number of carbon atoms in the chain.

Solubility Studies. VII. The Solubilities of Some Isomeric Ketones in Water

BY JOHN H. SAYLOR, VICTOR J. BAXT[1] AND PAUL M. GROSS

The possible existence of a linear relationship between the heats and entropies of solution of organic compounds has been suggested by several investigators[2,3] and is of considerable interest from the standpoint of the energy relationships involved in the solution process.

In a previous communication from this Laboratory[4] it was shown that a linear relationship between the heats and entropies of solution existed for three of the ketones studied. These ketones, methyl propyl, methyl isopropyl and diethyl, have approximately the same molar volumes at the temperatures of the measurements. It was suggested that equality of solute volumes as well as chemical similarity may well be a prerequisite for the existence of such a linear relationship between the heats and entropies of solution. The present investigation of the solubilities of the three isomeric ketones, dipropyl, diisopropyl and methyl *n*-amyl, was undertaken with this suggestion in mind.

Experimental

The saturated solutions were prepared and analyzed by means of a Zeiss combination liquid and gas interferometer as previously described.[4,5]

The ketones were obtained from the Carbide and Carbon Chemical Company. They were purified by repeated shaking with ammoniacal silver nitrate until no discoloration appeared on allowing the ketone to stand for thirty minutes in contact with fresh reagent. Then they were washed, dried over calcium sulfate and fractionated in a 50-cm. Widmer still using calibrated thermometers. The boiling points of the fractions used are given in Table I.

TABLE I

BOILING POINTS OF THE COMPOUNDS

Substance	B. p. at 760 mm., °C.	Previously observed b. p., °C.	Ref.
Dipropyl ketone	144.00–144.10	144.1	6
Diisopropyl ketone	124.06 ± 0.05	124.0 123.7	7,8
Methyl *n*-amyl ketone	150.18–150.32	150.2	9

It was necessary to determine the densities of diisopropyl and methyl *n*-amyl ketone in order to calculate the corresponding molar volumes. This was done at 10, 30, 50 and 75° by means of appropriate specific gravity bottles.

Results

The observed solubilities are listed in Table II. Vapor solubilities,[4,10] C_s, were calculated from these and are listed in Table II along with the vapor pressures, P_L, of the solute. The vapor solubility is defined as that concentration C_s in equilibrium with the vapor of the substance under a standard pressure of 100 mm. at the particular temperature in question. It is calculated by means of Henry's law from the observed solubilities and the vapor pressure of the liquid solute at the same temperature.

Table II also lists the mole fraction, N, corresponding to C_s as well as the densities and molar volumes, V_m, at each temperature.

The free energies of hydration as given by the relation $\Delta F = RT \ln (P/N)$ have been calculated from the mole fractions, N, given in Table II. The corresponding entropy of hydration ΔS was evaluated graphically from a plot of ΔF *vs.* T. The heats of hydration ΔH were calculated from the values of ΔF and ΔS by means of the relation

$$\Delta F = \Delta H - T\Delta S$$

These quantities are listed in Table III.

Figure 1 is a plot of ΔS *versus* ΔH for dipropyl, diisopropyl and methyl *n*-amyl ketones as well as for methyl propyl, methyl isopropyl and diethyl ketones taken from the previous investigation. The linear relationship is not as good in the present investigation. Nevertheless, within the limits of experimental error and the assumptions involved the data point to its validity. It is likely that the relation may have limited validity for the longer carbon chains with their many possible configurations. Butler[3] has shown that such a linearity exists in a series of alcohols. It

	65	7.42	52.7	10.39
	75	7.90	50.2	9.57

appears, however, that the alcohols with the longest carbon chains do not follow the relationship as closely.

Figure 2 is a plot of vapor solubility against molar volume. There is a still greater temperature dependency in the solubility of these compounds than that found previously for ketones of lower molecular weight. At 10° methyl *n*-amyl ketone is 3.9 times more soluble than diisopropyl ketone but this ratio diminishes with increase in temperature until at 75° it is 2.4. This greater temperature dependency would be predicted from the explanation previously offered.

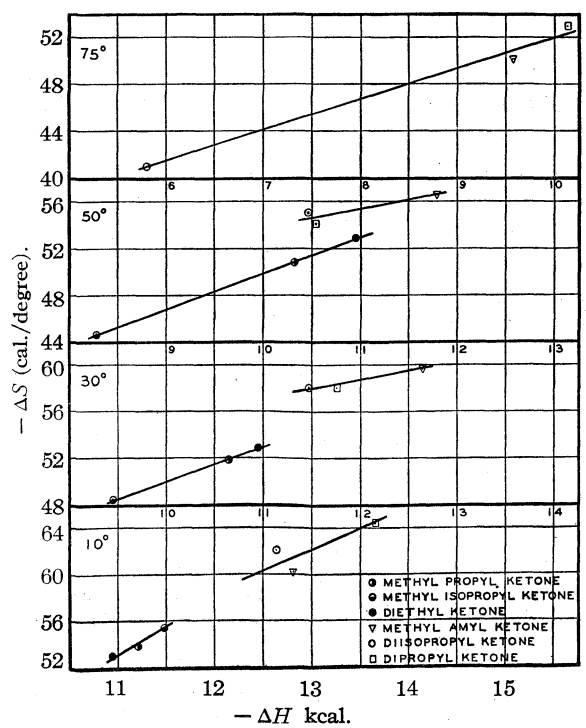

Fig. 1.—Relation between heats and entropies of solution.

According to this, compounds such as methyl *n*-amyl ketone with longer unbranched side-chains

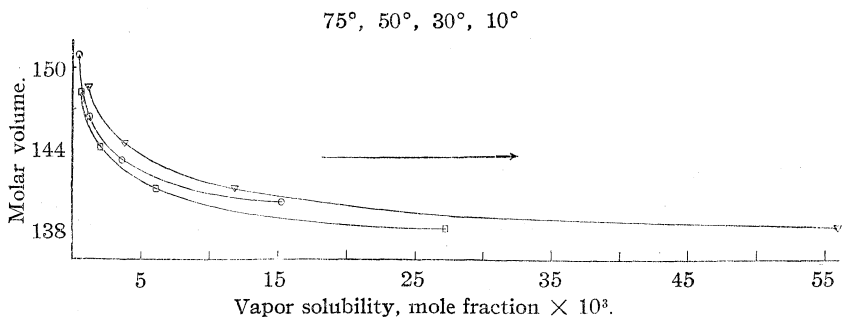

Fig. 2.—Effect of temperature on solubilities in relation to volume: ▽, methyl amyl ketone; O, diisopropyl ketone; □, dipropyl ketone.

may be stretched out at low temperatures so that the CH_2 groups are surrounded by the maximum possible number of water molecules, the attractive forces between these groups and water thus adding to the main interaction between the carbonyl dipole and water. When the temperature increases, the molecule may assume other more compact configurations which will be such as to decrease the number of water molecules adjacent to the CH_2 groups. On the other hand, molecules such as that of diisopropyl ketone having compact branched structures can only assume a limited number of configurations and, hence, their solubilities are less temperature dependent.

Summary

The solubilities in water of dipropyl, diisopropyl and methyl *n*-amyl ketones have been determined at various temperatures from 10 to 75° and vapor solubilities have been computed.

Free energies, heats and entropies of solution have been calculated. Additional evidence was obtained which tends to confirm the previous suggestion that equality of solute volume as well as chemical similarity is necessary for a linear relation to exist between entropies and heats of solution.

Large solubility differences and a large temperature dependence of these differences were noted in agreement with those previously found for other isomeric ketones.

The Surface Tension of Solutions of Electrolytes as a Function of the Concentration. IV. Magnesium Sulfate

BY GRINNELL JONES AND WENDELL A. RAY

This paper is a continuation of work previously reported[1] on the surface tensions of aqueous solution of electrolytes relative to that of pure water. These earlier papers should be consulted for a description of the experimental technique and a discussion of the historical and theoretical background of the problem. The data given are "apparent relative surface tensions" in the sense defined in the second paper of this series.

Magnesium sulfate was chosen for this work because none of the salts already studied belonged to this valence type. The measurements have been carried out at 25.00° over a concentration range of 0.0001 up to 2 molar.

Analytical reagent grade magnesium sulfate was purified by two recrystallizations from water. The crystals were washed by centrifugation and slowly dried in an electric oven. As the salt was hygroscopic each sample before final weighing was kept in an electric furnace at 475° for several hours or until constant weight was assured. At this temperature the anhydrous salt was formed. The samples were weighed in platinum boats in stoppered weighing bottles. A saturated solution showed no red coloration with phenolphthalein. Two 50-ml. Ostwald type pycnometers were used for the density measurements and gave duplicate results differing by not more than a few parts per million. The surface tension measurements were made by the differential capillary rise method as described in the first and second papers of this series. The figures given in Table I are the mean of at least two independent determinations for each concentration. The results are shown graphically in Figs 1 and 2.

.49647	1.055099	1.01435	+ .02890
1.0000	1.110781	1.02836	+ .02836
1.98720	1.214289	1.06603	+ .03323

Interpretation of the Data

The densities of magnesium sulfate may be expressed over the range studied by an equation of the form suggested by Root.[2]

$$d^{25}_4 = 0.997074 + 0.124469c - 0.010756c^{3/2}$$

This equation agrees with the data with an average deviation of less than 0.001%.

From the curve it may be seen that the apparent relative surface tension of magnesium sulfate in the extreme dilute range becomes less than unity giving a minimum. The surface tension at the minimum is about 0.010% below that of pure water. The minimum occurs at about 0.0005 molar. This minimum is similar to that found by us for the other salts studied. At higher concentrations the surface tension is nearly a linear function of the concentration but a slight positive curvature may be noted at the highest concentrations which has been found typical of all the salts studied in this Laboratory in the past.

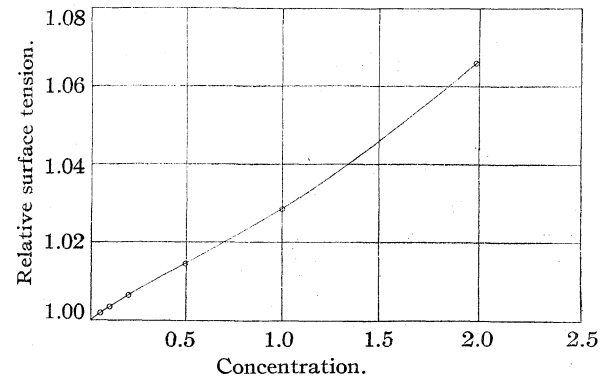

Fig. 1.

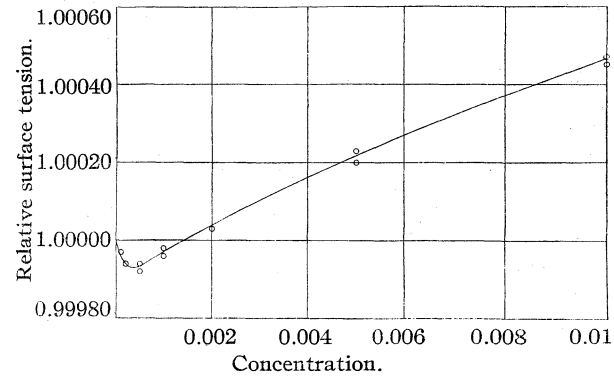

Fig. 2.

Summary

The apparent relative surface tensions of aqueous solutions of magnesium sulfate have been measured from 0.0001 to 2 molar at 25.00°.

At extreme dilution magnesium sulfate apparently gives a minimum in the surface tension–concentration curve. This same type of minimum has been observed for all of the other salts so far reported in this series.

At moderate and high concentrations magnesium sulfate increases the surface tension of water almost linearly with concentration and behaves as a typical "capillary-inactive" substance.

Some Isotherms of the System Sodium Chromate–Sodium Chlorate–Water

BY J. E. RICCI AND C. WELTMAN

Solubility measurements in the ternary system sodium chromate–sodium chlorate–water have been made with the purpose of testing any possible similarity with the behavior of the related system sodium sulfate–sodium chlorate–water, which forms a double salt of the formula $NaClO_3 \cdot 3Na_2SO_4$.[1] The present measurements, however, reveal neither compound formation nor solid solution between the salts Na_2CrO_4 and $NaClO_3$ over the temperature range studied, 19–50°.

Materials.—A C. P. grade of sodium chlorate was used, found to be 100.0% pure by reduction and precipitation of silver chloride. Recrystallized C. P. potassium dichromate was used for the standardization of the 0.2 *N* sodium thiosulfate titrating solution. Other chemicals used, such as sulfur dioxide and silver nitrate, were similarly of C. P. grade. The sodium chromate was used in the form of the tetrahydrate, supplied by the Mackay Company; the percentage of Na_2CrO_4 in this material, found by titration, was 69.15, and by dehydration, 69.25, as compared with the theoretical value of 69.21. The purity of this salt is further confirmed by the agreement of the solubility at 25° as determined by evaporation, with the value obtained by titration (see Table I): 45.63 and 45.59%, respectively.

Solubility Determinations.—Complexes were made up by weight from sodium chlorate, tetrahydrate and water, and rotated in a thermostat at the specified temperature (±0.02°), about three days being allowed for the attainment of equilibrium. Samples for analysis were taken in the usual way by means of pipets fitted with filter paper.

Analysis.—1. Sodium chromate in the presence of sodium chlorate. Gravimetric determination as barium chromate or as lead chromate (using excess of barium chloride or of lead nitrate) gave consistently high results in the determination of about 0.5 g. of potassium chromate in the presence of 0.5 to 2 g. of sodium chlorate, the errors being about +15 and +6 parts per 1000, respectively. These errors may indicate co-precipitation of the respective chlorates. A volumetric analysis was therefore employed, involving precipitation as barium chromate, filtration, re-solution in nitric acid and iodometric titration of the chromate with standard thiosulfate. The use of hydrochloric acid in re-dissolving the precipitate of barium chromate gave irregular, low results, by as much as thirty parts per thousand, apparently because of some reduction of chromate by the hydrochloric acid, during the process of solution of the precipitate. Nitric acid, however, gave satisfactory results (±0.5 part per thousand); the procedure was tested on samples of ~0.35 g. of potassium chromate in the presence of 1–4 g. of sodium chlorate, the final titration being carried out with 3 g. of potassium iodide and 8 cc. of 6 *N* nitric acid in a total volume of 200 cc. Whatever small amounts of chlorate may have accompanied the precipitated barium chromate apparently caused no measurable interference under these conditions.

2. Sodium chlorate can be determined by difference from the percentage of total solid obtained by evaporation of the saturated solution at 110°. But because of some difficulty and uncertainty in the complete drying of sodium chromate residues, it was decided to supplement this indirect determination of sodium chlorate by the following direct analysis.

3. Direct gravimetric determination of the chlorate, by reduction with sulfur dioxide gas followed by the usual gravimetric determination of the resulting chloride as silver chloride. This procedure gave exact results both on pure sodium chlorate and in the presence of sodium chromate, as can be seen of course in the close agreement of the algebraic extrapolation of tie-lines for the identification of solid phases in the ternary system, described below.

Results.—The results for the solubility determinations for three isotherms, 19, 25 and 50°, are given in Table I. All compositions are in weight per cent. The first two columns under the caption "saturated solution" are the directly determined percentages of the two individual salts, and the percentage of water for the actual phase diagram was calculated by difference, using the sum of these percentages for the total solid. The percentage of total solid obtained by direct evaporation was considered probably slightly less dependable than the sum of the separate determinations. The third column under "saturated solution" gives the percentage of water determined by evaporation, and it may be seen that the total solid so determined is nevertheless in good agreement in general with the sum of the first two columns. The average discrepancy is +0.8 to 1.0 part per thousand for the evaporation figure, the maximum difference being six parts per thousand. All but eight of the analytical values given in Table I are averages of at least two duplicates; the average disagreement of duplicates was 1.3 parts per thousand. The sodium chlorate solubilities given in parentheses were determined by evaporation. Table II compares the solubilities of the single salts here reported with values from the literature.

The results, shown graphically for two temperatures in Fig. 1, indicate that in the range of temperature studied, the system is simple, the only solid phases being anhydrous sodium chlorate and one of the hydrates of sodium chromate. This is

the tetrahydrate for the whole sodium chromate solubility curve at 50°. The binary transition temperature to the hexahydrate is 25.9°, and that between the hexahydrate and the decahydrate lies at 19.5°.[7] The stable solid phases for the solubility of the pure salt at the lower temperatures, 25 and 19°, are therefore the hexahydrate and the decahydrate, respectively, and they are so reported in the table. Apparently, however, these phases are in each case dehydrated to the next lower hydrate in the presence of even small concentrations of sodium chlorate, since the tie-lines for the ternary system in this region show only the tetrahydrate as the solid phase at 25° and

(7) Richards and Kelley, THIS JOURNAL, **33**, 847 (1911).

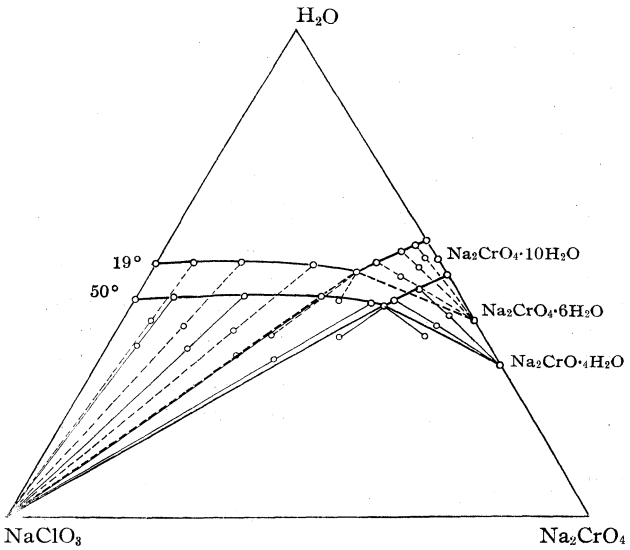

Fig. 1.—The system Na_2CrO_4–$NaClO_3$–H_2O at 19 and 50°.

only the hexahydrate at 19°. The isothermally invariant points for equilibrium, at each of these two temperatures, between the two adjacent hydrates in the ternary system were not determined.

The identity of the solid phases as reported is based on graphical and algebraic extrapolation of tie-lines. For the case of sodium chlorate as solid phase these tie-lines extrapolate to 100% sodium chlorate with an average absolute error, for all three isotherms, of 0.16%, calculated as % water. For the sodium chromate phases, the average error of extrapolation to the theoretical percentage of sodium chromate in the respective hydrates, is 0.11%, calculated as % sodium chlorate. There is consequently no indication, within the experimental error, of any solid solution formation between the equilibrium phases of the system.

Summary

Solubility determinations are reported for the ternary system sodium chromate–sodium chlorate–water at 19, 25 and 50°. No evidence is found for any compound formation or solid solution between the two salts in this temperature range.

Absorption Spectra of Some Double Salts Containing Cobaltous Chloride*

BY MELVIN L. SCHULTZ AND ERNEST F. LILEK

The blue color of solutions containing cobaltous chloride and hydrochloric acid or certain other chlorides in large excess has been shown by ion migration experiments[1] to be due to an anion of which cobalt is a constituent. It has been suggested frequently,[2] on the basis of indirect physico-chemical evidence, that this ion may be represented as $CoCl_4^{--}$.

The absorption spectra of solutions containing the ion in question have been observed, the most accurate measurements being those of Brode,[3] Brode and Morton,[4] and Kiss and Gerendas.[5] The spectrum consists of many relatively narrow bands extending from the near infra-red through the visible into the ultraviolet. In the present paper, the results of the comparison of the portion of this spectrum lying within the visible region with spectra of several blue double salts containing cobaltous chloride are reported.

The structure of one of these double salts, Cs_3CoCl_5, has been determined by X-ray diffraction measurements.[6] These experiments have shown that in the crystal there exists an approximately regular tetrahedral arrangement of four chloride ions about each cobalt ion, the cobalt–chlorine distance being 2.34 Å. The fifth chloride ion is separated from the cobalt ion by a much greater distance, about 6.0 Å. The absorption spectrum responsible for the blue color of this crystal may be ascribed to the presence of the tetrahedral $CoCl_4^{--}$ group.

If this same complex is present in other crystals or in solution the absorption spectra ought to re-

semble one another closely. It need not be expected, however, that the positions and relative intensities of corresponding absorption bands be identical. For the crystals, differences in the identity of the surrounding ions and differences in their arrangement about the $CoCl_4^{--}$ complex would be expected to give rise to differences in the spectra. The absorption bands for the solution should be more diffuse than those for the crystals with fewer details of structure resolved because of the less regular arrangement of neighbors about the complex ions and because of the effect of thermal agitation upon the arrangement. Any change in the binding energy between cobalt and chlorine for the complex in solution as compared with the crystal might produce shifts in the positions of the absorption bands. If, however, the complex responsible for the absorption, either in solution or in a crystal other than Cs_3CoCl_5, has a different composition or structure the absorption spectrum should be qualitatively different. From the results of measurements by Brode[7] it may be inferred that the blue color of solutions of cobalt chloride in various solvents is not always due to the same complex since the spectra of such solutions do show characteristic differences in their structure.

We have found that the absorption spectra of crystals of Cs_3CoCl_5, Cs_2CoCl_4, $(PyH)_2CoCl_4$, $(QuH)_2CoCl_4$ and $(QuH)_2CoCl_4 \cdot H_2O$, in which PyH represents the pyridinium ion and QuH the quinolinium ion, are nearly identical. Furthermore, there is a close correspondence between these spectra and the spectrum of the hydrochloric acid solution of cobalt chloride. It may be concluded, therefore, that in these crystals and in the blue aqueous cobalt chloride solutions containing large excess of chloride ion the characteristic color is due to a tetrahedral $CoCl_4^{--}$ complex ion.

Experimental

The spectra were photographed using a Hilger constant deviation wave length spectrometer, fitted with a camera of 30 cm. focal length, and Eastman Spectroscopic Plates types IV B, IV F and 144 N. The linear dispersion at 4500 Å. was about 50 Å. per mm. An image of the source, an automobile headlight bulb operated from a small motor generator, was focused on the crystal. An image of the illuminated crystal was then focused on the spectrograph slit which was set at a width of about 0.02 mm. Exposure times varied from a few seconds to about nine hours.

The double salts used were prepared by methods described in the literature.[8] The composition of each was confirmed by determination of chloride. Single crystals up to about 2 mm. in thickness were used in photographing the weak absorption bands. For the more intense bands the material was powdered and pressed between microscope slides whose surfaces had been ground with fine carborundum. With $(PyH)_2CoCl_4$ and $(QuH)_2CoCl_4 \cdot H_2O$ large single crystals could not be obtained. In order to photograph the weak bands of these two substances relatively thick layers of the powdered material were used which made long exposure times necessary.

The wave lengths of the bands were determined by first spotting visually on the plates the centers of the bands and by then determining the positions of the spots with respect to the comparison spectrum using a measuring microscope. For each band, with the exception of a few which were very weak, the value reported is the mean of at least five independent measurements. The average deviation, from the chosen value, of the individual measurements on a given band varied from about 1.5 Å. in the blue to about 6 Å. in the far red. The relative intensities of the bands were estimated visually from the plates and are expressed on a scale of 0–10. Since the absorption bands observed were rather sharp with clearly defined edges the band widths were estimated roughly by spotting, on the plates, the band edges. The values reported for the widths have been rounded off to the nearest 10 $cm.^{-1}$.

Results and Discussion

The wave numbers, calculated from the measured wave lengths, of the band centers for the five double salts studied are listed in Table I together with the band widths and estimated intensities. These data are plotted in Fig. 1, in which the vertical lines represent the positions of the band centers and the heights of the lines represent the relative intensities. The only marked differences among these spectra occur in the group of weak bands lying between 19,200 $cm.^{-1}$ and 20,300 $cm.^{-1}$. The remaining bands appear in all the spectra with nearly the same positions and relative intensities. Evidently, the energy levels characteristic of the complex ion are not very sensitive to changes in the surroundings.

The absorption curve for the solution of cobalt chloride in concentrated hydrochloric acid is plotted also in Fig. 1 with wave numbers as abscissas and log ϵ as ordinates. This curve was constructed from the data of Brode[3] and Brode and Morton.[4] The similarity between the curve for the solution and the spectra of the crystals is apparent. Each consists of four regions of absorption: a group of intense bands in the red, a group of smaller intensity in the green and yellow and two groups of weak bands in the blue. The

number of components, six, of the group in the red is the same for the solution and for the crystals although the bands in solution are somewhat more diffuse. The remaining groups of bands show less structure in the spectrum of the solution than in the spectra of the crystals. For these groups, however, the curve for the solution follows approximately the envelope of the bands for the crystals if slight shifts in the positions of some of the groups are made. This comparison indicates that the differences between the two spectra are due principally to the effects of thermal agitation in solution. Therefore, the conclusion that the same complex is responsible for the absorption by the solution and by the crystals may be drawn.

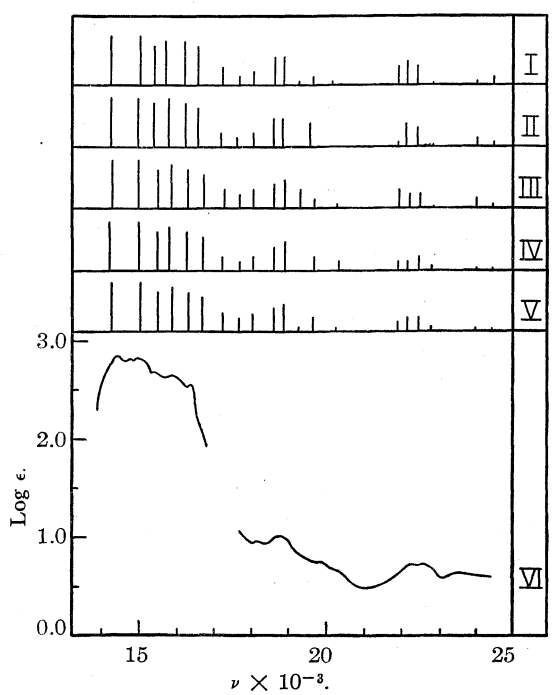

Fig. 1.—The absorption spectrum of $CoCl_4^=$ in: I, Cs_3CoCl_5; II, Cs_2CoCl_4; III, $(PyH)_2CoCl_4$; IV, $(QuH)_2CoCl_4$; V, $(QuH)_2CoCl_4 \cdot H_2O$; VI, cobalt chloride in hydrochloric acid (from data of Brode and Morton[3,4]).

Brode[3] and Brode and Morton[4] have shown that their absorption curve for the solution may be analyzed into components each of which is a multiple of a frequency of 409 cm.$^{-1}$. Although there are minor discrepancies between their data and those of Kiss and Gerendas,[5] the spectrum reported by the latter for these same solutions may be analyzed in the same fashion. The wave numbers, ν, of the bands found, including those in the ultraviolet which were not studied by Brode and Morton, may be represented by an expression of the form

$$\nu = a + bn$$

in which a and b are constants and n is a running positive integer. The values of a and b which give the best fit between the calculated and experimental wave number values are found in Table II. The constant frequency difference, 416 cm.$^{-1}$, is in approximate agreement with the value of Brode and Morton.

The absorption spectra of the crystals may be represented by similar expressions. The con-

[a] Analysis based on the data of Kiss and Gerendas.[5]

stants, together with the average deviations between the calculated and experimental values of ν, are listed in Table II. The latter are somewhat larger than the experimental uncertainties in the wave number values of the bands but are of the same order of magnitude. Since the bands are from 100 to 300 cm.$^{-1}$ in width, the deviation might be due, in part, to slight systematic errors in picking out the band maxima.

In view of these regularities, following a suggestion made recently by one of us[9] for several other complex ions, these spectra may be interpreted as having originated in electronic transitions for which vibrational structure characteristic of the $CoCl_4^{--}$ complex ion is developed. It may be noted that the average frequency for the complex in solution, 413 cm.$^{-1}$, differs by 22 cm.$^{-1}$ from the average value of the crystals, 391 cm.$^{-1}$. Since the frequencies of the normal vibrations of the complex depend on the force constant of the cobalt–chlorine bond and since the frequency found here is probably that of the totally symmetric vibration, the existence of this difference indicates that the binding energy of the complex ion in the crystal is smaller than in solution.

(9) M. L. Schultz, *J. Chem. Phys.*, **10**, 194 (1942).

Although each observed band in the spectra of the crystals (and in the solution as well) is represented by an integral value of n, not all values of n represent observed bands. This, together with the somewhat unsatisfactory fit of the group of bands at 22,000 cm.$^{-1}$ into the suggested analysis, indicates that this analysis is too simple. Probably several electronic transitions, each with its associated vibrational structure, occur. With the data at present available, no reliable energy level diagram can be constructed. It is the intention in this Laboratory to study the spectra of these crystals at low temperatures in order to obtain information which might permit the construction of such a diagram and also in order to study in more detail the effect of the environment upon the spectrum.

Summary

1. The absorption spectra of crystals of two cesium cobaltous chlorides, dipyridinium cobaltous chloride, diquinolinium cobaltous chloride and diquinolinium cobaltous chloride monohydrate have been measured.

2. Comparison of the spectra of these crystals with the spectrum of the solution of cobaltous chloride in concentrated hydrochloric acid shows that the same complex ion, $CoCl_4^{--}$, is present in all.

3. A tentative analysis of the spectra of the crystals has been made. This analysis suggests that the spectra may be considered to originate in coupled electronic-vibrational transitions.

Some Boron Trifluoride Catalyzed Alkylations of Halobenzenes[1]

BY G. F. HENNION AND V. R. PIERONEK

Introduction

Previous work in this Laboratory has shown that boron trifluoride, in the presence of a strong dehydrating agent such as phosphoric anhydride or sulfuric acid, is an excellent catalyst for the alkylation of benzene[2] and its homologs[3] with alcohols. This method was extended in the present work to the halobenzenes.

In many respects boron trifluoride has been found superior to aluminum chloride for these alkylations. With aluminum chloride there may be considerable halogen migration to produce benzene, dihalobenzene and alkylbenzene as well as the desired alkylhalobenzene.[4,5] Furthermore, the aluminum chloride methods result in both meta and para substitution,[6,7] thus giving an

[a] Cryoscopic in cyclohexane. [b] Sodium-liquid ammonia method. [c] Polyalkylation product 15.1%.

undesirable mixture. Boron trifluoride is a less drastic catalyst. No migrations of the halogen on the benzene nucleus were observed, nor were any dehalogenated products isolated. Moreover, oxidation of the alkylhalobenzenes to the *p*-halobenzoic acids reveals that the orientation of the product is entirely para when boron trifluoride is used as a catalyst.

The reactions were found to proceed analogously to those described in previous papers.[2,3] The yields decrease with the increasing molecular weight of the alcohol or halobenzene used, and with the increasing tendency of the alcohol toward dehydration. Isomeric primary and secondary alcohols were found to give the same product, *p*-*s*-alkylhalobenzene. This was proved by the reaction of *p*-*s*-butylchlorobenzene (from *n*-butyl alcohol) with sodium in liquid ammonia at −34°, which gave a 10% yield of *p*-*s*-butylaniline and a 50% yield of *s*-butylbenzene. The various reaction products are described in Table I.

Experimental

Procedure.—The halobenzene was weighed into a one-liter, three-neck, round-bottom flask, equipped with an efficient oil-sealed stirrer, a reflux condenser and a thermometer. The alcohol was then added and mixed with the halobenzene. The flask was cooled in ice-water and boron trifluoride introduced below the liquid surface until the appearance of white fumes above the condenser indicated that the reactants were saturated. It was found, in every case, that the mixture at this point had absorbed one mole of boron trifluoride per mole of alcohol. Phosphorus pentoxide (0.25 mole per mole of alcohol) was then added as quickly as possible. The temperature was raised *slowly* to about 75–85° and maintained there for about six hours. The heating was then stopped, the mixture cooled with ice-water and then poured into a separatory funnel. The lower layer was discarded and the upper washed with water, twice with 10% solution of sodium carbonate, and finally with water. After drying with calcium chloride the material was distilled through an efficient column. The yields in Table I represent products of narrow refractive index range after two distillations.

Oxidation.—Small samples (0.2 to 0.3 g.) were oxidized with sodium dichromate (3.5 g.) and sulfuric acid (5.0 ml.) in (6.0 ml.) acetic acid solution at 70–75°. Melting points of the *p*-halobenzoic acids agree with literature values: *p*-chloro, 242°; *p*-bromo, 252°; *p*-iodo, 269–270°.

Summary

1. Boron trifluoride, with phosphoric anhydride as an adjunct, has been shown to be an effective catalyst in the condensation of alcohols with chloro-, bromo- and iodobenzenes.

2. Satisfactory yields of *p*-*s*-alkylhalobenzenes are readily obtained in this manner.

The Nitrogen Compounds in Petroleum Distillates. XXIV. Isolation and Identification of a $C_{11}H_{17}N$ Base from California Petroleum

BY H. L. LOCHTE, W. W. CROUCH[1] AND E. D. THOMAS

The identification of the $C_{16}H_{25}N$ base isolated by Thompson and Bailey[2] from the kerosene distillates of California petroleum as 2-(2,2,6-trimethylcyclohexyl)-4,6-dimethylpyridine[3] suggests that the so-called "non-aromatic" bases of Perrin and Bailey[4] might consist of mixtures of highly substituted pyridines. These bases are separated from the other bases present in kerosene distillates by extraction of an aqueous solution of the mixed base hydrochlorides with chloroform, the "non-aromatic" base hydrochlorides being found in the chloroform layer. The mixture of bases remaining in the water layer always has the higher refractive index and density, and a number of these compounds have been identified by Bailey and co-workers as alkylated quinolines.

Besides the $C_{16}H_{25}N$ base, two other bases having physical constants and chemical properties similar to the known alkylated pyridines have been isolated previously from the chloroform-soluble hydrochlorides of petroleum bases. These are a $C_{10}H_{15}N$ base isolated by Roberts[5] and a $C_{13}H_{21}N$ base isolated by Armendt,[6] neither of which has been identified.

The bases used in this study were recovered from the hydrochlorides found in the chloroform layer after extraction of an aqueous solution of the hydrochlorides of kerosene bases boiling at 210–213°. After fractional distillation and fractional extraction with hydrochloric acid, the fractions were sufficiently pure to form crystalline picrates from which pure bases were recovered. A $C_{11}H_{17}N$ base was isolated and identified as *dl*-2-*s*-butyl-4,5-dimethylpyridine by the following facts: (1) condensation of the base with benzaldehyde to form a mono-addition compound indicated that one methyl group was in position 2, 4 or 6 on the pyridine ring. (2) Failure of the base to condense with acetic anhydride to form a picolide showed that the reactive methyl group was not in position 2 or 6. (3) Ozonolysis to produce diacetyl indicated that two methyl groups were present in adjacent positions. (4) Isolation of the amide of *dl*-methylethylacetic acid after ozonolysis showed that a secondary butyl group was at position 2. (5) The structure was confirmed by permanganate oxidation to give pyridine-2,4,5-tricarboxylic acid.

Small quantities of two other bases were isolated by means of crystalline picrates analysis of which corresponded to formulas of $C_{12}H_{19}N$ and $C_{13}H_{21}N$ for the bases. While not obtained in sufficient quantities for identification, the physical characteristics and formulas of the bases suggest that they are probably alkylated pyridines.

Experimental

The material for this investigation consisted of 6.8 liters of bases that had been obtained from kerosene distillates, carefully fractionated and donated to this Laboratory in 1940 by the Union Oil Company of California. The boiling point of the material used ranged from 210–213° and the index of refraction at 20° from 1.4982 to 1.5040. The mixture was acidified with 3750 cc. of concentrated hydrochloric acid in 4 kg. of chipped ice, then divided into six aliquots and extracted by stirring successively with six portions of 1500 cc. of chloroform, the chloroform then being washed with 800-cc. portions of water similar to the multiple-fractional-extraction method described by Morton.[7] The chloroform was distilled off and the base was recovered by addition of sodium hydroxide solution. In this way there was obtained 2 liters of material with $n^{20}D$ 1.4922–1.4904. It was combined and distilled at 20 mm. through a 12-ft. packed column with 10:1 reflux ratio; b. p. 99–103° (20 mm.).

Fractional Acid Extraction.—The highest boiling material from the distillation, 190 g. with $n^{20}D$ 1.4916, was dissolved in 500 cc. of petroleum ether and extracted in thirteen fractions using the apparatus of Fig. 1. A 1.5 *N* solution of hydrochloric acid was introduced into the top flask, extracting the base from the solvent and passing down the spinner[8] column. At the bottom of the column, 1.5 *N* sodium hydroxide solution was added at one-half the rate of addition of the acid so that one-half of the base was released and carried up the column by the rising stream of petroleum ether, thus furnishing reflux for the descending salt solution. The aqueous extract was taken off in 300-cc. portions from which the base was recovered, volume and refractive indices of the fractions being shown in Table I.

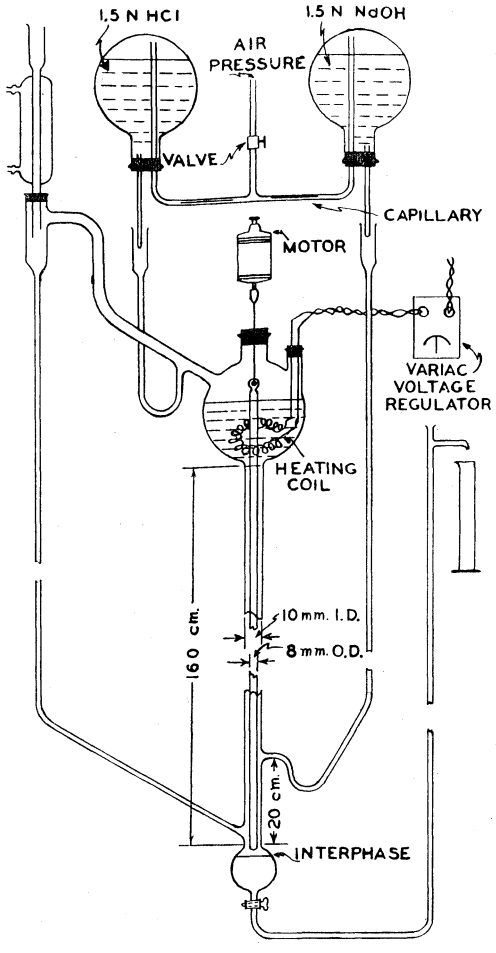

Fig. 1.

Isolation of the $C_{11}H_{17}N$ Base.—To one-gram samples of these fractions dissolved in sulfurous acid solution, 1.5 g. of picric acid in saturated aqueous solution was added. Oily picrates formed but after several days in the icebox the picrate of fraction 6 crystallized. It was recrystallized from ethyl alcohol and dilute acetic acid to a constant melting point of 127–128°.

Anal. Calcd. for $C_{17}H_{20}O_7N_4$: C, 52.04; H, 5.14; N, 14.28. Found: C, 52.12; H, 4.99; N, 14.13.

By seeding the other fractions with the pure picrate, crystals were obtained from fractions 4–8. They were recrystallized until pure and warmed with excess concentrated ammonium hydroxide to give the free base which was separated, washed, dried over solid sodium hydroxide and distilled; b. p. 214° (752 mm.); d^{20}_4 0.8991; $n^{20}D$ 1.4947.

Anal. Calcd. for $C_{11}H_{17}N$: C, 80.92; H, 10.50; N, 8.58. Found: C, 80.89; H, 10.44; N, 8.47.

From fractions 5 and 6, 40% by weight of the mixture was recovered as pure base. More of the base was obtained by processing in a similar way petroleum bases from the same source boiling at 214–215.5°.

TABLE I

Fraction no.	Volume, cc.	$n^{20}D$
1	8	1.4943
2	12	1.4921
3	12	1.4921
4	13	1.4931
5	10	1.4938
6	14	1.4938
7	14	1.4936
8	13	1.4925
9	13	1.4907
10	15	1.4901
11	14	1.4880
12 (Residue)	33	1.4871

Condensation of the $C_{11}H_{17}N$ Base with Benzaldehyde.—Two grams of the base, 4 g. of benzaldehyde and 0.5 g. of zinc chloride were heated for twenty-four hours at 200° in a sealed tube. The dark, viscous product was shaken with 2 *N* hydrochloric acid but only a few drops of base was recovered from the water layer. The residue was washed twice with ether to remove benzaldehyde, made alkaline with sodium hydroxide solution, separated, dissolved in alcohol and added to two grams of picric acid in alcohol. Three grams of the picrate of the benzal derivative was obtained which was recrystallized to a constant melting point of 143°.

Anal. Calcd. for $C_{24}H_{24}O_7N_4$: C, 59.99; H, 5.03. Found: C, 59.98; H, 5.05.

Attempted Condensation of the $C_{11}H_{17}N$ Base with Acetic Anhydride.—Following the procedure employed by Scholtz[9] for the condensation of acetic anhydride with 2-methyl- and 2,4-dimethylpyridine, 1.7 g. of the natural base was heated with 10 g. of acetic anhydride for eight hours at 210° in a sealed tube. The dark, resinous product was heated with water, alcohol and chloroform in an attempt to obtain a crystalline picolide. No such compound was obtained by cooling or evaporating the solvents.

Ozonolysis of the $C_{11}H_{17}N$ Base.—Through 4 g. of the $C_{11}H_{17}N$ base dissolved in 20 cc. of carbon tetrachloride and cooled to 0° there was passed a stream of 10% ozone at a rate of 1200 cc. per hour for four hours. Five grams of 30% sodium hydroxide solution was added and the mixture shaken vigorously for ten minutes, during which white crystals separated. They were filtered off, the carbon tetrachloride layer was dried, and the ozonolysis repeated. In this way, 250 mg. of amide was obtained melting, after recrystallization from benzene–petroleum ether, at 112°. A mixed melting point showed it to be the amide of *dl*-methylethylacetic acid.

Anal. Calcd. for $C_5H_{11}ON$: N, 13.85. Found: N, 13.71.

The ozonolysis was repeated, the ozonide was decomposed by adding water and stirring, and *p*-nitrophenylhydrazine hydrochloride solution was added to the product. The mixture was warmed and the dark red crystals of the *p*-nitrophenylosazone of diacetyl separated. It was recrystallized from nitrobenzene and melted with decomposition at 332°. The melting point and mixed melting point of this derivative of synthetic diacetyl showed the two compounds to be identical.

Permanganate Oxidation of the $C_{11}H_{17}N$ Base.—Ten grams of the base was added to two liters of 2% potassium

(9) Scholtz, *Ber.*, **45**, 734 (1912).

permanganate solution and the mixture was stirred on a steam-bath with reflux. After twelve hours the solution was decolorized and 40 g. more of potassium permanganate was added in concentrated solution. After twelve hours the addition was repeated, after which the solution was not completely decolorized by heating for four days. The excess permanganate was reduced with formaldehyde, the solution was filtered, concentrated to 200 cc. and neutralized with dilute nitric acid. Silver nitrate solution was added and the flocculent precipitate of silver salt was filtered, washed, dissolved in ammonium hydroxide and reprecipitated in three fractions by the slow addition of 1 *N* nitric acid. The second fraction was suspended in water and hydrogen sulfide passed into the mixture. The silver sulfide was removed and the solution evaporated to leave white crystals of pyridine-2,4,5-tricarboxylic acid, melting with decomposition at 242–243°. It was recrystallized from dilute hydrochloric acid from which it precipitated slowly. The air-dried sample was heated one hour at 120° to remove water of crystallization.[10]

Anal. Calcd. water of crystallization for $C_8H_5O_6N \cdot H_2O$: H_2O, 7.86. Found: H_2O, 7.90.

The anhydrous acid was analyzed for nitrogen.

Anal. Calcd. for $C_8H_5O_6N$: N, 6.63. Found: N, 6.69.

The acid was readily soluble in water and gave a dark red color with ferrous sulfate solution. It was heated to 170° without appreciable carbon dioxide evolution, a reaction that is reported[11] to be rapid above 140° for pyridine-2,3,6-tricarboxylic acid. It was apparently unaffected by boiling for two hours with acetic anhydride, giving none of the chloroform-soluble cinchomeronic anhydride which is formed[12] by this treatment of pyridine-2,3,4-tricarboxylic acid.

Isolation of a $C_{12}H_{19}N$ Base.—An intermediate fraction of bases from the distillation described above, 80 g. with $n^{20}D$ 1.4904 and b. p. 101° (20 mm.), was extracted from 500 cc. of petroleum ether in seven fractions using the apparatus of Fig. 1. Fraction 6 was converted to the picrate as described above, giving a crude picrate which was recrystallized repeatedly from dilute ethanol and dilute acetic acid to a constant melting point of 174°.

Anal. Calcd. for $C_{18}H_{22}O_7N_4$: C, 53.20; H, 5.46. Found: C, 53.20; H, 5.51.

One-half gram of the picrate was heated with concentrated ammonium hydroxide to liberate the base which was extracted in ether, dried and distilled in a semi-micro distillation apparatus. A middle fraction gave the following constants: b. p. 214° (754 mm.); $n^{20}D$ 1.4832.

Anal. Calcd. for $C_{12}H_{19}N$: N, 7.90. Found: N, 7.79.

Isolation of a $C_{13}H_{21}N$ Base.—Fraction 7 of the extraction series described above from which the $C_{12}H_{19}N$ base was obtained was converted to the picrate and recrystallized repeatedly to give yellow needles having a constant melting point of 121°.

Anal. Calcd. for $C_{19}H_{24}O_7N_4$: C, 54.28; H, 5.75; N, 13.33. Found: C, 53.87; H, 5.74; N, 13.52.

Summary

1. A sample of California petroleum bases boiling at 210–213° has been fractionated by efficient methods of extraction and distillation to yield products of sufficient purity that crystalline picrates of three new bases were obtained.

2. By a process of degradation a $C_{11}H_{17}N$ base has been identified as *dl*-2-*s*-butyl-4,5-dimethylpyridine.

3. Two other bases having molecular formulas of $C_{12}H_{19}N$ and $C_{13}H_{21}N$ were isolated in quantities too small for identification. It is believed that they are also alkylated pyridines.

Stereoisomeric Diphenyloctatetraenes

BY L. ZECHMEISTER AND A. L. LEROSEN

While some earlier authors[1] have denied the existence of *cis–trans*-isomers in the case of an extended conjugated double bond system, Kuhn[2] correctly summarized the situation in 1933 by the following statement: ". . . according to the available evidence a strong accumulation of double bonds does not exclude the occurrence of *cis–trans*-isomerism. That the higher diphenylpolyenes are known only in one spatial form is due to the inadequacy of the preparative methods." In the series mentioned, $C_6H_5(CH{=}CH)_nC_6H_5$, so far as we know, stereoisomeric forms have been obtained[3] only in the case $n < 3$. According to X-ray studies by Hengstenberg and Kuhn[4] the prepa-

(2) R. Kuhn, in Freudenberg's "Stereochemie," F. Deuticke, Vienna, 1933, p. 915.
(3) F. Straus, *Ann.*, **342**, 190 (1905). An alleged white modification of diphenyl-octatetraene (H. Stobbe, *Ber.*, **42**, 567 (1909)) was later identified as stilbene by R. Kuhn and A. Winterstein (footnote 5). Accordingly, text and formulas on pp. 179–180 of the following book should be corrected: G. Egloff, G. Hulla and V. I. Komarewsky, "Isomerization of Pure Hydrocarbons," Reinhold Publishing Corp., New York, N. Y., 1942.
(4) J. Hengstenberg and R. Kuhn, *Z. Krystall. Miner.*, **75**, 301 (1930).

rations of Kuhn and Winterstein[5] represent all-*trans* forms in case of $n = 3$ or 4.

In contrast, the existence of a great number of stereoisomers has recently been demonstrated for naturally occurring polyenes, the carotenoids. For example, 14 stereoisomeric lycopenes, $C_{40}H_{56}$, have been reported, and one of them, prolycopene containing 4 or 5 *cis*-double bonds, has been isolated from natural sources.[6] A partially *cis* γ-carotene, *viz.*, *pro*-γ-carotene,[7] $C_{40}H_{56}$, also occurs in nature. Many stereoisomers can be obtained from β-carotene[8] in addition to Gillam's pseudo-α-carotene.[9]

Considering these facts a stereochemical reinvestigation of diphenylpolyenes was desirable. We have mentioned briefly[10] that some methods in use for the isomerization of carotenoids are applicable to synthetic polyenes.

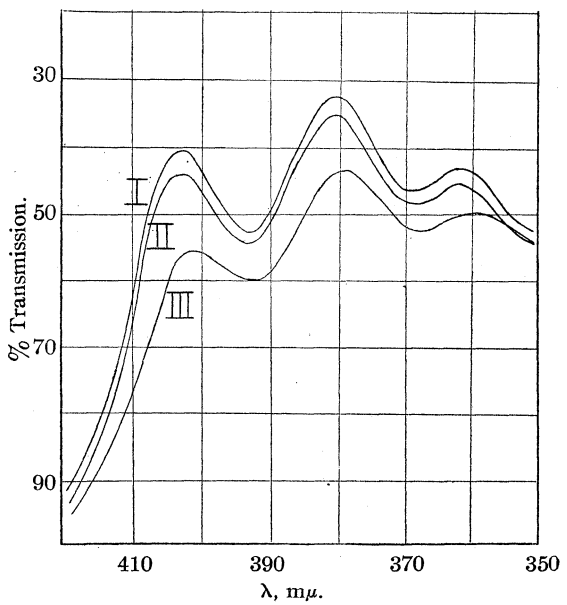

Fig. 1.—Isomerized diphenyloctatetraene in benzene. Light absorption curves of a chromatographic filtrate containing chiefly zone 2. The curves III, II, and I were taken after zero, one, and two days, respectively. Curve I remained constant on the fourth day. (Abscissa: wave length, ordinate: percentage transmission measured in the Beckman photoelectric spectrophotometer.[11])

The stereochemical homogeneity and the all-*trans* configuration of 1,8-diphenyloctatetraene (prepared according to Kuhn and Winterstein[5]) can be demonstrated chromatographically. A single zone, showing an intense light yellow fluorescence in ultraviolet light, appeared on the lime column. When, however, a benzene solution of this zone was refluxed, irradiated, or treated with iodine, or if crystals were melted for a short time, subsequent chromatography gave three well separated, fluorescing zones in each case. The upper one was identical with the single all-*trans* zone mentioned. The two other fractions possess *cis*-configurations of some double bonds which will be designated below.

It is easy to isomerize about one-sixth of the starting material, *e. g.*, the weight ratio of the three isomers was 83:15:2 from top to bottom of the Tswett column (weighed in form of the regenerated all-*trans* isomer). In some favorable cases two additional minor isomers appeared below the main zones. In this way five of the ten theoretically possible isomers were observed. They are designated as zones 1–5 (no. 1 = all-*trans* top zone).

All diphenyloctatetraenes containing *cis*-double bonds are labile. Their solutions when kept at room temperature contain a gradually increasing quantity of the all-*trans* form. The conversion becomes manifest by a decreasing light-transmission until a constant end value is reached (Fig. 1). This conversion has been followed and confirmed chromatographically.

Analogous changes were observed by starting from solid samples obtained by almost instantaneous evaporation of solutions of the zones 2–5 which had been washed through the column. Adsorption analysis showed that the fresh solution of the dry residue contained very little of the all-*trans* isomer, the quantity of which, however, rapidly increased on standing. Because of these circumstances we were unable (even working at 5°) to isolate samples of a *cis*-isomer for which the absence of the all-*trans* compound could be conclusively proved. Attempts to crystallize individual *cis*-compounds, contained in chromatographic zones, using the ordinary methods of elution and isolation so far gave only crystals of the *trans*-isomer. Combustion analysis of some isomerized, chromatographed and reconverted

samples (zones 2 and 3) proved, however, that no other change but a spatial shift within the molecule had taken place during the operations.

Another characteristic feature showing the lability of the new isomers is the very rapid reconversion of adsorbed material under the quartz lamp. In a suitably developed chromatogram those portions of zone 2 which were adsorbed on the cylindrical surface of the column, when exposed to ultraviolet light for a minute, showed on further washing a division into two fluorescing layers. The inside of the column showed only the original zone but none of the all-*trans* zone formed locally by the irradiation of the surface.

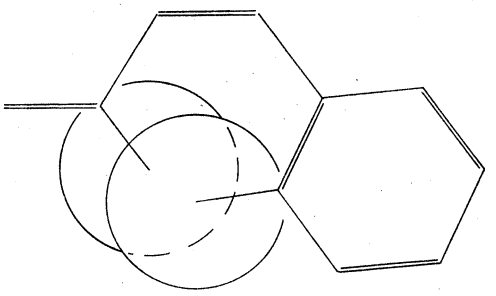

Fig. 2.—Model of one molecule end of diphenyloctatetraene (values used: C=C, 1.33 Å.; C—C, 1.46 Å.; C_6H_5—C, 1.44 Å.; C_6H_5—H, 1.08 Å.; C—H, 1.09 Å.; H-radius, 1.20 Å.; angles C=C—C and C=C—H, 124°20′.

With reference to the configuration of the individual diphenyloctatetraenes the following remarks can be made. Figure 2 shows that if an end double bond of the aliphatic chain assumes *cis*-configuration, a hydrogen atom of the nucleus, in opposition to the side chain, is spatially hindered by one of the hydrogens of the latter so that planar or approximately planar configuration becomes impossible for the molecule. The calculated deviation is about 52.5°. Therefore if the all-*trans* compound is isomerized, great preference will be given to the formation of stereoisomers in which the two end double bonds remain in *trans*-position. Instead of nine isomeric tetraenes possessing *cis*-bonds only two will be formed in any substantial quantity. We believe that these are contained in the two main zones produced by isomerization for which we suggest the following probable configurations

Zone 1 (top) *trans–trans–trans–trans*
Zone 2 (middle) *trans–cis–trans–trans*
Zone 3 (bottom) *trans–cis–cis–trans*

As with *cis*-stilbene, $C_6H_5CH{=}CHC_6H_5$, and *cis*-diphenylbutadiene, $C_6H_5(CH{=}CH)_2C_6H_5$, "hindered" isomers are also formed; this is shown by the minor zones 4 and 5 of the isomerized tetraene chromatogram. In the case of the octatetraene, isomerization is distributed between the several sterically possible types, some of which may be formed without significant steric hindrance others of which may involve definite spatial conflicts. Since the former types provide preferred configurations which may be assumed by the molecule, the sterically "hindered" types will not have the opportunity to play the prominent role which they have been found to assume in the case of stilbene (and diphenylbutadiene) in which the "hindered" isomer is without competition from other and more stable forms.

In the field of the carotenoids, according to Pauling,[12] the group >C=CH—C(CH$_3$)< constitutes a complete hindrance for a *trans–cis*-shift. The number of the expected *cis–trans*-isomers (occurring in substantial quantities) can be reduced on the basis of spatial considerations both in the class of natural and synthetic polyenes.

Acknowledgment.—The authors wish to thank Dr. R. B. Corey for valuable advice and Dr. G. Oppenheimer as well as Mr. G. Swinehart for microanalyses.

Experimental

1,8-Diphenyloctatetraene was synthesized according to Kuhn and Winterstein.[5] After recrystallization from

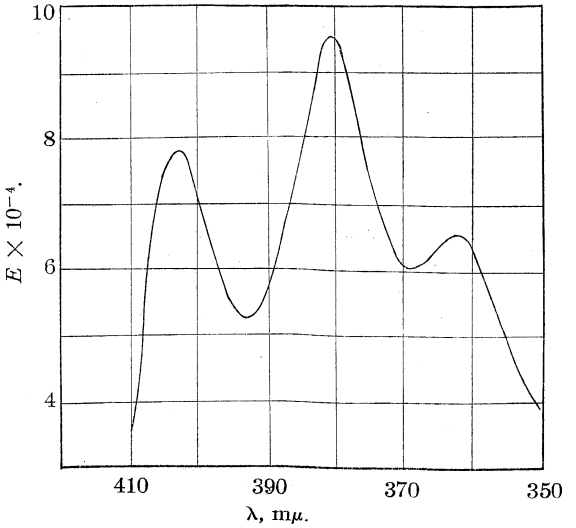

Fig. 3.—Absorption curve of all-*trans*-diphenyloctatetraene in benzene. (Abscissa, wave length; ordinate, mol. extinction coefficient.) $E = \frac{1}{Lc}\log\frac{I_o}{I}$.

chloroform the yellow plates melted at 235–237° (cor.). The absorption curve is given in Fig. 3.

Anal. Calcd. for $C_{20}H_{18}$: C, 92.97; H, 7.03. Found: C, 93.27; H, 7.23.

Chromatographed on calcium hydroxide (Shell brand chemical hydrate, 98% through 325 mesh) as described below, a solution of the crude or of the purified crystals showed homogeneity. The zones as well as those of stereoisomers are best located during the development on a Tswett column by means of a portable quartz lamp in the dark. Intense light yellow fluorescence appears.

1. Isomerization in Solution by Heat.—A solution of 0.4 g. of diphenyloctatetraene in about 200 ml. of benzene was gently refluxed for several hours, brought to 225 ml. (in order to prevent precipitation) and diluted with 3 volumes of light petroleum (b. p. 60–70°). The solution was immediately poured on the adsorbent in a percolator (40 × 16 × 8 cm.) under suction. After washing with light petroleum the chromatogram was developed with benzene–light petroleum 1:10 within a few hours. Below the main zones of unchanged all-*trans* compound a second and a smaller third zone appeared, followed by traces of two minor fractions. All zones (termed 1–5, from top to bottom) were well separated by non-fluorescing intermediate sections. Each of the main zones was cut out, eluted with benzene-methanol 3:1, quickly washed alcohol-free in a special apparatus,[13] dehydrated with sodium sulfate within a few minutes and completely evaporated *in vacuo*. Each dry residue was dissolved in dioxane and precipitated with water. The zones 1–3 yielded 0.25 g., 0.05 g. and 0.005 g. of substance, respectively. All were identified as all-*trans* compounds by mixing them together and chromatographing; only one zone appeared.

Anal. Calcd. for $C_{20}H_{18}$: C, 92.97; H, 7.03. Found (zones 1–3): C, 92.72, 93.07, 92.43; H, 7.72, 7.37, 7.94.

In other experiments the elution of the isomers formed was made with ether which was evaporated directly. Each residue when chromatographed gave only a zone of the all-*trans* form.

2. Isomerization by Melting.—A sealed tube containing several milligrams of diphenyloctatetraene was kept in a bath of boiling diphenyl ether (b. p. 259°) for fifteen minutes. After rapid cooling in ice-water the material was dissolved in cold benzene and diluted with light petroleum. The chromatogram showed two isomers below the main zone of unchanged starting material. A second adsorption of the lower zones revealed the presence of a strong zone of the all-*trans* isomer, formed during the operations (elution, filtration, washing, drying).

Similar results were obtained by heating diphenyloctatetraene in melted diphenyl at 140° for five hours.

3. Isomerization by iodine catalysis in benzene solution at 25° in the dark produced the zones 1–3 within fifteen minutes as demonstrated chromatographically.

4. Photochemical Isomerization.—A benzene solution containing 2 mg. of diphenyloctatetraene per ml. was divided into two parts. One part was kept in diffuse light at 25° while the other was irradiated for twelve hours with a mercury quartz lamp (4 amp. d. c., voltage drop 32 v.) in a quartz tube. A half ml. of the irradiated solution, chromatographed on a column (25 × 1.7 cm.), after suitable development showed the following zones from top to bottom (the figures on the left side denote width of zones, in mm.):

10 *zone 1* (all-*trans*), strongly fluorescing
5 dark interzone
20 *zone 2*, fluoresced more weakly than 1, contained much less material
5 dark interzone
2.5 *zone 3*, well defined, similar to 2 in fluorescence
2 dark interzone
2 *zones 4 and 5*, not well differentiated (traces), easily washed into the filtrate.

The non-irradiated portion showed a similar chromatogram but a much smaller fraction of the adsorbed material was contained in the zones 2–5 than after irradiation.

In another set of experiments the modifications *a* and *b* were made:

a. The irradiated solution was poured on a short column prepared in a Gooch funnel (8 × 4 cm.) which was attached to a side neck of a three-neck flask (1 liter). Three fluorescing layers were visible. The two lower zones were slowly washed into the flask with benzene-light petroleum (1:1). The flask was immersed in hot water; each drop of the filtrate was rapidly evaporated by a current of air under reduced pressure. The whole procedure was followed by an ultraviolet lamp in the dark. In this way a solid residue was obtained consisting of a mixture of all-*trans* diphenyloctatetraene and a preponderant quantity of its steroisomers. A subsequent chromatogram showed a narrow top zone 1 of the all-*trans* form while zone 2 was four times broader. It was followed by a smaller layer, all separated by non-fluorescing sections.

A portion of the solid mixture was investigated spectrophotometrically in benzene solution, immediately and after twenty-four hours of standing. It shows considerably decreased transmission, corresponding to the formation of more *trans*-isomer.

b. In other experiments the first portion of the chromatographic filtrate was rechromatographed and the two lowest isomers were washed through with pure benzene. The light absorption curve was determined immediately as well as after one, two and three days of standing at room temperature. The transmission decreased considerably in the course of the first day, less in the second day and thereafter it remained constant. An equilibrium had been reached in which the all-*trans* form was predominant (Fig. 1).

Summary

Ordinary (all-*trans*) 1,8-diphenyloctatetraene, $C_6H_5(CH{=}CH)_4C_6H_5$ when heated, irradiated or treated with iodine in benzene solution is partially converted into two main stereoisomers which can also be obtained by melting of crystals. These labile isomers are adsorbed below the unchanged, all-*trans* compound in the lime column. Their solution re-isomerize spontaneously at room temperature. This has been followed chromatographically and photometrically. A similar but

(13) A. L. LeRosen, *Ind. Eng. Chem., Anal. Ed.*, **14**, 165 (1942).

more rapid change occurs on irradiation of adsorbed material. The configurations *trans–cis–trans–trans* and *trans–cis–cis–trans* are suggested for the new isomers mentioned. As two minor isomers also appear, five out of the ten possible steric forms of diphenyloctatetraene have been observed. It is shown that the formation of substantial quantities of certain isomers is prevented by spatial conflicts.

Does the Parathyroid Hormone Influence Phosphatase Activity?

BY THOMAS R. WOOD AND WILLIAM F. ROSS

It is well established that serum phosphatase is markedly increased in rickets, hyperparathyroidism and other diseases characterized by lesions in the bones.[1,2,3] It has even been suggested that the action of phosphatases on organic phosphate compounds in bone "is the factor that controls the direction and intensity of calcification in bone."[3] This concept is supported by the increased serum phosphatase activity after parathyroid hormone injection,[4] and by similar changes in bone phosphatase of rats following injection of the hormone.[5,6]

The question arises, as to whether there is an *in vitro* influence of the parathyroid hormone on the activity of phosphatase. Such an effect, if reasonably pronounced, would afford a simple, economical, and rapid assay method for the hormone, which is sorely needed at the present time. Heymann[7] reported that glycerophosphatase and hexosediphosphatase of bone are inhibited by parathyroid extract, but Bakwin and Bodansky,[8] drew the opposite conclusion, that rat and cattle bone phosphatases are not affected. Both of the above studies involved the use of very small amounts of impure parathyroid preparations.

The effect of a very active parathyroid extract[9] on the hydrolysis of glycerophosphate by a kidney phosphatase preparation has therefore been investigated. The hormone concentrate had a nitrogen potency of 300 units per mg. of nitrogen, thus being three times as active as any preparation hitherto reported,[10] and many times more active than those used in the phosphatase studies referred to above.[7,8] At the same time experiments were carried out in which two other proteins, thrice-crystallized egg albumin and crystalline, carbohydrate-free horse serum albumin[11] were substituted for the hormone. Other conditions such as *p*H, temperature, and magnesium ion concentration were identical in all experiments.

The data obtained from these studies give the curves of Fig. 1. Under our conditions each of the three proteins has an activating effect upon phosphatase, and the parathyroid hormone is not unlike the other two substances in any respect. Characteristic of the curves is the tendency to approach a constant maximum, which is not followed by a subsequent decline in activity.

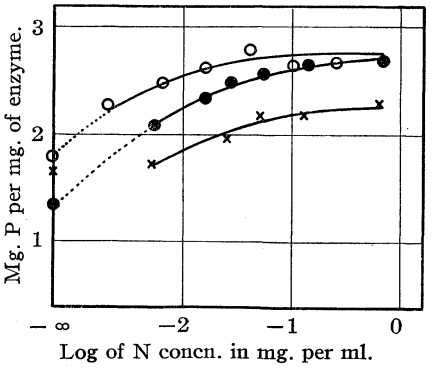

Fig. 1.—The *in vitro* effect of parathyroid hormone (O), horse serum albumin (●), and egg albumin (X) on phosphate liberation by kidney phosphatase.

This behavior of phosphatase recalls its activation by other nitrogen containing compounds, such as ammonia, amino acids and veronal. The activity in the presence of these substances, however, passes through a maximum and then decreases.

(11) McMeekin, THIS JOURNAL, **61**, 2884 (1939).

The published data for glycine[12,13] illustrate this quite satisfactorily, and we have obtained similar data for ammonia and veronal. On the basis of these results the nature of the activation by these simple organic compounds appears to differ from that caused by proteins, but the parathyroid hormone, even in the high concentrations employed (as much as 75 units per ml. of digest solution) has no individual and characteristic effect of its own.

Experimental

A concentrate of "alkaline" phosphatase was prepared from beef kidney cortex by the method of Albers and Albers.[14] The resulting solution was evaporated to dryness in the frozen state; such preparations are stable for months at 5°.

The digest solutions were 0.025 *M* in borate buffer of *p*H 9.75, 0.0005 *M* in magnesium chloride, and 0.015 *M* in sodium glycerophosphate (52% β); the enzyme was present in a concentration of 0.004%. The thoroughly dialyzed protein solutions were adjusted to *p*H 9.75 immediately before incorporation in the above mixture. The total volume was 10 ml.; hydrolysis was allowed to proceed at 30° for sixty minutes. The final values of *p*H were 9.55 ± 0.05 unit. Inorganic phosphate liberated during the digestion was estimated by the method of Fiske and Subbarow.[15] Control experiments in the presence of each of the three proteins demonstrated that no inorganic phosphate appeared if enzyme or substrate was omitted.

Summary

The parathyroid hormone, like two other typical proteins, egg and serum albumins, accelerates the liberation of phosphate by kidney phosphatase. It has no peculiar effect which can be attributed to its function as a hormone.

The Structure of Riddelliine, the Alkaloid in *Senecio Riddellii*. I

BY ROGER ADAMS, K. E. HAMLIN, JR., C. F. JELINEK AND R. F. PHILLIPS

The similarity of the alkaloids occurring in the plant genera *Senecio*, *Trichodesma*, *Heliotropium*, and *Crotalaria* has previously been discussed.[1] As was pointed out, these alkaloids are esters which on alkaline hydrolysis yield an acid and an alkanolamine, retronecine or some other closely related bicyclic base.

As a result of investigations on the alkaloid Riddelliine, obtained by ethanolic extraction of *Senecio Riddellii*, it can be stated that this compound possesses the properties characteristic of the group. Riddelliine was first isolated from the plant by Manske,[2] who reported a molecular formula of $C_{18}H_{23}O_6N$. His directions for extraction and isolation were followed and as a result of analytical data on the pure riddelliine, its hydrochloride and methiodide, Manske's formula was confirmed. Hydrolysis of riddelliine indicated that this alkaloid was typical of the *Senecio* group. Alkaline cleavage yielded a basic product, which proved to be retronecine, and a crystalline acid, $C_{10}H_{14}O_6$, designated as riddellic acid.

$$C_{18}H_{23}O_6N + 2H_2O \xrightarrow{Ba(OH)_2} C_8H_{13}O_2N + C_{10}H_{14}O_6$$

(1) Adams and Rogers, THIS JOURNAL, **61**, 2815 (1939).
(2) Manske, *Can. J. Res.*, **B17**, 1 (1939).

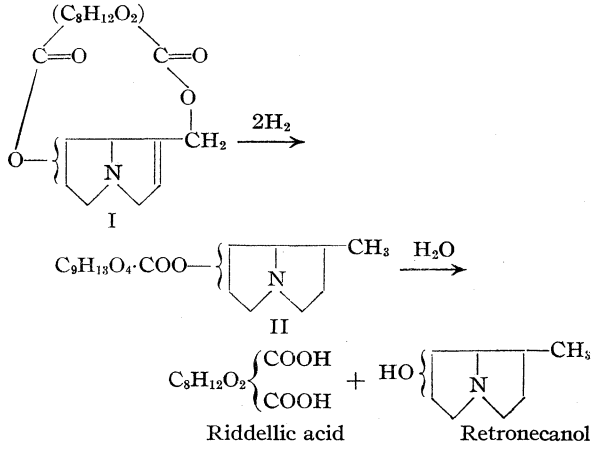
From the above equation it is to be noted that in common with most of the other *Senecio* alkaloids, water enters into the reaction with no loss of carbon dioxide and that the acid product contains ten carbon atoms. The retronecine, which was isolated in a nearly quantitative yield, was identified by comparison with an authentic sample.

Riddellic acid was obtained in both an anhydrous and hydrated form. It is optically active and is shown by direct titration to be dibasic. However, by addition of excess alkali and back titration, evidence for a third carboxyl was found which indicates the probability of the presence of a lactone linkage. The acid formed a dimethyl ester on treatment with diazomethane. Molecular weight determinations in dioxane and benzene indicate that dimethyl riddellate is a monomer, although in the latter solvent apparently one molecule of benzene associates with a molecule of solute. Preliminary hydrogenation experiments show that with a platinum oxide catalyst, two moles of hydrogen are absorbed to give a product which as yet has not been obtained in a pure state. Significantly, when the dimethyl ester of riddellic acid was hydrogenated with platinum oxide, only

one mole equivalent of hydrogen was absorbed to give a nearly quantitative yield of dimethyl dihydroriddellate.

On alkaloids analogous to riddelliine catalytic hydrogenation has also been employed as a degradative procedure. In the case of monocrotaline,[1] hydrogenolysis takes place upon absorption of one molecule of hydrogen followed by absorption of a second molecule and the reduction of the double bond in the basic portion of the molecule. Thus, monocrotalic acid and retronecanol are isolated.

Reduction of riddelliine using Raney nickel resulted in the absorption of two molecules of hydrogen. A single product was isolated in excellent yield, which indicated that no cleavage had occurred. This tetrahydroriddelliine (II), ($C_{18}H_{27}O_6N$), is optically active and possesses the physical properties of an amino acid. Hydrolysis by means of barium hydroxide yielded an acid identical with riddellic acid and a base identified as retronecanol. On the basis of this evidence riddelliine exists as a cyclic diester (I), one molecule of the dibasic riddellic acid being linked to the two hydroxyls of a molecule of retronecine. Thus it is an alkaloid similar in general structure to grantianine.[3] The first molecule of hydrogen apparently attacks the labile ester linkage and the second reduces the double bond of the basic moiety. Using the formulas recently proposed for retronecine and retronecanol,[4] the following equations may be written



If hydrogenation is carried out using a platinum oxide catalyst, somewhat different results are obtained. In this case, four mole equivalents of hydrogen are rapidly absorbed. The octahydroriddelliine has not yet been obtained in a pure state. However, alkaline hydrolysis of the crude reduction product has yielded an acid and the base retronecanol. Although the acid has not been purified, the additional two moles of hydrogen must have reacted with the acid portion of the molecule, a fact which agrees with the hydrogenation experiment on riddellic acid itself.

Experimental

Extraction of Riddelliine from *Senecio Riddellii*.—About 1.41 kg. of dried, finely ground *Senecio Riddellii* (entire plant) was extracted by percolation with 95% ethanol over a forty-eight hour period. Most of the solvent was removed *in vacuo* and the concentrate was poured into a large evaporating dish. After acidification to congo red with citric acid, the extract was mixed with water to precipitate the resins and the remaining ethanol was boiled off over a steam-cone. The mixture was then allowed to stand at room temperature overnight to permit caking of the resinous material. The solution was decanted from the resin and extracted with successive portions of ether until the ether extracts were colorless, then with two 50-cc. portions of chloroform. The aqueous solution was now made alkaline to litmus with aqueous ammonia and extracted with successive portions of chloroform until evaporation of the extract left no residue. After distilling off the solvent, 11.3 g. of crude, crystalline riddelliine was obtained. Recrystallization from absolute ethanol yielded 6.4 g. (0.45%) of product, m. p. 193–195° (cor.) with decomposition in an evacuated tube. It was noted that for several experiments, the yield of pure alkaloid varied from 0 to 0.70% depending on the plant material. Further purification from absolute ethanol produced white prisms, m. p. 197–198° (cor.) with decomposition in an evacuated tube.

Anal. Calcd. for $C_{18}H_{23}O_6N$: C, 61.92; H, 6.64; N, 4.01. Found: C, 61.87; H, 6.69; N, 4.00.

Rotation. 0.0889 g. made up to 5 cc. with chloroform at 25° gave α_D −3.90; *l*, 1; $[\alpha]^{25}D$ −109.5°.

These results are in satisfactory agreement with the work of Manske[2] who has reported 196° (cor.) as the melting point of the alkaloid and an analysis corresponding to the formula, $C_{18}H_{23}O_6N$.

Riddelliine Hydrochloride.—A solution of 0.5 g. of riddelliine in a slight excess of 0.1 *N* hydrochloric acid was evaporated under reduced pressure with gentle heating on the water-bath. The residue was recrystallized from absolute ethanol, m. p. 225–226° (cor.) with decomposition in an evacuated tube.

Anal. Calcd. for $C_{18}H_{24}O_6NCl$: C, 56.03; H, 6.27; N, 3.63. Found: C, 55.86; H, 6.40; N, 3.62.

Rotation. 0.0900 g. made up to 5 cc. with water at 25° gave α_D −1.45; *l*, 1; $[\alpha]^{25}D$ −80.6°.

Riddelliine Methiodide.—To a solution of 1 g. of riddelliine in 4 cc. of chloroform and 3 cc. of methanol was added 1.5 cc. of methyl iodide. After warming a few minutes, the mixture was cooled and filtered; yield 1.2 g. After recrystallization from water, the methiodide melts with decomposition at 260–262° (cor.) after beginning to

darken at 235°. Manske[2] has reported the melting point of riddelliine methiodide to be 259° (cor.) with decomposition.

Anal. Calcd. for $C_{19}H_{26}O_6NI$: C, 46.44; H, 5.29; N, 2.85. Found: C, 46.67; H, 5.55; N, 2.82.

Alkaline Hydrolysis of Riddelliine

A. Riddellic Acid ($C_{10}H_{14}O_6$).—A mixture of 5 g. of riddelliine, 10 g. of barium hydroxide octahydrate and 70 cc. of water was heated under reflux for one hour and cooled. The solution was saturated with carbon dioxide and the precipitated barium carbonate filtered off. After acidification to congo with hydrochloric acid, the solution was extracted continuously with ether for seventy-two hours. The ether extract, which contained an appreciable aqueous layer, was evaporated to dryness *in vacuo*. The residue was a viscous orange glass which began to crystallize after standing in a vacuum desiccator at refrigerator temperature. After recrystallization from ether-petroleum ether (b. p. 30–60°), the product was obtained as colorless needles, m. p. 62° (cor.); yield, 3.02 g. (85%).

Anal. Calcd. for $C_{10}H_{14}O_6 \cdot H_2O$: C, 48.40; H, 6.50. Found: C, 48.52; H, 6.63.

Rotation. 0.2038 g. made up to 5 cc. with absolute ethanol at 31° gave α_D −0.08; *l*, 1; $[\alpha]^{31}D$ −1.96°.

The anhydrous form of riddellic acid resulted if the ether extracts were withdrawn periodically from the continuous extraction, were dried over anhydrous magnesium sulfate and the ether removed *in vacuo*. Also the monohydrate was converted readily into anhydrous riddellic acid by boiling with benzene or by fractional crystallization from ether–petroleum ether. Recrystallization from ether–petroleum ether gave colorless prisms, m. p. 102–103° (cor.).

Anal. Calcd. for $C_{10}H_{14}O_6$: C, 52.17; H, 6.08. Found: C, 52.11; H, 6.21.

Rotation. 0.2644 g. made up to 5 cc. with absolute ethanol at 32° gave α_D −0.14; *l*, 1; $[\alpha]^{32}D$ −2.65°.

The neutral equivalents for both the hydrated and anhydrous forms of riddellic acid always ran about 5% high for a dibasic acid. However, the values for the hydrate checked satisfactorily those for the anhydrous form.

Hydrogenation of Riddellic Acid (PtO_2 Catalyst).—A solution of 1 g. of riddellic acid monohydrate in 25 cc. of absolute ethanol was hydrogenated at 2–3 atmospheres pressure using 0.05 g. of platinum oxide. Within fifteen minutes, hydrogenation was complete, a total of two mole equivalents being absorbed. After filtering the catalyst and removing the solvent *in vacuo*, a reddish glass remained. This product has not been obtained in a pure state.

Dimethyl Riddellate.—A suspension of 5 g. of riddellic acid monohydrate in 30 cc. of chloroform was treated with an excess of an ethereal solution of diazomethane. During the addition of the diazomethane, the mixture was shaken continuously and the temperature maintained below 10°. The solvents were distilled *in vacuo* leaving a yellow oil which readily distilled at 144–145° (1 mm.); yield, 5.10 g. (98%). This product was redistilled at 0.075 mm. to yield a pale yellow, viscous oil; d^{20}_4 1.171; $n^{20}D$ 1.4870.

Anal. Calcd. for $C_{12}H_{18}O_6$: C, 55.80; H, 7.03. Found: C, 55.96; H, 6.86.

Rotation. 0.4931 g. made up to 5 cc. with absolute ethanol at 32° gave α_D −0.28; *l*, 1; $[\alpha]^{32}D$ −2.84°.

Molecular weight determinations by the cryoscopic method in dioxane gave a value of 265; theoretical for dimethyl riddellate is 258. Using benzene as the solvent, a value of 340 was obtained. Assuming a molecule of benzene to be associated, the actual molecular weight would be 262.

Dimethyl Dihydroriddellate.—A solution of 5.1 g. of dimethyl riddellate in 50 cc. of absolute ethanol was hydrogenated at 2–3 atmospheres pressure using 0.1 g. of platinum oxide catalyst. Exactly one mole equivalent of hydrogen was absorbed within one hour and although shaking was continued one-half hour no additional hydrogenation occurred. The catalyst was filtered and the solvent removed *in vacuo*. The pale yellow oil remaining was distilled, b. p. 146–147° (1 mm.). The product was a colorless viscous oil; yield 5.0 g. (97%); $n^{20}D$ 1.4682; d^{20}_4 1.153.

Anal. Calcd. for $C_{12}H_{20}O_6$: C, 55.37; H, 7.75. Found: C, 55.37; H, 7.84.

Rotation. 0.4577 g. made up to 5 cc. with absolute ethanol at 32° gave α_D −1.40; *l*, 1; $[\alpha]^{32}D$ −15.3°.

B. Retronecine Hydrochloride.—The aqueous solution, remaining after ether extraction of the riddellic acid, was evaporated *in vacuo* to dryness. The crystalline residue was extracted with boiling absolute ethanol and the extracts concentrated. The crystalline product after recrystallization from absolute ethanol melted at 160–161° (cor.). A mixed melting point with an authentic sample of retronecine hydrochloride showed no depression; yield, 2 5 g. (91%).

Tetrahydroriddelliine.—A solution of 5 g. of riddelliine in 150 cc. of ethanol and 25 cc. of water[5] was hydrogenated at 2–3 atmospheres in the presence of 3 g. of Raney nickel. After three hours, two mole equivalents of hydrogen had been absorbed and the reduction was complete. The catalyst was filtered off and the solvent removed *in vacuo*. A white crystalline solid remained which was purified by dissolving in a little hot glacial acetic acid and adding absolute ethanol until the solution became cloudy. White microscopic prisms were obtained, m. p. 205° (cor.) with decomposition; yield 4.4 g. (87%).

Anal. Calcd. for $C_{18}H_{27}O_6N$: C, 61.17; H, 7.70; N, 3.96. Found: C, 60.75; H, 7.55; N, 4.05.

Rotation. 0.0944 g. made up to 5 cc. with absolute ethanol at 31° gave α_D −0.18; *l*, 1; $[\alpha]^{31}D$ −9.5°.

Tetrahydroriddelliine is fairly soluble in water, easily soluble in glacial acetic acid but practically insoluble in ethanol.

When first prepared by hydrogenation of riddelliine in absolute ethanol, the tetrahydroriddelliine was an amorphous solid, very hygroscopic and easily soluble in ethanol. However, after once obtaining the crystalline product, the original experiment could not be duplicated.

Alkaline Hydrolysis of Tetrahydroriddelliine

A. Riddellic Acid.—A mixture of 1 g. of tetrahydroriddelliine, 2 g. of barium hydroxide octahydrate and 15 cc. of water was refluxed for one hour and cooled. After

(5) It is necessary to have sufficient water present to dissolve the tetrahydroriddelliine formed during the reaction. If this precaution is not taken the precipitate formed inactivates the catalyst thus stopping hydrogenation.

saturating with carbon dioxide, the solution was filtered and made acid to congo. Continuous ether extraction for twenty-four hours and removal of the solvent *in vacuo*, yielded an oil which crystallized after seeding with riddellic acid. Recrystallization from ether–petroleum ether (b. p. 30–60°) gave 0.35 g. of a white crystalline solid melting at 61–62° (cor.). A mixed melting point with riddellic acid monohydrate (m. p. 62°) gave no depression.

B. Retronecanol.—The aqueous solution remaining after ether extraction of the acid just described was made alkaline with 10% aqueous sodium hydroxide and extracted with ether. After drying the ether extracts over anhydrous magnesium sulfate and distilling the ether, a solid remained. This product, recrystallized from petroleum ether (b. p. 30–60°), melted at 95–96° (cor.) which is identical with the melting point of retronecanol.

A picrate was prepared from water which melted at 211° with decomposition. A mixed melting point with retronecanol picrate (m. p. 211°) showed no depression.

Hydrogenation of Riddelliine (PtO_2 Catalyst).—A solution of 5 g. of riddelliine in 150 cc. of ethanol and 25 cc. of water was hydrogenated at 2–3 atmospheres pressure using 0.1 g. of platinum oxide catalyst. A total of four mole equivalents of hydrogen was absorbed within one hour. The catalyst was filtered off and the solvent removed *in vacuo*. A white amorphous solid material remained which was very hygroscopic and soluble in ethanol. Attempts to obtain a crystalline product failed.

One gram of this material was taken up in 5 cc. of water and 10 cc. of 50% aqueous sodium hydroxide added. After refluxing one hour and cooling, the mixture was extracted with ether. The ether extract was dried over anhydrous magnesium sulfate and the ether distilled. A solid product remained which after one recrystallization from petroleum ether melted at 95–96°. Retronecanol melts at 95–96°. A picrate of the above base was prepared in ethanol and melted at 213°. A mixed melting point with authentic retronecanol picrate showed no depression.

Acidification and continuous ether extraction of the aqueous solution remaining after removal of the retronecanol yielded an acid fraction as a brown viscous oil. This has not been obtained in a pure state.

Summary

1. Riddelliine, the alkaloid of *Senecio Riddellii*, has been isolated and shown to have the molecular formula reported by Manske, $C_{18}H_{23}O_6N$.

2. Upon saponification, riddelliine gives a molecule of retronecine and one molecule of a crystalline acid, $C_{10}H_{14}O_6$, designated as riddellic acid. It is dibasic and with diazomethane gives a dimethyl ester.

3. Riddellic acid, upon reduction with hydrogen and platinum oxide, absorbs two moles of hydrogen but no pure product was isolated. Dimethyl riddellate under similar conditions absorbs only one mole of hydrogen to give dimethyl dihydroriddellate.

4. Riddelliine, upon reduction with hydrogen and Raney nickel, absorbs two moles of hydrogen to form tetrahydroriddelliine which has the properties of an amino acid and can be hydrolyzed to retronecanol and riddellic acid. With platinum oxide as a catalyst, four moles of hydrogen are absorbed but the product has not been obtained in a pure state. On saponification the crude octahydroriddelliine yields retronecanol.

5. Riddelliine is thus shown to be an ester from one mole of the dibasic acid, riddellic acid, and one mole of retronecine, each of the two hydroxyls in the molecule being utilized.

Sulfanilamide Derivatives. VIII. Sulfanilylamidines[1]

BY E. H. NORTHEY, ALAN E. PIERCE AND D. J. KERTESZ

In view of the fact that most of the recently developed chemotherapeutic agents of high potency, including sulfapyridine, sulfathiazole and sulfadiazine, have the structure of sulfanilyl cyclic amidines, 4-$(NH_2)C_6H_4SO_2NHC(=N-)$ it was thought desirable to prepare an analogous series of amidine derivatives of the type 4-(NH_2)-$C_6H_4SO_2NHC(R)=NR'$. A number of such compounds have been made, however, the structure appears to be better represented by the formula 4-$(NH_2)C_6H_4SO_2N=C(R)NHR'$, because the monosulfanilylamidines did not form alkali salts corresponding to the well known sodium salts of the above sulfanilamido heterocycles. This would indicate lack of ionizable hydrogen associated with the amide nitrogen. Also, while sulfapyridine is stable to alkaline hydrolysis and is cleaved by mineral acids to sulfanilic acid and 2-aminopyridine,[2] the sulfanilylamidines are cleaved to sulfanilamide by either

acid or alkaline hydrolysis, indicating a different type of linkage between amide nitrogen and carbon.

Further information on structure was given by synthesis from the corresponding imido chloride, —SO_2N=C(R)Cl, by reaction with secondary amines giving compounds of the type, —SO_2N=C(R)N(R′)R″, where the possibility of tautomerism was eliminated.

As by-products in the reaction of unsubstituted amidines with sulfonyl chlorides, we isolated disulfonyl derivatives of the probable structure —SO_2N=C(R)NHSO_2—, which formed neutral alkali salts with one equivalent of base.

Preliminary pharmacological tests[3] showed low chemotherapeutic activities for all of the compounds with the possible exception of sulfanilylacetamidine which was approximately equal to sulfanilamide.

After the work here reported was completed, two patents[4,5] came to our attention. However, the preparation of disulfanilylamidines was not described in these references.

In preliminary work, acetylsulfanilylacetamidine was prepared from acetylsulfanilyl chloride and acetamidine, but it was not found possible to hydrolyze this product to sulfanilylacetamidine. Hence, this method of preparation was abandoned in favor of the preparation of nitrobenzene sulfonylamidines as intermediates. These were prepared in two ways. Amidine hydrochlorides, where readily available, were treated in acetone with *p*-nitrobenzenesulfonyl chloride, in the presence of excess sodium hydroxide. Both mono- and *bis*-nitrobenzenesulfonylamidines were formed in this reaction, the proportion varying with the amount of *p*-nitrobenzenesulfonyl chloride used in excess. The two types of products were easily separated, since only the latter were soluble in alkali. The first eight compounds in Table I were prepared through the use of this procedure. The second method involved the preparation of aromatic or heterocyclic N-acyl-*p*-nitrobenzenesulfonamides from the acid chloride and *p*-nitrobenzenesulfonamide in dry pyridine. The acyl sulfonamides were treated with phosphorus pentachloride to yield the corresponding imido chlorides which with ammonia or amines were converted to amidines. This method, as applied to N-benzoylbenzenesulfonamide, has been previously described[6,7,8] and was used for the preparation of the last four compounds listed in Table I.

All nitro compounds were reduced with iron to give the corresponding sulfanilylamidines, which were obtained as white microcrystalline substances upon purification by crystallization from alcohol or precipitation from acid or alkaline solution.

Experimental

N^4-Acetylsulfanilylacetamidine.—To 9.5 g. of acetamidine hydrochloride and 19.5 g. of 50% sodium hydroxide solution in 75 cc. of acetone, was added 25.2 g. of 95% acetylsulfanilyl chloride in portions, with vigorous stirring, over twenty minutes, at 10–20°. Cooling was necessary. After further stirring for twenty minutes, the slurry was diluted with 2 volumes of cold water, filtered, and the solid washed and dried. The yield of acetylsulfanilylacetamidine was 16.0 g., or 62.5%. A small sample recrystallized from hot water melted at 244.2 to 244.7° (all m. p.'s corrected).

Anal. Calcd. for $C_{10}H_{13}N_3O_3S$: C, 47.0; H, 5.1; N, 16.5; S, 12.6. Found: C, 47.0; H, 4.5; N, 16.8; S, 12.5.

Hydrolysis of acetylsulfanilylacetamidine was carried out in six moles of 7.5 *M* hydrochloric acid at 60°. Solu-

tion was complete in two and three-fourths hours, but hydrolysis of the acetyl group was not complete, as determined by titration with sodium nitrite, until the end of three and one-half hours, when heating was stopped. Sulfanilamide was isolated in 90% yield. No sulfanilylacetamidine was identified.

p-Nitrobenzenesulfonylamidines from Amidines.—The procedure given above for acetylsulfanilylacetamidine was followed using a 5–10% excess of *p*-nitrobenzenesulfonyl chloride instead of acetylsulfanilyl chloride. In the alkaline filtrate from the mono-nitrobenzenesulfonylamidines, the *bis*-nitrobenzenesulfonylamidines were precipitated by acidification with hydrochloric acid. The yields ranged from 40–80% for the monosubstituted amidines and 20 to 35% for the disubstituted derivatives.

p-Nitrobenzenesulfonylamidines from Imido Chloride.—This method is illustrated by the preparation of *p*-nitrobenzenesulfonylnicotinamidine. 76.8 g. of N^1-nicotinyl-*p*-nitrobenzenesulfonamide[9] was mixed with 57 g. of phosphorus pentachloride and 100 cc. of phosphorus oxychloride, then heated at 80–85° for five hours. The excess phosphorus oxychloride was removed by distillation at reduced pressure and by washing the residue with petroleum ether. The imido chloride was added with stirring to 300 cc. of 15% aqueous ammonia. The *p*-nitrobenzenesulfonylnicotinamidine was filtered off, in 44% yield, and the corresponding amide was recovered, in 50% yield, by acidification of the filtrate.

The preparation of N^1-substituted *p*-nitrobenzenesulfonylbenzamidines was analogous. Aqueous methylamine and an acetone solution of diethylamine or 2-aminopyridine was used instead of ammonia for reaction with the imido chloride.

Reduction of Nitro Compounds.—All the nitro compounds were reduced with iron. The procedure for preparation of sulfanilylbenzamidine is illustrative. A mixture of 84 g. of finely divided iron and 19 cc. of 5 *N* hydrochloric acid in 500 cc. of water was stirred at 95–100°. The mixture was alkaline to congo red. To the slurry was added 91.5 g. of *p*-nitrobenzenesulfonylbenzamidine. There was slight heat evolution, and the color of the insoluble substance changed from yellow to gray. After two hours of stirring at a temperature near the boiling point the mixture was made just alkaline with sodium carbonate solution, cooled and filtered. The dried iron sludge was extracted with 3A alcohol, which on evaporation yielded 73 g. of crude product. This was purified by crystallization from glacial acetic acid and from 3A alcohol, using decolorizing carbon; 35 g. of pure sulfanilylbenzamidine was obtained.

The disulfanilyl compounds were dissolved by the sodium carbonate addition, and were obtained by making the filtrate slightly acid. The other sulfanilylamidines were practically insoluble in hot water, except sulfanilylacetamidine.

The products were purified by reprecipitation from acid or alkaline solution, by crystallization from 60–95% ethyl alcohol or acetic acid, or by both methods.

Hydrolysis of Sulfanilylacetamidine.—Sulfanilylacetamidine (1.066 g., 0.005 mole) was distilled in a Kjeldahl distillation apparatus with 100 cc. of 0.25 *N* sodium hydroxide, catching the ammoniacal distillate in standard acid. During forty-five minutes, the still solution was evaporated to 15–25 cc., and 0.00496 mole of ammonia was distilled. The contents of the still were filtered and neutralized to *p*H 9; the white precipitate obtained was filtered off, washed, and dried. The product weighed 0.66 g. and was identified as sulfanilamide by m. p. and mixed m. p. with an authentic sample.

Sulfanilylacetamidine (1.066 g., 0.005 mole) was gently boiled for half an hour with 60 cc. of 2 *N* hydrochloric acid. The solution was made strongly alkaline and distilled as described in the preceding paragraph. The titer of the distillate corresponded to an evolution of 0.00498 mole of ammonia. No sulfanilic acid was detected in the still contents. The acid hydrolysis was repeated on another 1.066-g. sample of sulfanilylacetamidine. The resulting solution was concentrated and neutralized. The solid which precipitated was recrystallized from hot water and dried. The white crystalline product weighed 0.63 g. and was identified as sulfanilamide, as previously described.

Summary

1. A series of sulfanilylamidines of the structure 4-$(NH_2)C_6H_4SO_2N{=}C(R)N(R')R''$ were prepared, where R was alkyl, aryl, aralkyl or heterocyclic, and R′ and R″ were hydrogen, alkyl or heterocyclic. None of these compounds formed sodium salts.

2. As by-products in some preparations disulfanilylamidines were isolated having the probable structure, 4-$(NH_2)C_6H_4SO_2N{=}C(R)NHSO_2C_6H_4$-$(NH_2)$-(4)′. These formed neutral sodium salts.

3. None of the compounds was more active than sulfanilamide in preliminary chemotherapeutic studies.

Ionization and Dissociation by Electron Impact: Normal Propyl Chloride and Tertiary Butyl Chloride

BY D. P. STEVENSON[1,2] AND JOHN A. HIPPLE

In an effort to gain further insight into the unimolecular dissociation reactions of hydrocarbons and related molecules which follow ionization by electron impact, we undertook a mass-spectroscopic investigation of some alkyl halides. Due to circumstances beyond our control, the research was terminated with the work on *n*-propyl and *t*-butyl chlorides only partially completed. Since the data which have been acquired seem of interest, we report them herewith.

The apparatus and technique have been briefly described in an earlier paper.[3] The *n*-propyl and *t*-butyl chlorides were Eastman Kodak Co. white label compounds, used without further purification. The electrons were obtained from the same oxide-coated platinum filament used in the preceding work.[3] This pair of halides very markedly decreased the activity of the filament. When the vapors were removed from the tube the filament regained its original activity. A similar, but less pronounced, effect had been noted with the unsaturated hydrocarbons, propylene and isobutylene. The latter, however, left the voltage scale calibration (correction for contact potentials) unchanged. The propyl chloride decreased the correction, as determined from the ionization efficiency curve of argon, by a little over one volt. This effect provides full justification for the extra effort involved in admitting the calibration gas, argon, simultaneously with the substance under investigation.

The relative intensities of the principal ions in the mass spectrum of *t*-butyl chloride are given in Table I for some round values of the bombarding electron energy. Due to the almost immeasurably small current of the parent ion, $C_4H_9Cl^+$, the principal ion in the spectrum, $C_4H_9^+$, has been used as the reference standard. The complete lack of stability of the *t*-butyl chloride ion was both surprising and irritating. It precluded the measurement of the appearance potential of this ion and thus the vertical ionization potential of the molecule.

It will be noted that even though the breaking of a carbon–carbon bond (loss of a methyl radical) is favored by the greater number of such bonds,[3] the molecular ion has a greater tendency to lose a chlorine atom. Similarly, the isobutane molecular ion loses a methyl radical more readily than a hydrogen atom,[3] despite the greater number of C–H than C–C bonds. These reaction probabilities of the molecular ions are apparently directly related to the strength of the bond that breaks since in the order of their decreasing strength the bonds are C–H, C–C, and C–Cl.

One of the more characteristic reactions of propane and the butanes is the one giving rise to a lower olefinic ion and methane, ethane or hydrogen. By analogy one would expect the reactions

$$\text{(a)}\quad t\text{-BuCl} \longrightarrow C_3H_5Cl^+ + CH_4 + \epsilon^-$$
$$\text{(b)}\quad t\text{-BuCl} \longrightarrow C_3H_6^+ + CH_3Cl + \epsilon^-$$

to contribute to the spectrum of *t*-butyl chloride to a much greater extent than is observed. As in the isobutane spectrum, the relative abundance of the allene (or methylacetylene) ion, $C_3H_4^+$ is much smaller than those of the ions $C_3H_5^+$ and $C_3H_3^+$, and the ethylene (or ethylidene) ion is less abundant than $C_2H_5^+$ and $C_2H_3^+$.

The mass spectrum of normal propyl chloride, given in Table II, presents a marked contrast to that of tertiary butyl chloride. In the first place, the parent ion, $C_3H_7Cl^+$, is present in quite large abundance. Because of the apparent similarity of the dissociation reactions involved, one would expect $C_3H_7^+$ to be much more abundant than $C_3H_6^+$, since the current of $C_4H_9^+$ from *t*-butyl chloride is about twelve times as great as that of $C_4H_8^+$. That our expectation is not fulfilled is the more surprising when it is noted that the relative abundances of $C_2H_5^+$, $C_2H_4^+$ and $C_2H_3^+$ have the same pattern in both chlorides.

Although their relative abundances are not very large, it is to be noted that both $C_2H_5Cl^+$ and CH_3Cl^+ are present in the spectrum of the propyl chloride. Although methane and ethane are formed in the dissociation of the butane ions, careful search failed to reveal any trace of the ions CH_4^+ or $C_2H_6^+$ in the spectra.[3] It is conceivable

that the $C_2H_5Cl^+$ and CH_3Cl^+ are present in the spectrum of C_3H_7Cl because of ethyl and methyl chloride impurities. For this to be the case one would expect the relative abundances to be in the reverse order, *i. e.*, $C_2H_5Cl^+ > CH_3Cl^+$, rather than the observed $C_2H_5Cl^+ < CH_3Cl^+$.

The appearance potentials, which were determined from the "initial breaks"[3] of the ionization efficiency curves are listed in Table III. When two values are noted, the second refers to the position of a marked inflection in the ionization efficiency curve. The ionization potential of argon was taken equal to 15.76 e. v.[4] for calibration purposes.

TABLE III

APPEARANCE POTENTIALS IN THE *t*-BuCl AND *n*-PrCl SPECTRA

	Process	$A(X^+)$
t-C_4H_9Cl	$\longrightarrow C_3H_6Cl^+ + CH_3 + \epsilon^-$	$10.7_7 \pm 0.1$ e.v.
	$\longrightarrow C_4H_9^+ + \epsilon^- + Cl$	$10.2_7 \pm 0.2$; 18.5 ± 1
	$\longrightarrow C_3H_5^+ + \ldots + \epsilon^-$	$12.4_1 \pm 0.2$; 16.0 ± 1
	$\longrightarrow C_3H_3^+ + \ldots + \epsilon^-$	16.1 ± 1
n-C_3H_7Cl	$\longrightarrow C_3H_7Cl^+ + \epsilon^-$	10.7 ± 0.2 e. v.
	$\longrightarrow C_2H_4Cl^+ + CH_3 + \epsilon^-$	12.0 ± 0.3 e. v.
	$\longrightarrow C_3H_7^+ + Cl + \epsilon^-$	11.1 ± 0.3 e. v.

(4) R. F. Bacher and S. Goudsmit, "Atomic Energy States," McGraw-Hill Book Co., New York, N. Y., 1932. See footnote to Table I of the preceding paper on isobutylene, etc.

The value $A(C_3H_7Cl^+) = 10.7$ e. v. in the *n*-C_3H_7Cl spectrum is to be associated with the vertical ionization potential of this molecule. The vertical ionization potential of *t*-butyl chloride must be less than the appearance potential of the ion $C_4H_9^+$ in its spectrum, that is, I_{vert}-(*t*-BuCl) < 10.2 e. v. These values stand in contradiction to the suggestion made by Price[5] that there should be no further reduction in the ionization potentials of the alkyl chlorides beyond that found in going from methyl chloride to ethyl chloride. In the light of the large decrease in the vertical ionization potential in the sequence ethane, propane, butane (11.6, 11.0, 10.2, respectively[3]), the results on the propyl and butyl chlorides are not entirely surprising.

By use of the rules formulated by Kistiakowsky and co-workers[6] in combination with the data summarized by Rossini[7] one can estimate the heat of the reaction *n*-C_4H_{10} + HCl = *n*-C_3H_7Cl + CH_4, to be $\Delta H^\circ_{298.1} = 0.15 \pm 0.05$ e. v. From Table III we have *n*-$C_3H_7Cl \rightarrow$ *n*-$C_3H_7^+ + Cl +$

(5) W. C. Price, *J. Chem. Phys.*, **4**, 539, 547 (1936).

(6) J. B. Conn, G. B. Kistiakowsky and E. A. Smith, THIS JOURNAL, **60**, 2764 (1938).

(7) F. D. Rossini, *Chem. Rev.*, **27**, 1 (1940).

ϵ^-, $A(C_3H_7^+) = 11.1$ and from earlier work,[3] $n\text{-}C_4H_{10} \rightarrow n\text{-}C_3H_7^+ + CH_3 + \epsilon^-$, $A(C_3H_7)^+ = 11.2_1$. Herzberg[8] gives 4.43 e. v. for the dissociation energy of HCl. Combining these data with the assumptions described elsewhere,[9] we find $4.4_2 \pm 0.2$ e. v. for the strength of the first carbon–hydrogen bond in methane. The excellence of the agreement of this estimate of $D(CH_3\text{–}H)$ with that made from other similar pairs of appearance potentials, $4.3_8 \pm 0.2$ e. v., provides further justification for an assumption there made, namely, that in the reaction $C_3H_8 \rightarrow C_3H_7^+ + H + \epsilon^-$, the $C_3H_7^+$ is the isopropyl rather than the normal propyl ion.

If the value of $A(C_4H_9^+)$ in the *t*-BuCl spectrum is combined with that of the same ion in the isobutane spectrum and the heats of formation of isobutane[7] and tertiary butyl chloride,[10] one finds 3.7 e. v. for the dissociation energy of HCl. This value is 0.7 e. v. lower than the accurate value quoted above.[8] In making this estimate, we have assumed that the $C_4H_9^+$ in the isobutane spectrum has the tertiary structure. If the appearance potential $A(C_4H_9^+) = 11.6 \pm 0.3$ e. v.[3] corresponds to the formation of the isobutyl ion from isobutane, the calculated value of the dissociation energy of HCl would be too low by an amount equal to the energy of the isomerization process, $i\text{-}C_4H_9^+ \rightarrow t\text{-}C_4H_9^+$. Since this latter quantity is probably of the order of 0.4 e. v., the assumption that isobutane yields the isobutyl ion would explain most of the discrepancy. The determination of the appearance potential of $C_4H_9^+$ in the isobutyl chloride spectrum would make possible a decision as to whether or not the explanation of the discrepancy is the correct one.

The reaction giving rise to $C_3H_5^+$ in the spectrum of *t*-BuCl may be either of the following pair

$$t\text{-}C_4H_9Cl \longrightarrow \begin{cases} C_3H_5^+ + CH_3 + HCl + \epsilon^- \\ C_3H_5^+ + CH_4 + Cl + \epsilon^- \end{cases}$$

since the two pairs of un-ionized fragments are of very nearly the same energy. The following simple calculation shows the observed value of $A(C_3H_5^+)$ to be consistent with either of the reactions. From reference 10 we have

$$i\text{-}C_4H_8 + HCl = t\text{-}C_4H_9Cl \quad \Delta H^\circ_{298} = -0.73 \text{ e. v.}$$

while

$$i\text{-}C_4H_8 = C_3H_5^+ + CH_3 + \epsilon^- \quad A(C_3H_5^+) = 11.5_1 \text{ e. v.}^{11}$$

Adding, we find, $t\text{-}C_4H_9Cl \rightarrow C_3H_5^+ + CH_3 + HCl + \epsilon^-$, $A_{\text{calcd.}}(C_3H_5^+) = 12.2_5$ e. v. in excellent agreement with the observed value. Since $D(CH_3\text{—}H)$ and $D(H\text{—}Cl)$ are equal to within 0.1 e. v., the products could also be CH_4 and Cl. A possible reaction which can be eliminated is

$$t\text{-}C_4H_9Cl \longrightarrow C_3H_5^+ + CH_3Cl + H + \epsilon^-$$

From the data given by Bichowsky and Rossini[12] one finds $CH_4 + HCl = CH_3Cl + H$, $\Delta H^\circ_{291} = 0.91$ e. v. Thus $A_{\text{calcd.}}(C_3H_5^+)$ for the latter un-ionized products is 0.8 e. v. greater than the observed value.

Until further data on related molecules are acquired, it is not profitable to discuss the reactions $t\text{-}C_4H_9Cl \rightarrow C_3H_6Cl^+ + CH_3 + \epsilon^-$ and $n\text{-}C_3H_7Cl \rightarrow C_2H_4Cl^+ + CH_3 + \epsilon^-$, further than to state that the appearance potentials observed seem to be consistent with the reactions as written.

In closing, we should remark that no search was made for negative ions, which undoubtedly are formed.

Summary

The mass spectra of tertiary butyl and normal propyl chloride are tabulated and briefly discussed. The appearance potentials of a few ions in these spectra were measured. The vertical ionization potential of normal propyl chloride is 10.7 ± 0.2 e. v. An estimate of $D(CH_3\text{—}H)$ from the present data leads to the value $4.4_2 \pm 0.2$ e. v. in agreement with the value deduced from other electron impact data.

Ionization and Dissociation by Electron Impact: Isobutylene, Propane, and Propylene

BY D. P. STEVENSON[1] AND JOHN A. HIPPLE

In a recent paper the results of a mass-spectroscopic investigation of the dissociation products of normal and isobutane were reported.[2] We present here the results of a similar investigation of isobutylene. As a part of an extensive study of the form of ionization efficiency curves, we have examined certain processes in propane and propylene. Inasmuch as our results on these latter molecules differ from those of a previous investigation, we also report appearance potentials of some of the ions in the mass spectra of propane and propylene.

The instrument and general technique have been described in the preceding article.[2] The gas samples were given to us by the Standard Oil Company of Indiana.

The appearance potentials, determined from the "initial breaks,"[2] are summarized in Table I. The results of Delfosse and Bleakney[3] on propane and propylene are included for comparison. We can offer no explanation for the discrepancies between our results and those of Delfosse and Bleakney. Careful checks show the results we report are consistent with our previously reported work on ethane and the butanes.

The significance of the appearance potentials of the various ions in the spectra of propylene and propane has been discussed by Delfosse and Bleakney.[3] Our values are not sufficiently different to change their interpretation in any significant detail.

The value of the appearance potential of the parent ion in the isobutylene spectrum, $A(C_4H_8^+) = 8.9$ e. v., which is to be associated with I_{vert}-(i-C_4H_8) is surprisingly low. The substitution of two methyl groups in ethylene reduces $I_{vert}(\pi + \pi, \pi_u)$ by $\sim$2.0 e. v. The effect of methyl for hydrogen substitution is more marked in the ethylene series than in the corresponding ethane series, since $I_{vert}(C_2H_6) = 11.7$ e. v. and $I_{vert}(C_4H_{10}) = 10.4$ e. v.[2] The I_{vert}(ethylenes) decrease more or less smoothly with methyl substitution, while the ethane series shows a greater decrease from propane to butane than from ethane to propane.

It will be noted that while in the ethylene series there is a difference of over 2.2 volts between the appearance potentials of R–H$^+$ and R$^+$ + H, the difference is less than 1.2 e. v. for the saturated hydrocarbons. A similar situation obtains when one compares the appearance potentials of R–CH_3^+ and R$^+$ + CH_3 for R olefin or saturate. These observations are consistent with the assumption which is usually made with respect to the relative strengths of single bonds to unsaturated and saturated carbon atoms.[4]

The ionization efficiency curve for $C_4H_8^+$ from isobutylene shows inflections at $\sim$12.5 e. v. and at $\sim$18 e. v. The inflection at 12.5 probably is to be attributed to the removal of the electron from a C–H bond orbital instead of from a C–C double bond orbital. Although we can make no assignment of the higher ionization potential ($\sim$18 e. v.), it should be remarked that isobutane also has an ionization potential about 9 volts above the appearance potential. The ionization efficiency curves for $C_4H_8^+$ from i-C_4H_8 and for $C_4H_{10}^+$ from i-C_4H_{10} are shown in Fig. 1.

Barring molecular rearrangement, the ion $C_3H_5^+$ formed from isobutylene has the structure $CH_3CCH_2^+$. One might expect the $C_3H_5^+$ formed from propylene to be the isomeric CH_2-$CHCH_2^+$ since the bonds to carbon atoms attached to unsaturated carbon atoms are generally weaker (more reactive) than the bonds to an unsaturated atom. The fact that $A(C_3H_5^+)$ from C_3H_6 is 2.2 e. v. greater than $A(C_3H_6^+)$ while $A(C_3H_7^+)$ from C_3H_8 is but 0.5 e. v. greater than $A(C_3H_8^+)$ suggests that the hydrogen atom lost by propylene was attached to one of the ethylenic carbon atoms. In either case we can write

(a) $C_3H_6 \longrightarrow CH_3CCH_2^+ + H + \epsilon^-$ $\quad A(C_3H_5^+) \geq 11.9_6$

(b) i-$C_4H_8 \longrightarrow CH_3CCH_2^+ + CH_3 + \epsilon^-$ $\quad A(C_3H_5)^+ = 11.5_1$

(c)[5] i-$C_4H_8 + 2H = C_3H_6 + CH_4$ $\quad \Delta H^\circ_{298.1} = -4.93$

These equations lead to D(CH_3—H) $\leq$ 4.48 e. v. This is in good agreement with the value of 4.38 e. v. deduced from other data.[6] This agreement

i-$C_4H_8 \longrightarrow C_2H_5^+ + \ldots + \epsilon^-$	15 ±1	
i-$C_4H_8 \longrightarrow C_2H_4^+ + C_2H_4 + \epsilon^-$	12.1 ±0.5	
i-$C_4H_8 \longrightarrow C_2H_3^+ + C_2H_4 + H + \epsilon^-$	15.2 ± .5	

[a] The ionization potential of argon, I = 15.76 e. v., was taken in accordance with the new conversion factor, 1 e. v. = 8066 cm.$^{-1}$. The appearance potentials in reference 2 should all be raised 0.07 e. v. We should like to thank the referee who called attention to the inconsistency on this point which existed in our original manuscript. [b] Ref. 3 of text.

suggests either that the unsymmetrical structure for the $C_3H_5^+$ from C_3H_6 is correct or that the isomerization energy of the reaction $CH_2CHCH_2^+ \rightarrow CH_3CCH_2^+$ is quite small. The latter seems very likely, since the allene → methylacetylene reaction involves but −0.07 e. v.

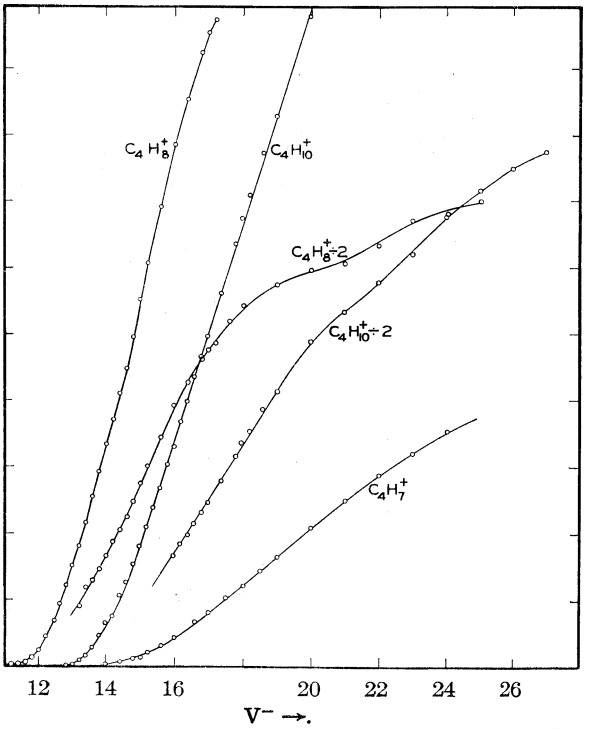

Fig. 1.—Ionization efficiency curves for the reactions i-$C_4H_8 \rightarrow C_4H_8^+$; i-$C_4H_8 \rightarrow C_4H_7^+ + H$; i-$C_4H_{10} \rightarrow C_4H_{10}^+$. The voltage scale is uncorrected. The ordinates for isobutylene and isobutane are not comparable.

The $C_3H_4^+$ from isobutylene may have either the allene or the methylacetylene structure. From the data summarized by Rossini,[5] we can write

(d) i-$C_4H_8 = CH_2CCH_2 + CH_4$ $\Delta H^\circ_{298.1} = 1.36$ e. v.

or

(d′) i-$C_4H_8 = CH_3CCH + CH_4$ $\Delta H^\circ_{298.1} = 1.29$ e. v.

Subtracting from i-C_4H_8; $A(C_3H_4^+) = 11.62$, we have either $I(CH_2CCH_2) = 10.26$ or $I(CH_3CCH) = 10.33$ e. v. Delfosse and Bleakney[3] found from direct measurement on allene, $A(C_3H_4^+) = 9.9$ e. v. The ionization potential of methylacetylene has not been measured. In acetylene, $A(C_2H_2^+) = 11.2$ e. v.[7] By analogy with the observed decreases in the vertical ionization potential brought about by substituting a methyl group into ethane and ethylene, one may guess that $I_{vert}(CH_3CCH)$ is 1 e. v. less than $I_{vert}(C_2H_2)$ or $I_{vert}(CH_3CCH) = 10.2$ e. v. Thus we are unable to reach a decision with regard to the structure of the $C_3H_4^+$ in the isobutylene spectrum. It may be noted that regardless of the structure of this ion, the methyl and hydrogen which form the methane come from adjacent carbon atoms rather than from the same atom.[8]

The relatively low values of the appearance potentials of the ions $C_2H_5^+$ and $C_2H_4^+$ in the isobutylene spectrum indicate that a minimum number of bonds are lost in the course of the rearrangement and dissociation reactions through which they are formed. The essential sharpness

(7) J. T. Tate, P. T. Smith and A. L. Vaughan, *Phys. Rev.*, **48**, 525 (1935).

(8) See the discussion in refs. 2 and 3.

with which the ionization efficiency curves (see Fig. 2) rise to their maximum values suggests that but one process is involved in each case, *i. e.*, one set of products. The low precision of $A(C_2H_5^+)$ precludes the unique assignment of the un-ionized fragments which accompany the formation of $C_2H_5^+$.

From the data of Rossini[5] we can write

(e) $i\text{-}C_4H_8 = 2C_2H_4$ $\quad \Delta H^\circ_{298.1} = 1.23$ e. v.

while Tate and co-workers[9] give

(f) $C_2H_4 \longrightarrow C_2H_4^+ + \epsilon^-$ $\quad A(C_2H_4^+) = 10.8$ e. v.

Adding, we find

(g) $i\text{-}C_4H_8 \longrightarrow C_2H_4^+ + C_2H_4 + \epsilon^-$

$A_{\text{calcd.}}(C_2H_4^+) = 12.0$ e. v.

in excellent agreement with the observed value (Table I). If, instead of the electron impact value of $A(C_2H_4^+)$, we had used Price's[10] spectroscopically determined $I^z(C_2H_4) = 10.4$ e. v., the value of $A(C_2H_4^+)$ calculated for (g) would be 0.4 e. v. below the observed value. This suggests 0.4 e. v. as a limit to the activation energy of the reverse of reaction (g). We have assumed that the products are of the ethylene rather than the ethylidene structure, an assumption which is unwarranted at present. Until the energies of ethylidene and its ion are known from other data, this ambiguity in the foregoing discussion must remain unresolved.

The ionization efficiency curve of the ion of mass 27 (primarily $C_2H_3^+$) of the isobutylene spectrum is similar in form to the curves for this ion in the spectra of ethane and the butanes. The rather large range of electron energies through which the slope increases suggests that one or more secondary processes, involving more fragmentation than the primary process, are involved. Combining reaction (e) with C_2H_4, $A(C_2H_3^+) = 14.1$ e. v.,[9] we find

(h) $i\text{-}C_4H_8 \longrightarrow C_2H_4 + C_2H_3^+ + H + \epsilon^-$

$A_{\text{calcd.}}(C_2H_3^+) = 15.3$ e. v.

in good agreement with the observed value of $A(C_2H_3^+) = 15.(2)$ e. v. We cannot exclude C_2H_5 as the un-ionized product which accompanies the $C_2H_3^+$. The association of C_2H_4 and H to C_2H_5 gives off about 1.7 e. v., thus for the reaction

(h′) $i\text{-}C_4H_8 \longrightarrow C_2H_5 + C_2H_3^+ + \epsilon^-$

one would estimate $A(C_2H_3^+) \cong 13.6$ e. v., well below the observed value. The 1.5 e. v. discrepancy could easily be assigned to an activation energy of the reverse of reaction (h′).

(9) P. Kusch, A. Hustrulid and J. T. Tate, *Phys. Rev.*, **52**, 843 (1937).
(10) W. C. Price, *ibid.*, **47**, 444 (1935).

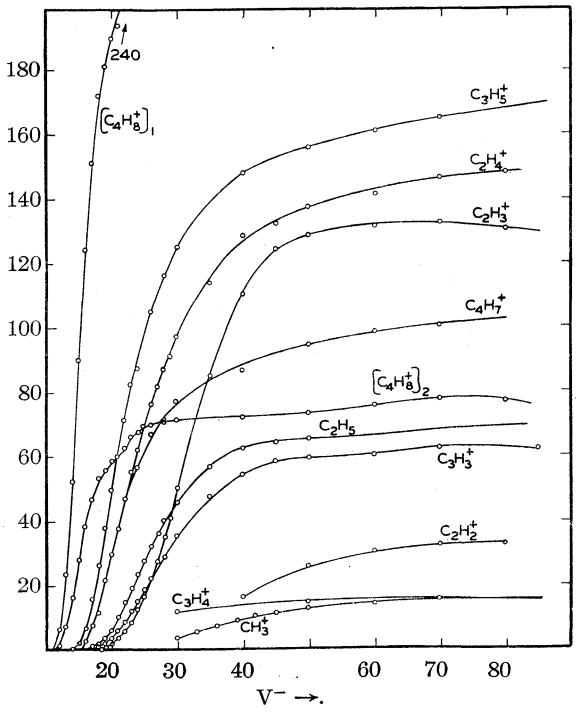

Fig. 2.—Ionization efficiency curves for various processes in isobutylene. $(C_4H_8^+)_1$ is to be compared with the C_2 masses. $(C_4H_8^+)_2$ is to be compared with the C_3 masses.

The form of the ionization efficiency curve of CH_3^+ from propane is of a character intermediate to those of this ion in ethane and the butanes. The formation of the methyl ion in the ethane spectrum involves mainly single ionization and in the butanes only double ionization. The value of $A(CH_3^+)$ from propane, while only rough, indicates that a process involving only single ionization contributes. The very pronounced curvature of the ionization efficiency curve in the vicinity of 26 volts indicates double ionization to be the more important source of methyl ions. The CH_3^+ current from propane attains about 10% of its maximum value for 30 volt electrons, while for similar electrons in ethane, CH_3^+ is 50% of its maximum value. The methyl ion current is but 6% of its maximum value for 30 volt electrons in the butanes.

The relative abundances of the various ions in the mass spectrum of isobutylene are given, for round values of the bombarding electron energy in Table II. Qualitatively, the distribution of intensities is very like that observed in the butane spectra. As is the case in the spectra of propylene, propane and the butanes, the principal reaction is

$R\text{–}CH_3 \longrightarrow R^+ + CH_3 + \epsilon^-$

In the C_4 region of the spectrum, isobutylene

shows its generic relationship to isobutane. The manner in which the spectrum changes with electron energy is illustrated in Fig. 2.

Summary

The results of a mass-spectroscopic investigation of the ionization and dissociation of propylene, propane and isobutylene by electron impact are reported. The vertical ionization potentials of these three molecules were found to be $I_v(C_3H_6) = 9.8 \pm 0.1$ e. v., $I_v(C_3H_8) = 11.2 \pm 0.1$ e. v., and $I_v(i\text{-}C_4H_8) = 8.9 \pm 0.1$ e. v. The significance of some of the observed appearance potentials of ions in the isobutylene spectrum is discussed. The mass spectrum of isobutylene is given in detail.

Reactions of Cobalt(III), Cobalt(II), and Iron(II) Oxides in Liquid Ammonia

BY THOMAS E. MOORE AND GEORGE W. WATT

With the single exception of the reduction studies described by Watt and Fernelius,[1] the only available information relative to reactions of metal oxides in liquid ammonia consists of a number of incidental qualitative observations[2] together with certain partially erroneous[3] results on reactions of the acidic oxides of chromium, molybdenum and tungsten published by Rosenheim and Jacobssohn.[4] The experiments described in this paper represent the first of a series of studies initiated for the purpose of providing information on the behavior of metal oxides toward liquid ammonia and liquid ammonia solutions of ammonium salts (acids), alkali amides (bases) and strong reducing agents.

Experimental

Methods.—Unless otherwise indicated, the experimental techniques were those employed by Watt and Fernelius.[1] All analytical data were obtained using standard methods of analysis.

Materials.—All materials were carefully dried before use. All chemicals other than the oxides were either reagent grade materials or consisted of commercial products which were subjected to careful purification.

Cobalt(III) Oxide.—Baker "reagent grade" oxide was dried for ten hours at 100° and used without further treatment.

Anal. Calcd. for Co_2O_3: Co, 71.06. Found: Co, 70.75.

Cobalt(II) Oxide.—The most satisfactory method for the preparation of this material was found to be that of Le Blanc and Möbius.[5] However, the use of this method in the original or in modified form, as well as other known methods,[6] failed to yield a product of the desired composi-

TABLE I

REACTIONS WITH AMMONIUM SALTS AT 100°

Oxide		Salt				Oxide dissolved	
Formula	Wt., g.	Formula	Wt., g.	NH_3, ml.	Time, hr.	Wt., g.	%
Co_2O_3	0.4186	NH_4Cl	11.00	20	36	0.0000[a]	0.00
Co_2O_3	.4979	NH_4NO_3	36.80	30	36	.0000[a]	.00
CoO	.1960	NH_4Cl	12.90	20	20	.0163	8.32
CoO	.1896	NH_4NO_3	25.80	25	20	.0083	4.38
FeO	.4596	NH_4Cl	11.50	20	24	.0082	1.80
FeO	.3878	NH_4NO_3	20.00	25	24	.0049	1.26

[a] The aqueous extracts failed to give positive tests for cobalt with α-nitroso-β-naphthol reagent which, according to Atack [*J. Soc. Chem. Ind.*, **34**, 641 (1915)] will detect one part of cobalt in one million parts of solution.

tion. The best product obtained contained 75.0% cobalt as compared with a calculated cobalt content of 78.7% for CoO.

Iron(II) Oxide.—Kahlbaum iron(II) oxide was used. The chief impurity in this material was found to be elemental carbon. *Anal.* Calcd. for FeO: Fe, 77.71. Found: Fe, 73.64. The method of Chaudron[7] and other known methods[8] failed to provide a product of purity greater than that of the Kahlbaum product.

Reactions with Liquid Ammonia.—Weighed quantities of the oxides were allowed to remain in contact with a large excess of liquid ammonia in sealed tubes at 25° over a period of twenty-four hours. After removal of the ammonia, the oxides were shown by analysis to have undergone no change in composition. For example, a sample of iron(II) oxide (0.5388 g.) contained 73.81% iron before treatment and was found to contain 73.84% iron after treatment with ammonia.

Reactions with Ammonium Salts.—Weighed samples of the oxides were treated with liquid ammonia solutions containing large excesses of ammonium salts in sealed "Pyrex" tubes which were heated to 100° in an autoclave of the type described by Bergstrom.[9] After removal of the solvent, unchanged oxides of cobalt were separated by extraction with water. Both the soluble and insoluble portions were thereafter analyzed for cobalt. Unchanged iron(II) oxide was separated on the basis of its insolubility (as shown by preliminary experiments) in 1.2 *N* hydrochloric acid solution. In each case the identity of the unchanged oxide was established by analysis. Results of these experiments are given in Table I.

Reactions with Potassium Amide.—The methods used were those employed by Watt and Fernelius[10] with the exception that the stopcocks were removed from the Faraday tubes prior to mixing the reactants. This procedure was found necessary in order to avoid loss of solvent due to leakage over the long periods of time and under the pressures developed due both to solvent vapor pressure and that of gases evolved during the reactions. This practice, however, suffers a disadvantage in that it does not permit of the ready collection and identification of insoluble gaseous reaction products.

Cobalt(III) Oxide.—When treated with a liquid ammonia solution of potassium amide (from 1.3110 g. of potassium) at room temperature for ten days, cobalt(III) oxide (0.5847 g.) reacted slowly to form an apparently complex mixture of insoluble products. The only product identified was elemental cobalt which was deposited on the walls of the tube in the form of a thin bright metallic mirror. This deposit was dissolved by hydrochloric acid with evolution of hydrogen. In any case, the quantity of elemental cobalt isolated was small; for example, in a typical case 0.0085 g. of cobalt was separated from the heterogeneous insoluble products.

Cobalt(II) Oxide.—Treatment of 0.2984 g. of cobalt (II) oxide with an ammonia solution of the potassium amide from 1.1847 g. of potassium over a period of ten days at room temperature resulted in a three-fold increase in the bulk of the insoluble solid phase, the liberation of small quantities of an insoluble gas, and the production of an intensely green colored ammonia solution. Following separation of the ammonia solution from the insoluble material, the former was cooled to −70°, whereupon deep blue crystals separated together with crystals of potassium amide. Attempts to separate the blue crystalline product by fractional crystallization from ammonia were unsuccessful. The heterogeneous insoluble material reacted with hydrochloric acid with liberation of hydrogen. A representative sample of this material (0.3231 g.) was found to contain: N, 5.76; K, 17.49; Co, 58.94.

Iron(II) Oxide.—Potassium amide (from 1.4111 g. of potassium) in liquid ammonia solution was allowed to remain in contact with iron(II) oxide (0.4286 g.) at room temperature over a period of ten days, without any visible evidence of reaction. However, the insoluble black solid phase (after thorough washing with liquid ammonia) was found to contain: N, 7.73; K, 5.40; Fe, 73.80.

Reduction Reactions.—Cobalt(III) and iron(II) oxides were reduced by liquid ammonia solutions of potassium at 0° using the same procedures as those employed by Watt and Fernelius[1] with the exception that provision was made for the collection of hydrogen resulting from the interaction of potassium and ammonia under the catalytic influence of the oxides and/or reduction products. In effecting several reactions involving the heterogeneous reduction of a given oxide, efforts were made (but none too successfully) to control (a) the concentration of the potassium solutions, (b) the rate of addition of the reducing agent, and (c) the uniformity of agitation of the reactants. After washing each insoluble product, the tube was evacuated at 80–90° at an oil pump to remove adsorbed ammonia and hydrogen.

Unchanged cobalt(III) oxide was separated from the insoluble reduction products on the basis of its insolubility (as shown by preliminary experiments) in 1 *N* hydrochloric

acid. It was found impossible to separate iron(II) oxide by any similar procedure even when buffered acetic acid solutions were employed. Consequently, the gross insoluble product was analyzed as such. Data relevant to reduction reactions are given in Tables II and III.

TABLE II[a]

REDUCTION OF COBALT(III) OXIDE BY POTASSIUM IN LIQUID AMMONIA AT 0°

Co_2O_3, g.	Potassium G.	Potassium Equivalents	H_2, cc. at S. T. P.	Co (g.) in acid-soluble[b] product	Reduction,[c] %
0.5248	0.7559	6.1	157	0.1860	50.1
.2572	0.7429	12.0	163	.1328	74.5
.2569	1.4453	23.9	341	.1700	93.6

[a] Data recorded in this table represent the average results of at least three independent experiments which agreed as well as could be expected in view of the variables previously indicated. [b] In each case, the *acid-insoluble* product was shown to consist of unchanged cobalt(III) oxide. For example, *Anal.* Calcd. for Co_2O_3: Co, 70.75. Found: Co, 70.59. [c] Based on soluble cobalt.

TABLE III

REDUCTION OF IRON(II) OXIDE BY POTASSIUM IN LIQUID AMMONIA AT 0°

FeO, g.	Potassium G.	Potassium Equivalents	Analysis of insoluble products[a] Weight, g.	Fe, %	K, %
0.8732	0.9590	1.41	0.8914	72.01	4.42

[a] Analysis showed that nitrogen was absent or present only in traces.

Discussion

With regard to the preparation of the oxides of divalent cobalt and iron, this study has confirmed conclusions reached by earlier investigators[6,8] to the effect that pure compounds corresponding to the formulas CoO and FeO cannot be produced by at present available methods. Apparently the most that can be accomplished is the preparation of materials in which the lower oxides predominate.

That these oxides, and cobalt(III) oxide as well, are insoluble in and unreactive toward liquid ammonia is in full accord with the earlier observations of Franklin and Kraus.[11] In their reactions with ammonium salts, the behavior of the oxides included in this work parallels their behavior toward the corresponding aquo acids. If it may be assumed that the ability of a liquid ammonia solution of an onium type salt to dissolve metal oxides may be looked upon as a true manifestation of acidity, then it may be concluded that the acidic solutions employed in this investigation are of considerably lesser acidic strength than the corresponding aqueous acid solutions and that (in liquid ammonia) ammonium chloride is a stronger acid than ammonium nitrate. That cobalt(III) oxide proved to be entirely unreactive even at 100° is not surprising since this oxide is dissolved only very slowly by hot concentrated hydrochloric acid.

The reactions with potassium amide proved to be slow, very complex, and probably incomplete. The presence of elemental cobalt among the reaction products provides new evidence of the reducing action of the amide ion. The insoluble heterogeneous products also may have contained unchanged oxides, lower oxides, potassium hydroxide, and possibly salts of amphoteric bases resulting from the interaction of the reduced metals and potassium amide.[12] That mixtures were produced is shown by the fact that in every one of a considerable number of cases, the analytical data failed to conform to the composition of any known or probable compound.

The reduction of cobalt(III) oxide is believed to occur in two stages

$$Co_2O_3 + 2K + NH_3 \longrightarrow 2CoO + KOH + KNH_2$$
$$CoO + 2K + NH_3 \longrightarrow Co + KOH + KNH_2$$

This view is supported by the physical appearance of the products obtained when six, twelve and twenty-four equivalents of potassium are used, and by the fact that the insoluble product obtained using six equivalents of potassium is dissolved by hydrochloric acid without appreciable liberation of hydrogen whereas hydrogen is evolved extensively when the products obtained using twelve or twenty-four equivalents of potassium are treated similarly. Furthermore, the weights of potassium amide found by analysis[13] of the ammonia-soluble products were found to agree only with the theoretically possible weights of amide corresponding to the assumption that cobalt(II) oxide is the principal product of reactions involving six equivalents of potassium. Similarly, the weights of potassium amide found in reactions involving twenty-four equivalents of potassium agree only with values calculated on the assumption of essentially complete reduction to elemental cobalt. Of the possible bases for the determination of extent of reduction, analysis for soluble cobalt is believed to be the most reliable. Reproducible values for hydrogen evolved by the catalyzed reaction between potassium and

2.81	.6015	.0190	.5825	.0742	.5083	16.5	99.5
5.66	.4594	.0180	.4414	.0582	.3832	17.1	99.2

[a] Calculated on the basis of potassium found by analysis of the insoluble products. [b] Corrected by subtraction of the weight of KOH—column 3.

ammonia could not be obtained due probably to leakage around the stopcocks and to the absorption of hydrogen by the reduction products.[14] Calculations based on analyses of ammonia-soluble products also led to divergent results probably as a result of difficulty encountered in complete removal of the solvent ammonia.

Iron(II) oxide is incompletely reduced to elemental iron in accordance with the equation

$$FeO + 2K + NH_3 \longrightarrow Fe + KOH + KNH_2$$

If it is assumed that the insoluble product consists of iron, iron(II) oxide, and potassium hydroxide, the values given in Table IV may be calculated from the data of Table III. The validity of this interpretation is supported by the excellent agreement between the weights of iron(II) oxide used initially and that accounted for in terms of the analytical data.

The fact that the extent of reduction of iron(II) oxide does not increase appreciably [as in the case of cobalt(III) oxide] with increase in the quantity of potassium used provides evidence that iron(II) oxide (or its reduction products) is a much more active catalyst for the conversion of potassium to potassium amide than is cobalt(III) oxide (or its reduction products). Although no rate measurements were made, it was observed that evolution of hydrogen is, in either case, relatively slow until some of the oxide has been reduced. Hence, it seems likely that the observed catalytic activity is to be attributed more to the reduction products than to the parent oxides.

(14) *Cf.* Burgess and Eastes, THIS JOURNAL, **63**, 2674 (1941).

Summary

1. Cobalt(III), cobalt(II) and iron(II) oxides are insoluble in and unreactive toward liquid ammonia at room temperature.

2. Cobalt(III) oxide is unreactive toward liquid ammonia solutions of ammonium chloride or nitrate at 100° while, under the same conditions, cobalt(II) and iron(II) oxides are partially dissolved.

3. Cobalt(III), cobalt(II) and iron(II) oxides react slowly with liquid ammonia solutions of potassium amide at room temperature to form complex mixtures of soluble and/or insoluble products.

4. Cobalt(III) oxide is reduced to cobalt(II) oxide and finally to elemental cobalt by liquid ammonia solutions of potassium at 0° to an extent dependent upon the Co_2O_3/K ratio. Under the same conditions, iron(II) oxide is reduced to elemental iron only to a very limited extent.

The Vapor Pressure of Phenylhydrazine as a Function of the Temperature[1]

BY GLENN E. WILLIAMS AND E. C. GILBERT

Work now in progress in this Laboratory required a knowledge of the vapor pressure and latent heat of vaporization of phenylhydrazine. A search of the literature revealed an almost total lack of information based on any adequately purified and protected sample. The present work was therefore undertaken to obtain the required data over a considerable range of temperature.

Procedure and Apparatus.—The isoteniscopic apparatus of Smith and Menzies[2] was used, suitably modified so that samples could be introduced by distillation at reduced pressure and protected during the experimental manipulation in an atmosphere of dry nitrogen. Temperatures were controlled to ±0.02° and the thermometers had been compared with standards calibrated by the National Bureau of Standards. The manometer was of the Germann[3] design and was read to 0.1 mm. with a cathetometer, the readings being corrected to 0°, sea level, and latitude of 45°.

As a check on the accuracy of the procedure, the vapor pressure of water was measured in the temperature range 20–75°, and that of aniline in the range 100–150°. The arithmetical mean deviation of the twelve measurements with water was ±0.24 mm., with a maximum deviation of ±0.40 mm. The results for aniline agreed with the data of Ramsay and Young[4] rather than with those of Garrick,[5] obtained with a different type of apparatus unsuitable for use with phenylhydrazine. The maximum deviation of our experimental points from the smoothed values of Ramsay and Young at eight temperatures was 0.8 mm., the mean being ±0.3 mm.

Materials.—The nitrogen supply was passed through sodium pyrogallate to remove oxygen, and dried over a long column of calcium chloride and "anhydrone." The phenylhydrazine was prepared by the method of Coleman[6] and purified by fractionation under reduced pressure (18 mm.) in an atmosphere of nitrogen. The middle fraction from 250 cc. was distilled onto crushed stick sodium hydroxide. After standing, the phenylhydrazine was redistilled and a 20-cc. middle fraction was introduced into the isoteniscope. Four different samples were used including one from the Eastman Kodak Company. All were purified in the same manner. The aniline (Eastman Kodak Company) was purified in essentially the same manner as the phenylhydrazine.

Results and Discussion.—Fifty-five values of the vapor pressure were obtained between 100 and 192° using the four samples. Some sets of readings were taken with falling temperatures and some rising. It was found that these data fitted well an empirical equation of the form used by Cox[7] and Davis[8] and shown by them to be valid with a considerable variety of substances over a range of 340°. This equation is essentially $\log P = A - B/(t + 230)$, where t = centigrade temperature and P is the pressure in mm. Utilizing the 50 experimental points between 105 and 150°, the values of the constants A and B of this equation were derived by the method of least squares and found to be as follows: $A = 7.9046$; $B = 2366.4$.

The arithmetical mean deviation of the vapor pressures calculated by this formula from those observed was ±0.4 mm., with a maximum deviation of ±1.0 mm. In terms of percentage, the mean deviation above 125° was ±1.0%, while at lower temperatures the smaller absolute values of the vapor pressure (7–17 mm.) resulted in a larger mean deviation, approximately 3.0%.

As a further test of the adequacy of the equation, the vapor pressures measured at the five higher temperatures in the range 160–192° were compared with those calculated. The average arithmetical mean deviation of these measurements was ±0.7 mm. or ±0.5%, the maximum deviation being +0.75%. This showed that a fit, practically equal to the precision of the measurements was afforded by this equation.

The normal boiling point of phenylhydrazine calculated from the equation was 241°, slightly lower than the highest value given in the literature,[9] but in good agreement with others.

For the estimation of the latent heat of vaporization, values of the vapor pressure were calculated at 10° intervals, and from adjacent pairs the latent heat was calculated by the Clausius–Clapeyron equation, which is the best approximation that can be had, lacking critical data. The results are shown in Table I.

TABLE I

THE HEAT OF VAPORIZATION OF PHENYLHYDRAZINE

Temp., °C.	25	95	105	115
	125	135	145	240
Heat of vaporization, cal./mole	(14690)	13886	13788	13693
	13610	13526	13455	(12903)

Summary

The vapor pressure of phenylhydrazine has been measured by means of the isoteniscope over the range 105–192° with a precision of about ±0.4 mm. From the resulting data an empirical equation was derived by the method of least squares which reproduced these values to within the experimental precision.

From these values of the vapor pressure the latent heat of vaporization at temperatures from 25–240° has been computed and tabulated.

Kinetics of the Transformation of Hydrazine Cyanate into Semicarbazide[1]

BY ELTON M. BAKER AND E. C. GILBERT

The transformation of ammonium cyanate into urea has been the subject of numerous and exhaustive studies but the analogous reaction of hydrazine cyanate to form semicarbazide has never been subjected to critical examination. Such examination is complicated by the reactive nature of the substances involved and also by the fact that semicarbazide is definitely basic whereas urea is so weakly basic that for practical purposes its proton affinity in dilute aqueous solution is entirely negligible. The present work, however, represents a study of the kinetics of the reaction, simple salt effects, equilibrium measurements and the effect of temperature on the rate.

Experimental Part

Preparation of Materials.—Potassium Cyanate (Baker C. P.) was suspended in absolute ethanol by vigorous shaking, to dissolve any small amount of cyanide present. It was then collected on a filter, washed with ether and dried. It was then preserved in a vacuum desiccator and stored in the dark. Prepared in this manner, analysis by the Volhard method showed a purity of 99.6%.

Two neutral salts of hydrazine, the perchlorate and monohydrochloride, were prepared from Kahlbaum 100% hydrazine hydrate and the corresponding pure acids. These salts were recrystallized from 80% methanol and dried over sulfuric acid. They were analyzed by the iodate method.

For equilibrium measurements semicarbazide was necessary. Eastman Kodak Co. semicarbazide hydrochloride was recrystallized from 80% methanol, and checked for purity by Volhard analysis for chloride content. Foreign salts added to increase ionic strength were Baker C. P. quality.

Procedure.—The unexpected rapidity of the reaction precluded the preparation of pure hydrazine cyanate (free from other ions) from silver cyanate and hydrazine chloride in a manner analogous to that used by Warner and Stitt[2] to prepare ammonium cyanate.

All solutions were made up by adding hydrazine monochloride or perchlorate in solution to exactly equivalent amounts of potassium cyanate. This was accomplished by a vessel of special design which permitted almost instantaneous mixing of small amounts of these solutions. Measurements were made at 25 and 15° in a bath controlled to ±0.05°.

The progress of the reaction was followed by withdrawing samples which were added to excess standard silver nitrate solution. The precipitated silver salts were filtered out and the excess silver ions in an aliquot portion were determined by titration with standard thiocyanate using ferric alum indicator.

From these results the amount of unreacted cyanate present at any time was calculable.

Equilibrium measurements were made from both forward and backward directions. Reaction mixtures of hydrazine and cyanate were allowed to react until the cyanate titer was constant. Similarly semicarbazide solutions of equivalent concentrations were allowed to stand at constant temperature and analyzed for cyanate from time to time. Equilibrium lies so far toward completion that the reverse reaction has no detectable effect in the early stages of the process.

Discussion

The rapidity of the reaction as measured was quite unexpected as the laboratory directions for the preparation of semicarbazide by this method[3] called for elevated temperature and twenty to twenty-four hours of standing. It was therefore thought desirable to demonstrate that the reaction being followed was actually that which was postu-

(3) Beilstein, 4th edition, Vol. III, p. 98.

lated. This was done by adding benzaldehyde solution at intervals to samples of reaction mixture. With unchanged hydrazine the yellow insoluble compound benzalazine was formed, while with semicarbazide the white semicarbazone of the benzaldehyde was formed. This was also insoluble. The two were readily separated by differential solubility in ether and their identity established by mixed melting points with known samples. As the reaction proceeded the amount of yellow benzalazine rapidly decreased and that of the semicarbazone increased. Had it not been for the time lag in formation of these compounds it would have provided an excellent method of following the reaction. There thus is no reason to doubt that the reaction measured is that of the formation of semicarbazide. No evidence was ever found indicating the presence of carbonate, which is known to be a disturbing factor in the urea reaction.[2] This is probably due to the lower temperatures and shorter times used in this work.

The main points of interest lie in the conclusions that may be drawn concerning the possible mechanism of the reaction, the possibility of general or specific ion catalysis and the energy of activation.

The assumption that the process would likely prove to be bimolecular was borne out by the fact that in all cases the graph of time against the reciprocal of cyanate concentration was a very satisfactory straight line (Fig. 1) until the reaction was at least 50% complete.

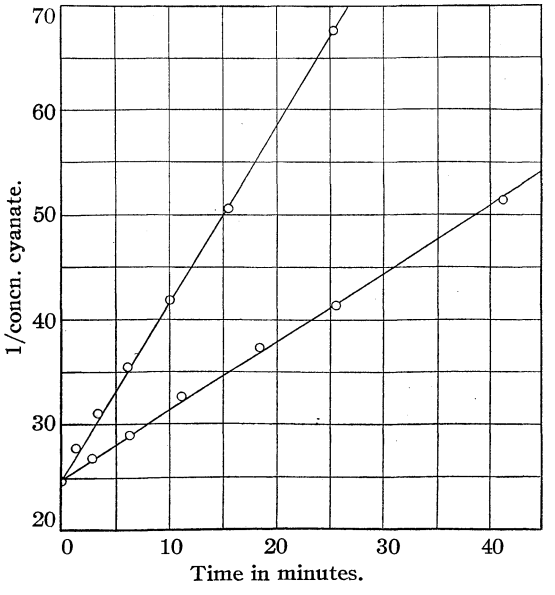

Fig. 1.—Graph showing bimolecular characteristics of reaction, also temperature effect: upper curve, temp. 25°; lower curve, temp. 15°.

For the elucidation of the mechanism useful evidence is obtainable from the effect of ionic strength on the velocity, as shown in Table I. Since the ionic strength diminished due to the disappearance of the hydrazine and cyanate ions during the reaction it was necessary to approximate the mean ionic strength during the time over which the constant was determined.

[a] Mean ionic strength taking into account salts present plus mean concentration of hydrazine and cyanate ions during time used in establishing bimolecular constant, k: (1) potassium chloride only; (2) potassium perchlorate only; (3) potassium nitrate and chloride.

There was a definitely negative primary salt effect though the concentrations which it was necessary to use were too high to expect quantitative agreement with the limiting law. When the expression for the limiting law, modified to allow for higher ionic strength

$$\log k = \log k_0 + Z_1 Z_2 \frac{\sqrt{\mu}}{1 + A\sqrt{\mu}}$$

is used, excellent agreement is obtained even at the higher concentrations.

According to Brönsted's theory such a negative salt effect is to be expected for a reaction between ions of unlike charge, whereas if uncharged molecules were involved the salt effect should be negligible. The effect is shown graphically in Fig. 2, in which has been shown also the limiting slope (−1) predicted for a reaction in which the ions have unit positive and negative charges, in solutions of low ionic strength.

This evidence, like that in the urea conversion, points strongly to the theory that the rate governing step is one between ions, presumably hydrazine and cyanate.

The effect of temperature is also illustrated in Fig. 1 showing runs at 15 and 25° for solutions of low ionic strength. The mean k_{15} for 5 runs was 0.0107 and the mean k_{25} for 4 runs was 0.0284 giving a temperature coefficient of 2.65 for ten degrees, and a calculated energy of activation of 16,600 cal./mole. The data probably do not possess sufficient precision to merit calculation of the entropy of activation.

Equilibrium data are shown in Table II. Due to the greater time required for attainment of equilibrium at lower temperatures with the attendent complications of side reactions and oxidation only measurements at 25° are reported. Equilibrium is apparently reached only when approximately 97% of the hydrazine cyanate has reacted.

TABLE II

EQUILIBRIUM CONSTANT, AT 25°

$$K = \frac{(\text{MOLALITY OF CYANATE})^2}{(\text{MOLALITY OF SEMICARBAZIDE})}$$

Run	Molality of semicarbazide	Molality of cyanate	$K \times 10^5$
60	0.02409	0.00091	3.44
61[a]	.03903	.00124	3.94
62[a]	.03924	.00111	3.14
62[a]	.03927	.00108	2.97
64	.03907	.00128	4.19

[a] Semicarbazide was allowed to decompose into hydrazine cyanate. In all other runs the reactant was hydrazine cyanate.

Using the equilibrium data, in equations of Walker and Appleyard[4] it was possible to calculate k_2 for the postulated reverse unimolecular decomposition of semicarbazide. This is shown in the summarizing table, Table III.

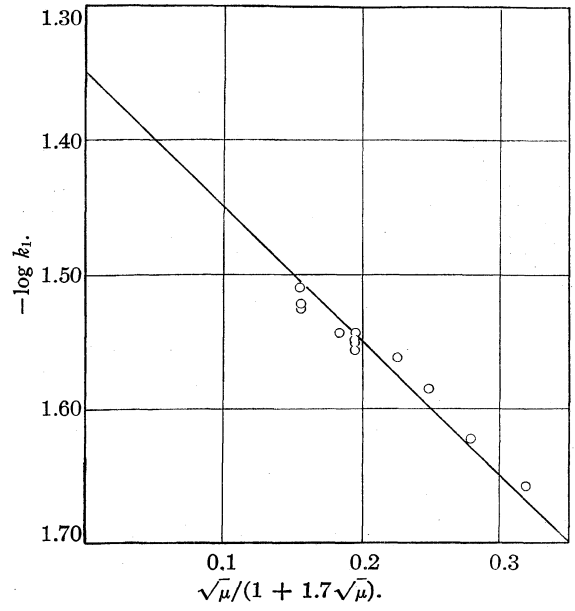

Fig. 2.—Change of velocity constant k_1 at 25° with change in ionic strength. Solid line is limiting slope for reaction between univalent ions of opposite charge.

the hydrazine salts were of the monovalent series and the potassium cyanate neutral the reaction mixture at the start was at a *p*H of approximately 6. As semicarbazide was formed, there was a gradual increase in *p*H. At this *p*H, calculation shows that the semicarbazide is practically entirely in the basic form. Buffers which are effective in this range have the disadvantage that practically without exception their silver salts are insoluble, unless acid is added, in which case error is introduced by the concomitant solubility of the silver cyanate.

TABLE III

SUMMARY OF CONSTANTS

Conversion of Hydrazine Cyanate to Semicarbazide

Equilibrium constant K_{25}	(μ = *ca.* 0.05)	3.5×10^{-5}
Equilibrium constant K_{15}	(μ = *ca.* .05)	(2.9×10^{-5})
k_1 forward at 25°	(μ = *ca.* .08)	2.85×10^{-2} mole liter^{-1} sec.$^{-1}$
k_2 reverse at 25°		9.98×10^{-7} mole liter^{-1} sec.$^{-1}$
k_1 forward at 15°	(μ = *ca.* .08)	1.07×10^{-2} mole liter^{-1} sec.$^{-1}$
k_2 reverse at 15°		4.93×10^{-8} mole liter^{-1} sec.$^{-1}$
k_0 (extrap.) at 25°	(μ = 0)	4.46×10^{-2} mole liter^{-1} sec.$^{-1}$
Temperature coefficient k_{25}/k_{15}		2.65
Energy of activation		16,600 cal. mole^{-1}

Due to limitations imposed by the method of analysis which so far have not seemed avoidable, and the basicity of the semicarbazide, investigation of possible specific or general catalysis was confined to qualitative observations. Since one set of experiments using an acetate buffer at *p*H 5 (slightly lower than that of the unbuffered mixture) showed apparently an increase in reaction rate which might indicate a hydrogen ion catalysis. There was no change in the bimolecular characteristics, however. So far as could be de-

(4) Walker and Appleyard, *J. Chem. Soc.*, **69**, 193 (1896).

termined, an increase in buffer concentration caused no increase in rate, indicating no general catalysis at least for the acetate–acetic acid buffer.

To convert semicarbazide predominantly into its salt requires a *p*H of about 2. Efforts were made to study the rate of reaction in this *p*H range by adding acid from a micro buret at a rate sufficient to keep the *p*H at 2.2 (in which case the acid added is a measure of the semicarbazide formed) following the procedure of earlier work.[5] Evidence showed however that the cyanic acid was decomposing with little semicarbazide being formed, and this approach was not carried further.

(5) Gilbert, THIS JOURNAL, **51**, 3394 (1929).

Summary

1. The formation of semicarbazide from hydrazine cyanate takes place readily at room temperature.

2. Increase in ionic strength reduces the velocity of reaction in a manner which agrees with the postulate that the rate determining process is the reaction between the hydrazine and cyanate ions.

3. The reaction reaches an equilibrium far to the side of formation of semicarbazide.

4. Quantitative results are presented on the velocity constants of the reaction at 15 and 25°, the equilibrium constant, salt effects, temperature coefficient and heat of activation.

The Role of Neighboring Groups in Replacement Reactions. I. Retention of Configuration in the Reaction of Some Dihalides and Acetoxyhalides with Silver Acetate[1]

BY S. WINSTEIN[2] AND R. E. BUCKLES

Three mechanisms for nucleophilic replacement reactions at a saturated carbon atom are currently recognized.[3,4] One is the now familiar[5] bimolecular (S_N2) substitution with complete Walden inversion. A second mechanism (S_Ni) involves the rearrangement of an intermediate product[3,6] in such a way that retention of configuration is the steric result.

The third mechanism has been termed unimolecular[3] (S_N1) or polymolecular.[3,4,7] It seems to consist of at least two steps, the most probable rate-determining step being an ionization. There are several indications that the carbonium ion intermediate is, in some respects, quite unfree.[4] For example, the steric result of reaction by this mechanism generally is predominant inversion. Quite analogous to the S_N1 mechanism is a process involving the electrophilic attack of a reagent such as silver ion on a halogen atom.[3,4]

Ionization to an ion-pair, solvated in a way characteristic of ions, may be thought to be the rate-determining step in the S_N1 mechanism. Solvation of the ions makes this step feasible; therefore, the rate varies with the arrangement of solvent molecules around what is to be the ion-pair. Solvent molecules must be included in the transition state, without, however, drawing bonds between the solvent molecules and the carbonium ion.[8,9,10] If the carbonium ion is very reactive it will react preferentially with a molecule in the solvation cluster to give inversion as the major steric result.[3] There may thus be some connection between rates and final product compositions in mixed solvents.[3,8] If reaction of the carbonium ion takes place after dissociation of the ion-pair, complete racemization is the steric result.[7]

(10) It is possible that the failure of a tertiary halide with the halogen atom on a bridge-head to undergo solvolytic reaction, as demonstrated by Bartlett and co-workers, [THIS JOURNAL, **61**, 3184 (1939); **62**, 1183 (1940)] should be ascribed partly to the fact that the solvation energy of the cationic end of the ion-pair to be formed is apt to be much smaller than usual. Solvent is kept away from the cationic carbon atom by the hydrocarbon cage more effectively than is possible with the most highly hindered open-chain compounds in which the cationic carbon atom can flatten out.

To understand the rates and steric results of nucleophilic replacement reactions of the most complex compounds (perhaps with several functional groups) it is necessary to demonstrate and understand the effects of substituent groups other than their supply or withdrawal of electrons to the seat of substitution by induction and resonance.[3] One of the most interesting effects is that of participation of a group on a neighboring or more distant carbon atom in a replacement process at a carbon atom. Thus, a replacement reaction might really consist of two steps, the first one an intramolecular S_N2 reaction, the second the opening of a ring. Two inversions or apparent retention will be the steric result.

Even more interesting is the involvement of a neighboring group in a replacement reaction which appears to be of the S_N1 type. In this connection, several reactions have been found to proceed with retention of configuration because of an extra functional group.[3,11,12,13]

In this article we present and discuss several additional examples of reactions which similarly involve participation of a neighboring group and we include a discussion of general expectations as to the scope and results of such participation.

We have now studied the steric result of the reaction of silver acetate in dry acetic acid with the *threo-* and *erythro*-2-acetoxy-3-bromobutanes, the *dl-* and *meso*-2,3-dibromobutanes, *trans*-1-acetoxy-2-bromocyclohexane and *trans*-1,2-dibromocyclohexane. Table I gives a summary of the results of the conversions. The steric results are based on configurations of the starting materials and products which are either proved or highly probable.[12,14,15,16,17]

It is seen that the acetoxybromobutanes and the butene dihalides react with silver acetate to give diacetates with quite high retention of configuration. Thus, retention of configuration is the steric result in the replacement of both the first and second bromine atom of the dibromide by the acetoxy group. Similarly the cyclohexene derivatives react with retention of configuration to give *trans*-diacetate under conditions which cause no configurational change of *cis*-diacetate.

TABLE I

SUMMARY OF STERIC RESULTS OF REACTION OF SILVER ACETATE WITH SOME HALIDES IN ACETIC ACID

Starting halide	Diacetate[a] M. p., °C.	Config.	Corrected[b] steric result
trans-1-Acetoxy-2-bromocyclohexane	102[c]	97% *trans*	97% Retention
threo-2-Acetoxy-3-bromobutane	41	95.5% *dl*	98% Retention
erythro-2-Acetoxy-3-bromobutane	0.5	91% *meso*	91% Retention
trans-1,2-Dibromocyclohexane	103[c]	98% *trans*	98% Retention
dl-2,3-Dibromobutane	39	91% *dl*	94% Retention
meso-2,3-Dibromobutane	−1.5	87% *meso*	>87% Retention[d]

[a] Melting point of *dl*-2,3-diacetoxybutane, 42.9°; *meso* isomer 3.0°. [b] There is included a correction for slight configurational impurity of two starting materials. [c] Melting point of glycol from saponification of the diacetate. Melting point of *trans*-1,2-cyclohexanediol, 104°. [d] This result is a lower limit since it was obtained early in the course of the work and the acetic acid solvent was not freed from water as thoroughly as in later work; see ref. 18.

The retentions of configuration are almost complete and would appear even better were one able to eliminate small configurational impurity of starting materials; also, if one were able completely to eliminate another reaction to be discussed elsewhere,[18] which gives rise to inverted products and which can be made predominant under other conditions. Also, there is the possibility that the halides are to a very small degree isomerized to diastereomers by silver halide in the course of the conversions. This would give rise to a small amount of apparent inversion in the steric result.

Besides acetic acid as a solvent medium for the reaction of the cyclohexene derivatives with silver acetate, acetic anhydride was also employed. The results obtained were entirely similar in steric result to those in acetic acid but the yields of diacetate were much inferior and it was difficult to fractionate out pure material.

The retentions of configuration observed are best accounted for by the participation in the replacement process of the —Br atom or —OAc group on the carbon atom neighboring the seat of substitution. This participation involves bond formation to the carbon atom being substituted either simultaneously with or very shortly after the removal of halide ion by silver ion in some form with the production of intermediate I or II with quite complete inversion. The reaction of these intermediates with acetate ion[19] with a

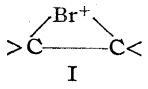
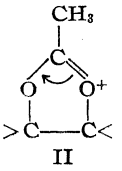
(19) Although the reaction is formulated in this way, it is not entirely clear whether acetate ion or acetic acid[12b] is the reagent in this case. This point will be settled later.



I

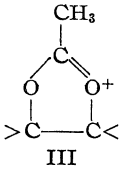


II

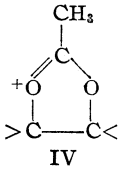
second inversion gives a net apparent retention of configuration as the steric result.

The bromonium ion I has been considered an intermediate in the reaction of the 3-bromo-2-butanols with hydrobromic acid[12] and in one ionic mechanism of addition of bromine to the ethylenic linkage.[12,20] Lucas and Gould have recently presented evidence for an analogous chloronium ion.[13]

For two reasons, the ion II is chosen as the intermediate when a neighboring acetoxy group participates in the replacement process. First, II should be energetically preferable over other possible forms because of freedom from strain and because of resonance between equivalent forms III and IV. The arrow in formula II indicates



III



IV

the symmetrical nature of II. Secondly, in reactions similar to the one being dealt with, ortho-acetate derivatives are often isolated.

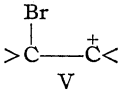
The argument in favor of the mechanism involving intermediates I and II for the retentions of configuration is strengthened by the results with some optically active materials (Table II). 2-Bromoöctane with α_D (1 dcm.) 5.39° was converted by silver acetate in acetic acid to an acetate with α_D (1 dcm.) − 0.61°. On the basis of densities and specific rotations in the literature[3a,21] for 2-bromoöctane and 2-acetoxyoctane, it appears that 72% of the optical activity survives in the process and that the results correspond to 86% inversion and 14% retention. Thus, in the absence of a neighboring group the reaction conditions lead to a typical[3,4] S_N1 steric result. 2,3-Dibromobutane with α_D (1 dcm.) − 2.43° yielded a diacetate which was completely inactive in spite of the fact that active diacetate did not lose its activity under the conditions of the experiment. Also, *trans*-1-acetoxy-2-bromocyclohexane with α_D (1 dcm.) −0.19° yielded a completely inactive diacetate. These results are in perfect accord with the prediction[12] of complete loss of activity for a mechanism involving an inactive internally compensated intermediate (I or II).

TABLE II

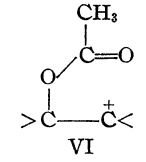
SUMMARY OF THE RESULTS OF THE TREATMENT OF ACTIVE COMPOUNDS WITH SILVER ACETATE IN DRY ACETIC ACID

Starting compound Name	α_D (1 dcm.)°	Final product α_D (1 dcm.)°
2-Bromoöctane	5.39	−0.61
2,3-Dibromobutane	−2.43	.00±0.01
trans-1-Acetoxy-2-bromocyclohexane	−0.19	.00± .01
2,3-Diacetoxybutane	− .48	− .45

We are still inquiring into the question whether the closings of the rings in intermediates I and II are one-stage[12] or two-stage[3] processes. The two-stage processes would involve the bromine-substituted carbonium ion V and the acetoxy-substituted carbonium ion VI. In this connection



V



VI

some relative reactivities are pertinent. There is a tremendous difference in reactivity of the 2-butene chlorohydrins and bromohydrins toward fuming hydrobromic acid. This has been mentioned by Lucas and Gould[13] and we have independently noticed it. A similar difference in reactivity appears in the cyclohexene series.[22] It does not appear reasonable that inductive effects can account for such a large difference. Bromine and chlorine atoms generally have effects of comparable magnitude[23] and thus would hinder about equally well the formation of conjugate acid from halohydrin and the departure of a water molecule with the shared pair of electrons from the halohydrin-conjugate acid. Thus, the bromine atom is able to meet much better than the chlorine atom a demand of the carbon atom being substituted. This effectiveness of the bromine atom must rest in its larger size and larger polarizability.

Also, there is a tremendous difference in the reactivity of the *cis*- and *trans*-1-acetoxy-2-chlorocyclohexanes toward silver acetate.[24] Under conditions more drastic than those needed to

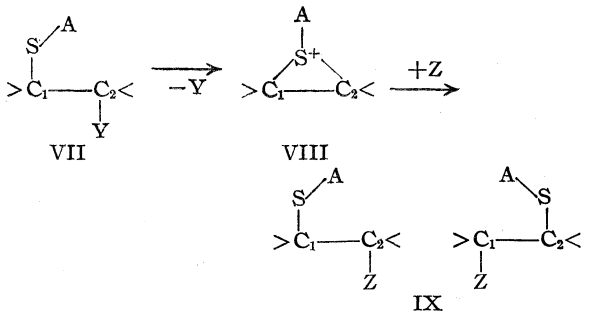
bring about reaction of the *trans*-compound, the *cis*-compound is completely unreactive. The *trans*-acetoxy group seems to be able to supply some driving force for the reaction and the *cis*-acetoxy group is essentially unable to do this. These relative reactivities are more easily understood on the basis of a one-stage closing of the ring in intermediates like I or II than on another basis. This holds also for the rather complete inversion accompanying the formation of I or II together with the rather complete lack of competition of outside reagents (solvent, AcO^-, etc.) with the neighboring group for attachment to the carbon atom being substituted.

We are also attempting to decide whether the opening of the ring in intermediates like I or II occurs in one or two stages.[25]

Participation of Neighboring Groups.—The observed retentions of configuration due to the participation of a neighboring group in an S_N1-like replacement process involve the effect of a carboxylate ion group[11] in solvolytic and analogous reactions of salts of α-halogen acids; the effect of a neighboring bromine atom in the reaction of a bromohydrin with hydrogen bromide[12] and in the reaction of a dibromide with silver acetate; the effect of a neighboring chlorine atom in the reaction of a chlorohydrin with thionyl chloride[13]; and the effect of a neighboring acetoxy group in the reaction of acetoxybromides with silver acetate. One would expect this effect to be very general, likely neighboring groups for such participation, including those already mentioned, being $-O^-$ of a carboxylate ion group, halogen, —OCOR, $-NH_2$ or $-NR_2$, —SR, —OR, —OH and of course $-O^-$.

It is worth pointing out briefly some expected results of the participation of neighboring groups in replacement processes of the S_N1 type. We will symbolize VII as the starting compound with Y the group to be replaced and AS the neighboring group, Z being the entering group.

First, if VII is the derivative of an unsymmetrical olefin, it becomes possible for some or most of



the product IX to have Z on a different carbon atom than the one left by Y.

A second expectation involves the results when VII is either the *cis*- or *trans*-derivative of a cyclic olefin. If the new ring in the intermediate VIII is a small one, it is possible for the neighboring group to participate in the replacement process only when one starts with *trans*-VII and not when one starts with *cis*-VII. Thus, retention of configuration will be the steric result when one starts with *trans*-VII and the usual predominating inversion will be the steric result when one starts with *cis*-VII. There will then be a tendency for both isomeric VII's to give, in reactions of the S_N1 type, a product with the groups Z and SA *trans* to each other.[26]

A situation which appears to illustrate this point arises in the reaction of silver acetate with acetohalogen sugars to form normal polyacetates. Tipson[27] has made the generalization that acetate groups 1 and 2 in the product are *trans* to each other and Isbell[28] has pointed out that this result arises because of the ability of acetate group 2 to enter into the replacement process if it is *trans* to the original halogen and not if it is *cis* to the original halogen.

Somewhat the same differences which are foreseen for *cis*- and *trans*-derivatives of cyclic olefins may be looked for in the case of pairs of open-chain diastereomers where rotation is seriously restricted about the bond between carbon atoms C-1 and C-2. The configurations about this bond might be so preferred[29] that it is easy for a neighboring group to participate in a replacement process of one diastereomer and difficult in the case of the other.

(25) If generalizations such as rate sequences, *t*-Bu > *i*-Pr > Et > Me for S_N1 reactions and *t*-Bu < *i*-Pr < Et < Me for S_N2 reactions hold[13] for intermediates like I or II it would be possible to learn the nature of a reaction from the direction of the opening of the ring of an unsymmetrical intermediate. Considerable success[22] can be attained in this way in understanding the direction of opening of oxide rings but even with oxides one generalization, at least, does not hold. For S_N2 reactions, hydroxide ion should be a reagent superior to a water molecule. However, in kinetic work on reactions of oxides which appear to be S_N2, hydroxide ion has proved to be an ineffective reagent while water is an effective one [Brönsted, Kilpatrick and Kilpatrick, THIS JOURNAL, **51**, 428 (1929)].

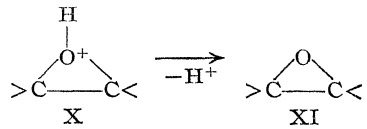
(26) The effect of the neighboring group might contribute toward the existence of a large difference in reactivity of *cis*- and *trans*-VII in S_N1 type reactions.

(27) Tipson, *J. Biol. Chem.*, **130**, 55 (1939).

(28) (a) Isbell, "Annual Review of Biochemistry," Annual Reviews, Inc., Stanford Univ. Press, Stanford Univ. P. O., Calif., 1940, page 65; (b) Frush and Isbell, *J. Research Natl. Bur. of Standards*, **27**, 413 (1941).

(29) Weissberger, *J. Org. Chem.*, **2**, 245 (1937).

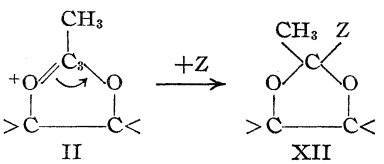
Finally, reactions involving the intermediate VIII might yield products other than IX in view of the ability of VIII to undergo other reactions. Thus, if VIII were to become X, we might expect to get oxide XI by the loss of a proton. Indeed



X XI

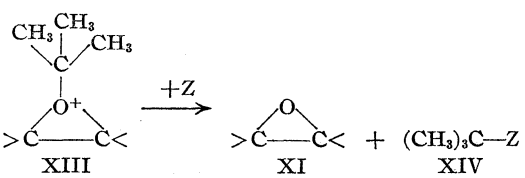
oxides are often isolated from S_N1 or analogous reactions of halohydrins, monotosylates of glycols, etc.

If II is the intermediate, then reaction at carbon C-3 should give an orthoacetate derivative XII. Isbell[28] has pointed out that acetohalogen sugars often give rise to orthoacetate derivatives, and that these orthoacetate derivatives are obtained only when the neighboring acetate group is *trans* to the halogen and not when it is *cis*. This is because an intermediate like II is easily possible only for the *trans*-compound.



II XII

It seems possible that other intermediates might discard, instead of a proton, some other group. Thus, it seems possible that an intermediate such as XIII might give rise to oxide XI and a tertiary butyl derivative XIV.



XIII XI XIV

Experimental

***trans*-2-Bromocyclohexanol.**—This material was prepared from cyclohexene and acetbromamide.[30] 1.56 moles of cyclohexene and an equivalent amount of acetbromamide were stirred under reflux with 1200 ml. of water for one and one-half hours. The reaction was controlled by addition of concd. sulfuric acid, 2 ml. at the start, 2 ml. after one half hour and 1 ml. at the end of an hour. The temperature of the reaction mixture was kept below 50° with an ice-bath. At the end of the one and one-half-hour period the mixture had returned to room temperature. The bromohydrin layer was separated and the aqueous layer was extracted with 150 ml. of ether. The extract and bromohydrin were combined and washed with 250 ml. of water to remove acetamide. The ether was distilled off and the bromohydrin was distilled rapidly through a Weston-type[31] column at reduced pressure. The yield was 219 g. (79%), b. p. 86.6–88.4° (10 mm.), $n^{25}D$ 1.5184.

***trans*-1-Acetoxy-2-bromocyclohexane.**—Acetylation of the bromohydrin was carried out with a 20% excess of acetic anhydride. To 45 g. of bromohydrin, acetic anhydride and 2 drops of concd. sulfuric acid were added. The mixture warmed up and soon returned to room temperature. The mixture was shaken with a little calcium carbonate to neutralize the catalyst, filtered and distilled at reduced pressure through a short column. 48 g. (87%) of the acetate was obtained; b. p. 109–110° (12 mm.), $n^{25}D$ 1.4857.

***trans*-1,2-Dibromocyclohexane.**—Bromine was added to cyclohexene by the method of Greengard.[32] Material, b. p. 99.6–99.9° (13 mm.), $n^{25}D$ 1.5506, was used in this work.

***trans*-1,2-Cyclohexanediol.**—This material was some prepared from cyclohexene oxide in connection with other work[16] and some prepared by saponification of the diacetate obtained from the action of silver acetate on dibromocyclohexane in dry acetic acid. Recrystallization from carbon tetrachloride yields a product, m. p. 104°.

***cis*-1,2-Cyclohexanediol.**—This material was some prepared in another study.[18]

***cis*- and *trans*-1,2-Diacetoxycyclohexanes.**—These substances were prepared by acetylation of the glycols by the procedure used with the bromocyclohexanol. The diacetates were obtained in 90 to 95% yield, the *cis*, b. p. 117.8–118.0° (12 mm.), $n^{25}D$ 1.4475, the *trans*, b. p. 120° (12 mm.), $n^{25}D$ 1.4457.

***threo*-3-Bromo-2-butanol.**—This substance was prepared from the reaction of acetbromamide and *cis*-2-butene[12] obtained from *meso*-2,3-butanediol by way of the diacetate and dibromide.[33] The general procedure has been described previously.[12] The reaction was controllable when 0.4 mole of butene was added to the acetbromamide in 250 ml. of water to which 4 ml. of 6 *N* sulfuric acid had been added. Under these conditions the reaction mixture was worked up after one and one-quarter to two hours and the yield, 82%, (107 g. bromohydrin from a total of 0.855 mole of butene used in two runs) was superior to that formerly obtained.[12]

***erythro*-3-Bromo-2-butanol.**—This material was prepared from pure oxide.[12]

***threo*- and *erythro*-2-Acetoxy-3-bromobutanes.**—These substances were prepared by acetylation of the corresponding bromohydrins as previously described.[34] In the acetylation of bromohydrins from the reaction of olefin with acetbromamide, a drop or two of concd. sulfuric acid was needed as a catalyst, and the reaction mixture was shaken with a little calcium carbonate before distillation.

***dl*-2,3-Dibromobutane.**—This material was prepared from *meso*-diacetate.[33,34]

***meso*-2,3-Dibromobutane.**—This dibromide was some prepared by the action of fuming hydrobromic acid on pure oxide or the bromohydrin or the acetoxybromobutane derived from it.[12,34]

Reaction of the Dibromides and Acetoxy-bromides with Silver Acetate.—The reaction of the halides with silver acetate in acetic acid at 100–110° with automatic stirring yielded results superior to some[35] reported for other conditions. Silver acetate (approximately 25% excess) was precipitated by adding excess aqueous sodium or potassium acetate to aqueous silver nitrate. It was filtered and washed carefully three times with glacial acetic acid on a Büchner funnel. The moist mass was then transferred to the reaction flask equipped with a mercury-sealed stirrer and reflux condenser protected by a drying tube. 100 ml. of reagent grade glacial acetic acid for each 0.1 mole of halide was added and the mixture was stirred for fifteen minutes. Then a sample of the acetic acid solvent was pipetted through cotton and the water content of the acid estimated from the melting point. An amount of acetic anhydride, in excess by 2 or 3 ml. of the amount necessary to react with the water in the solvent, was then added and the mixture was kept warm for about two hours[36] with stirring with an oil-bath at 100–110°. Then the halide was added and to insure complete reaction the mixture was stirred for eight hours in the case of the butene derivatives and eleven hours for the cyclohexene derivatives, the oil-bath being maintained at 100–110°. Sometimes the reaction was vigorous at the start and it was necessary to interrupt the heating for a short while. At the end of the proper time, the reaction mixture was allowed to cool and it was filtered. The filtrate was distilled at reduced pressure through the Weston-type column to isolate the diacetates. Starting with 0.1-mole quantities of the halides the yields averaged 70%, and they were better on larger runs. The products agreed within experimental error in boiling point, refractive index and saponification equivalent with authentic samples.

When acetic anhydride was used as a reaction medium in the case of the cyclohexene derivatives the procedure was the same in preparing and washing the silver acetate. Then acetic anhydride was added instead of acetic acid, the mixture was heated for a time to remove water, and the reaction was then carried on as usual and the product was isolated as usual. A good deal of high-boiling residue was formed in these reactions and only a 30–40% yield of somewhat impure diacetate could be distilled out with difficulty.

Analysis of Products.—The 1,2-diacetoxycyclohexane samples were identified by saponification to the glycol. 1 ml. of the ester was refluxed two hours with 2 ml. of 35% aqueous sodium hydroxide and 2 ml. of pure alcohol. The solution was washed into a separatory funnel with a minimum of water (1 or 2 ml.). Then the glycol was extracted with five 25-ml. portions of pure chloroform, the extracts were dried over potassium carbonate, distilled to a small volume and the residue was allowed to evaporate to dryness. The solid glycol was thus obtained in nearly quantitative yield. The melting points of the glycol and its mixtures with authentic specimens yielded an estimate of the composition of the glycol. Recrystallization of the crude glycols from carbon tetrachloride yielded pure *trans*-glycol. The saponification procedure was carried out on mixtures of *cis*- and *trans*-diacetates made up by weight, the temperatures of disappearance of solid when the glycol was melted being summarized in Table III.

The diacetoxybutanes were identified by melting point and mixed melting point with the aid of melting point-composition data of Lucas and Mitchell.[37]

TABLE III

MELTING POINTS OF GLYCOLS FROM THE SAPONIFICATION OF MIXTURES OF THE *cis*- AND *trans*-1,2-DIACETOXYCYCLOHEXANES

% *trans*	M. p., °C.	% *trans*	M. p., °C.
0	98	45	72
4	93.5	51	74
5.7	91	66	82
8.7	89	83	92.5
12	88	89	99
23	80.5	93	100.5
35	71.5	100	103.5

The melting points of the solid diacetate were taken by melting the whole sample in a flask or test-tube. In the case of the liquid diacetate, the dependence of composition on melting point is so sensitive that some standardization of the procedure was necessary. About a 10-g. sample of the diacetate was frozen in a test-tube and then with stirring at room temperature allowed to melt, the melting point being taken with a thermometer in the melt. With this technique and the thermometer in use, the very purest diacetate (prepared from glycol, m. p. 34.5°, by acetylation, removal of the sulfuric acid catalyst with calcium carbonate, and careful purification) gave a temperature 0.5° below the value of Lucas and Mitchell. Thus 0.5° was added to the temperature values near the melting point of *meso*-diacetate. To discover on what side of the eutectic a low-melting sample was it was sufficient to add a small amount of *meso*-diacetate and notice whether a decrease or increase in melting point was observed.

The products from the reaction of the cyclohexene derivatives in acetic anhydride gave glycols a little less pure than those obtained from the acetic acid reaction, the acetoxybromocyclohexane product giving a glycol, m. p. 101.5° and the dibromocyclohexane product giving a glycol m. p. 96°. These glycols were again predominantly *trans*.

Corrections for Slight Impurity of Starting Isomers.—In the preparation of *threo*-2-acetoxy-3-bromobutane (from the butene from the dibromide) and the *dl*-2,3-dibromobutane, *meso*-diacetate of slightly low melting point was used. This impurity was partly due to impurity of the glycol used and perhaps partly due to the failure to neutralize the sulfuric acid, used as a catalyst in the acetylation of the glycol, before distillation. This impurity in the starting diacetate is corrected for in Table I.

Preparation of Active 2-Bromoöctane and its Reaction with Silver Acetate.—5.0 ml. of active 2-octanol (kindly supplied by Dr. P. D. Bartlett) α_D (1 dcm.) −7.38°, was mixed with 15.0 ml. of Eastman Kodak Co. *dl*-2-octanol and the mixture was sealed up with hydrobromic acid which was prepared by saturating[12,34] 130 g. of 48% acid with hydrogen bromide gas at 0°. The reaction mixture was left at room temperature with occasional shaking for several days when the reaction vessel was opened and the

(35) Bainbridge, *J. Chem. Soc.*, **105**, 2291 (1914).

(36) For the reaction of *meso*-2,3-dibromobutane the water was removed by allowing the mixture to stand nearly two days at room temperature before the dibromide was added.

(37) Private communication.

bromide layer separated. The bromide was washed with water, twice with 10 ml. of concd. sulfuric acid, then with water and finally with potassium carbonate solution. The bromide was dried over potassium carbonate and the 21.5 g. of crude material was then distilled through the Weston-type column. 18.5 g., b. p. 74.7–75.3° (14 mm.), α_D (1 dcm.) 5.39°, was obtained. The bromide, 18.0 g., was converted to acetate with silver acetate in dry acetic acid as for the butene and cyclohexene derivatives. Distillation through the Weston-type column yielded 9.5 g. (59%) of acetate, b. p. 81.3–82.0° (12.5 mm.), $n^{22}D$ 1.4140, α_D (1 dcm.) −0.61°.

Active 2,3-Dibromobutane and its Conversion to Diacetate.—Partial resolution of a 2,3-dibromobutane which was mostly the *dl*-isomer was accomplished by the method of Lucas and Gould.[15] 64.8 g. (0.30 mole) of the dibromide and 39.5 g. of brucine were mixed and allowed to stand for eighteen hours. The brucine was dissolved in excess hydrochloric acid and the dibromide was removed with the aid of 200 ml. of petroleum ether. The extract was washed with water and dried over potassium carbonate. The dibromide was obtained by distillation at reduced pressure; 46 g., b. p. 73.0–73.5° (50 mm.), α_D (1 dcm.) − 2.43°. When this material was converted to diacetate in the usual way, the product proved to be completely inactive.

A 2,3-diacetoxybutane with α_D −0.48° (mostly diacetate of Lucidol glycol) was subjected to the reaction conditions using a mixture of silver acetate and bromide. The recovered diacetate α_D − 0.45° showed a change in the rotation no larger than one would expect due to fractionation.

Active 1-Acetoxy-2-bromocyclohexane and its Conversion to Diacetate.—The method of treating the bromohydrin with a deficiency of acetic anhydride in the presence of brucine as described previously[12b] for butene derivatives yielded a slight resolution. A solution of 30 g. of brucine, 54 g. of 2-bromocyclohexanol and 13 ml. of acetic anhydride in 300 ml. of carbon tetrachloride was refluxed for two hours. The reaction mixture was treated as before and fractionation at 12 mm. yielded 23.2 g. of bromohydrin, b. p. 88.5–91.0°, α_D (1 dcm.) − 0.20° and 17.8 g. of acetoxybromocyclohexane, b. p. 106.0–107.2°, α_D (1 dcm.) − 0.19°. Each fraction was treated with acetic anhydride to convert all the bromohydrin to acetate. The bromohydrin fraction yielded 23.6 g. of acetate, b. p. 109–110° (12 mm.), α_D (1 dcm.) − 0.19°. The bromoacetate fraction[38] yielded 14 g., b. p. 109–110° (12 mm.), α_D (1 dcm.) − 0.17°.

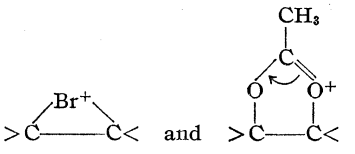
When the acetoxybromocyclohexane, α_D (1 dcm.) − 0.19° was converted to diacetate with silver acetate in dry acetic acid in the usual way the diacetate, b. p. 120.0–120.5° (12 mm.) showed no activity at all. The intermediate fraction lower-boiling than the diacetate also showed no activity.

Behavior of *cis*-1,2-Diacetoxycyclohexane under the Reaction Conditions.—A small quantity of *cis*-1,2-diacetoxycyclohexane was heated eleven hours in dry acetic acid with a mixture of silver acetate and silver bromide. The reaction mixture was filtered and diluted with water. The diacetate was then extracted with ether. The ether extract was neutralized with carbonate solution and then dried over potassium carbonate. Evaporation of the ether and saponification of the ester by the procedure in use gave *cis*-glycol, m. p. 97.5° before recrystallization. Thus at least 99% of the glycol maintains its configuration.

It is a pleasure to thank Professor H. J. Lucas and Messrs. C. W. Gould and F. W. Mitchell, Jr., of the California Institute of Technology for data in advance of publication and Professor P. D. Bartlett of Harvard University for the optically active 2-octanol used. Also, one of us (S. W.) wishes to acknowledge several helpful discussions with Professors P. D. Bartlett and H. J. Lucas.

Summary

The reactions of silver acetate in dry acetic acid with the *erythro*- and *threo*-2-acetoxy-3-bromobutanes, *trans*-1-acetoxy-2-bromocyclohexane, the *meso*- and *dl*-2,3-dibromobutanes, and *trans*-1,2-dibromocyclohexane proceed with predominant retention of configuration. Also, optically active 2,3-dibromobutane and *trans*-1-acetoxy-2-bromocyclohexane give rise to completely inactive diacetates. The steric results are believed due to the participation of a neighboring bromine or acetoxy group in the replacement processes, with production of the intermediates



A discussion of the scope of this kind of participation of neighboring groups in replacement processes and the results to be expected from such participation is included.

LOS ANGELES, CALIFORNIA RECEIVED APRIL 14, 1942

(38) The fact that the same sign of rotation is displayed by the acetoxybromocyclohexanes from both fractions shows that the slight resolution obtained by this procedure is not due to a selective acetylation but to some other reaction.

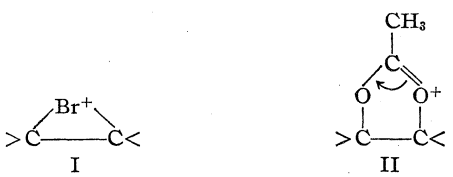
The Role of Neighboring Groups in Replacement Reactions. II. The Effects of Small Amounts of Water on the Reaction of Silver Acetate in Acetic Acid with Some Butene and Cyclohexene Derivatives[1]

BY S. WINSTEIN[2] AND R. E. BUCKLES

In a previous[3] publication on the effects of neighboring groups in replacement reactions we reported that the reaction of silver acetate in dry acetic acid with *trans*-1-acetoxy-2-bromocyclohexane, *threo*- and *erythro*-2-acetoxy-3-bromobutane, *trans*-1,2-dibromocyclohexane and *dl*- and *meso*-2,3-dibromobutane proceeded with what appears to be quite complete retention of configuration. This and other evidence pointed to the participation of the neighboring —Br and —OAc groups in the replacement process, intermediates I and II being involved.



In the course of this investigation, we noticed a pronounced and interesting effect of the presence of water in the acetic acid on the nature of the product and the steric result. The presence of water causes the appearance of roughly 65–75% of the equivalent amount of monoacetate in the product and shifts the steric result to as much as 95–98% of inversion of configuration. This is shown in Table I.

That monoacetate of the glycol is the direct product of the reaction in the presence of water is shown by the behavior of some of the monoacetates and diacetates toward the reaction conditions (Table II). The monoacetates are converted to diacetates to a considerable extent, while the diacetates are converted to monoacetates to only a negligible extent.

Since monoacetate is the direct product of reaction, the presence of water is able to cause the introduction of an hydroxyl group instead of an acetate group by the action of silver acetate on the bromoacetates. However, it appears unlikely

[a] This material was 84 mole % monoacetate, 16 mole % diacetate. [b] In all these experiments an equimolar mixture of silver acetate and silver bromide was added.

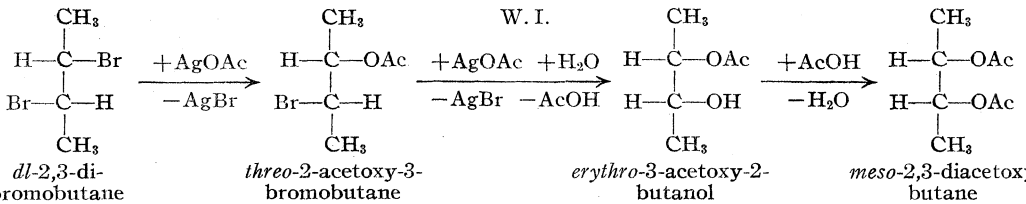

Fig. 1.—*erythro*-3-Acetoxy-2-butanol and *meso*-2,3-diacetoxybutane from *dl*-2,3-dibromobutane or *threo*-2-acetoxy-3-bromobutane.

that water causes the introduction of an hydroxyl group instead of an acetate group when silver acetate reacts to replace the first bromine atom of the dibromides. This is evident from the behavior of the bromohydrins which would thus be formed (Table III).

TABLE III

THE BEHAVIOR OF BUTENE AND CYCLOHEXENE BROMOHYDRINS TOWARD SILVER ACETATE IN ACETIC ACID

Compound	Moles H_2O	N	% retention
threo-3-Bromo-2-butanol	1.0	..	75[a]
trans-2-Bromocyclohexanol	1.0	78	92
trans-2-Bromocyclohexanol	0.64[b]	71	93

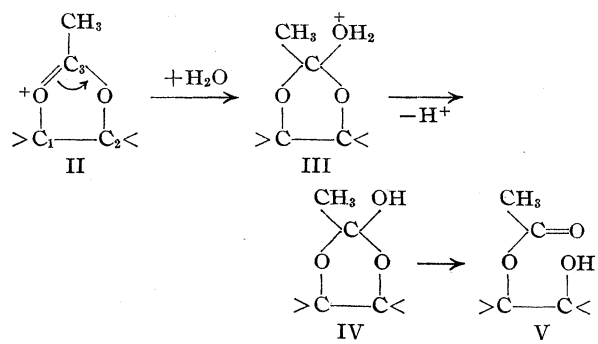
[a] The yield of diacetate on acetylating the crude ester product of the reaction was only 26%. [b] One mole of silver bromide was added also.

Firstly, *threo*-3-bromo-2-butanol gives only a poor yield[4] of expected product with silver acetate in acetic acid. Secondly, with the butene bromohydrin, the steric result is 75% retention,[5] while with the cyclohexene bromohydrin it is at least 93% retention. All our experience[3,6] would lead us to expect bromohydrin to be formed from dibromide with retention of configuration, so retention of configuration should be the steric result for the conversion of dibromide to monoacetate by way of bromohydrin. Actually inversion is the major steric result in the presence of enough water.

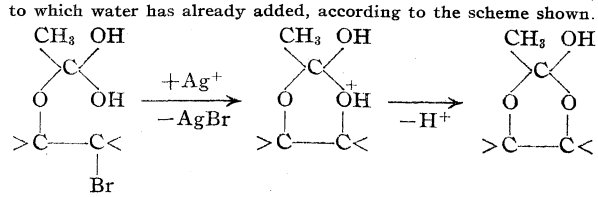
Figure 1 illustrates the reaction course for the preparation of a mixture of monoacetate and diacetate from one of the dibromides or bromoacetates with silver acetate in wet acetic acid containing moderate amounts of water.[7] If dibromide is the starting material, bromoacetate is produced with retention of configuration just as in the absence of water.[3] Then bromoacetate gives rise to monoacetate with inversion of configuration, the monoacetate then slowly being acetylated. The inversion of configuration is denoted by W. I.

In the presence of small amounts of water the scheme shown in Fig. 1 apparently proceeds until the water is largely consumed and then the scheme for dry acetic acid (with retention of configuration) operates. Since water is slowly produced from the monoacetate, it becomes clear why there is a tendency for the amount of inversion of configuration to run somewhat higher than equivalent to the amount of water in the original reaction mixture.

The most probable explanation of the effect of the water involves the formation of intermediate II even when some water is present. Then intermediate II reacts with water at carbon atom C-3 to give the conjugate acid of the orthomonoacetate of the glycol III which by loss of a proton



gives rise to the orthomonoacetate of the glycol IV.[8] The orthomonoacetate IV and the ordinary



This scheme involves the participation of a neighboring orthoacetate group in the process of replacement of the bromine atom.

(4) With the cyclohexene bromohydrin the yield of expected product was not much inferior to that obtained from dibromide.

(5) The reason for this steric result in the case of the butene bromohydrin is not yet clear. In view of the poor yield, the amount of inversion observed could be due to reaction of a small amount (*ca.* 7%) of bromoacetate produced from bromohydrin.

(6) (a) Winstein and Lucas, THIS JOURNAL, **61**, 1576 (1939); (b) Winstein and Lucas, *ibid.*, **61**, 2845 (1939).

(7) Mr. Robert Henderson has found that very much larger amounts of water in the reaction mixture for the treatment of the dibromobutanes have some marked effects such as depressing the yield of product greatly.

(8) At least part of the orthomonoacetate formation in the presence of water may arise from reaction of molecules of acetoxybromide, to which water has already added, according to the scheme shown.

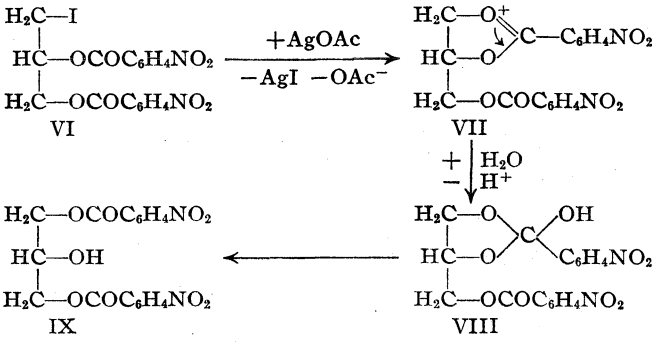
monoacetate V are presumed to be readily interconvertible without any configurational changes under the conditions of the replacement reaction.[9] Thus, the preparation of monoacetate is attended by one Walden inversion which occurs in the formation of intermediate II.

There are several favorable aspects to this explanation. First, intermediates of type II must be reactive at carbon atom C-3, for acetohalogen sugars in which the neighboring acetoxy group is *trans* to the halogen atom often give rise to orthoacetate derivatives in reactions similar in nature to the one discussed in this paper.[10,11] Secondly, the ability of water to affect the reaction only when the acetoxy group is the neighboring group becomes understandable. Thirdly, the very high percentage of inversion of configuration that occurs when enough water is present is to be expected from a process involving the production of an intermediate such as II.

Other Halides with Silver Acetate in Wet Acetic Acid.—Rothstein[12] obtained *cis*-ester from cyclohexene dibromide and Brunel[13] obtained what is now known to be *cis*-ester from 1-acetoxy-2-iodocyclohexane,[14] 1-bromo-2-iodocyclohexane,[14] and 1-chloro-2-iodocyclohexane.[14] These results demand the presence of water in the acetic acid used as solvent, by analogy with the results we have reported.

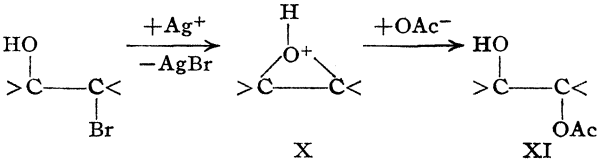
A case which comes to mind of the introduction of an hydroxyl group on treatment of an acyloxyhalide with silver acetate in acetic acid is the conversion[15] of such compounds as 1-iodo-2,3-di-*p*-nitrobenzoxypropane VI to 1,3-di-*p*-nitrobenzoxypropanol-2 IX.

This work is interesting here not only because an hydroxyl group is introduced instead of an acetoxy group but because an acyl group has migrated[3] in the process. If our mechanism for the effect of water in acetic acid on the course of the reaction of acyloxyhalide with silver acetate is correct, the transformation VI → IX proceeds according to the scheme[16] VI → VII → VIII → IX.



Form VIII was suggested by E. Fischer[15] as an intermediate for the migration of acyl groups in partially acylated polyhydroxy compounds.

The Neighboring Hydroxyl Group.—The quite high retention of configuration observed in the treatment of cyclohexene bromohydrin with silver acetate in acetic acid and the predominating retention of configuration in the similar treatment of the butene bromohydrin suggest that the ester product XI is produced chiefly by way of the conjugate acid of the oxide X, the opening of



the oxide ring occurring with inversion.[17] Thus, it would appear that a neighboring hydroxyl group can be similar in action to a bromine or acetoxy group.[3]

Experimental

***trans*-2-Bromocyclohexanol, *threo*-3-Bromo-2-butanol, *trans*-1-Acetoxy-2-bromocyclohexane, *trans*-1,2-Dibromocyclohexane, *erythro*- and *threo*-2-Acetoxy-3-bromobutane and *dl*-2,3-Dibromobutane.**—These substances were either the same as or prepared similarly to the ones used in the previous work.[3]

***meso*-2,3-Dibromobutane.**—This material, b. p. (50 mm.) 73.3–73.5°, was prepared by the action of fuming hydrobromic acid[17,18] on the *dl*-2,3-diacetoxybutane which was obtained in the course of this and the previous[3] work and which was purified by recrystallization from petroleum ether.

***cis*-1,2-Cyclohexanediol.**—This substance, m. p. 98°, was prepared by saponification of esters obtained in the

(9) The ready interconversion of IV to V would be expected from the available work on compounds such as these (Meerwein and Sönke, *J. prakt. Chem.*, **137**, 295 (1933); Hibbert and Greig, *Can. J. Research*, **4**, 254 (1931)).

(11) Generalizations are still lacking as to the factors which determine relative reactivity at carbons C-1 and C-2 as compared to C-3. In the present work it seems necessary to say that acetate ion reacts at C-1 and C-2, while water reacts very rapidly at C-3.

(13) Brunel, *ibid.*, [8] **6**, 200 (1905).

(14) These compounds are all presumably *trans*.

(15) E. Fischer, *Ber.*, **53**, 1621 (1920).

(16) One desirable support for this scheme would be to show that the α,β-diglyceride does not proceed rapidly enough to the α,α'-glyceride by way of the ortho form VIII.

(17) Winstein and Lucas, THIS JOURNAL, **61**, 1581 (1939).

(18) Wilson and Lucas, *ibid.*, **58**, 2396 (1936).

present work. It was purified by recrystallization from carbon tetrachloride. When prepared in large batches by saponification of the ester from the reaction of 1 mole of dibromide with silver acetate in wet acetic acid, the glycol was sometimes not as pure as from the 0.1-mole runs. It was helpful to dissolve the glycol in acetone, filter off an acetone-insoluble impurity, evaporate the acetone from the filtrate and then recrystallize the residue from carbon tetrachloride.

***cis*- and *trans*-1,2-Diacetoxycyclohexanes.**—These substances were the same ones used before.[3]

Monoacetate of *meso*-2,3-Butanediol.—This material was the one previously[17] prepared. Most of it, b. p. 79.2° (10 mm.), $n^{25}D$ 1.4215 was from butene oxide and a little, b. p. 74.5–75.5° (8 mm.),[19] was from *meso*-glycol.

Monoacetate of *cis*-1,2-Cyclohexanediol.—A mixture of 29 g. (0.25 mole) of *cis*-glycol, 25.5 g. (0.25 mole) of acetic anhydride, and 25 ml. of acetic acid was treated with several drops of concd. sulfuric acid. After the heat evolution had ceased and the solution had returned to room temperature, the mixture was diluted with 300 ml. of water and extracted with three 100-ml. portions of ether. The ether extracts were washed with carbonate solution and dried over potassium carbonate. Distillation at 12 mm. through the Weston-type[20] column yielded 27.5 g., 67%, of product boiling at 114–115°, $n^{25}D$ 1.4607. This product had a saponification equivalent weight of 142, indicating a composition of 84 mole per cent. monoacetate and 16 mole per cent. diacetate.

Conversion of Dibromides and Acetoxybromides to Mixtures of Mono- and Diacetates.—The halogen compounds were allowed to react with silver acetate in acetic acid as described previously.[3] The amount of water in the reaction mixture before addition of the halogen compound was estimated as before. Enough additional water was added to make up the desired quantity and the halogen compound was added after the mixture was stirred for a few minutes. Sometimes potassium acetate was added along with the water. The product was isolated as before except when potassium acetate was used in the experiment. Then, the reaction mixture was filtered as before and concentrated at reduced pressure. Ether was added to enable separation from solid potassium acetate. Then the ether was distilled off and the product isolated at reduced pressure.

The mixtures of mono- and diacetates distilled over a small range of temperatures but the mono- and diacetates boil sufficiently near the same temperature to enable sharp separation from acetic acid and high-boiling residue. The yields in the presence of water were about the same as in its absence.

Analysis of Ester Mixtures.—Usually a small portion of the mono- and diacetate mixture obtained by distillation was used for a determination of the saponification equivalent of the sample by the method of Redemann and Lucas.[21] Then the mole fraction of monoacetate in the sample could be calculated.

To obtain a configurational analysis of the ester product, the procedure was similar to the one used before.[3] The cyclohexene derivatives were saponified to glycol. The butene derivatives were acetylated, distilled and the diacetates analyzed as before.

Behavior of Mono- and Diacetates.—The behavior of mono- and diacetates toward the reaction conditions was studied by using a mixture of silver acetate and bromide to best simulate the actual reaction conditions and isolating and analyzing the products as for the conversion reactions.

With *trans*-1,2-diacetoxycyclohexane only a very small amount of ester was treated. It was not distilled but separated with ether after diluting the filtered acetic acid solution with water. The ether solution was neutralized and dried, the ether was evaporated and the residue was subjected to the saponification procedure.

The diacetates on treatment with silver salts in wet acetic acid, gave rise to products with refractive indices and saponification equivalents slightly high. The values of N, the mole fraction of monoacetate in the product, are given in Table II. There seems to be a very slight change to monoacetate, but it is not possible to estimate such small changes very accurately with the methods we used.

Behavior of Butene and Cyclohexene Bromohydrins.—The bromohydrins were treated with silver acetate and silver bromide in wet acetic acid in the same way as for an acetoxybromide. The *threo*-3-bromo-2-butanol yielded only a small amount of ester product which was at once acetylated. The cyclohexene bromohydrin gave products which, in spite of the approximate character of the temperature control of the bath, etc., seemed definitely higher in monoacetate content than the *cis*-products obtained from dibromide and acetoxybromide.

Summary

The presence of small amounts of water in the acetic acid used as a medium for the action of silver acetate on the *erythro*- and *threo*-2-acetoxy-3-bromobutanes, *trans*-1-acetoxy-2-bromocyclohexane, the *meso*- and *dl*-2,3-dibromobutanes, and *trans*-1,2-dibromocyclohexane, gives rise to a steric result shifted toward inversion and a product containing monoacetate. The percentage of inversion is usually slightly greater than equivalent to the water present in the acetic acid solvent and approaches 100 quite closely.

There is evidence that monoacetate is directly produced when water is involved in the replacement process and that the monoacetate is slowly esterified. Also, water seems to be involved in the replacement process for only the second bromine atom of the dibromides.

All the facts are best accounted for by the idea that the water exerts its effect through formation of the orthoester intermediate,

The Role of Neighboring Groups in Replacement Reactions. III. Retention of Configuration in the Reaction of the 3-Bromo-2-butanols with Phosphorus Tribromide

BY S. WINSTEIN

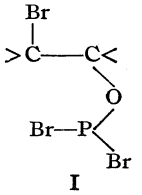
When the *erythro*- and *threo*-3-bromo-2-butanols react with phosphorus tribromide, the steric result is predominant retention of configuration. This is clear from Table I which lists the properties and compositions of the dibromobutanes derived from the bromohydrins.[1] It is seen that *erythro*-3-bromo-2-butanol gives a dibromide which is 95% *meso* and *threo*-3-bromo-2-butanol yields one which is approximately 90% *dl*. Thus, the retention of configuration in the reaction is rather high. Perhaps it would be higher if one learned if there should be made a correction for stereomutation of the dibromides under the reaction conditions.

TABLE I

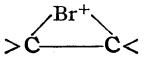
PROPERTIES AND COMPOSITIONS OF 2,3-DIBROMOBUTANES PREPARED FROM 3-BROMO-2-BUTANOLS AND PHOSPHORUS TRIBROMIDE

Bromohydrin	*erythro*	*threo*
Dibromide, b. p., °C.	74.0–74.2 (51 mm.)	76.0–76.7 (50 mm.)
Dibromide, $n^{25}D$	1.5087	1.5115
Dibromide, K_2^2	0.0531	0.0324
Dibromide, % *meso*	95	11
Dibromide, % *dl*	5	89

The steric result of predominant retention of configuration may be accounted for by the operation, for the most of the reaction, of one or the other of two mechanisms. One mechanism is the cyclic rearrangement[3] of an intermediate compound such as I.



I



II

The other mechanism involves the formation of the bromonium ion[1,4] II. Then II reacts with bromide ion with another inversion.

A definite choice between these two mechanisms would be possible from the results with active *threo*-3-bromo-2-butanol.[1,4] However, it seems very probable that the retention of configuration observed is another result of the participation of a neighboring group (Br) in the replacement process. Lucas and Gould[5] have shown that the 3-chloro-2-butanols react with thionyl chloride by way of a chloronium ion, in spite of the small tendency for a chlorine atom to participate in this manner.[1,5] Thionyl chloride is the type reagent most addicted to the cyclic mechanism; thus there seems to be no great tendency for the cyclic rearrangement mechanism to operate in systems such as those under consideration.

It is interesting to compare the present results with the findings of Lucas and Gould[5] for the reaction of phosphorus trichloride with the 3-chloro-2-butanols. Phosphorus trichloride reacted with the 3-chloro-2-butanols with predominant inversion of configuration, whereas phosphorus tribromide reacted with the bromohydrins with predominant retention of configuration. This would seem to be at least partly due to the greater tendency to participate in a replacement process that a neighboring bromine atom displays relative to a chlorine atom.

Experimental

***erythro*- and *threo*-3-Bromo-2-butanols.**—The *erythro*-bromohydrin was an old sample prepared from pure low-boiling 2,3-epoxybutane.[1] It was quite dark by the time it was used in this work. The *threo*-bromohydrin was prepared as previously described[1] by way of 2-butene starting with *meso*-diacetate.

Conversion of Bromohydrins to Dibromides with Phosphorus Tribromide.—The bromohydrin (0.1–0.15 mole) was added dropwise with cooling and stirring to a 50% excess of phosphorus tribromide in a 3-necked flask equipped with a mercury-sealed stirrer, a reflux condenser and a dropping funnel and protected against moisture. With the *threo*-bromohydrin the addition was too rapid at first and the reaction mixture erupted once, causing some loss. There appears to be considerable heat evolution in some reaction step before the one producing the final products. After the bromohydrin was added, the reaction mixture was surrounded by a bath which was brought to 100° and kept at this temp. for one and one-half hours. Then the

reaction mixture was cooled and poured onto ice. The dibromide was separated with the aid of some carbon tetrachloride and the extract was washed with potassium carbonate. Distillation at reduced pressure through a Weston-type[6] column yielded 39 and 42% yields of dibromides, from *threo*- and *erythro*-bromohydrins, respectively.

Analysis of Dibromides.—Comparison of the boiling points and refractive indices of the dibromides with the known[2,7] properties of the 2,3-dibromobutanes indicates that the dibromide samples are largely either *meso*- or *dl*-2,3-dibromobutane. Also, the samples are contaminated with a trace of some low-refractive index impurity, possibly bromohydrin. For samples not absolutely free of foreign materials, the best method of analyzing a mixture of *meso*- and *dl*-2,3-dibromobutanes is by way of the rate constant K_2 for the reaction of the sample with potassium iodide in methanol.[2] Mr. Harold Pokras kindly determined these rates and they are included in Table I along with the calculated compositions for the dibromide samples. The values of K_2 are slightly in doubt because of an uncertainty about the solvent correction of the solvent used in the rate measurements. The uncertainty in the compositions is about 4%.

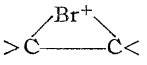
Summary

The *erythro*- and *threo*-3-bromo-2-butanols are converted to dibromides by the action of phosphorus tribromide with a steric result of predominant retention of configuration.

It is considered probable that the steric result is due to the participation of the neighboring bromine atom in the replacement process with the formation of the bromonium ion



as an intermediate.

The Role of Neighboring Groups in Replacement Reactions. IV. The Identity of Various Preparations of 1,2-Dibromocyclohexane

BY S. WINSTEIN

A number of reactions leading to 1,2-dibromocyclohexane have been investigated as to the steric result because of the interest in effects[1,2] of neighboring groups on replacement processes.

All of the preparations of 1,2-dibromocyclohexane, summarized in Table I, have been compared with the dibromide from cyclohexene. The latter dibromide has been assigned the *trans*-configuration for the following reasons. First, the predominance of *trans*-addition of halogen to olefins[3] leads one to this configuration. Further, the second-order rate constant at 74.90° for the reaction of cyclohexene dibromide with potassium iodide in methanol is 0.0204.[4] This value compares favorably with 0.0301 for *dl*-2,3-dibromobutane[5] and 0.0562 for *meso*-2,3-dibromobutane.[5] Since the favored mechanism[6] of the reaction is a *trans*-elimination of bromine by potassium iodide, the *trans*-configuration for cyclohexene dibromide is strongly indicated.

TABLE I

PROPERTIES OF DIFFERENT PREPARATIONS OF 1,2-DIBROMOCYCLOHEXANE

One group of dibromocyclohexane samples was prepared from 2-bromocyclohexanol. The 2-bromocyclohexanol, which is prepared from cyclohexene and which is presumably[2,7] of the *trans*-configuration, reacts smoothly with fuming hydrobromic acid to yield dibromide. In preparing

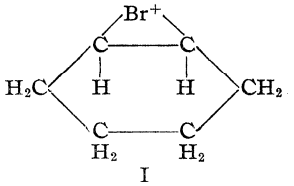
cyclohexene dibromide in this manner, one can treat cyclohexene oxide directly with fuming hydrobromic acid without first converting it to bromohydrin.[8] Phosphorus tribromide reacts with *trans*-bromohydrin[2,7] from cyclohexene oxide to yield, along with what is probably some elimination product, considerable 1,2-dibromocyclohexane. Cyclohexene bromohydrin can be converted to dibromide by way of the *p*-toluenesulfonate. The *p*-toluenesulfonate was non-crystalline but its behavior on treatment with fuming hydrobromic acid was reasonable for the *p*-toluenesulfonate of the bromohydrin. Smooth conversion to dibromide occurred.

The products of these three reactions are almost indistinguishable, on the basis of physical properties and mixed melting points, from the dibromide prepared directly from cyclohexene. Thus complete retention of configuration obtains in these reactions. It would seem that all three reactions proceed by way of the cyclohexene bromonium[1,2] ion I.



I

The reaction[2] of I with bromide ion with inversion gives a net apparent retention of configuration as the steric result.

The bromohydrin from the reduction of 2-bromocyclohexanone with aluminum isopropoxide[9] was also converted to dibromide with fuming hydrobromic acid. Whether the bromocyclohexanol, a somewhat impure product which did not keep well, contained any *cis*-compound[7] is uncertain. The dibromide was almost identical with the dibromides from the other reactions.

The *cis*- and *trans*-1,2-diacetoxycyclohexanes yielded the other preparations of cyclohexene dibromide by some reactions which merit further investigation.[8] Both esters yield dibromide smoothly on treatment with hydrogen bromide in acetic acid. The *cis*-diacetate yields dibromide on treatment with fuming hydrobromic acid. All three of these dibromides are almost indistinguishable from the dibromide from cyclohexene.

On treatment with fuming hydrobromic acid, *trans*-1,2-diacetoxycyclohexane behaves differently from the *cis*-isomer. The reaction mixture turns very dark and yields no dibromide. Possibly the diacetate yields the glycol, which undergoes rearrangement.

The various preparations of 1,2-dibromocyclohexane all appeared to be quite pure *trans*-isomer. A similar tendency for the production of only one dihalide of a cyclic olefin by replacement reactions is seen in the results of other workers. Thus, Mousseron and Granger[10] report that 2-bromocyclohexanol and phosphorus pentabromide and 2-chlorocyclohexanol and phosphorus pentachloride give rise to the same dihalides obtained from the fixation of halogen to cyclohexene. Also, Suter and Lutz[11] have reported that the treatment of *trans*-indene chlorohydrin with phosphorus pentachloride and both *cis*- and *trans*-indene chlorohydrins with thionyl chloride gives one and the same dichloride. This dihalide is apparently the same as indene gives with chlorine. Suter and Lutz[11] have drawn attention to the fact that apparently the only report of a pair of isomeric dihalides of a simple cyclic olefin is that of the cyclohexene dichlorides.[12]

The factors operating to make one dihalide, the *trans*-isomer, the favored product in nucleophilic replacement reactions have been partly discussed already.[2] Thus it has been pointed out that S_Ni type replacement reactions with *cis*- and *trans*-derivatives of cyclic olefins will tend to give *trans*-product if a neighboring group such as a halogen atom is available for participation in the replacement process.

It is possible that a neighboring halogen atom contrives in another way to make the *trans*-dihalide the favored product of replacement reactions. Evidence from studies on restricted rotation[13] of dihalides leads to a considerable barrier for passage through a configuration with two bromine atoms *cis* to each other. With this kind of energy effect to modify the activation energy of an S_Ni or S_N2 reaction leading to *cis*-dihalide, it is possible for the S_Ni or the S_N2 mechanism to disappear to the exclusive operation of mechanisms leading to *trans*-product.

This latter kind of effect of a β-halogen atom we hope to demonstrate independently. This is desirable first, because it is not clear to what

extent S_N2[14] and S_Ni mechanisms operate in cyclic systems such as those being discussed. Secondly, except for the above-postulated effect, a β-halogen atom would be expected to increase[15] the rate of an S_N2 process.

Experimental

Cyclohexene Oxide.—Cyclohexene was converted to chlorohydrin, which, without being isolated as a pure product, was converted to oxide. 123 g. (1.5 moles) of cyclohexene was treated with hypochlorous acid solution.[16] The chlorohydrin layer was separated, the aqueous layer was extracted with a 300-ml. portion of isopropyl ether and the chlorohydrin and ether extracts were stirred for one and one-quarter hours with a solution of 80 g. of sodium hydroxide in 400 ml. of water. The ether layer was then separated, usually dried over potassium carbonate and distilled through a Vigreux column. There was obtained 53–66 g. of oxide, b. p. 127–130°, 69.5–71.0° (100 mm.), yield 36–45%.

trans-**1,2-Cyclohexanediol.**—Cyclohexene oxide, 114.5 g., was shaken with 330 ml. of water to which 8 drops of 60% perchloric acid had been added. The mixture became warm and was homogeneous after about a half hour. The solution was neutralized with sodium hydroxide, the water was distilled off at reduced pressure, and the residue was recrystallized from 300 ml. of benzene. 108 g., 80%, of glycol, m. p. 103–104°, was obtained without working up the mother liquor.

trans-**1,2-Diacetoxycyclohexane.**—This substance was prepared from glycol as described previously.[2]

cis-**1,2-Diacetoxycyclohexane.**—This substance was some prepared previously.[2] Most of the work with *cis*-diacetate was performed on the product of the reaction of 1,2-dibromocyclohexane with silver acetate in acetic acid on the basis of Rothstein's report.[17] We have since[2,18] investigated this reaction and now know that the product must have been a mixture of mono- and diacetates of the *cis*-glycol, the mole per cent. of monoacetate being about 65.

2-Bromocyclohexanol from Oxide.—This was carried out in the same manner in which butene oxide was converted to bromohydrin.[1] Forty-nine grams of oxide and 100 ml. of 48% hydrobromic acid yielded 65 g., 73%, of bromohydrin, b. p. (10 mm.) 86°, $n^{25}D$ 1.5178.

2-Bromocyclohexanol from Cyclohexene.—Cyclohexene was converted to bromohydrin by treatment with acetbromamide as directed by Schmidt, Knilling and Ascherl.[19] The product was obtained in 60% yield, b. p. (10 mm.) 86°, $n^{25}D$ 1.5165. Later,[2] the use of acid as a catalyst in this reaction was found advantageous, but it is possible that these conditions give rise to a little dibromide with the bromohydrin.

2-Bromocyclohexanol from 2-Bromocyclohexanone.—The reduction of 2-bromocyclohexanone with aluminum isopropoxide has already been described.[9] The product from this method darkened rapidly and underwent some change for, on redistillation after ten days, it showed $n^{25}D$ 1.5142 instead of $n^{25}D$ 1.5165 first obtained. The density was now d^{25}_4 1.3990 compared to d^{25}_4 1.4542 for the product from cyclohexene. When samples of about 0.8 g. of this material were left in 20 ml. of 0.4 *N* sodium hydroxide diluted with 20 ml. of alcohol and the mixtures then back-titrated with standard acid, the sample was found to use up 88% of the theoretical amount of alkali in four minutes at room temperature, 90% in twenty-four minutes at room temperature, and 91% in six minutes at the boiling point. The bromohydrin from cyclohexene, similarly treated, consumed 98% of the theoretical amount of alkali in five minutes at room temperature.

1,2-Dibromocyclohexane from Cyclohexene.—Cyclohexene was converted to dibromide by the method of Greengard.[20] The dibromide turns dark rapidly on standing, as is reported, due to impurities. When the impure material is stored over potassium carbonate and fractionated twice through a Weston[21] column, the bulk of the material distils at 99.6–99.9° (13 mm.). This substance remains colorless indefinitely whether exposed to air or not.

Preparation of 1,2-Dibromocyclohexane from Diacetates and Hydrogen Bromide in Acetic Acid.—The method was the same as for the diacetoxybutanes.[8] A heating period of ten hours on a water-bath was used. The crude yield of product was approximately 85%, the bulk of material distilling at constant temperature at reduced pressure.

Preparation of 1,2-Dibromocyclohexane Using Fuming Hydrobromic Acid.—The procedure was the same as for the butene derivatives.[1,8] The reaction mixtures became cloudy in a half hour or less and were left at room temperature several days. Crude yields were about 90% for the products except the one from bromohydrin from bromoketone. These products distilled sharply through the Weston column. In the case of the experiment with bromohydrin from bromoketone the yield was lower and the reaction mixture was very dark. The product was separated with the aid of some carbon tetrachloride. On distillation, the yield of product, not as pure as some of the others, was 55%.

cis-1,2-Diacetoxycyclohexane, on treatment with fuming hydrobromic acid, behaved, from external appearances, just as the monoacetate–diacetate mixture.

When *trans*-1,2-diacetoxycyclohexane was dissolved in fuming hydrobromic acid and the mixture left at room temperature, no dibromide layer formed, but instead, the reaction mixture became somewhat colored in one day and extremely dark in a week. Heating a small portion of the reaction mixture after two days at room temperature at 75° in a sealed tube for one and one-quarter hours and steam-distilling afterwards yielded only traces of oil, $n^{22}D$ 1.527.

Dibromocyclohexane from Bromohydrin and Phosphorus Tribromide.—26.8 g., 0.15 mole, of bromohydrin was dropped with stirring into 6 ml. of phosphorus tribromide in a three-necked 100-ml. flask equipped with a dropping funnel, a mercury-sealed stirrer, a drying tube and an ice-bath. The bromohydrin was added over a period of twenty minutes and a little hydrogen bromide

was evolved at the end of the addition. After a half-hour at the ice-bath temperature the material in the reaction flask was still one phase. The ice-bath was removed. After two hours' standing, there was still no change. Then, 5 ml. more of phosphorus tribromide was added and the reaction mixture was warmed. After one and one-half hours the temperature had been raised to 100°, with slight evolution of hydrogen bromide. A gummy viscous deposit had formed on the walls. Two hours further heating at 95–100° was allowed. The reaction mixture was then cooled and poured onto ice and sodium bicarbonate with which it was well stirred. The dibromide was separated with the aid of 25 ml. of carbon tetrachloride after hydrochloric acid was added to break an emulsion. The extract of the dibromide was washed with potassium carbonate solution, dried over potassium carbonate, filtered and distilled through the Weston column. There were obtained 15 g., 41%, of dibromide, b. p. 93.1–94.1° (10 mm.) as well as 7 g. of a low boiling fraction, b. p. 50.3–51.0 (13 mm.), $n^{25}D$ 1.4941, d^{24}_4 1.325 (in a 2-ml. pycnometer). The low boiling fraction gave an immediate precipitate with aqueous 1 *N* silver nitrate and it absorbed bromine in carbon tetrachloride, not instantaneously but at a moderate rate, without evolution of hydrogen bromide.

1,2-Dibromocyclohexane from Bromohydrin *p*-Toluenesulfonate.—Ten grams, 0.056 mole, of cyclohexene bromohydrin from the oxide, 10.9 g. of *p*-tosyl chloride and 4.4 ml. of pyridine were mixed, whereupon the mixture warmed up to 40 or 50° and cooled off after about an hour. Solid precipitated. After two days the mixture was poured into dilute hydrochloric acid and stirred well. An oil settled out which was not induced to crystallize. The oil was separated and added to 30 ml. of 48% hydrobromic acid. The oil remained as an upper layer after the mixture was saturated with hydrogen bromide gas at 0° and sealed off in an ampoule. After several hours at room temperature, a good deal of solid seemed to have formed, presumably *p*-toluenesulfonic acid. After several days of standing at room temperature, the ampoule was cooled and opened, and the contents were poured into water. The dibromide was washed with potassium carbonate and dried over potassium carbonate, 11.0 g. (81% yield) of crude product being obtained. The bulk of this material distilled at 110.8–111.0° at 16 mm.

Properties of Dibromide Preparations.—About 90 ml. combined preparations 1, 2, 3, 4, 5 and 6, Table I, in a large test-tube equipped with a thermometer, mercury-sealed stirrer and a drying tube was frozen out and allowed to melt while the test-tube was kept in a Dewar flask for insulation. The temperature was −5.0° when the mixture was too thick to stir even by hand and all the solid was gone at −4.0°, so the combined material melted substantially over a range of 1.0° and negligible amounts of isomeric impurities were indicated.

The melting points of individual preparations were taken by freezing about 10-ml. portions in test-tubes and warming the portions with stirring. The points of disappearance of solid are given in Table I. Mixed melting points were taken on various pairs of samples and no melting point lowerings were ever experienced.

Boiling ranges of the dibromides were very narrow and the spread in the values was from 98.6–99.9° at 13 mm., mostly because of difficulty in reproducing pressures.

It is a pleasure to acknowledge the many suggestions of Professor H. J. Lucas and Dr. E. R. Buchman of the California Institute of Technology.

Summary

Preparations of 1,2-dibromocyclohexane from the action of: fuming hydrobromic acid on cyclohexene oxide, 2-bromocyclohexanol derived from cyclohexene, and 2-bromocyclohexanol derived from 2-bromocyclohexanone; phosphorus tribromide on 2-bromocyclohexanol derived from oxide; fuming hydrobromic acid on 2-bromocyclohexyl *p*-toluenesulfonate; fuming hydrobromic acid on *cis*-1,2-diacetoxycyclohexane; and hydrogen bromide in acetic acid on *cis*- and *trans*-1,2-diacetoxycyclohexane all proved to be essentially pure and identical with the known dibromide derived from cyclohexene.

The known 1,2-dibromocyclohexane is assigned the *trans*-configuration. It is pointed out how a β-halogen atom contrives to make the *trans*-dihalide the favored product of nucleophilic replacement reactions.

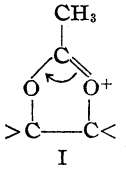
The Role of Neighboring Groups in Replacement Reactions. V. The Effect of the Neighboring Acetoxy Group on the Course of the Replacement of the Tosylate Group of *trans*-2-Acetoxycyclohexyl *p*-Toluenesulfonate[1]

BY S. WINSTEIN, H. V. HESS AND R. E. BUCKLES

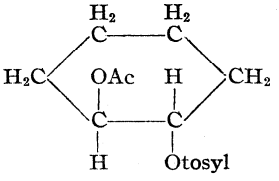
In a recent communication it was reported that the *erythro*- and *threo*-2-acetoxy-3-bromobutanes and *trans*-1-acetoxy-2-bromocyclohexane are converted by silver acetate in dry acetic acid to diacetates with retention of configuration.[2] This steric result and the loss of optical activity when active 1-acetoxy-2-bromocyclohexane was treated with silver acetate in dry acetic acid led to the idea that the acetoxy group participated in the replacement process to give rise to the intermediate I. The presence of enough water in the acetic



I

acid used as a medium for the action of silver acetate on the halides mentioned gave rise to an odd number of inversions[3] in contrast to the even number of inversions under anhydrous conditions.

We now report quite analogous results in the homogeneous solvolysis of *trans*-2-acetoxycyclohexyl *p*-toluenesulfonate[4] II in acetic acid containing potassium acetate.



II

When *trans*-2-acetoxycyclohexyl tosylate is refluxed with potassium acetate in dry acetic acid a diacetate is produced which is at least 93% *trans* so that retention of configuration is by far the predominant steric result.[5] Thus the bulk of the replacement process must be by way of the intermediate I, which reacts with acetate ion.[2] This is further indicated by the loss of activity[2] which is experienced when the replacement process is carried out with the acetate-tosylate derived from active *trans*-1,2-cyclohexanediol by first tosylating and then acetylating the glycol. Almost pure levorotatory glycol, m. p. 111°, $[\alpha]$D 30.2°, (0.221 g. in 25.0 ml. solution, chloroform as solvent) when converted to active acetate–tosylate, then to diacetate and then back to glycol, gave rise to completely inactive, almost pure *trans*-glycol. This, on recrystallization, yielded pure inactive *trans*-glycol, m. p. 104°. This is a more satisfactory demonstration of the loss of activity due to a neighboring acetoxy group than was possible before.[2]

In the presence of enough water in the acetic acid, the acetate-tosylate gave rise to the ester of pure *cis*-glycol, and intermediate amounts of water caused the production of esters of both *cis*- and *trans*-glycol.[6] A series of experiments was carried out in which small amounts of acetate–tosylate were treated with potassium acetate in acetic acid of varying water content. The crude diacetate was saponified and the resulting crude glycol was recrystallized. Under the conditions of concentration employed, acetic acid of higher melting point than 15.75° yielded a glycol mixture from which *trans*-glycol could be obtained by recrystallization. Acetic acid of melting point below 15.50° yielded a mixture from which *cis*-glycol was obtained.

Table I summarizes the results of the series of experiments. The third column indicates where very low recoveries of pure glycol were obtained by the recrystallization. The arrows indicate the directions of increase in these recoveries. Included in Table I are the results of three other qualitative experiments which yielded glycols very largely *cis*.

Several larger runs were made in which the acetate–tosylate was treated with potassium acetate in acetic acid of varying water content and

(1) A portion of the material reported in this paper was presented before the Organic Division at the St. Louis meeting of the American Chemical Society, April, 1941.

14.6[b]	*cis*	high
[c]	*cis*	high

[a] Small excess of acetic anhydride present. [b] No potassium acetate added. [c] Solvent was absolute alcohol.

the ester was isolated by distillation. Here it is possible to estimate the steric results quite accurately.[2] Table II summarizes some of the results.

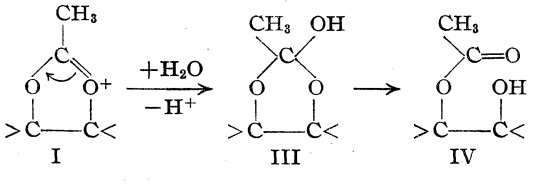
TABLE II

STERIC RESULTS AND PRODUCTS OF REACTION OF *trans*-2-ACETOXYCYCLOHEXYL TOSYLATE WITH POTASSIUM ACETATE IN ACETIC ACID

M. p. of AcOH, °C.	% H_2O	Mole ratio H_2O/-tosylate	Mole % mono-acetate	M. p. of glycol,[a] °C.	Steric result
..	0	0	0	100	93% Retention
16.0	0.35	0.20	16	85	68% Retention
10.3	4.0	2.3	65	98	100% Inversion

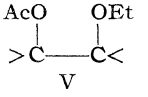
[a] M. p. of *trans*-glycol, 104°; *cis*-glycol, 98°.

In line with the previous discussion,[3] the most likely explanation of the effect of water is that it reacts with intermediate I to give orthomonoacetate III which isomerizes to ordinary monoacetate IV. The validity of this explanation has

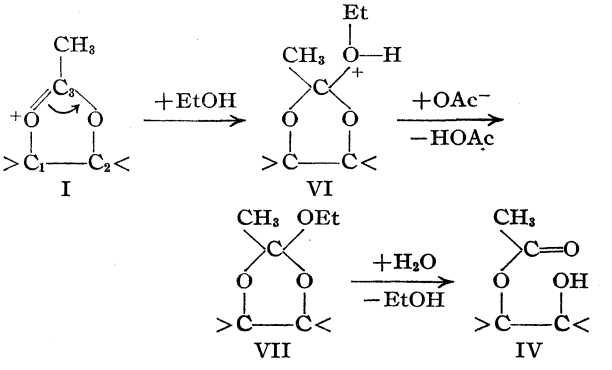


been indicated by the study of the acetate-tosylate II in alcohol. Criegee and Stanger[4] have already reported that the acetate–tosylate gives rise to quite pure *cis*-ester on refluxing with potassium acetate in absolute alcohol. We have confirmed this steric result in alcohol (see Table I and experimental part). Also, we have isolated the ester product and found it to be pure monoacetate. Potassium acetate can be dispensed with. When the *trans*-acetate–tosylate is heated in absolute alcohol, to which a trace of water is added and in which calcium carbonate is suspended, a product is obtained which can be saponified directly to quite pure *cis*-glycol without being isolated.

The facts that acetate ion may be dispensed with in alcohol and that little or no ethyl ether V is produced are consistent only with the following mechanism for the replacement process.

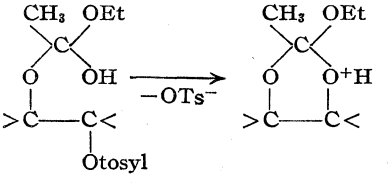


There is formed intermediate I which reacts with ethyl alcohol to give VI.[7] This loses a proton to give an orthoacetate derivative VII which eventually[8] gives the ordinary monoacetate IV. We plan to prepare VII and show whether the conversion to monoacetate does indeed proceed. Also we shall attempt to isolate VII from the reaction mixtures.

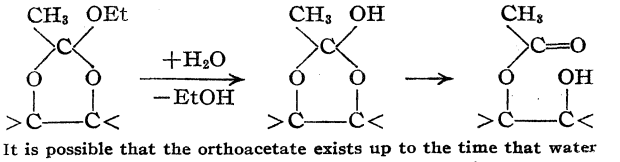


From the previous[3] and the present work, it appears that intermediate I reacts with water and alcohol at carbon atom C-3 and with acetate ion

(7) It must be noticed that part, at least, of VI might be formed from reaction of molecules to which alcohol has already added, as follows



(8) A possible route from VII to IV is as follows



It is possible that the orthoacetate exists up to the time that water is added in isolating monoacetate from the reaction mixture.

TABLE III

SOME REPLACEMENT REACTIONS WITH A STERIC RESULT OF RETENTION OF CONFIGURATION BECAUSE OF PARTICIPATION OF NEIGHBORING GROUPS

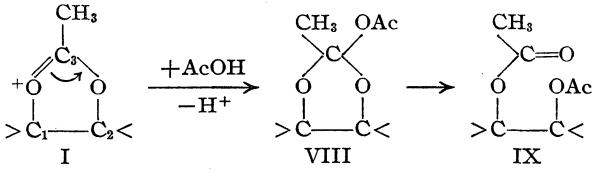
at carbon atoms C-1 and C-2. Also, the reactions with water and alcohol are very much faster than with acetate ion. One more reaction of intermediate I seems indicated. In dry acetic acid in the absence of potassium acetate, the acetate–tosylate II yields, on heating, a diacetate which is about 90% *cis*, so that predominant inversion is the steric result (see Table I and experimental part). Apparently, without any acetate ions to react with intermediate I at carbon atoms C-1 or C-2, a reaction path to *cis*-diacetate is available. This may be as follows



I VIII IX

I reacting at carbon atom C-3 with even the poor electron-donor, acetic acid. The subsequent loss of a proton gives the orthodiacetate VIII which, under the conditions prevailing, is isomerized to the normal diacetate IX.[9] The only inversion in the whole process is during the formation of intermediate I. We may attempt to synthesize and study VIII.

(9) If the mechanisms we have outlined are correct, acetate ion reacts with intermediate I at C-1 and C-2 faster than acetic acid at C-3. Therefore, it must react at C-1 and C-2 very much faster than acetic acid at C-1 and C-2. This seems to be evidence that the opening[2] of the ring of I by acetate ion is S_N2 in character. Also, it would appear that in the previous[2] work with silver acetate, the intermediate I reacts with acetate ion and not acetic acid. In the reaction mixtures using silver acetate, acetate ion is as effective as it is in 1 *M* potassium acetate solution in the homogeneous work.

Summary of Retentions of Configuration.—There has been reported by us and others a number of S_Ni type replacement reactions which have a steric result of predominant retention of configuration. These have been discussed from the standpoint of the role of a neighboring group in causing this steric result and they are summarized in Table III.

Experimental

***cis*- and *trans*-1,2-Cyclohexanediol.**—These substances were the same as those previously used.[2,3,12]

***cis*- and *trans*-1,2-Diacetoxycyclohexane.**—These materials were prepared as before.[2]

Cyclohexene Oxide.—This material was prepared as before.[12]

***dl-trans*-2-Hydroxycyclohexyl-*p*-toluenesulfonate.**—The monotosylate of *trans*-1,2-cyclohexanediol was produced from cyclohexene oxide and purified by the method of Criegee and Stanger.[4]

As mentioned by Criegee and Stanger,[4] the glycol monotosylate may also be prepared from *trans*-1,2-cyclohexanediol. To 1.00 g. of glycol in 10 ml. of dry pyridine was added 1.64 g. of good grade tosyl chloride and the mixture was allowed to stand overnight. Treatment of the mixture with dilute sulfuric acid and stirring yielded after several minutes a solid product, 1.58 g., 68%, after washing and drying. This product was suitable to acetylate without further purification.

***dl-trans*-2-Acetoxycyclohexyl-*p*-toluenesulfonate.**—The acetylation of the glycol monotosylate was performed with excess acetic anhydride containing a trace of concentrated sulfuric acid (1 drop in 10 ml.). After the mixture had

stood overnight, it was poured into water. There was obtained a nearly quantitative yield of product which soon crystallized; m. p. 73–76°; recryst. from ligroin, m. p. 78°. The acetates from the monotoluenesulfonates prepared from oxide and glycol proved identical in melting point and mixed melting point.[4]

Active *trans*-1,2-Cyclohexanediol.—This substance was obtained by the resolution of *trans*-1,2-cyclohexanediol as carried out by Wilson and Read.[15] *l*-Menthoxyacetic acid was prepared by the method of Frankland and O'Sullivan[16] but the acid was distilled as Read and Grubb did.[17] The rotation of the distilled acid agreed with the report of Read and Grubb.

The *l*-menthoxyacetate from the *trans*-1,2-cyclohexanediol and *l*-menthoxyacetyl chloride in pyridine was obtained in ether solution by treatment of the reaction mixture with hydrochloric acid, extraction with ether, washing of the ether extracts with potassium carbonate solution, and drying of the ether extracts over potassium carbonate. Evaporation of the ether solvent yielded a residue of which nearly all turned solid on cooling. Washing of the residue with petroleum ether yielded a dry white solid. Several crystallizations of this solid from benzene consistently gave a small yield of the high-melting diastereomer of mono-*l*-menthoxyacetate of *trans*-1,2-cyclohexanediol, m. p. 126–127°.

The active glycol was conveniently obtained from the menthoxyacetate by saponification and then vacuum sublimation of the glycol from salts. A mixture of 1.00 g. of menthoxyacetate, 17 ml. of alcohol, and 1 ml. of 35% aqueous sodium hydroxide was refluxed for two hours. Then the solution was poured into an evaporating dish and saturated with carbon dioxide by the careful addition of dry-ice. Evaporation of the solvent left a solid, from which the glycol was sublimed at about 3 mm. A total of 3.46 g. menthoxyacetate yielded 1.11 g., 86%, of glycol, m. p. 109–110.5°, 109–111° (different preparations). This glycol was evidently not quite as pure as that of Wilson and Read,[15] m. p. 113–114°, but as pure as that of Derx,[18] m. p. 110.5°. The glycol on mixing with *dl-trans*-glycol showed a m. p. of 95–98°. A chloroform solution of 0.221 g. of the glycol in 25 ml. had α_D (2 dcm.) 0.53°, $[\alpha]_D$ 30.2°.

Qualitative Experiments on the Conversion of *dl-trans*-2-Acetoxycyclohexyl-*p*-toluenesulfonate to Glycol.—To 10 ml. of acetic acid of known melting point was added 1 g. of potassium acetate. Sometimes a slight excess of acetic anhydride was added and the mixture heated two hours to destroy the water. Three grams of acetate–tosylate was added and the solution was heated four hours under reflux. The reaction mixture was allowed to cool and then it was poured into water. The mixture was neutralized with potassium carbonate and extracted with ether. The ether extracts were dried over potassium carbonate, the ether was distilled off and then the residue was directly saponified to glycol according to the saponification procedure previously[2] used for analyzing ester mixtures.

When the conversion was carried out in the absence of potassium acetate, the procedure was similar except that 50 ml. of acetic acid was used and the reaction time was five hours at 100°.

To obtain the glycols, the saponification mixtures were at first saturated with carbon dioxide and allowed to evaporate, whereupon the glycol was extracted out of the solid with chloroform. The yields by this procedure were about 60%. Later, the glycols were extracted from the saponification mixture as in the saponification-analysis method used on the esters previously.[2] The yields by this method were in excess of 80%.

The glycols thus prepared tended to be impure and they melted at temperatures considerably lower than when the ester product could be isolated by distillation. However, by recrystallization from carbon tetrachloride, the predominant glycol could be obtained pure or still contaminated with the other glycol if the mixture was originally one with comparable amounts of the two glycols.

When sodium acetate replaced potassium acetate in dry or quite wet acetic acid, the results were quite unchanged.

When absolute alcohol was used as the solvent, 4.5 g. of acetate–tosylate, 6 g. of potassium acetate and 50 ml. of Commercial Solvents Gold Shield absolute alcohol were refluxed for thirty-six hours. At the end of the heating period, the mixture was filtered, the solid was washed with ether, the alcohol and ether were boiled off of the combined filtrate and ether washings and the residue was treated according to the saponification procedure. A 71% yield of glycol was obtained, which on recrystallization from carbon tetrachloride gave better than an 80% recovery of pure *cis*-glycol, m. p. 98.5°.

Conversion Reactions with Isolation of the Ester Products.—To a mixture of 100 ml. of glacial acetic acid (m. p. 16.0°), 5 ml. of acetic anhydride and 9.8 g. of potassium acetate, which had been refluxed one hour, was added 30 g. of acetate–tosylate and the solution was refluxed five hours. It was allowed to cool, poured into water, neutralized, extracted with ether and then the ether extracts were dried. Evaporation of the ether and distillation of the residue through a Weston[19] type column yielded 13.0 g., 68%, of diacetate, b. p. (12.5 mm.) 120.4–121.4°, n^{25}_D 1.4476. The saponification method yielded a glycol melting at 100°, which corresponds to 93% *trans*. The refractive index of the sample was somewhat high. On redistillation, the main fraction had b. p. (12 mm.) 119.5–119.8°, n^{25}_D 1.4470, the refractive index still high.

The same experiment was carried out using acetic acid of different water contents. Acetic acid, m. p. 10.3°, yielded 14.1 g., 85%, of product, b. p. (12 mm.) 114–116°, n^{25}_D 1.4574 and saponification equivalent,[20] 128. This product yielded *cis*-glycol, m. p. 98°, on saponification. Acetic acid, m. p. 16.0°, yielded 15.4 g., 83%, of product b. p. (12 mm.) 114–118°, n^{25}_D 1.4490 and saponification equivalent 105. This material yielded a glycol, m. p. 85°, predominantly *trans*.

In the absence of potassium acetate, 480 ml. of acetic acid (m. p. 16.4°) and 8 ml. of acetic anhydride were refluxed one hour, 30 g. of acetate–tosylate was added, and the mixture was held at about 100° for five hours. After the reaction mixture was cool, 0.1 mole of potassium acetate was added. Most of the acetic acid was distilled off

at reduced pressure and the residue was poured into water. The mixture was neutralized with potassium carbonate and the diacetate was taken up in ether. The ether extract was dried over potassium carbonate, the ether was distilled off and the diacetate was isolated at reduced pressure; 12.9 g., 67%, of material, b. p. (12 mm.) 117.5–117.8°, $n^{25}D$ 1.4480, saponification equivalent 99 (theoretical 100). By the saponification procedure, this product appeared to be 89% *cis*. A small part of the steric result may be due to reaction of some unreacted acetate–tosylate with potassium acetate during the distillation of acetic acid.

For the reaction in absolute alcohol, the procedure was as for the qualitative experiment except that 30 g. of acetate–tosylate was used. When the ether washings and alcohol solution were concentrated, the residue was poured into water and the ester was extracted out with ether. The ether extract was dried over potassium carbonate and the ester isolated by distillation at reduced pressure; 9.2 g., 60%, of material, b. p. (12 mm.) 113–113.2°, $n^{25}D$ 1.4650, saponification equivalent 156.5, 99 mole per cent. monoacetate, was obtained. By the saponification procedure a glycol, mostly *cis*, m. p. 93°, was obtained. This result, together with the melting point of 96° obtained for the product in the absence of potassium acetate (see later) and the melting point of 96–98° reported by Criegee and Stanger[4] indicates that essentially pure *cis*-product is obtained in alcohol.

Conversion of Acetate–Tosylate of Active *trans*-1,2-Cyclohexanediol to the Diacetate of *dl-trans*-1,2-Cyclohexanediol.—1.02 g. of active glycol was tosylated as in the case of the *dl*-glycol, yielding 1.67 g., 70%, of crude monotosylate. As in the case of the *dl*-compound, the crude monotosylate was acetylated directly. The addition of water to the reaction mixture gave an oil which did not crystallize. The oil was finally extracted with 100 ml. of warm ligroin and the solution was dried over potassium carbonate. When the ligroin solution was cooled an oil came down which turned solid in a dry-ice bath and more loose solid developed on longer cooling. The solid could be filtered rapidly but it melted on the filter paper as it warmed up toward room temperature. Thus it appeared that the acetate–tosylate of the active glycol was quite low melting compared to the analogous *dl*-compound. The solid which was filtered off rapidly at low temperature was taken up in carbon tetrachloride, the carbon tetrachloride solution was washed with carbonate solution to remove any traces of acetic acid present and then dried over potassium carbonate. The volume of the solution was 34.5 ml., and the αD (2 dcm.) 1.22°. The carbon tetrachloride was pumped off at low pressure with the aid of a bath at 40–50° and the residue was refluxed four hours with a solution of potassium acetate in dry acetic acid. The reaction mixture was poured into water and treated in the usual way. The extracted diacetate was saponified in the usual way after the ether was driven off. The saponification mixture was saturated with carbon dioxide and allowed to evaporate. Vacuum sublimation yielded 0.24 g. of glycol. A much larger yield of glycol was obtained when *dl-trans*-glycol was carried through this whole procedure. One reason for the low yield was that considerable active acetate–tosylate was left in the ligroin solvent. When the ligroin solution remaining after filtration from the active acetate–tosylate was washed with carbonate solution, dried over potassium carbonate, and pumped down to a volume of 29 ml., it had αD (2 dcm.) 0.44°. Another reason for the lower yield is the loss attending the extra handling which was necessary for the liquid acetate–tosylate.

The glycol in 25 ml. of chloroform showed αD (2 dcm.) ±0.00°. It melted over a range up to 96°. Mixing with *dl-trans*, m. p. 104°, raised the melting point. Recrystallization from carbon tetrachloride yielded 0.18 g. of glycol, m. p. 103.5–104°, no change on mixing with pure *dl-trans* glycol. The glycol in 25 ml. of chloroform showed αD (2 dcm.) ±0.00°.

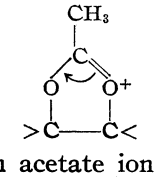
Conversion of Acetate–Tosylate to *cis*-Ester in Alcohol without Potassium Acetate.—A mixture of 1.50 g. of acetate–tosylate, 0.50 g. of calcium carbonate, 17 ml. of absolute alcohol and two drops of water was heated under reflux for thirty-nine hours, and then filtered. Saponification of the ester and sublimation of the glycol yielded 0.33 g., 59%, of product, m. p. 90–96°. Recrystallization from carbon tetrachloride gave a nearly quantitative recovery of *cis*-glycol, m. p. 98° and the same on mixing with authentic *cis*-glycol.

Tests on the Stability of Esters under Reaction Conditions.—Two-gram portions of *cis*- or *trans*-1,2-diacetoxycyclohexane were subjected to the reaction conditions prevailing in the conversion reactions. Then the reaction mixtures were worked up as for the small qualitative experiments previously described.

cis-1,2-Diacetoxycyclohexane, after refluxing four hours with 1 g. of potassium acetate in 10 ml. of dry acetic acid yielded nearly pure *cis*-glycol, m. p. 96.5°. The *trans*-diacetate on refluxing four hours with 1 g. of potassium acetate and 0.54 g. of water in 10 ml. of acetic acid yielded nearly pure *trans*-glycol, m. p. 102.5°. The *trans*-diacetate after being held five hours at 100° with 1.72 g. of *p*-toluenesulfonic acid in 50 ml. of dry acetic acid yielded nearly pure *trans*-glycol, m. p. 102°.

Summary

trans-2-Acetoxycyclohexyl *p*-toluenesulfonate is converted to diacetate with predominant retention of configuration when it is heated with potassium acetate in dry acetic acid. Also, active *trans*-2-acetoxycyclohexyl *p*-toluenesulfonate gives rise to inactive diacetate. These results are explained by the participation of the neighboring acetoxy group in the replacement process to give rise to the intermediate



which reacts with acetate ion with a second inversion.

When *trans*-2-acetoxycyclohexyl *p*-toluenesulfonate is heated in sufficiently wet acetic acid with or without potassium acetate, in absolute alcohol with or without potassium acetate, or in dry acetic acid without potassium acetate, there are

isolated products (mono- or diacetates or mixtures) which are entirely or very largely of the *cis*-configuration. It is considered most probable that orthoacetate intermediates are involved in these transformations.

Reversible Photochemical Processes in Rigid Media: The Dissociation of Organic Molecules into Radicals and Ions

BY GILBERT N. LEWIS AND DAVID LIPKIN

In previous papers[1] we have studied the phosphorescent state of dye molecules. This phosphorescent state returns to the initial state with light emission and is to be regarded as isomeric with the normal molecule. On the other hand, the present paper deals with the photo-dissociation of organic molecules into radicals, ions and electrons.

In a study of the absorption spectra of odd molecules we desired to investigate diphenylnitrogen, the free radical of tetraphenylhydrazine, but at any temperature at which the dissociation is appreciable the radical disappears as fast as it is formed, through processes of rearrangement or disproportionation. We therefore attempted to produce diphenylnitrogen by illuminating a solution of tetraphenylhydrazine in our EPA solvent (see experimental section) at low temperature.

The solution in a quartz tube was immersed in liquid air contained in a quartz Dewar. After a minute or two of exposure to the light from a high-pressure mercury arc the solution acquired a green color which we attributed to the formation of the diphenylnitrogen radical, although we shall see presently that other substances are also produced. The color persists for many days at the temperature of liquid air but rapidly disappears when the temperature is raised sufficiently to make the solvent fluid.[2] This rise of temperature for EPA is about 10°. That the disappearance of color is not primarily the effect of temperature but of the change in rigidity of the solvent is shown by the fact that most of the phenomena that we are going to describe are duplicated when the tetraphenylhydrazine is dissolved in glycerol or triethanolamine and illuminated at 190°K. and in a few cases similar phenomena have been obtained in glucose at room temperature.[3]

When the green solution is studied spectroscopically we find that, instead of one band, several prominent bands appear and we shall see that these belong to different substances, since their relative intensities vary greatly according to the way in which the solutions are prepared and treated. The absorption curves are shown in Fig. 1, in which the ordinates of each curve are proportional to the extinction coefficient, but with an arbitrary proportionality factor for each curve, since we have not yet determined the absolute concentration of any one of the substances.

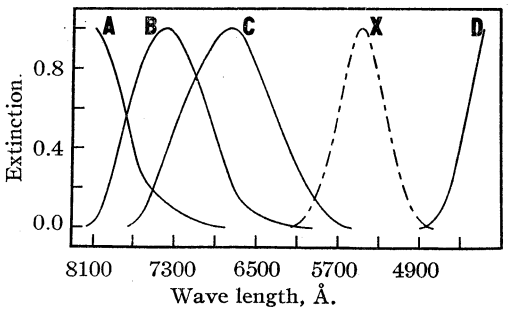

Fig. 1.—Absorption bands of tetraphenylhydrazine illuminated and measured in EPA at about 90°K. The ordinates for each curve are in arbitrary units.

In attempting to identify substances produced by illumination we are handicapped by

(1) (a) Lewis, Lipkin and Magel, THIS JOURNAL, **63**, 3005 (1941); (b) Lewis, Magel and Lipkin, *ibid.*, **64**, 1774 (1942).

(2) The production of color by illumination in the cold and its disappearance on warming may be repeated many times with the same sample, although eventually a permanent yellow color appears. Quantitative experiments show that when the initial illumination is carried to the point where all of the tetraphenylhydrazine is gone, more than 90% of it is regenerated on warming. From the fact that diphenylnitrogen is one of the chief products of the photo-dissociation and that this returns to tetraphenylhydrazine, even at very low temperatures, we have recently drawn certain conclusions regarding the heat of dissociation of the latter compound [Lewis and Lipkin, THIS JOURNAL, **63**, 3232 (1941)].

(3) The only antecedents that we have been able to find in the literature to the phenomena that are to be here described are in the inorganic field the coloration of glasses after long exposure to light and in the organic field the observations of Wieland [*Ann.*, **381**, 216 (1911)], who exposed crystalline substances such as the tetraarylhydrazines to electron bombardment at the temperature of liquid air. He obtained strong coloration which he attributed to free radicals. The color disappeared within a few minutes after the bombardment ceased.

being unable to study any of the physical properties of the new substances except their reactions with photons (absorption and luminescence).[4] On the other hand, we have the great advantage of working with isolated molecules. At the small concentrations that we use, 10^{-4} M or less, the individual molecules are on the average over 100 Å. apart and when the solution is cooled to rigidity no appreciable diffusion can occur, and therefore no bimolecular reactions. Except in cases where the solute is polymerized before the state of rigidity is attained, the simple molecule and the group of solvent molecules in its immediate neighborhood alone can participate in the photochemical process or in the reactions which occur after illumination. This restriction of all processes in the rigid solvent to the zone of a single molecule limits the number of possible structures that may be assigned to the photochemical products.

In order to investigate the several absorption bands obtained by illuminating tetraphenylhydrazine the frequency of the activating light may be varied, the effect of further illumination by light of various frequencies may be observed, and if the temperature is gradually raised we may see which substances first disappear, and whether the disappearance is accompanied by an increase in any of the other bands. Finally, we may activate with polarized light and study the molecular orientation of the products. In addition to these experiments on tetraphenylhydrazine itself we may illuminate other substances containing the diphenylnitrogen group and find whether we can reproduce any of the bands already observed.

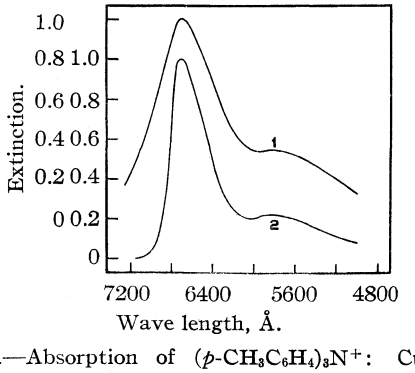

Fig. 2.—Absorption of $(p\text{-}CH_3C_6H_4)_3N^+$: Curve 1, Granick and Michaelis by chemical oxidation; Curve 2, by photo-oxidation in EPA at about 90 °K.

(4) We have not attempted to study the magnetic susceptibility of our solutions. Such an investigation, while difficult, would be profitable.

We shall find three types of photochemical reaction. The first is the one already mentioned, namely, splitting into two uncharged radicals, and this for brevity will be called *photo-dissociation*. Second, a molecule may be split by light into a positive and a negative ion. This *photo-ionization* is also observed under ordinary conditions in such substances as the leucocyanides of crystal violet and malachite green.[5] Since these positive ions behave as secondary acids[6] the recombination of the ions in the dark is observably slow at room temperature. Third, the illuminated molecule may merely eject an electron. To distinguish this from the preceding type of process we shall call it *photo-oxidation*, and indeed the simplest of all oxidation processes is the loss of an electron. Since this photo-oxidation is a new and somewhat surprising phenomenon we shall first present the evidence for its existence.

Photo-oxidation by the Loss of an Electron

Upon illuminating a variety of substances in rigid media it soon became apparent that one of the commonest photochemical processes is the mere loss of an electron by the activated molecule. When triphenylamine was illuminated at liquid air temperature in EPA a blue color was obtained. The absorption curve showed a maximum at 6560 Å. and a shoulder in the neighborhood of 5700 Å. The curve was so similar to a curve obtained by Granick and Michaelis[7] (Curve 1, Fig. 2) for the ion of tri-*p*-tolylamine, $(p\text{-}CH_3C_6H_4)_3N^+$, produced by chemical oxidation of tri-*p*-tolylamine, that it seemed very probable that our blue substance was $(C_6H_5)_3N^+$. This *odd* ion is so unstable because of the lability of the para hydrogens that it cannot readily be obtained by chemical oxidation. We were, therefore, very grateful to Drs. Granick and Michaelis for sending us a sample of the tri-*p*-tolylamine used in their investigation. When this was illuminated in the rigid solvent we obtained the substance whose absorption is given in Curve 2 of Fig. 2. There can be no question that chemical oxidation at room temperature and photo-oxidation at liquid air temperature have given the same substance, namely, the positive ion left when one electron has been removed. In order to produce photo-oxidation of triphenylamine and tri-

(5) This phenomenon has recently been carefully studied by Harris, Kaminsky and Simard [THIS JOURNAL, **57**, 1151 (1935)].

(6) Lewis, *J. Franklin Institute*, **226**, 2093 (1938); Lewis and Seaborg, THIS JOURNAL, **61**, 1886 (1939).

(7) Granick and Michaelis, *ibid.*, **62**, 2241–2242 (1940).

p-tolylamine it is necessary to illuminate with the full mercury arc through quartz, but even so it is surprising to find the energy sufficient to expel an electron according to the process

$$Ar_3N \longrightarrow Ar_3N^+ + e^-$$

As to what becomes of the electron we can only speculate. It presumably becomes attached to a solvent molecule,[8] or to a group of molecules, or even to some unique point in the solvent determined by its rigid structure. The electron must lie in a potential hole which is deep enough so that the large electrostatic field of the ion is unable to dislodge it. The color persists at liquid air temperature for several days, but at only slightly higher temperatures the color disappears. Then presumably the electron has returned to the ion.

Another case where we may compare our results with those of Michaelis and his collaborators is that of Wurster's blue, $(CH_3)_2N\langle\bigcirc\rangle N(CH_3)_2]^+$. They prepared this odd ion by chemical oxidation, and their absorption spectrum[9] obtained at room temperature in partly aqueous solutions is given in Curve 1, Fig. 3. We dissolved the colorless base of Wurster's blue in EPA and illuminated in liquid air. The absorption spectrum was then measured above rapidly boiling liquid air.[10] The results are given in Curve 2, Fig. 3. In spite of the difference in solvent and in temperature the agreement of the two curves is remarkable, and definitely proves the ejection of an electron by light.[11]

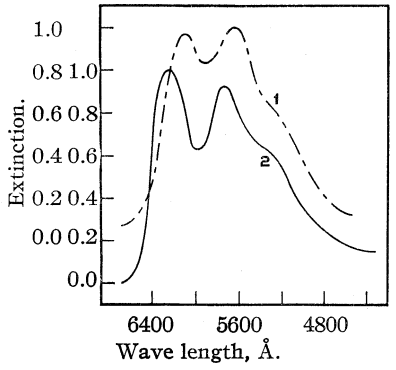

Fig. 3.—Absorption of Wurster's blue: Curve 1, Michaelis, Schubert and Granick by chemical oxidation; Curve 2, by photo-oxidation in EPA at about 90 °K.

Owing to the complete elimination of bimolecular reactions in a rigid solvent we may by this method of photo-oxidation obtain and study numerous odd ions which, under ordinary circumstances, would engage in further reactions almost as soon as formed. The triphenylamine ion is an example. As further illustrations of odd ions produced by light through the ejection of electrons, we give in Fig. 4 the very complex spectrum of tetramethylbenzidine ion, $(CH_3)_2N\langle\bigcirc\bigcirc\rangle N(CH_3)_2]^+$, and in Fig. 5 the spectrum of methyldiphenylamine ion, $(C_6H_5)_2NCH_3^+$. The spectra of several other odd ions will be given in later sections.

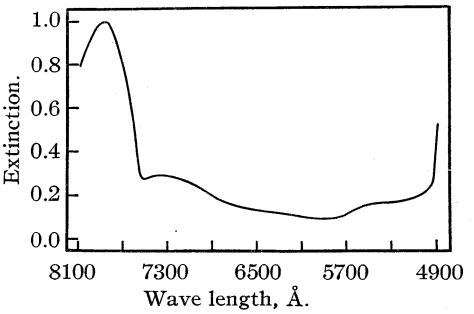

Fig. 4.—Absorption of tetramethylbenzidine ion produced by photo-oxidation in EPA at about 90 °K. The sample was not specially purified.

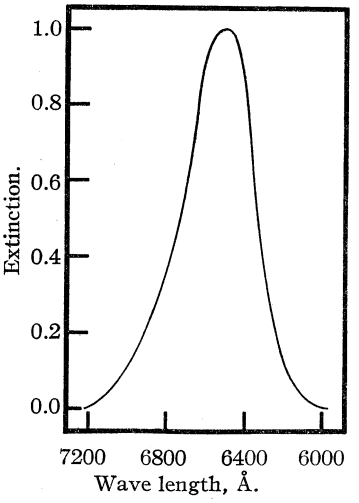

Fig. 5.—Absorption of methyldiphenylamine ion produced by photo-oxidation in EPA at about 90 °K.

(8) In a mixture of equal volumes of ether and isopentane the same results were obtained as in EPA. On the other hand, in a solvent of mixed hydrocarbons (3 vols. of isopentane to 1 vol. of methylcyclohexane) little or no blue color was produced. Whether, however, this failure was due to lack of oxygen atoms in the solvent or to a lesser rigidity of the hydrocarbon solvent, we have not as yet ascertained.

(9) Michaelis, Schubert and Granick, THIS JOURNAL, **61**, 198 (1939).

(10) Lewis, Magel and Lipkin, *ibid.*, **62**, 2973 (1940).

(11) When the ion of Wurster's blue was produced in a solvent containing air a slight blue color remained after warming. If this is due to the permanent capture of electrons by the oxygen molecules, a study of the amount of residual color as a function of the oxygen concentration might indicate how far the electron is ejected.

Further cases of presumable photo-oxidation were found in a cursory examination of the following substances which gave the colors noted, the color disappearing when the solvent became liquid. These experiments should be repeated with more carefully purified materials.

Substance	Color
Hydroquinone	Orange-yellow
α-Naphthol	Reddish-orange
p-Hydroxydiphenyl	Orange
Thiophenol	Yellow
o-Thiocresol	Yellow
Thio-β-naphthol	Orange-red
p-Hydroxythiophenol	Orange

Photo-dissociation into Free Radicals

In order to make sure that dissociation into free radicals does occur under the conditions of our experiments, we slowly cooled in a sealed quartz tube a solution of triphenylmethyl in EPA. At about $-50°$ it was so completely converted into hexaphenylethane that the free radical could no longer be detected spectroscopically. It was then placed in a quartz Dewar containing liquid air and illuminated by the mercury arc. After ten minutes of exposure the solution showed the sharp and unmistakable absorption bands of triphenylmethyl. The slow formation of the free radical, in spite of the small energy of dissociation, may indicate that the main absorption of hexaphenylethane comes at higher frequencies than are afforded by the mercury arc.

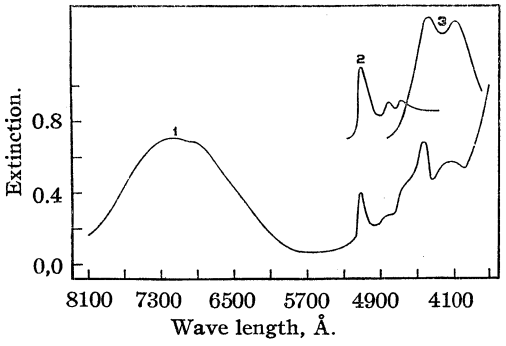

Fig. 6.—Curve 1 obtained by illuminating triphenylmethyldiphenylamine in EPA at about 90°K.: Curves 2 and 3 (with a higher base line), absorption curves of $(C_6H_5)_3C$ and $(C_6H_5)_3C^+$, respectively.

The next substance investigated was diphenyl disulfide. A solution of this substance becomes yellow on heating and nearly colorless on recooling. According to Schönberg[12] it does not obey Beer's law, so that it has been concluded that there is partial dissociation to give the free radical C_6H_5S. We have studied photographically the absorption of diphenyl disulfide in ethyl benzoate at 210°, with 1- and 5-cm. cells, and have found entirely similar but fainter absorption in ethanol with a 61-cm. cell at room temperature. While we have not yet studied the plates photometrically, the absorption band is a broad one beginning in the visible region and still rising at 3900 Å. The disulfide was next dissolved in EPA and illuminated at liquid air temperature. The resulting yellow solution showed, as was expected, the same band of C_6H_5S, but there is also a strong band with a maximum at 4600 Å. Obviously, another process besides photo-dissociation occurs and we believe that it is another case of photo-oxidation and that the new band is due to $C_6H_5SSC_6H_5^+$. As in all our experiments, except when there is an explicit statement to the contrary, the color disappeared as the solvent was warmed to fluidity. Therefore both processes are reversed at very low temperature, showing that, as in the case of diphenylnitrogen, there is no appreciable heat of activation for the dimerization of the phenylsulfur radical.

The next substance studied (EPA, liquid air) was triphenylmethyldiphenylamine, $(C_6H_5)_3CN(C_6H_5)_2$. Here we expected to find photo-dissociation into the two radicals triphenylmethyl and diphenylnitrogen, but the process proved to be more complicated, as may be seen from the absorption spectrum of Fig. 6. In addition to Curve 1, which shows the result of this experiment, we give in Curve 2 the absorption of triphenylmethyl according to our own measurements (90°K., EPA), which agree very closely with those of Anderson,[13] and in Curve 3 the absorption of $(C_6H_5)_3C^+$ as obtained by Anderson. It is evident that both of these substances are present.[14] On the other hand, the ions $(C_6H_5)_3C^-$ for which Anderson obtained an absorption maximum at 4800 Å., and $(C_6H_5)_2N^-$ whose absorption we give in Fig. 8, are not present in appreciable amount. There is, therefore, no evidence of photo-ionization into positive and negative ions. On the other hand it appears that we must write at least two

(12) Schönberg, *Trans. Faraday Soc.*, **30**, 17 (1934).

(13) Anderson, THIS JOURNAL, **57**, 1673 (1935).

(14) While the parent substance is not sensitive to air at room temperature and below, we found that the absorption band of triphenylmethyl did not appear in the low temperature illumination unless the solution had been carefully freed from oxygen. Since in the rigid solvent it seems hardly possible for the oxygen to diffuse to the triphenylmethyl that is formed, we seem forced to the conclusion that the oxygen molecule is already there; in other words, that the parent substance must form some loose complex with the oxygen on cooling.

photochemical equations, which are, presumably

$$(C_6H_5)_3CN(C_6H_5)_2 \longrightarrow (C_6H_5)_3C + (C_6H_5)_2N$$
$$(C_6H_5)_3CN(C_6H_5)_2 \longrightarrow (C_6H_5)_3CN(C_6H_5)_2^+ + e^-$$

the last substance then breaking into $(C_6H_5)_3C^+$ and $(C_6H_5)_2N$, and possibly into $(C_6H_5)_3C$ and $(C_6H_5)_2N^+$. Obviously our hope of obtaining in this way the pure spectrum of $(C_6H_5)_2N$ was a vain one and the left-hand portion of our curve is a superposition of the curves for $(C_6H_5)_2N$, $(C_6H_5)_2N^+$, and perhaps $(C_6H_5)_3CN(C_6H_5)_2^+$.

Photochemical Reactions of Other Compounds Containing the Diphenylnitrogen Group

With the object of identifying the bands obtained in the illumination of tetraphenylhydrazine we have treated by a similar procedure several substances in which the diphenylnitrogen group occurs.

Nitrosodiphenylamine, $(C_6H_5)_2NNO$, and Diphenylhydrazine, $(C_6H_5)_2NNH_2$.—The illumination of these two substances in EPA at liquid air temperatures gave green solutions of which the absorption spectra are given, respectively, in Curves 1 and 2 of Fig. 7. While we shall later discuss these curves briefly it may be noted now that their appearance is not inconsistent with the assumption that we have produced in varying amounts the two substances responsible for the B and C bands of illuminated tetraphenylhydrazine.

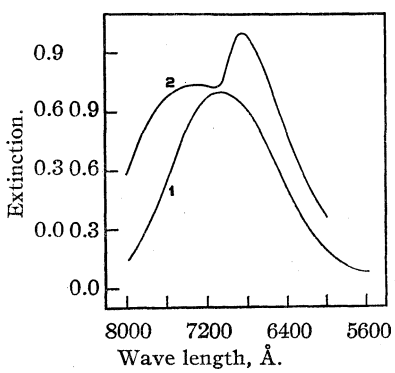

Fig. 7.—Absorption after illumination of (1) $(C_6H_5)_2NNO$ and (2) $(C_6H_5)_2NNH_2$.

Lithium Diphenylamide, $(C_6H_5)_2NLi$.—In order to study the diphenylamide ion it was necessary to use a solvent containing no alcohol, since the ion is an even stronger base than alcoholate ion. The lithium diphenylamide was found to be sufficiently soluble for our purpose in a mixture of two parts of isopentane and one part of ether. The absorption curves at this temperature before and after illumination are given in Curves 1 and 2 of Fig. 8. It appears that the second curve is identical with that of the B band of tetraphenylhydrazine.

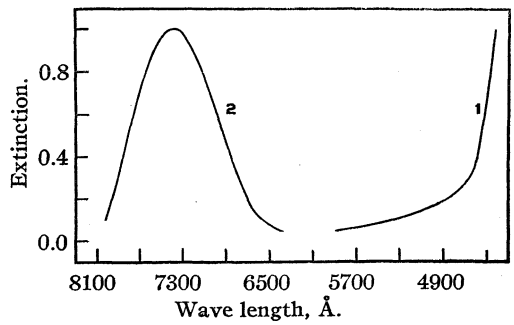

Fig. 8.—Absorption of a solution of lithium diphenylamide in ether and isopentane at about 90°K.: (1) before illumination, (2) after illumination.

Diphenylamine, $(C_6H_5)_2NH$.—While the illumination of triphenylamine and methyldiphenylamine gave simple photo-oxidation, the phenomena attending the illumination of diphenylamine proved to be of such complexity as to require a thorough investigation. When this substance in a rigid solvent is illuminated by the mercury arc, through quartz, it shows by transmitted light a purple color which takes an appreciable time, not more than a second, to rise to full intensity and disappears in about the same time after the illumination has ceased. The absorption spectrum while the sample is subjected to cross-illumination by the mercury arc is shown in Curve 3, Fig. 9. Since the half-life of the purple substance seems to correspond to that of the blue fluorescence of diphenylamine, it is probable that this absorption curve belongs to a phosphorescent state, such as we have previously studied in the case of fluorescein[1a] and of crystal violet.[1b]

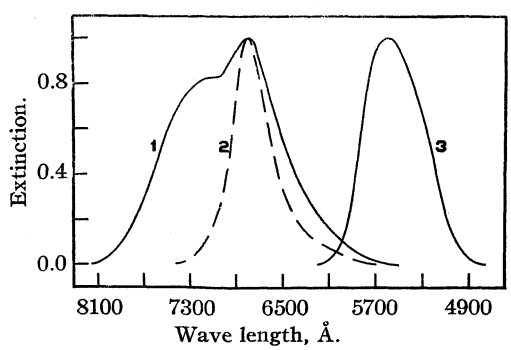

Fig. 9.—In EPA at about 90°K.: Curve 1, an example of the absorption curve obtained after prolonged illumination of diphenylamine; Curve 2, after brief illumination; Curve 3, absorption of the phosphorescent state of diphenylamine obtained while it is being illuminated.

As the illumination is prolonged the purple color disappears and is replaced by a green color which persists indefinitely after illumination has ceased. Ordinarily the absorption curve of the solution so obtained is not simple. One such curve is reproduced in Curve 1 of Fig. 9. If, however, we use only a brief illumination we obtain Curve 2 of Fig. 9. This so strongly resembles the curve of the positive ion of methyldiphenylamine (Fig. 5) that we have little hesitation in ascribing it to the corresponding ion, $(C_6H_5)_2NH^+$.

Numerous curves obtained on longer illumination, the analysis of which we shall not describe in detail, indicated the presence, in addition to $(C_6H_5)_2NH^+$, of the two substances responsible for the B and C bands of tetraphenylhydrazine. More recent experiments of Mr. J. Bigeleisen have shown that in the absence of air the C band does not appear, and the only bands are that of $(C_6H_5)_2NH^+$ and the B band of tetraphenylhydrazine, in amount depending on the length of illumination. Both of these bands disappear gradually as the temperature is raised, that of the $(C_6H_5)_2NH^+$ going more rapidly.

Interpretation of the Several Bands Obtained with Tetraphenylhydrazine

The X and D Bands.—Before considering the three main bands of Fig. 1 we shall say what we can of the elusive X band which sometimes is nearly one-third as strong as the B band, but sometimes does not appear at all. It never appeared when the illumination was by the full mercury arc through quartz. It appeared at its strongest when the illumination was with light lying between 3600 and 3800 Å. The difference proved to be due to the fact that the X substance is destroyed by all ultraviolet light as well as by the visible, in the range of absorption. Only when the frequency is in the neighborhood of 3700 Å. is the rate of its formation large compared with the rate of its destruction. On the other hand, the X substance is not very sensitive to temperature and persisted on warming as long as any color remained in the solution. Suspecting that the X band might be due to an impurity, a new preparation of tetraphenylhydrazine was made which gave under similar conditions the same curves as the preceding preparation but the X band was never more than one-half as intense. Until further preparations are tested we must doubt that the X band belongs to tetraphenylhydrazine.

The D band lay nearly outside the scope of our measuring apparatus and has therefore been little studied. It presumably does not represent an additional substance, but is part of a second band system of substance B, or substance C, or both.

The A Band.—This band, lying altogether in the infrared and with a maximum beyond the limits of our experiments, probably at about 8200 Å., might not have been discovered except for the short life of the A substance. We found that in the course of our absorption measurements over boiling liquid air that the absorption at the lowest frequencies fell off rapidly with time. It seemed, therefore, that the A absorption might readily be obtained by subtracting the curve obtained after the disappearance of A. The problem, however, was not so simple as this, for sometimes, as the A absorption diminished, that in the B and C regions substantially increased. It was finally found that A disappears by two processes, the first of which produces no change in the amounts of B and C, and the second of which produces both B and C. Fortunately at low temperatures (*ca.* 90°K.) the first process occurs almost alone and under these circumstances our method of subtracting the curves obtained before and after standing, enable us to obtain the curve for the A band given in Fig. 1.

We are going to identify the A substance with the positive ion of tetraphenylhydrazine, $(C_6H_5)_2NN(C_6H_5)_2^+$. This is the one band that does not appear when other compounds containing the diphenylnitrogen group are illuminated, and its absorption maximum in the infrared is about that which would be expected for an odd ion possessing such great possibilities of resonance.[15]

The B and C Bands.—We have seen that at higher temperatures the disappearance of A is accompanied by the production of B and C. By studying the light absorption at 8100 Å. and its change with time we have followed the kinetics of this reaction at about 90°K. The process proved to be strictly unimolecular with a half-life of twenty minutes. Concurrently the change of absorption in other parts of the spectrum were followed and it was seen that the B and C bands increased as they would if B and C were being

(15) In arriving at this conclusion it has been necessary to disregard the work of Weitz and Schwechten [*Ber.*, **60**, 1203 (1927)] and of Weitz and Müller [*ibid.*, **68**, 2306 (1935)] who by a variety of methods obtained violet substances which they believed to be the positive ions of tetraarylhydrazines. Some experiments similar to theirs but leading to a quite different interpretation will be discussed in the immediately following paper by Lewis and Bigeleisen.

produced from A. It is to be assumed that this thermal reaction is

$$(C_6H_5)_2NN(C_6H_5)_2^+ \longrightarrow (C_6H_5)_2N + (C_6H_5)_2N^+$$

These observations, together with the appearance of the B and C bands in illumination of other compounds containing the diphenylnitrogen group, lead us to identify these bands with the substances $(C_6H_5)_2N$ and $(C_6H_5)_2N^+$. It remains to decide which substance should be assigned to which curve. The first evidence came from the observation that upon brief illumination only the A and B bands appeared. The two most likely reactions in a primary illumination, that is, an illumination which is not long enough to excite further the first products of illumination, are

$$(C_6H_5)_2NN(C_6H_5)_2 \longrightarrow (C_6H_5)_2NN(C_6H_5)_2^+ + e^-$$
$$(C_6H_5)_2NN(C_6H_5)_2 \longrightarrow 2(C_6H_5)_2N$$

We believe that these two photochemical reactions occur in about equal amount and conclude that the B band is due to $(C_6H_5)_2N$ and therefore that the C band is due to $(C_6H_5)_2N^+$. By illuminating briefly and allowing the sample to stand at not too high a temperature, we were able to obtain the very satisfactory B band given in Fig. 1. On the other hand, the C band, which was obtained by a rough analysis of various compound curves, cannot be considered very accurate.

The assignment of the B and C bands enabled us to interpret satisfactorily the results obtained with other substances containing diphenylnitrogen. The illumination of triphenylmethyldiphenylamine gave $(C_6H_5)_2N$, $(C_6H_5)_3C$, $(C_6H_5)_2N^+$ and $(C_6H_5)_3C^+$, all of which can be recognized in Fig. 6. The illumination of $(C_6H_5)_2NNH_2$ seems from Fig. 7 to give largely photo-ionization according to the reaction

$$(C_6H_5)_2NNH_2 \longrightarrow (C_6H_5)_2N^+ + NH_2^-$$

The illumination of $(C_6H_5)_2NNO$ apparently gives both $(C_6H_5)_2N$ and $(C_6H_5)_2N^+$, but we should like to study this case more carefully before attempting to write the photochemical reactions.

The case of diphenylamine is interesting. We have seen that the primary illumination produces only photo-oxidation to give $(C_6H_5)_2NH^+$, but then on further illumination there is a second reaction which must be written

$$(C_6H_5)_2NH^+ \longrightarrow (C_6H_5)_2N + H^+$$

and thus the B band is obtained.[16]

(16) It is to be presumed that the proton attaches itself to the basic oxygen of the ether or alcohol of the solvent. It is probable also that in some of our other reactions the neighboring solvent molecules may take part to the extent of forming loose addition compounds presumably without causing appreciable change in the absorption spectra.

Perhaps the least ambiguous evidence for our assignment of the B band to the diphenylnitrogen radical is obtained in the experiment with diphenylamide ion. It seemed unlikely in this case that the primary illumination would cause anything except simple photo-oxidation

$$(C_6H_5)_2N^- \longrightarrow (C_6H_5)_2N + e^-$$

and the appearance in Fig. 8 of the pure B band seems almost by itself sufficient to identify this band with $(C_6H_5)_2N$.

Illumination by Polarized Light and the Production of Permanent Dichroism in Homogeneous Media.—We planned to resolve the complicated band system obtained by the illumination of tetraphenylhydrazine by using polarized light, and thus obtain an orientation of the resulting molecules which would be permanent as long as the medium remained rigid, but otherwise would be entirely similar to the orientation in the phosphorescent state that we previously studied.[1a] We have not been able to carry out this program but have nevertheless, with one or two simpler substances, shown that the method is practical. In these cases colored solutions were obtained which when studied with polarized light showed a notable variation of the absorption with the direction of polarization.

Experimental

In several cases (hexaphenylethane and the several di- and triarylamines) light between 2500 and 3000 Å. proved to be necessary for rapid photochemical action, and direct light from the high-pressure mercury arc was employed. In other cases the light passed first through a large quartz cell containing aqueous copper sulfate in order to use a high intensity of light without overheating the samples. Such overheating may easily occur even when the samples are immersed in liquid air. Various color filters were occasionally used to give selected spectral regions. The cells of quartz, or of "Pyrex" glass when permissible, were ordinarily about 1 cm. in thickness. Sometimes the color obtained was nearly uniform throughout the cell, but sometimes it all appeared near the face, in which case both faces were illuminated in turn. The depth of penetration of color depends upon the concentration and also upon the position and intensities of the ultraviolet absorption bands of the initial and final substances. Occasionally, a very dilute solution was illuminated in a tube 10 cm. long and 3 cm. in diameter, the illumination being across, and the absorption measurements along, the tube. The absorption measurements were made by methods that we have previously described.[1a]

Materials.—Tetraphenylhydrazine was prepared by the oxidation of diphenylamine with potassium permanganate, as described by Gattermann and Wieland.[17] It was not

(17) Gattermann and Wieland, "Laboratory Methods of Organic Chemistry," The Macmillan Co., New York, N. Y., 1934.

easy to determine the purity of the product since the substance decomposes before melting. We have mentioned that the X band shown in Fig. 1 may be due to impurity.

The hexaphenylethane was prepared *in vacuo* by the action of silver amalgam on triphenylchloromethane by a method that we shall describe more fully in another place. The triphenylmethyldiphenylamine was also made *in vacuo* by the method of Wieland.[18] Tetraphenylhydrazine was added to a solution of hexaphenylethane in toluene and heated two hours at 100°. When once formed the product can be filtered and recrystallized in the air, although after some months it deteriorates on standing in air.

Lithium diphenylamide was prepared as follows. A small amount of lithium and a slight excess of diphenylamine were placed in a tube on the vacuum line and ethylamine was distilled into the tube. After the completion of the reaction the ethylamine was pumped off and the mixture of ether and isopentane was distilled in. The tube was then sealed off. *unsym*-Diphenylhydrazine was prepared from the hydrochloride by adding alkali and shaking out with benzene. It was purified by vacuum distillation, as were also diphenylamine and methyldiphenylamine. Diphenyl disulfide was purified by recrystallizing from toluene at −80°.

Rigid Solvents.—At room temperature transparent glasses of boric acid or of glucose may be used. At −60 to −80° glycerol, triethanolamine, sulfuric and phosphoric acids make good rigid solvents. At the temperature of liquid air most supercooled liquids crack. Others have too little solvent power. We have found[10] that for most purposes the best solvent is a mixture of 5 parts of ether, 5 parts of isopentane,[19] and 2 parts of alcohol by volume. This we designate as EPA or more explicitly $E_5P_5A_2$. We have used higher alcoholic contents up to EPA_4, but the chance of the solvent cracking in the midst of an experiment increases with the alcoholic content. In the experiment with lithium diphenylamide the solvent was EP_2. In other cases triethylamine may replace the alcohol in EPA. If a rigid solvent containing only hydrocarbons is desired, a mixture of 3 parts isopentane and 1 part methylcyclohexane is useful.

(18) Wieland, *Ann.*, **381**, 214 (1911).

(19) We are indebted to the Shell Development Company for a liberal donation of isopentane of high purity.

Summary

When tetraphenylhydrazine in a rigid solvent is illuminated by ultraviolet light, the solution becomes colored and shows three main absorption bands, each of which is shown to be due to a separate substance. In order to identify these substances and to find what types of photochemical reaction are possible under these circumstances, various substances have been similarly studied. It is found that a molecule may be dissociated by light into two radicals, into positive and negative ions, and into a positive ion and an electron. In two cases the last type of dissociation, which may be called photo-oxidation, gives substances identical with those obtained by Michaelis and associates by chemical oxidation. From the illumination of several substances containing the diphenylnitrogen group it has been possible to find the absorption bands of $(C_6H_5)_2N$ and $(C_6H_5)_2N^+$. These are two of the main substances produced in the illumination of tetraphenylhydrazine. The third is $(C_6H_5)_2NN(C_6H_5)_2^+$, which disappears by two processes: one is the return of the electron, the other is dissociation into $(C_6H_5)_2N$ and $(C_6H_5)_2N^+$. The latter process is shown to be unimolecular.

The Initial Step in the Action of Acids on Tetraarylhydrazines

BY GILBERT N. LEWIS AND JACOB BIGELEISEN

Wieland[1] observed that tetraarylhydrazines react with acids to give colored substances which according to circumstances are green, violet or blue. In fact, a single preparation passes, sometimes rapidly, through a succession of color changes. If the solution has not aged much, Wieland showed that neutralization by alkali restores a large part of the original hydrazine and therefore concluded that the acid produces a mere addition complex without splitting the hydrazine. However, it has not been found possible to suggest any such addition compound that would have any of the observed colors. Weitz and others[2] have assumed a more or less reversible reaction which in the case of tetraphenylhydrazine may be written

$$3(C_6H_5)_2NN(C_6H_5)_2 + 2H^+ = 2(C_6H_5)_2NH + 2(C_6H_5)_2NN(C_6H_5)_2^+ \quad (1)$$

It is to such odd ions as the one appearing in this equation that Weitz ascribes the violet color obtained by the action either of acids or of oxi-

(1) Wieland, "Die Hydrazine," Ferdinand Enke, Stuttgart, 1913.

(2) Weitz and Schwechten, *Ber.*, **60**, 1203 (1927); Weitz and Müller, **68**, 2306 (1935).

dizing agents on tetraarylhydrazines. However, it has been shown in the adjoining paper of Lewis and Lipkin[3] that this ion, which is produced from tetraphenylhydrazine by the loss of an electron, is certainly not violet, for its chief absorption is in the infra-red. In fact, the violet color as described by Wieland and by Weitz must be the resultant of a complicated series of reactions; we have never observed the violet color in non-hydroxylic solvents in the absence of air.

Another objection to regarding equation (1) as the primary step in the process is that such a reaction would presumably have a considerable heat of activation, but we find that the production of color upon acidifying tetraphenylhydrazine is extremely rapid nearly down to the temperature of liquid air.[4] It is possible that on the way to some of the end-products that have been identified by Wieland, reaction (1) may play a part, but here we are concerned only in finding what the first step in the reaction is.

Considering the various possible initial reactions the only one that seems reasonable is the one that assumes that tetraphenylhydrazine is in rapid equilibrium with a small amount of its two ions according to the equation

$$(C_6H_5)_2NN(C_6H_5)_2 \rightleftarrows (C_6H_5)_2N^+ + (C_6H_5)_2N^- \quad (2)$$

and that upon addition of acid the negative ion is removed[5] allowing the positive ion to accumulate to such extent as to show its green color. We should expect, therefore, to obtain initially, in the absorption spectrum, the band designated as the "C" band in the preceding paper.

Our first experiments were made between 200°K. and room temperature. Solutions of tetraphenylhydrazine in various solvents such as acetone, ether, isopropyl chloride, β-*n*-amylene, and several mixtures of these, sometimes including isopentane, were exhausted on the vacuum bench after cooling with liquid air, and dry hydrogen chloride gas was allowed to enter. Then either the containing tubes were sealed off or the solution was gradually warmed and stirred by a simple magnetic stirrer. All the solutions showed apparently the same green color. However, on spectrophotometric examination the absorption curves varied greatly from sample to sample, depending upon the solvents and the temperature attained before making the measurements; none showed the expected pronounced maximum at the position of the "C" band (about 6800 Å.). It is evident that even under the conditions of these experiments numerous colored substances have been produced.

The first indication of the "C" band appeared in a solution in ether, isopentane and isopropyl chloride (1,1,2 by volume). After freezing the solution in liquid air, passing in hydrogen chloride (in moles about equal to the amount of tetraphenylhydrazine used) and warming to about 160°K., the solution was stirred, and once again cooled. The absorption measurements were made just above rapidly boiling liquid air. The experiment was unsatisfactory because of the clouding of the solvent, but there appeared to be definite evidence of an absorption maximum in the neighborhood of the "C" band.

A more conclusive experiment was then performed using our EPA solvent, ether, isopentane and ethanol (5,5,2 by volume). The procedure was that just described except that the solution was treated with hydrogen chloride at about 130° K., was stirred about half a minute and then cooled to 90°K., where the absorption measurements were made. The absorption curve obtained is shown as curve 1 in Fig. 1. In the same figure curve 2 taken from the preceding paper of Lewis and Lipkin[3] shows roughly the "C" band attributed to $(C_6H_5)_2N^+$. There seems little doubt that the positive ion of diphenylnitrogen is one of the first substances produced in the action of an acid on tetraphenylhydrazine. That it is this ion, and not the accompanying substance with an absorption chiefly in the infra-red, that is actually the first colored product of the reaction, is shown by the fact that when the solution is warmed to a little higher temperature the "C" band disappears and only the infra-red band remains.[6]

(3) Lewis and Lipkin, THIS JOURNAL, **64**, 2801 (1942).

(4) As far as we can judge the reaction may still be instantaneous at temperatures below that of liquid air, but at these low temperatures even the most fluid solvents, such as isopentane, become very viscous and the reaction time is the time required for mixing.

(5) We shall not attempt to decide whether hydrogen ion adding to $(C_6H_5)_2N^-$ forms diphenylamine immediately or whether possibly the nitrogen acts as a secondary base, and therefore the hydrogen ion attaches itself at a para position in one of the rings. When dry hydrogen chloride is added to a solution of tetraphenylhydrazine in isopentane at low temperatures a typical green solution is formed, but further addition of acid produces a red precipitate. This phenomenon, which is evidently due in some way to the addition of a second hydrogen ion or acid molecule, may be avoided by buffering the solvent with any base such as ether, acetone or alcohol to keep down the acid strength. The use of such buffers in solvents which are not sources of hydrogen ion will be obvious to those familiar with the theory of generalized acids and bases (see Lewis, *J. Franklin Institute*, **226**, 293 (1938)).

(6) It seems likely that the substance responsible for the infra-red band is formed from the positive diphenyl nitrogen ion by a disproportionation involving the para hydrogen. Our experiments, therefore, should be repeated with tetra-*p*-tolylhydrazine so as to exclude this type of side-reaction.

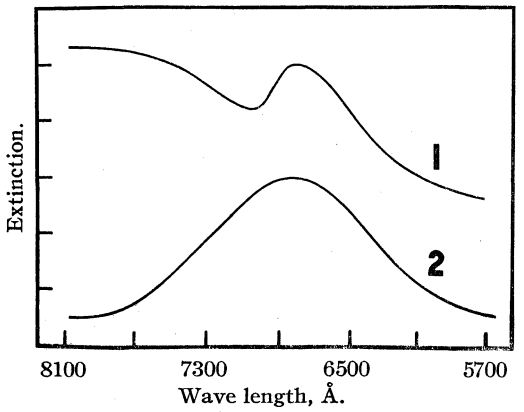

Fig. 1.—1, Absorption curve of the products of reaction of HCl and $(C_6H_5)_2NN(C_6H_5)_2$ in EPA at low temperature; 2, absorption curve of $(C_6H_5)_2N^+$. In both cases the vertical scale is arbitrary.

The difficulties encountered in establishing the presence of $(C_6H_5)_2N^+$ seem to be attributable not merely to its remarkable instability but also to the small contribution that it makes to the total absorption. This is not due to a small absorption coefficient; presumably this ion and the chloride ion are in equilibrium with diphenylchloramine according to the equation

$$(C_6H_5)_2NCl \rightleftharpoons (C_6H_5)_2N^+ + Cl^- \qquad (3)$$

the diphenylchloramine being ionized only to a small extent. The situation is quite analogous to that of triphenylchloromethane in such a solvent as chlorobenzene.

Summary

Of the many reactions that are ordinarily observed when acid is added to tetraphenylhydrazine, none is the initial reaction. The first process, which occurs rapidly even near the temperature of liquid air, is the formation of $(C_6H_5)_2N^+$, which we have identified by its absorption spectrum. If tetraphenylhydrazine is assumed to be in rapid equilibrium with the positive and negative diphenylnitrogen ions, the effect of an acid is to remove the negative ion and thus cause accumulation of the colored positive ion, a considerable part of which, however, presumably combines with chloride ion to form colorless diphenylchloramine. The chloramine and its positive ion are too unstable to be observable except at extremely low temperatures.

A Study of Heterogeneous Equilibria in Aqueous Solutions of the Sulfates of Tetravalent Vanadium at 30°

BY CHARLES S. ROHRER, OSCAR E. LANFORD AND SAMUEL J. KIEHL

Introduction

The hydrates of the sulfates of tetravalent vanadium reported in the literature by previous investigators are divided into two series by Mellor[1]: the one, $VO_2 \cdot SO_3 \cdot xH_2O$ and the other $2VO_2 \cdot 3SO_3 \cdot xH_2O$. However, we believe that he entertains some doubt as to the number of hydrates in each, for he states: "... some of them may be mixtures representing arbitrary states in the process of dehydration." This uncertainty is more clearly substantiated if one considers the water ratio of each series. There are reported[2-5] for the first series the following molecular ratios of $H_2O/VO_2 \cdot SO_3$: 0, 1, 1.5, 2, 2.5, 3, 3.5, 5, 6.5, and for the second series, the molecular ratios of $H_2O/2VO_2 \cdot 3SO_3$: 0, 1, 1.5, 2, 3, 4, 6, 14 and 16.

Doubtless in many of the preparations, since the products depended upon drying at various temperatures up to 360°, it is quite possible that intermediate states of incomplete hydration were reached. For, at 360° insoluble $VO_2 \cdot SO_3$ is invariably precipitated from concentrated sulfuric acid. Then, too, Gerland[3] dried the pentahydrate at 100° and reported not only $VO_2 \cdot SO_3 \cdot 2.5H_2O$, but also $VO_2 \cdot SO_3 \cdot 1.5H_2O$ by prolonged heating at that temperature.

By the same procedure Koppel and Behrendt[5] reported $VO_2 \cdot SO_3 \cdot 2.5H_2O$ and $VO_2 \cdot SO_3 \cdot 2H_2O$. If, however, the heating was done at 125°, they obtained $VO_2 \cdot SO_3 \cdot 1.5H_2O$ and $VO_2 \cdot SO_3 \cdot H_2O$ at 150°. Moreover, by heating $2VO_2 \cdot 3SO_3 \cdot 4H_2O$ in the second series at from 140 to 160° they obtained

$2VO_2 \cdot 3SO_3 \cdot 3H_2O$; upon further heating, however, at 175° $2VO_2 \cdot 3SO_3 \cdot 1.5H_2O$ was obtained, which finally, by continued heating to 200°, changed to the anhydrous salt $2VO_2 \cdot 3SO_3$.

Furthermore, there is little information given as to the ratios of vanadium dioxide to sulfur trioxide or to water in the reported preparations of the salts. Other authors,[3-5] besides, have reported failure in attempts to prepare hydrates by methods previously described.

From the above considerations and since nothing more than qualitative statements have been made as to the solubility of the various hydrates, it appears that a study of the system VO_2–SO_3–H_2O would not only provide solubility data for the various hydrated sulfates of tetravalent vanadium, but also tend to clarify the available data. The results of such a study at 30° and under ordinary atmospheric pressure are given below.

Preparation of Materials

Vanadium Dioxide.—The vanadium dioxide was prepared from a very good commercial product which by analysis gave 99.92% of vanadium pentoxide and showed no measurable loss of weight upon ignition. The material was very finely divided and quite insoluble in water. However, a suspension of it was slowly reduced to a solution of tetravalent vanadium by sulfur dioxide, the excess of which was removed by heating the solution for about twenty-four hours on a water-bath while a stream of nitrogen passed through it. During this process a lilac to orchid precipitate was formed which Gain and Dritte[6] identify as $V_2O_4 \cdot 2H_2O$. The expulsion of the sulfur dioxide by boiling, recommended in their procedure, was found to be impractical with more than a few grams of the vanadium pentoxide, because the very finely powdered oxide attached itself so firmly to the sides of the vessel that severe bumping approaching explosive violence at times, occurred. This difficulty was overcome by passing a stream of nitrogen through the solution while it was being heated on the water-bath.

The resulting precipitate was filtered on a fritted glass funnel and washed twenty times with hot water. In order to eliminate from our experiments any of the traces of soluble impurities which may have been in the anhydrous pentoxide, this washed precipitate only was used in preparing mixtures which were to be brought to equilibrium. By analysis this prepared dioxide was free from sulfur dioxide and was shown to have undergone no oxidation during exposure to the atmosphere in its preparation. The analysis, however, showed the compound to contain 1.3 ± 0.7% by weight of sulfur trioxide as an impurity which really was no impurity in the preparation of the vanadyl sulfates. In preparing the mixtures for solubility measurements of the solid phase $VO_2 \cdot H_2O$, however, it was an impurity. In this case the sulfur trioxide content was reduced to 0.3 ± 0.2% by agitating the finely ground material in an atmosphere of nitrogen for one month in pure water which was changed twice each week. The dioxide was reground in a mortar each time the water was changed.

The sulfuric acid, the potassium permanganate and the barium chloride, have been discussed heretofore.[7]

Apparatus.—All apparatus and their standardizations for temperature control, for stirring, for analytical work and for other purposes have been described previously.[8,9]

The containers were 250-ml. "non-sol" bottles tested for water tightness. The stoppers were sealed to the bottles with paraffin, as an added precaution, to prevent leakage while the samples were being agitated.

Analytical Determinations

Vanadium.—Since the vanadium to be determined was in the pure tetravalent state, the procedure was simple. The sample was dissolved and made up to a volume, aliquot portions of which were titrated directly with a standard solution of potassium permanganate in the presence of sulfuric acid. As an assurance that no oxidation had occurred, frequent checks were made by treating one of the aliquot parts with sulfur dioxide and titrating after removal of the excess. In no case was oxidation of the tetravalent vanadium observed.

In order to get the moist residue of the solid phase $VO_2 \cdot H_2O$, which is quite insoluble, into solution, the addition of an acid was necessary. Since the chloride ion did not interfere with the sulfate determinations, hydrochloric acid was used. Nevertheless, it was necessary to remove it from the aliquot by evaporation almost to dryness with sulfuric acid before titrating with permanganate. The sulfate thus formed, however, is the insoluble form of the normal vanadyl sulfate identified by Gerland[3] as $VO_2 \cdot SO_3$ which is not to be confused with the $VO_2 \cdot SO_3$ discussed later in this investigation, a form quite soluble. This insoluble form was dissolved by boiling in a quite concentrated solution of sulfuric acid. The solutions so obtained were reduced with sulfur dioxide, prepared and titrated with a standard solution of potassium permanganate in the usual manner.

An alternate method for the analysis in the hydrochloric acid solution was used. In this procedure the tetravalent vanadium was oxidized to the pentavalent state with chlorine, and the determinations made, after the removal of the excess, according to a method developed by Walden, Hammett and Edmonds.[10] The results obtained by the two methods were in close agreement.

Sulfate Determinations.—Sulfur trioxide determinations were made according to the standard method for sulfates.[11] Moreover, in our analytical procedure the removal of the vanadyl ion was deemed unnecessary because no serious interference due to coprecipitation occurred. This fact was confirmed by taking aliquot portions of a concentrated solution of the vanadyl ion and determining the sulfur trioxide content first in the presence of the ion and, second,

after its removal from the aliquot portion by precipitation with ammonium hydroxide. The results from these experiments were in agreement within experimental error. The samples were filtered in a porous bottom Gooch type crucible, and dried in a muffle furnace at 600 to 700°.

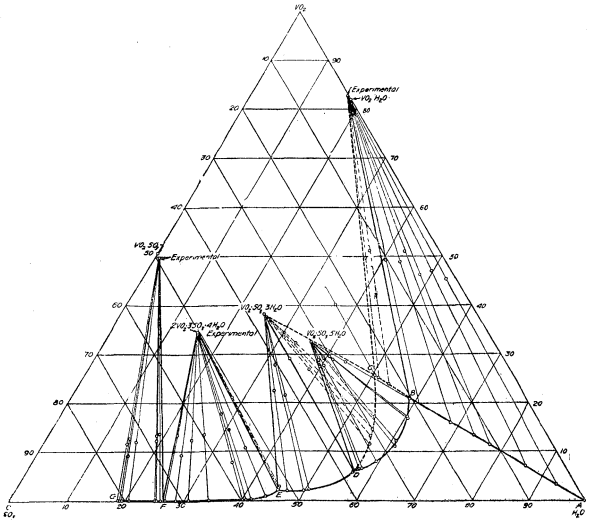
Experimental Procedure

Individual mixtures were prepared by adding the moist vanadium dioxide monohydrate to solutions of water and sulfuric acid of definite ratio ranging from pure water to pure sulfuric acid. For mixtures with higher concentrations of sulfur trioxide, it was necessary to use fuming sulfuric acid. As a precautionary measure against oxidation all samples were placed under an atmosphere of nitrogen and hermetically sealed with paraffin. These mixtures were stirred by end over end rotation for a period of time which exceeded that necessary for the attainment of equilibrium.

In order to determine the time necessary for the attainment of equilibrium, duplicate samples were prepared by taking one of the mixtures, as prepared above, at apparent equilibrium, and dividing it into two parts: one of these was maintained at 0° for twenty-four hours with frequent stirring; the other was treated likewise at 70 to 100°; they were then agitated again at 30 ± 0.01° until equilibrium, with identical phases, was reached in both.

Three criteria were used to determine the establishment of equilibrium: first, the densities of the mother liquors remained constant at the same value for both of the duplicates; this served as preliminary criterion before analyses were made; second, the analyses of the mother liquors agreed within experimental error; third, microscopic examinations revealed a single identical solid phase of definite crystalline form in both samples.

The time necessary to establish equilibrium ranged from three days, approximately, with $VO_2 \cdot SO_3 \cdot 5H_2O$, where the crystals grew rapidly in the less viscous solutions, to a year or more for the $2VO_2 \cdot 3SO_3 \cdot 4H_2O$ and $VO_2 \cdot SO_3$ in the highly viscous solutions of concentrated sulfuric acid.



Percentage by weight of H_2O.

Fig. 1.—System $VO_2 \cdot SO_3 \cdot H_2O$, 30° isotherm, data in weight percentage.

The attainment of equilibrium by approach from both higher and lower temperatures was employed, because it afforded an opportunity for formation of all possible hydrates. While temperatures of 0 and 70° or above were not the most satisfactory for economy of time, they nevertheless gave further opportunity during a period of several weeks for the crystallization of any other possible hydrates from the various concentrated solutions. During this time, moreover, they were repeatedly subjected to alternate changes from high to low temperatures as well as to stirring. No matter what compound separated at lower temperatures or higher temperatures, the mixtures obtained finally at equilibrium by stirring at 30° were the hydrates represented in Fig. 1.

After equilibrium was attained, rotation of the solutions was halted, and the solid phase was allowed to settle. Samples for density determinations and for analyses of the mother liquor were taken by the use of the pycnometer and

sampling tube described by Kiehl and Manfredo.[8] The solid phase was sampled by placing some of the mixture at equilibrium in a glass porous bottom Gooch type crucible which permitted a rapid and more complete withdrawal of the mother liquor. Thus, in turn the accuracy of the extrapolation in the determination of the solid phase was increased. These samples of mother liquors and precipitates were in due course diluted and dissolved, respectively, with water in a volumetric flask and aliquot parts taken for the determinations of both vanadium dioxide and sulfur trioxide. The water was determined by difference.

Experimental Results

Table I gives the results of the analysis for the mother liquor and for the moist solid phase expressed in percentage by weight of vanadium dioxide, sulfur trioxide. The percentage of water may be obtained by difference. In order to be consistent throughout the paper, all reference to tables, solubility, etc., will, likewise, be expressed in percentage by weight of the respective components. The results plotted on triangular coördinate paper are shown in the accompanying figure.

Calculations

The composition of the solid phase at equilibrium was determined by the method of Schreinemakers.[12] But because the errors in plotting do not permit a sufficiently accurate determination of the composition of the pure solid phase, the tie-lines were expressed by algebraic equations as described by Roozeboom.[13]

As a more objective and a more highly satisfactory procedure for the evaluation of the composition of the pure compounds by the algebraic method, the method of least squares was used, because it affords a comprehensive solution of all the equations for the tie-lines for each respective compound. For example, there were in one case ten equations which would give forty-five possibly different intersections, representing forty-five possibly different values for each of the components. By the use of the method of least squares the one most probable value for each of the components within the limits of the analytical results was obtained. The values listed below for each of the pure compounds were determined by the method of least squares.

The values of the most probable compositions of the various compounds together with the deviation from theoretical composition are listed in Table II. Moreover, these values for the composition of the pure compound as finally determined are burdened with the errors which accumulated from all sources in the course of the work. The

(12) Schreinemakers, *Z. physik. Chem.*, **11**, 76 (1893).

(13) Bakhuis Roozeboom, "Die heterogene Gleichgewichte vom Standpunkte der Phasenlehre," 1911, Vol. 3, Part I, p. 149.

method of computation of the errors has been described.[9,14]

There is more consistency in some of the most probable values for composition than the errors would indicate. For example, if one determines the deviation from the most probable value in each equation by substituting the value for one component (the one most probable value) and solving for the other, one obtains for the composition of $VO_2 \cdot SO_3$: 49.81% ± 0.99 vanadium dioxide, 49.28% ± 0.96 sulfur trioxide, and 0.91% ± 0.25 water. The larger deviations listed for this compound in the table are, of course, due to the acute angles of intersection of the tie-lines on the one hand and to the closely located points which represent the composition of the saturated solution and that of the moist solid phase, respectively, on the other.

Discussion of Results

The isothermal diagram Fig. 1 shows five solid phases: $VO_2 \cdot H_2O$, $VO_2 \cdot SO_3 \cdot 5H_2O$, $VO_2 \cdot SO_3 \cdot 3H_2O$, $2VO_2 \cdot 3SO_3 \cdot 4H_2O$, and $VO_2 \cdot SO_3$, at equilibrium, with their isothermally univariant liquid phase, respectively, in contact. Sufficient determinations were made to follow the course of the solubilities from pure water to 81.02% sulfur trioxide. No higher concentrations of sulfur trioxide were practicable since tetravalent vanadium was oxidized in the more concentrated solutions.

The Solubility Curve A-B-C for the Solid Phase $VO_2 \cdot H_2O$.—The stable portion of the curve A-B has a range of solubility from 0.0068% of the unhydrated oxide in pure water to 21.2% VO_2 at 20.1% SO_3, the invariant point B. This is the invariant point for the solid phases $VO_2 \cdot H_2O$ and $VO_2 \cdot SO_3 \cdot 5H_2O$ in contact with the solution. It was determined by intersection. The portion B-C is a metastable range in which the solubility extends to a maximum value of 25.90% vanadium dioxide at the metastable invariant point C where the percentage of sulfur trioxide is 23.83. The invariant point C was established by direct analysis of the solution at equilibrium with the two solid phases $VO_2 \cdot H_2O$ and $VO_2 \cdot SO_3 \cdot 3H_2O$. The solutions of this hydrate vary in color from an almost clear solution at point A to a solution which is so blue that it is almost opaque at the invariant point C. This hydrated oxide was described and identified by Gain and Dritte.[6] A comparison of the calculated value with one obtained by analyzing the purified compound as well as with the theoretical composition is given in Table II.

The Solubility Curve B-D for the Solid Phase $VO_2 \cdot SO_3 \cdot 5H_2O$.—The stable range of solubility for the solid $VO_2 \cdot SO_3 \cdot 5H_2O$ in this system is from invariant point B in Fig. 1 to the invariant point D. This point is the intersection of the two solubility curves B-D and C-D-E. At this point the percentage of vanadium dioxide is approximately 6.2 and that of sulfur trioxide about 37.3. No metastable equilibrium of this hydrate was observed. The color of the solutions of the compound in this region ranges from a very dark blue translucent solution at point B, 21.1% vanadium dioxide, to a blue of medium intensity at point D which contains about 6.2% vanadium dioxide.

Moreover, it was necessary to seed all the solutions in order to prepare this hydrate. After the crystals were once obtained, no difficulty was encountered in preparing the samples, as equilibrium was reached within three days or less after the seeding. The hydrate first appeared from a metastable saturated solution of the trihydrate which had been standing for a year or more.

On account of its stability, the slight viscosity of the solutions, and the larger size of the crystals, the removal of almost all of the mother liquor was accomplished quite easily. This made possible a much greater distance between the points representing the composition of mother liquor and that of the moist solid which determine the tie-lines on the diagram. For this reason the determination of the composition of this pure solid phase was made with greater precision.

In Table II a comparison of the most probable composition with the analytically determined composition and that of the theoretical will be found.

Gerland[3] prepared the pentahydrate by heating the insoluble anhydrous $VO_2 \cdot SO_3$ with a little water in a sealed tube to 150°. The resulting oily solution was boiled with alcohol to a gummy mass and dried over sulfuric acid. This remaining hard transparent mass when moistened with alcohol and left under a loose cover gradually assumed a crystalline form. The formula for it, he established by analysis. Koppel and Behrendt[5] by allowing one of the lower hydrates to deliquesce on standing in air prepared small well-defined crystals from the resulting dark blue solution. These

(14) O. E. Lanford, "A Study of Heterogeneous Equilibria in Aqueous Solutions of the Sulfates of Pentavalent Vanadium at 30° C.," Ph.D. Dissertation, Columbia University, 1939.

crystals when washed with alcohol and ether gave analyses corresponding to $VO_2 \cdot SO_3 \cdot 5H_2O$.

The Solubility Curve C-D-E for the Solid Phase $VO_2 \cdot SO_3 \cdot 3H_2O$.—The solid phase $VO_2 \cdot SO_3 \cdot 3H_2O$ has a stable solubility range from the invariant point D to the invariant point E, 2.19% vanadium dioxide in 52.45% sulfur trioxide, in Fig. 1, which was established by direct analysis of a solution at equilibrium with the solid phases $VO_2 \cdot SO_3 \cdot 3H_2O$ and $2VO \cdot 3SO_3 \cdot 4H_2O$. A metastable range extends from the invariant point D to the metastable invariant point C for this solid phase and vanadium dioxide monohydrate. It is of interest to note that there are two complete metastable solubility curves B-C and D-C above B-D, the curve for the pentahydrate in the diagram. The color of the saturated solutions of this solid varies from a very dark blue, almost opaque, solution at point C to a very clear, light blue solution at point E.

The trihydrate of the normal vanadyl sulfate may be isolated and purified without decomposition. It crystallizes readily into large, clear light blue crystals which permit removal of practically all of the mother liquor. A close agreement of the experimental with the theoretical value of the composition was therefore obtained, Table II.

In this study the hydrate was easily prepared at room temperature or slightly above by slowly adding concentrated sulfuric acid to the oxide suspended in a concentrated solution of vanadyl sulfate. These crystals of normal vanadyl sulfate trihydrate are reported by Koppel and Behrendt[5] to appear when an acid solution is evaporated at 90°.

The Solubility Curve E-F for the Solid Phase $2VO_2 \cdot 3SO_3 \cdot 4H_2O$.—The solid phase of $2VO_2 \cdot 3SO_3 \cdot 4H_2O$ has a stable range of solubility from the invariant point E to the invariant point F. Invariant point F is somewhat indefinitely located at 0.10%, approximately, vanadium dioxide in about 73.0% sulfur trioxide. The difficulty in locating the percentage of sulfur trioxide for this point is apparent if one notes in Fig. 1 how nearly the curves E-F and G-F approach each other as an almost continuous line. However, in Table I it may be observed that there is a slight but definite tendency for increased solubility which would give an intersection at point F. A metastable range extends from point E to 2.80% vanadium dioxide in 51.91% sulfur trioxide.

The solutions of this solid phase vary in color from a very light blue in solutions of minimum sulfur trioxide to an almost clear solution in higher concentrations of sulfur trioxide.

Due to increased viscosity of the solutions and to the decreasing solubility of the solid phase, equilibrium was slowly attained. One to two months for the attainment of equilibrium was required in solutions of minimum sulfur trioxide while even longer times were required in the more concentrated solutions.

In Table II a comparison of the most probable calculated value with the analytical value and that of the theoretical value may be made.

While hydrates have been reported in this series carrying 16, 14, 6, 4, 3, 2, 1.5, and no molecules of water of hydration, the tetrahydrate alone appeared as a compound at equilibrium in this study. Throughout the course of this investigation it was found that if an insufficient time was permitted for attainment of equilibrium, intermediate stages were encountered. In these cases the tie-lines would fall at random between those for this solid phase and those for $VO_2 \cdot SO_3$. This behavior would tend to support Mellor's[1] suggestion that some of the hydrates reported were intermediate stages in the process of dehydration.

The compound was found to be readily soluble in water and more slowly but quite soluble in absolute alcohol. Partial purification, nevertheless, was secured by first washing with ether–alcohol mixtures and finally with pure ether. It was reported by Gerland[3] that this compound may be purified by washing with water or alcohol. Koppel and Behrendt[5] also prepared it.

The Solubility Curve F-G for the Solid Phase $VO_2 \cdot SO_3$.—The anhydrous vanadyl sulfate has a short range of stability in concentrated solutions of sulfur trioxide. In concentrations higher than about 83 or 84% sulfur trioxide, the tetravalent vanadium is oxidized to the pentavalent state. The solubility at 81.02% sulfur trioxide is 0.036%, expressed as vanadium dioxide, which increases to 0.097% in 73.67% sulfur trioxide. These solutions are almost clear.

The time necessary for attainment of equilibrium for this compound was not determined exactly, but a year or more was required. The samples described were agitated for several months and then allowed to stand for two years before consistent analytical results were obtained. The

crystals are white with a slight tint of blue. Direct analysis of the crystals was not successful since but a small amount was available. The crystals were very small and were contaminated always with the mother liquor of highly concentrated sulfur trioxide. They are very soluble in ether–alcohol or water solutions.

In Table II a comparison of the most probable calculated value with the theoretical value of the composition is shown.

Gerland[3] identified an anhydrous normal vanadyl sulfate which he prepared by boiling the soluble hydrated sulfates in concentrated sulfuric acid. His resulting gray compound is very insoluble even in boiling water. While Gerland's insoluble compound was encountered in the course of this work, as previously mentioned, our anhydrous sulfate is quite soluble in water and dilute acid as well as in alcohol.

Summary

Solubility measurements are given for the ternary system VO_2–SO_3–H_2O at 30° and an isothermal ternary diagram has been constructed.

Over the total range of solubilities these five compounds only, $VO_2 \cdot H_2O$, $VO_2 \cdot SO_3 \cdot 5H_2O$, $VO_2 \cdot SO_3 \cdot 3H_2O$, $2VO_2 \cdot 3SO_3 \cdot 4H_2O$, and VO_2SO_3, were found to exist as stable solid phases at equilibrium with the various solutions.

For purposes of inoculation, attempts were made to prepare other compounds prepared previously by methods described in the literature in order to establish equilibrium relationships for the other reported hydrates. But no evidence was found for their existence.

A soluble form of the anhydrous normal vanadyl sulfate found in our study has not previously been reported.

The Second Virial Coefficients of Gaseous Mixtures[1]

BY A. E. EDWARDS[1a] AND W. E. ROSEVEARE[2]

Introduction.—Accurate p–V–T data at low pressures are few for pure gases and are almost non-existent for gaseous mixtures. This paper reports on the theory and experimental techniques of an indirect method of determining the second virial coefficients of gaseous mixtures. The method consists of measuring the change in volume on mixing two different gases at constant temperature and pressure and does not require determinations of absolute densities of gaseous mixtures.

Theoretical.—In this paper the virial equation of state is used in the form[3]

$$PV = RT + BP + CP^2 + DP^3 + \ldots \quad (1)$$

where B, C, D . . . are the second, third, fourth . . . virial coefficients. Pressures are expressed in mm. of mercury and volumes are expressed either in cc. or in Amagat units. The Amagat unit is considered to be 2.24×10^4 cc. for all gases used.

If two different gases are mixed at constant temperature and pressure, there is usually a change in total volume. The magnitude of this volume change depends upon the intermolecular forces between the molecular species making up the mixture and may be interpreted in terms of the virial coefficients of the pure gases and of the gaseous mixture in the following manner.

If n_1 moles of gas 1 and n_2 moles of gas 2, occupying volumes v_1 and v_2, respectively, are mixed at constant pressure P and constant temperature T and if we neglect the effect of virial coefficients higher than the second,[4] we may write

$$P(v_1/n_1) = RT + B_1P \quad (2)$$

$$P(v_2/n_2) = RT + B_2P \quad (3)$$

$$P(v_m(n_1 + n_2)) = RT + B_mP \quad (4)$$

where v_m is the volume occupied by the mixture and B_m is the second virial coefficient of the mixture. By combining these equations, we have for the volume change on mixing at constant temperature and pressure

$$\Delta v = v_m - (v_1 + v_2) = (n_1 + n_2)B_m - n_1B_1 - n_2B_2 \quad (5)$$

or in terms of the mole fractions in the mixture

$$\Delta v/n = B_m - N_1B_1 - N_2B_2 \quad (6)$$

(1) Original manuscript received February 25, 1942.

(2) Present address: E. I. du Pont de Nemours and Co., Richmond, Va.

(3) For a discussion of the various forms of the virial equation of state, see Hirschfelder, Ewell and Roebuck, *J. Chem. Phys.*, **6**, 205 (1938).

(4) The contribution of virial coefficients higher than the second is very small at low pressures. It will be shown that no significant error is introduced in this work by neglecting these terms.

where n denotes the total number of moles of gas. By combining this equation with that derived by Lennard-Jones and Cook[5] for molecules having symmetrical fields, *i. e.*

$$B_m = N_1^2 B_1 + 2N_1N_2B_{12} + N_2^2 B_2 \qquad (7)$$

we have

$$\Delta v/nN_1N_2 = 2B_{12} - (B_1 + B_2) \qquad (8)$$

where B_{12} may be interpreted as the second virial coefficient representing only the interaction between the unlike molecules in the mixture.

Therefore, if known volumes of two gases are mixed at constant temperature and pressure and the resulting volume change measured, the value of B_{12} may be calculated providing the second virial coefficients of the pure gases are known.

Experimental.—The apparatus is shown in Fig. 1. The gases were first contained in the Pyrex bulbs A and B, each bulb having a capacity of approximately 3 liters. Bulb C, which was used to maintain gas at a constant reference pressure, had a volume of approximately one liter. Bulbs A and B were separated by magnetically operated mercury sealed glass valves V_1 and V_2 and by the diaphragm gage G. The gage consisted of a thin Pyrex diaphragm on which was mounted a small mirror M_1. Minute movement of the diaphragm could be detected by means of the optical lever, shown in Fig. 1, used in conjunction with a reference mirror M_2, the position of which was fixed with respect to the equilibrium position of M_1, a straight filament lamp L and a scale. The diaphragm gage used in this work would withstand pressure differentials of 10 cm. in either direction without rupture. Since the gage was used only as a null indicator it was unnecessary to calibrate it in terms of pressure differential.

Stopcocks S_1 and S_2 were similar in design to those described by Roper[6] and were lubricated with sirupy phosphoric acid. The consistency of the lubricant made it advantageous to maintain a pressure of 200 mm. of nitrogen in the space within the stopcock below the plug rather than to evacuate this space completely. The other stopcocks were of the ordinary type and were lubricated by stopcock grease. This made it necessary to fill bulbs B and C only with those gases which were not affected by stopcock grease and to interpose a 20-cm. length of 1-mm. capillary tubing between bulb B and stopcock S_3 in order to prevent diffusion of the gas mixture to the stopcock.

After evacuation, bulbs B and C were filled with one gas simultaneously with the filling of bulb A with the other gas. The pressures were balanced to within 0.01 mm. by means of the gage, and stopcocks S_3 and S_6 were closed, thus isolating the gas in bulb C. The valves V_1 and V_2 were opened and the contents of A and B mixed by the all glass pump P. This pump was a modification of that described by Funnell and Hoover[7] and circulated an estimated 2 to 4 liters per hour. After thorough mixing of the two gases the pressure was returned to the original value (the pressure in bulb C being used as a reference) by adding or removing mercury by means of the calibrated buret Bu. The volume change could then be determined from the initial and final mercury levels in the buret.

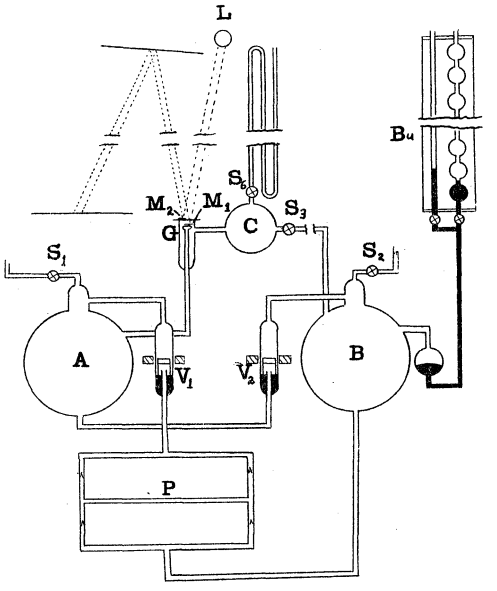

Fig. 1.

The apparatus, except for the buret and the manometer was held on a frame of brass and transite in a water thermostat which was maintained at 25 ± 0.01° throughout all experiments. The buret was held at 25 ± 0.1° by pumping thermostated water through the outer tube. The apparatus was arranged in such a manner that all stopcocks and valves could be operated from outside the thermostat.

Materials.—The hydrogen, oxygen and nitrogen used were 99.7% pure, the carbon dioxide was 99.5% pure and the helium and ethylene had a minimum purity of 99%. Further purification of the gases used in a number of runs had no observable effect upon the experimental results. Care was taken in all runs to sweep out all inlet tubes thoroughly and the bulbs were flushed several times before each run with the gases with which they were to be filled.

Experimental Results.—The data obtained for nine pairs of gases are given in Table I. Two runs were made at 760 mm. and two at 380 mm. for each pair of gases. The absolute error in the values of Δv is constant throughout the data. The percentage error in values of the function $2B_{12} - (B_1 + B_2)$, which are calculated by use of the relationship derived above, vary inversely with the magnitude of the function. It is estimated to be not more than 2% in the case of the H_2–C_2H_4 mixture but may be as much as 12 to 15% at most, *i. e.*, for the CO_2–C_2H_4 mixture.

It will be noted that values obtained for the function $2B_{12} - (B_1 + B_2)$ at 760 and 380 mm. are the same within the limits of the experimental error. Hence, omission of the virial coefficients

higher than the second appears to be justified in work of this accuracy at pressures near one atmosphere.

Discussion.—For a number of gases, p–V–T data have been expressed in terms of the virial equation of state, the range of pressures covered being determined by the number of virial coefficients used. Such equations, calculated by Newitt[8] from the data of Holborn and collaborators,[9,10,11] over a pressure range 0–200 atm. yield for the second virial coefficient of hydrogen 6.60×10^{-4}; of nitrogen -2.0×10^{-4}; and of helium 5.26×10^{-4}. These values are considered to be the best available for these gases at the present time.

If we consider the virial equation

$$PV = RT + BP \qquad (9)$$

or, rearranged

$$B = (PV - RT)/P \qquad (10)$$

the value of B as expressed by this equation may be termed the *apparent* second virial coefficient and it must approach the true second virial coefficient as the pressure approaches zero. Hence if values of B apparent are plotted against pressure the intercept of the extrapolated curve and the axis $P = 0$ will be the true second virial coefficient. This procedure has been followed for carbon dioxide, oxygen and ethylene, using the data of Masson and Dolley[12] and Michels[13] for carbon dioxide. The best curves through these data yield for the second virial coefficient of oxygen -9.2×10^{-4}; of ethylene -62.5×10^{-4}; and of carbon dioxide -52.5×10^{-4}. Roper's data[14] give B for ethylene as -65.9×10^{-4} which agrees with the above value within Roper's maximum experimental error. Schafer's data[15] give B for carbon dioxide as -56×10^{-4} by extrapolating B from data at 0 to −70°.

These values of the second virial coefficients of the pure gases and the values of B_{12} calculated by substitution of them into the function $2B_{12} - (B_1 + B_2)$ are collected in Table II.

TABLE II

SECOND VIRIAL COEFFICIENT OF GASES AND OF GASEOUS MIXTURES AT 25°

nard-Jones and Cook. This equation, derived on the assumption of symmetrical fields about the molecules, has been introduced into the derivations above and has been shown elsewhere[16] to be valid in similar cases.

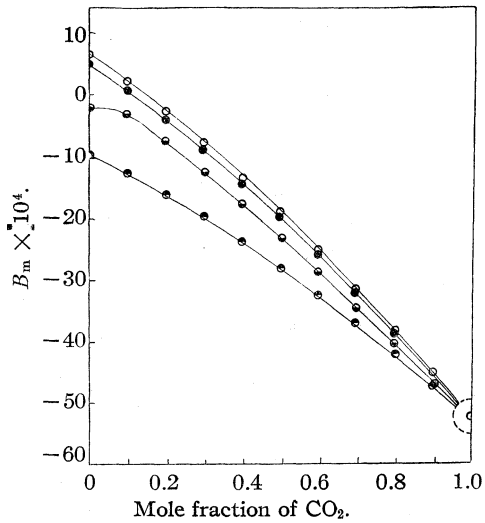

Fig. 4.—Second virial coefficients of mixtures: O, H_2–CO_2; ●, He–CO_2; ◒, N_2–CO_2; ◓, O_2–CO_2.

The values of B_m thus obtained have been plotted against mole fractions in Figs. 2, 3, and 4.

Summary

The theory and practice of a method for determining the second virial coefficients of gaseous mixtures has been described. The method gives data for mixtures corresponding in accuracy to those obtained by gas density measurements to approximately 0.002%.

Values for the second virial coefficients B_{12} for nine pairs of gases at 25° have been reported.

Values of B_m for each of the nine pairs of gases have been plotted as functions of the compositions of the mixtures.

Adsorption of Simple and Complex Cobalt Ions on Titanium Dioxide

BY DOUGLAS G. NICHOLSON[1]

It is a well-known fact that the addition of small amounts of certain metallic soaps to drying oils accelerates the rate of gelation of these substances. A recent report[2] has indicated that pigmented drying oil films containing drier metal ions coördinated with ortho-phenanthroline tend to absorb oxygen more rapidly and at a more uniform rate than did similarly pigmented films containing uncoördinated metal ions. In this respect the films pigmented with titanium dioxide showed the greatest differences, while those containing zinc oxide or zinc sulfide exhibited slight differences.

Authorities in the drying field agree on the fact that cobalt ions are adsorbed on the surface of titanium dioxide particles suspended in a drying oil. This adsorption has been thought to be a rather slow process involving rather long periods of time. A recent study[3] has indicated that the adsorption of a monomolecular film of cobalt ions on the surface of the titanium dioxide particles would account for the loss in catalytic drying properties of such materials.

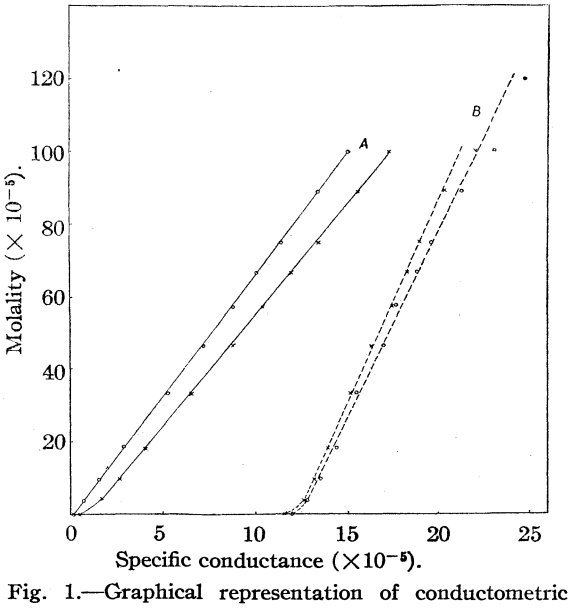

Fig. 1.—Graphical representation of conductometric data obtained by the addition of cobalt acetate and cobalt *o*-phenanthroline acetate to (A) conductivity water and (B) conductivity water containing a known quantity of commercial rutile type titanium dioxide: o—o, $Co(o\text{-}A)_3Ac_2$; x—x, $CoAc_2$; o---o, $Co(o\text{-}A)_3Ac_2 + TiO_2$; x---x, $CoAc_2 + TiO_2$.

In an effort to show that these ion adsorptions progress to a considerable extent in the early stages of the aging of suspensions of titanium dioxide and cobalt materials, as well as to account for the reported rapid oxygen absorption of drying oils containing coördinated cobalt ortho-phenanthroline materials and titanium dioxide, a conductometric study of the subject was undertaken. As the work progressed, it was decided that spectrophotometric data obtained from the experimental solutions would also yield interesting related data.

Conductometric Measurements.—To 10 ml. of conductivity water in a Freas type conductivity cell maintained in a thermostat at 25 ± 0.1°, ten successive additions of 0.1 ml. of 0.002 *M* solutions of cobaltous acetate were made. The cell was shaken after each addition and allowed to come to the temperature of the thermostat. This experiment was then repeated except that instead of the cobaltous acetate, an equivalent solution of cobaltous ortho-phenanthroline acetate was added.

This pair of experiments was then repeated, except that in each experiment 5 g. of commercial, rutile type, titanium dioxide was first added to the conductivity water.

Another pair of similar experiments was carried out identical to the above except that the conductivity water was replaced in the first by glacial acetic acid, and in the second by glacial acetic acid 0.0005 *M* in cobaltous acetate. Small, but accurately measured, quantities of solid ortho-phenanthroline were added to each of these solutions and the resistance of the cell determined after each.

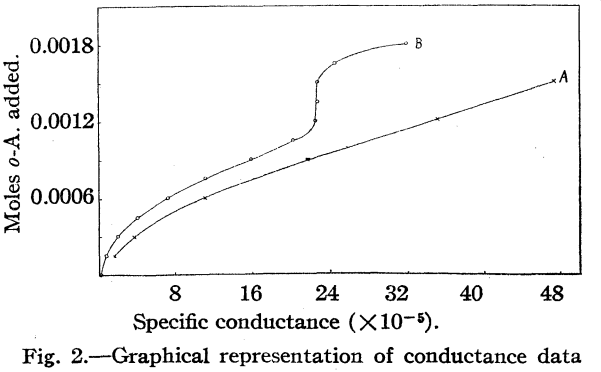

Fig. 2.—Graphical representation of conductance data obtained from the addition of *o*-phenanthroline to (A) glacial acetic acid and (B) to a 0.0005 *M* solution of cobalt acetate in glacial acetate acid: o—o, HAc + 10 cc. of 0.05 *M* $CoAc_2$; x—x, HAc.

(2) Douglas G. Nicholson, paper presented before The Paint and Varnish Group of The American Chemical Society, 103rd meeting, Memphis, Tenn., April, 1942.

(3) *Am. Paint J.*, **26**, 4-B, October, 29, 1941.

The results of these experiments are shown in graphical form in Figs. 1 and 2.

Spectrophotometric Measurements.—Samples of cobaltous acetate and of cobaltous ortho-phenanthroline acetate, 0.025 *M* in cobalt ion, were prepared and spectrophotographic transmittancy curves obtained for each by means of a General Electric Recording Spectrophotometer. Additional portions of each of these solutions were shaken with commercial, rutile type, titanium dioxide and after allowing approximately twelve hours of standing and filtering off the pigment, transmittancy curves were again obtained from the resulting solutions.

These data appear in graphical form in Figs. 3 and 4.

Discussion.—Figure 1 shows that the solutions containing the coördinated cobalt ions are poorer conductors than are uncoördinated solutions of equal ion concentration. When titanium dioxide is present in the solution, the reverse effect is true. Thus it appears that the loss of conductivity of the uncoördinated ions may be due to adsorption of some on the surface of the pigment particles. The presence of the large coördinating molecules surrounding the cobalt ions, apparently reduces the tendency for this adsorption, with the result that the coördinated ions are better conductors when the pigment is present.

Figure 2 shows quite conclusively that cobalt acetate does form a coördination compound with ortho-phenanthroline in glacial acetic acid. The break in the curve occurs at approximately three molecules of the coördination agent per ion of cobalt. The data appearing in this graph also indicate that ortho-phenanthroline also reacts with the glacial acetic acid, with the probable formation of ortho-phenanthroline acetate.

Figures 3 and 4 show, respectively, the transmissivity curves obtained from the uncoördinated and the coördinated cobalt acetate–glacial acetic acid solutions, before and after the suspension of titanium dioxide pigment. It is to be noted (Fig. 3) that there is an increased transmissivity after the titanium dioxide contact with the solution. This tends to indicate that some of the coloring material (cobalt ions) had been removed by the treatment. This point supports the adsorption idea. In Figure 4, there is actually a slight loss of transmissivity after the contact with the titanium dioxide. No explanation is offered to justify this anomalous behavior. However, there is little doubt regarding the fact that the pigment reacts differently toward the simple and the coördinated cobalt ions of equal concentration. These spectrophotometric data support the information obtained from the conductometric portion of this work.

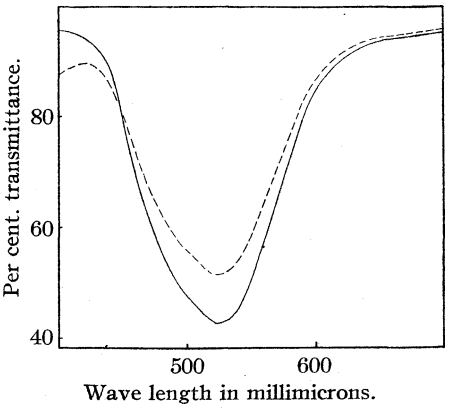

Fig. 3.—Spectrophotometric transmittancy curves obtained from 0.025 *M* cobalt acetate dissolved in glacial acetic acid: (a) solid line is control material; (b) dotted line is same material after having titanium dioxide suspended and filtered.

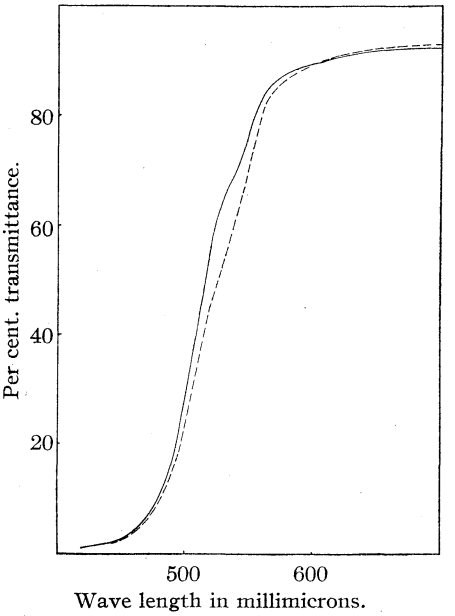

Fig. 4.—Spectrophotometric curves obtained from 0.025 *M* cobalt *o*-phenanthroline acetate dissolved in glacial acetic acid: (a) solid line is control solution; (b) dotted line is same solution after exposure to titanium dioxide.

Summary

Titanium dioxide suspended in water or glacial acetic acid solutions of cobalt acetate adsorbs cobalt ions in a relatively short time.

Coördination of cobalt ions with ortho-phenanthroline materially reduces this adsorption tendency. Ortho-phenanthroline forms a coördination compound with cobalt acetate in glacial

acetic acid. The shortened induction period, which is characteristic of titanium dioxide-pigmented drying oils containing metal-ortho-phenanthroline complex driers can be attributed to this reduction in the adsorption tendency.

The Solubility Effect in Solvents of Low Dielectric Constant. II. A Study of the Solubility Effect in Benzene[1]

BY ARTHUR A. VERNON AND JOHN P. MASTERSON[2]

I. Introduction

In continuation of the work of Vernon, Luder and Giella[3] this paper reports the results of further solubility measurements of quaternary ammonium salts in benzene. In addition to the literature references cited in the earlier paper by these authors it should be noted that Partington[4] and co-workers have reported results using alcohols as solvent. Also Geer[5] studied some solubility effects in acetic acid, Gross, Kuzmany and Wald[6] in ethyl alcohol and Anhorn and Hunt[7] in liquid ammonia.

II. Experimental

Materials.—C. P. thiophene-free benzene, after standing for several days over anhydrous calcium chloride, was distilled from anhydrous aluminum oxide, the first and last fifth portions being discarded. It was collected and stored in five-pint, ground glass stoppered bottles.

Tetraisoamylammonium iodide was prepared by heating an equimolar mixture of Eastman Kodak Co. tri-isoamylamine and isoamyl iodide to 70° in a constant temperature oven. The crude yield was washed with petroleum ether and dissolved in hot ethyl acetate and treated while hot with alcoholic potassium hydroxide until pink to phenolphthalein. On decanting and cooling in an ice-bath, amine free iodide crystals separated out. The final leafy product was obtained after several recrystallizations from ethyl acetate (m. p. 146.5°).

Tetraamylammonium iodide was prepared similarly except that the crude yield was dissolved in 95% ethyl alcohol before treatment with potassium hydroxide. The iodide was precipitated in water and recrystallized from ethyl acetate (m. p. 134°).

The corresponding picrates were prepared by the method of Cox, Kraus and Fuoss[8] except that the recrystallizations were from 95% ethyl alcohol. They were tetraisoamylammonium picrate (m. p. 86°) and tetraamylammonium picrate (m. p. 73°).

Tributylammonium picrate was prepared by the method of Mead, Fuoss and Kraus.[9]

Procedure.—The method was essentially the same as described by Vernon, Luder and Giella[3] with the modifications that only 600 cc. of benzene was used and a water solution of silver nitrate was substituted for the alcoholic solution. It was found that using alcoholic silver nitrate, the iodide was precipitated colloidally and on aging it settled and adhered to the bottom of the beakers. Transfer of this type of solid to a Gooch crucible was very difficult and relatively inaccurate.

On using a water solution of silver nitrate, however, the precipitated silver iodide came down immediately in flocculent form and on standing settled out at the interface of the benzene and water layers. In this form it was readily transferred to a Gooch crucible since it rode along with the interface and any small particles that adhered to the beaker wall were easily transferred using a rubber policeman and a wash bottle stream. The reproducibility of results was very good, often being within one part in five hundred. Analysis of a known weight of quaternary iodide showed this technique subject to about one per cent. error. The Gooch crucible containing the transferred silver iodide was dried for twenty-four hours over phosphorus pentoxide in a desiccator to consistent weight.

Results.—The results of the determinations are recorded in Tables I and II. All concentrations are in moles per liter and are the averages of duplicate measurements. Since these data are of most value when combined with

TABLE II

SOLUBILITY OF TETRAAMYLAMMONIUM IODIDE IN THE PRESENCE OF EITHER (a) TETRAAMYLAMMONIUM PICRATE OR (b) TRIBUTYLAMMONIUM PICRATE IN BENZENE AT 25°

Concn. of (a) × 10^4	Solubility of iodide × 10^4	Concn. of (b) × 10^4	Solubility of iodide × 10^4
0.00	0.539	0.00	0.539
1.00	0.583	1.00	1.07
5.00	0.992	3.00	2.04
10.00	1.43	10.00	3.85
20.00	2.50	30.00	7.39
		50.00	10.65

previous results, they are plotted in Fig. 1 with the curves previously obtained by Vernon, Luder and Giella.[3]

III. Discussion

A usual treatment of solubility data is to compare the curve of variation of activity coefficient *versus* the square root of salt concentration with that predicted by the Gronwall, LaMer and Sandved equations using arbitrary values of "ionic diameters." If the experimental and theoretical curves can be made to agree closely by assigning "reasonable" values to the "ionic diameter" then the theoretical equation is considered applicable in the region investigated.

To apply such calculations to the solutions investigated in benzene is fruitless. In such a low dielectric solvent, conductivity and freezing point measurements indicate that association becomes very manifest and the electrolytes behave as if incompletely dissociated. Obviously the value of an "ionic diameter" of a supposed single ion would have little meaning under such conditions.

An approach such as that of Gronwall, Sandved and LaMer might be possible if there were some means of calculating the number of charged ion aggregates in the solution. At present this is not the case.

The increase in solubility in every case on the addition of an electrolyte whether with or without a common ion seems to be further proof of other than single ion phenomena. If the predominant effect were that of single ions we should expect a decrease in solubility on adding a common ion. The fact that the tri-salt gives a greater solubility increase than the tetra-salt with tetraisoamylammonium iodide may be due to a greater interionic attraction.

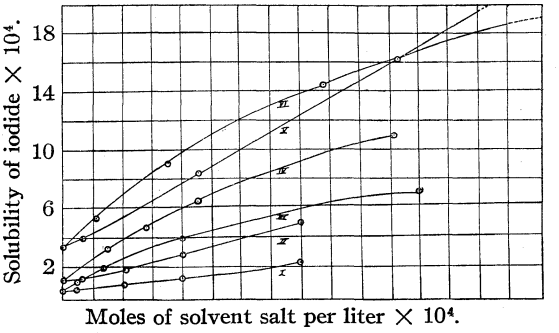

Fig. 1.—I, $(Am)_4NI$ in presence of $(Am)_4N$ picrate; II, $(Isoamyl)_4NI$ in presence of $(isoamyl)_4N$ picrate; III, $(Am_4)NI$ in presence of $(Bu)_3HN$ picrate; IV, $(Isoamyl)_4$-NI in presence of $(Bu)_3HN$ picrate; V, $(Bu)_4NI$ in presence of $(Bu)_4N$ picrate; VII, $(Bu)_4NI$ in presence of $(Bu)_4N$-NO_3.

IV. Summary

1. The solubility of tetraisoamylammonium iodide in benzene solutions of tetraisoamylammonium picrate and tributylammonium picrate was determined.

2. The solubility of tetraamylammonium iodide in benzene solutions of tetraamylammonium picrate and tributylammonium picrate was determined.

3. An increase in solubility of the saturating salt was found in both cases and the relation of this to multiple ion phenomena is indicated.

Studies on High Molecular Weight Aliphatic Amines and Their Salts. IX. The Behavior of Various Salts of Dodecylamine in Water, Ethanol and Benzene

BY C. W. HOERR AND A. W. RALSTON

Previous papers in this series have presented various aspects of the behavior of the normal primary aliphatic amine hydrochlorides and hydroacetates in water,[1-4] and in ethanol and benzene.[5] These studies have shown that in water these salts are colloidal electrolytes, similar in their behavior to compounds in which the paraffin chain is in the anionic portion of the molecule. In dilute solution they act as simple, completely dissociated, uni-univalent electrolytes, while at certain concentrations dependent upon the length of the paraffin chain, a colloidal transformation results from the formation of micelles. With ethanol and with benzene, the amine salts form simple eutectic systems in which the eutectic composition is located in the region of very small concentration of amine salt.

This investigation is carried further by the preparation of a wide variety of salts of dodecylamine. While this paper is primarily a report of the solubilities of these salts in water, ethanol and benzene, a study of the phase changes of several of the salt–water systems has been included, together with a study of the state of some of the salts in solution, as indicated by their effects in depressing the freezing point of water and that of benzene.

Preparation of Materials.—The dodecylammonium chloride and the acetate were of the same lots which were used in previous experiments, and their preparations and constants have been reported.[1,2,5] The preparations of the following salts have not been reported elsewhere. These salts were prepared by adding equimolar portions of the appropriate acids to dodecylamine in the most satisfactory solvent, as noted below.

Dodecylammonium *n*-propionate and dodecylammonium *n*-butyrate were prepared in the manner of the acetate,[2] the propionate by repeated recrystallizations from ethyl ether and benzene, alternately, and the butyrate from petroleum ether (Skellysolve "F," b. p. 30–60°), until their melting points were constant. The melting point of the propionate was 56.7–56.9° and that of the butyrate was 41.0–41.2°.

Dodecylammonium formate, bromide and iodide were prepared by the method used for the chloride[1] with benzene as the solvent to facilitate the removal of the water introduced by the addition of the acids. No melting points could be obtained for these salts since they decompose at temperatures above 160°. Dodecylammonium formate transforms above 63° to a firm semi-solid liquid crystalline state.

Dodecylammonium acid sulfate and primary dodecylammonium phosphate were crystallized from 95% ethanol. Since dodecylammonium normal sulfate and secondary dodecylammonium phosphate are not appreciably soluble in any of the usual solvents, these salts were refluxed with ethanol for several hours, washed repeatedly with hot water and with ethanol, and finally with hot benzene. No melting points could be obtained for either of the sulfates or the phosphates since they decompose on heating above 250°. Attempts to prepare *t*-dodecylammonium phosphate were unsuccessful.

Dodecylammonium dodecylcarbamate was prepared in this Laboratory by Dr. F. M. Garland. Pure, dry carbon dioxide was passed into liquid dodecylamine at about 30°. Measurement by means of a gas buret of the quantity of carbon dioxide which reacted indicated that two moles of amine combine with one mole of carbon dioxide. This compound was purified by repeated crystallization from 95% ethanol. It melts at 92–93°, and decomposes at 98° to dodecylamine and carbon dioxide.

The secondary and tertiary amine salts were prepared in this Laboratory by Dr. W. O. Pool. Primary dodecyl alcohol (133 g.) was refluxed with resublimed iodine (97 g.) and red phosphorus (7.2 g.) for one hour at 170°. The dodecyl iodide (b. p. 118–120° at 0.7 mm.) was removed from the mixture by solution in ethyl ether and purified by fractional distillation under reduced pressure. The iodide (184 g.) was then heated with methylamine (635 g. of methanol solution containing 13.6 g. methylamine per 100 ml.) in a bomb for eight hours at 135 ± 5°. Excess methanol and methylamine were removed by distillation, and the N-methyldodecylamine was purified by fractionation *in vacuo*. Its boiling point was 88–89° at 1 mm. The hydrochloride of this amine was prepared in the manner of the corresponding primary salt. It melts with decomposition at about 180°, which agrees with a recent observation.[6]

N-Dimethyldodecylamine was prepared by the same method as was used for the corresponding secondary amine, except that a methanol solution of dimethylamine was used. The boiling point of the tertiary amine was 87–88° at 0.9 mm. The hydrochloride and hydroacetate of this amine were prepared by the methods used for the corresponding primary salts, the hydrochloride melting at 170–171° and the hydroacetate at 38.8–39.0°.

The water used in these experiments was freshly distilled conductivity water. The ethanol was commercial "absolute" (99.4% by weight) diluted to 95.0% by weight, ex-

cept where other dilutions are noted below. The ethanol concentration was determined by measurement of its density at each dilution with a 25-ml. pycnometer, and interpolation of these values with those from the "International Critical Tables."[7] The benzene was Baker C. P. thiophene-free grade and was dried over sodium wire.

Apparatus and Procedure.—The experimental procedures were essentially those used in the previous investigations of this series. Visual observations were made by the synthetic method first proposed by Alexejew.[8] The samples were prepared in small glass tubes and rotated in a water-bath with the apparatus and by the procedure described elsewhere.[1,5] Temperatures were measured with a calibrated thermometer which was graduated in 0.1° intervals. The temperatures of solution of the amine salts investigated were reproducible to ±0.1°, and are, in general, considered accurate within ±0.2°.

Transition temperatures of the system dodecylammonium acetate–water below approximately 80° were determined by analysis of cooling curves. These were obtained by carefully controlled cooling of 5–7 g. samples contained in test-tubes (1.5 × 15 cm.) immersed in a bath (800 ml.) of light mineral oil (acetone was used as the bath for sub-zero temperatures). After preliminary heating to homogeneity, the acetate–water samples were allowed to cool slowly while being agitated with a small "Chromel" wire stirrer. The temperature of the bath was at no time more than 2° below that of the sample. Undercooling, in general, did not occur. Temperatures of the samples were read with the calibrated thermometer. The transition temperatures of this system are considered to be accurate to ±0.5° above 80°, while below this temperature they are probably accurate within ±0.2°.

The depression of the freezing points of water and of benzene by several of the salts was measured by means of a Beckmann thermometer which had been calibrated by the National Bureau of Standards, and the temperatures obtained were considered accurate to ±0.001°.

Various compositions of dodecylammonium acetate in water were examined microscopically with polarized light to confirm the preliminary gross visual observations of the nature of the phases which were present.

Results

The Acetate–Water Systems.—A preliminary study of the system dodecylammonium acetate–water has been reported previously.[2] In the light of recent investigation of the higher amine–water systems,[9] this acetate–water system was studied further, and the complete temperature-concentration diagram is shown in Fig. 1. On this diagram, A represents the freezing point of dodecylammonium acetate (69.3°) and K that of water. Area 1 is clear, isotropic solution. Two hydrates are found, a tetrahydrate (m. p. 129.0°) and an eicosahydrate (m. p. 86.0°).

The eutectic between dodecylammonium acetate and its tetrahydrate is represented by B. Areas 2 and 3 are two phase mixtures. Area 5 is a region of microscopically homogeneous material in a mesomorphic state. This region is analogous to the solid solutions of metallic systems and is physically identical with the corresponding phases of the amine–water systems,[9] with reference to which a sufficiently thorough discussion has been presented. Area 4 consists of a mixture of acetate crystals and the solid solution phase of concentration on curve EN. A eutectoid between the acetate and water is represented by N. Area 6 consists of a mixture of crystals of these components. F represents a eutectic between the tetrahydrate and the eicosahydrate. After passing through a narrow two phase region upon cooling, samples containing mixtures of these two hydrates become physically identical with other samples in area 5. J represents a eutectic between the eicosahydrate and water.

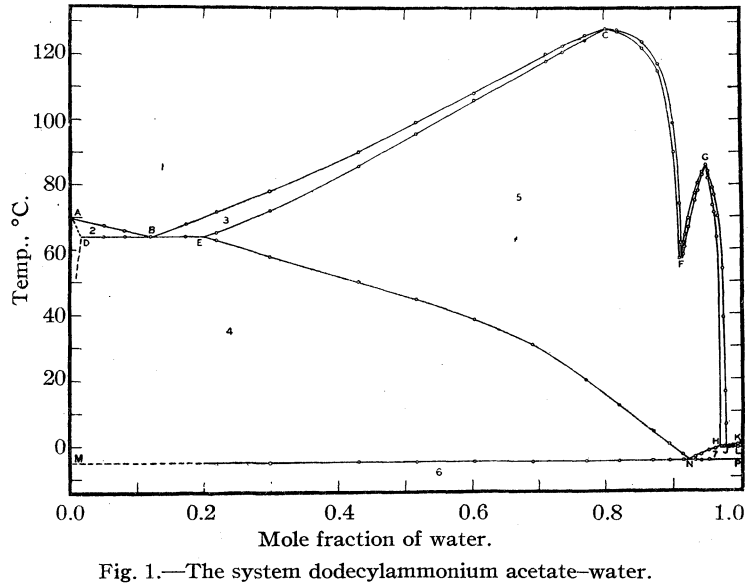

Fig. 1.—The system dodecylammonium acetate–water.

The broken lines at the left of Fig. 1 represent the existence of a region of solid solution, which was indicated by observation, though not verified by direct measurement.

Other Solubilities in Water.—Dodecylammonium formate and *n*-propionate and N-dimethyldodecylammonium acetate exhibit be-

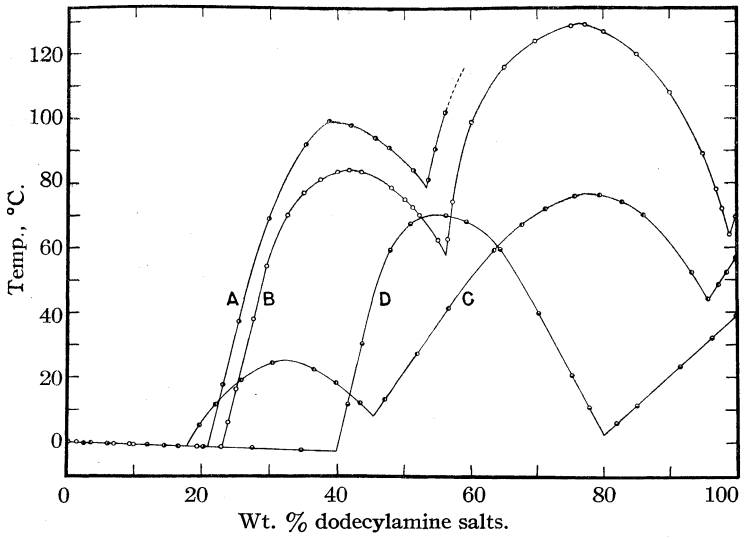

Fig. 2.—Liquidus curves of dodecylamine salts in water: dodecylammonium formate, A; acetate, B; propionate, C; N-dimethylammonium acetate, D.

havior with water similar to that of the acetate. Since the latter system has been described sufficiently, only the liquidus curves of these salts are shown graphically in Fig. 2. Due to thermal instability of the formate, this system was not investigated beyond approximately 60%.

Study of these systems shows the presence of the following hydrates. The formate forms at least one hydrate, an eicosahydrate (m. p. 99.6°). The propionate, like the acetate, forms two hydrates, a tetrahydrate (m. p. 77.0°) and a triacontahydrate (m. p. 24.8°). N-Dimethyldodecylammonium acetate forms one hydrate, a dodecahydrate (m. p. 70.0°).

While it has not been thoroughly investigated, the butyrate-water system is qualitatively similar to the system octadecylammonium acetate–water.[2] Above 33°, the butyrate system exists as two conjugate solutions over practically the entire range of concentration, similar to the behavior of the octadecylamine salt. In the case of dodecylammonium butyrate, the region of isotropic solution exists over a much smaller range of concentration than does the corresponding region of the octadecylamine salt system.

Figure 3 shows the solubilities of dodecylammonium bromide and iodide, primary dodecylammonium phosphate, N-methyldodecylammonium chloride and N-dimethyldodecylammonium chloride, together with the curve which has been reported for dodecylammonium chloride.[1] All of these salts pass through the same phase changes as does the chloride. In all cases, except that of N-dimethyldodecylammonium chloride, there is an abrupt change in the solution temperature at approximately 0.39%. In the case of the bromide, a metastable form precipitates from solution upon cooling, as indicated by the broken line in Fig. 3. This behavior recalls that of dodecylammonium chloride.[1] No metastable compound formation by the other salts was observed.

From the freezing point data, the osmotic coefficient g was calculated for dodecylammonium formate, acetate and propionate, and for the hydroacetate and hydrochloride of N-dimethyldodecylamine. These values are plotted against the square root of the molality ($\sqrt{N_w}$) in Fig. 4.

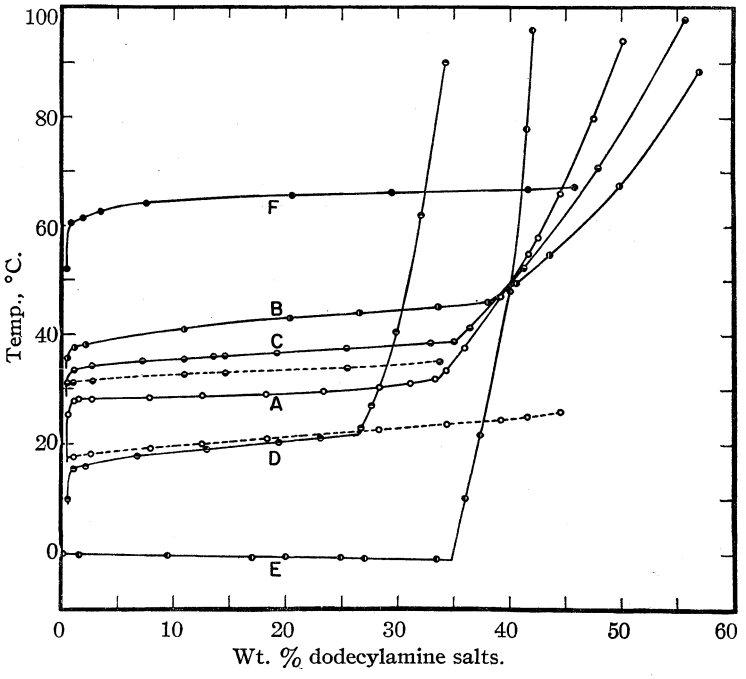

Fig. 3.—Solution temperatures of dodecylamine salts in water: dodecylammonium chloride, A; iodide, B; bromide, C; N-methylammonium chloride, D; N-dimethylammonium chloride, E; primary dodecylammonium phosphate, F. The broken lines refer to the corresponding metastable modifications.

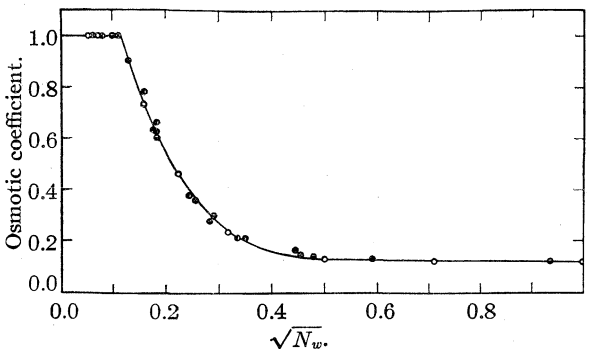

Fig. 4.—Osmotic coefficients of dodecylamine salts in water: ⊗ formate, O acetate, ● propionate, ◐ N-dimethylammonium chloride, ◒ N-dimethylammonium acetate.

It can be seen from Fig. 4 that the values for the osmotic coefficients of all of the salts investigated fall on the same curve, within experimental error. Up to approximately 0.013 molal these salts behave as simple, completely dissociated, uni-univalent salts, as shown by the fact that their osmotic coefficients are 1.0 in this range. At 0.013 molal, the values of g decrease abruptly, indicating the formation of micelles in these solutions. This molality agrees with the value of the critical concentration for the formation of micelles which has been reported[3,4] for the dodecylammonium ion.[10] The interesting fact to be noted in this connection is that the values of the osmotic coefficients of the N-dimethyldodecylamine salts fall on the same curve as the primary dodecylamine salts. Evidently, in the case of these salts at least, N-substitution by methyl groups has no apparent effect upon the concentration at which micelles are formed.

Solubilities in Ethanol.—In Figs. 5 and 6 are shown the solubilities of the dodecylammonium halides, the acetate series, the dodecylcarbamate, the primary phosphate and the acid sulfate in 95.0% ethanol.

In preliminary study of dodecylammonium acetate it was observed that the solubility of this salt was increased by the dilution of ethanol with water. To investigate this further, a number of samples containing 50.0% dodecylammonium acetate were prepared in various dilutions of ethanol in small sealed glass tubes, and the temperatures at which solution occurred were determined by visual observation. The results of this experiment are shown graphically in Fig. 7; 41% aqueous ethanol gave the lowest solution temperature observed for a 50.0% mixture of dodecylammonium acetate–solvent. Minimum solution temperatures of other concentrations of this salt occur at approximately 45 ± 5% ethanol.

Solubilities in Benzene.—The solubilities of the dodecylammonium halides in anhydrous benzene are shown in Fig. 6, and Fig. 8 shows those of dodecylammonium formate, acetate, propionate, butyrate and dodecylcarbamate in the same solvent. The propionate and butyrate (and no doubt the other salts also) form simple eutectics with benzene. In the case of the butyrate, the eutectic is located at 3.6%, and that of the propionate occurs at 0.75%, while those of the acetate and formate occur at considerably greater dilutions.

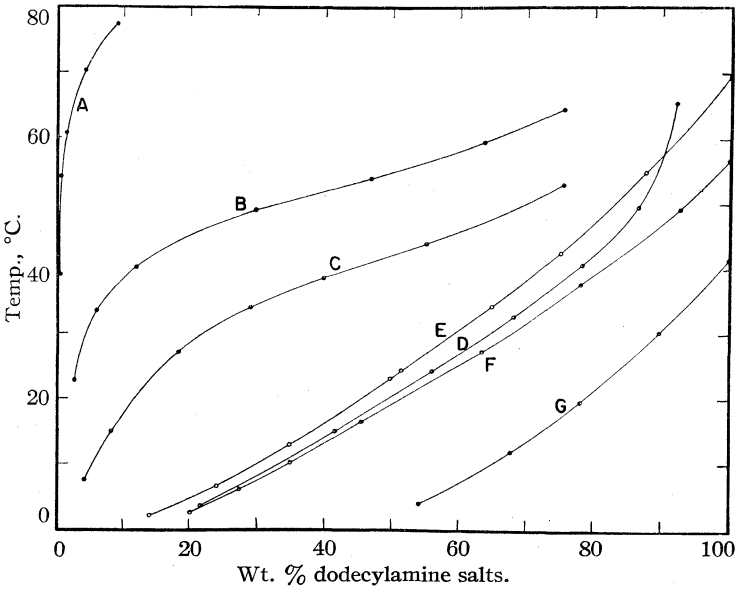

Fig. 5.—Solution temperatures of dodecylamine salts in 95.0% ethanol: primary dodecylammonium phosphate, A; dodecylammonium dodecylcarbamate, B; dodecylammonium acid sulfate, C; dodecylammonium formate, D; acetate, E; propionate, F; butyrate, G.

The lowering of the freezing point of benzene by dodecylammonium butyrate was measured accurately up to the concentration of the eutectic (3.6%). The apparent molecular weight of the butyrate was calculated from the amount of the freezing point depression at each concentration measured. The results are shown graphically in

(10) While this value was reported in terms of molarity, the values of molality and molarity are, for all practical purposes, equal in these dilutions.

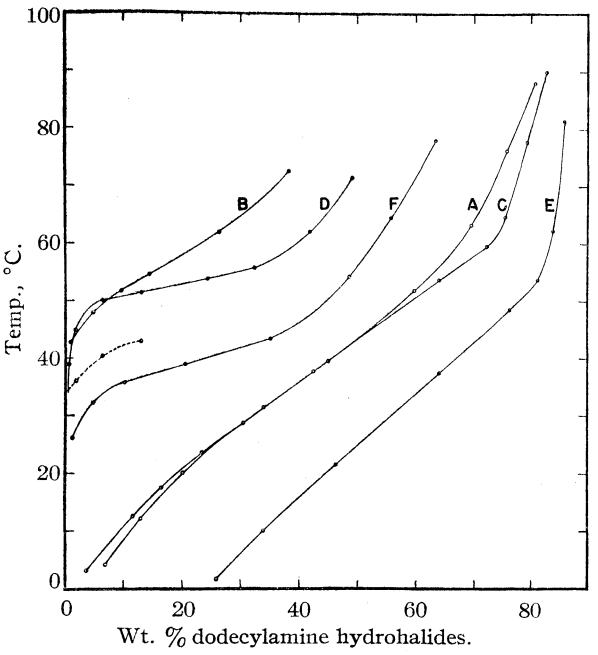

Fig. 6.—Solution temperatures of dodecylamine hydrohalides in 95.0% ethanol and in anhydrous benzene: dodecylammonium chloride in ethanol, A, and in benzene, B; bromide in ethanol, C, and in benzene, D; iodide in ethanol, E, and in benzene, F. The broken line refers to the metastable modification of the bromide in benzene.

phase.[11] However, it can be assumed safely that if associated molecules exist in the vapor, they also occur in the solution which is in equilibrium with it, though the extent of the association in the latter case is problematical. At any rate, molecu-

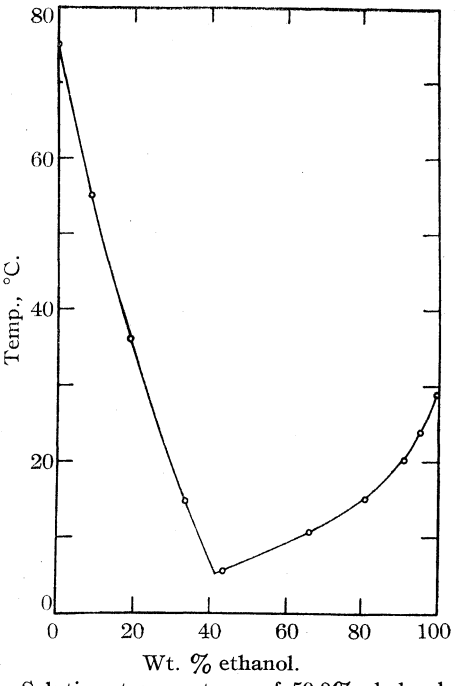

Fig. 7.—Solution temperatures of 50.0% dodecylammonium acetate in aqueous ethanol.

Fig. 9 as the ratio of apparent to true molecular weight (M/M_0) against the square root of the molality ($\sqrt{N_w}$). At approximately 0.1 molal, M/M_0 approaches a value of 2.0. A few measurements of the effects of the propionate upon the freezing point of benzene showed that its M/M_0 values fall on the curve for the butyrate.

The increase of the apparent molecular weight of dodecylammonium butyrate in benzene indicates that there is probably some degree of molecular association. Figure 9, however, cannot be interpreted literally to demonstrate that double molecules exist in solution, even though the M/M_0 values approach a value of 2.0 in higher concentrations, since, in the derivation of the equations involved, the solutions were assumed to be ideal, and certain pertinent factors have been omitted. Moreover, it has been proved with reasonable certainty that the values obtained by this method are actually the molecular weight of the solute in the vapor

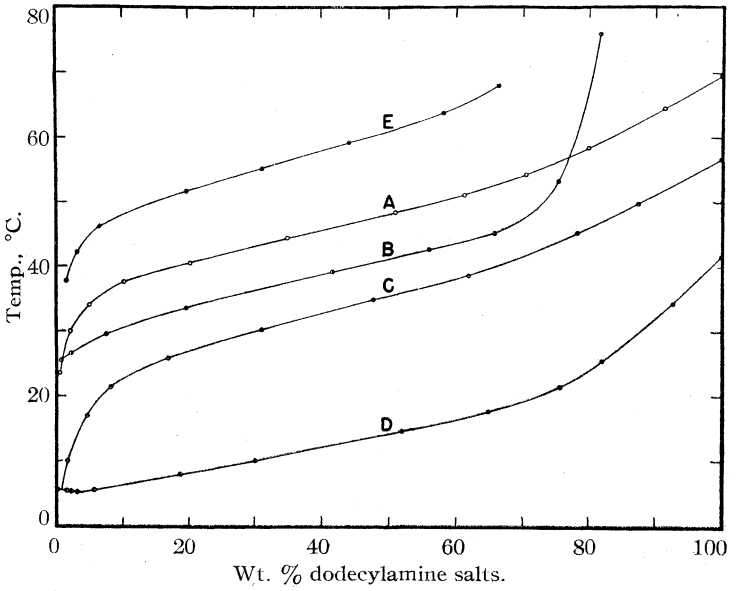

Fig. 8.—Solution temperatures of dodecylamine salts in anhydrous benzene: dodecylammonium acetate, A; formate, B; propionate, C; butyrate, D; dodecyl carbamate, E

(11) Peterson and Rodebush, *J. Phys. Chem.*, **32**, 709 (1928).

lar association of dodecylammonium butyrate to some extent in benzene is evidenced by the data presented.

Further evidence of molecular association is indicated by the rather irregular displacement of the solubility curves of dodecylamine salts toward the ethanol and benzene axes. Similar behavior of the higher fatty acids in benzene has been attributed[12] to molecular association in solution.

Summary

1. The solubilities of dodecylammonium formate, acetate, *n*-propionate, *n*-butyrate, chloride, bromide, iodide, dodecylcarbamate, primary and secondary phosphates and acid and normal sulfates, N-methyldodecylammonium chloride and N-dimethyldodecylammonium chloride and acetate in water, ethanol and benzene have been determined.

2. The phase changes of the water systems of dodecylammonium formate, acetate, propionate and N-dimethyldodecylammonium acetate have been investigated, and the hydrates formed by these salts are reported.

3. The colloidal nature of aqueous solutions of these salts has been demonstrated by a study of their osmotic coefficients.

4. Molecular association of dodecylammonium butyrate in benzene has been discussed.

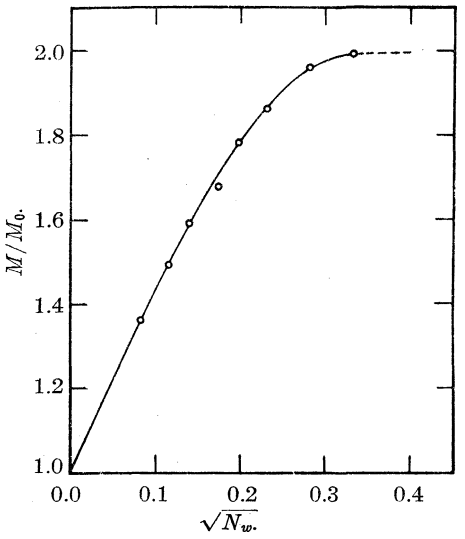

Fig. 9.—Molecular weight of dodecylammonium butyrate in benzene solutions.

Dipole Moment, Induction and Resonance in Nitroethane and Some Chloronitroparaffins

BY EVERETT C. HURDIS AND CHARLES P. SMYTH

Recent investigations[1] have shown an increase of moment of 0.21–0.23 from nitromethane to α- and β-nitropropane and 2-methyl-2-nitropropane, presumably because of the effect of induction upon the α- and β-carbons, since branching of the carbon chain did not increase the moment appreciably above that of the straight-chain nitropropane. One would, therefore, expect the moment of nitroethane to be close to those of the nitropropanes and nitrobutanes. This appeared to be true in the earlier measurements of Groves and Sugden,[2] who found 3.58, 3.57 and 3.55 for nitroethane, α-nitropropane and α-nitrobutane, values barely distinguishable from their value 3.54 for nitromethane. As this discrepancy between the two sets of investigations left a slight possibility of further increase of moment and, hence, of inductive effect, from nitroethane to the propanes, it seemed desirable to make a careful redetermination of the moment of nitroethane. This has been done, together with measurements upon three chloronitroparaffins, from which conclusions as to induction effects may be drawn. At the same time, measurements upon certain previously measured substances have been carried out as a check upon the absolute accuracy of the determinations.

Preparation and Purification of Materials

Carbon Dioxide.—The gas was taken from a cylinder of commercial material, passed through a tube containing eight-mesh calcium chloride and used without further purification.

Benzene.—The material used had been purified by Dr. P. F. Oesper for use in solution measurements and had been dried over sodium wire.

***n*-Octane.**—This hydrocarbon was supplied as a part of the American Petroleum Institute Pure Hydrocarbon Program. It was prepared and/or purified at the Pure Hydro-

carbon Laboratory, Department of Chemistry, operating as project No. 31 of the Ohio State University Research Foundation. A full description of this product will be published at a later date.

Water.—Ordinary distilled water was used for this measurement.

Nitroethane, Sample I.—Material kindly furnished by the Commercial Solvents Corporation was dried over calcium chloride and fractionally distilled under low pressure. The fraction used for measurements had a boiling point of 65.6° (153 mm.), $n^{20}D$ 1.3917.

Nitroethane, Sample II.—Material prepared by the reaction of silver nitrite with ethyl bromide[3] was fractionally distilled under low pressure. The fraction used for measurements had a boiling point of 81.5–82.0° (263 mm.), $n^{20}D$ 1.3912.

Monochloronitromethane.—Material kindly furnished by Professor R. H. Ewell of Purdue University was fractionally distilled under vacuum in an all glass trap system connected to the gas apparatus.

1-Chloro-1-nitroethane.—Material kindly furnished by Professor Ewell was fractionally distilled under low pressure in an all glass system. The fraction used for measurements had a boiling point of 55° (60 mm.), $n^{20}D$ 1.4224.

1-Chloro-1-nitropropane.—Material kindly furnished by Professor Ewell was fractionally distilled under low pressure in an all glass system. The fraction used for measurements had a boiling point of 67° (56 mm.), $n^{20}D$ 1.4251.

Experimental Method

The dielectric constants of the vapors were measured with the apparatus and much the same technique as that previously described.[4] A polarization value, P, was usually obtained at an absolute temperature, T, by plotting the results over a wide range of pressure and thus eliminating the error caused by possible deviations from the ideal gas law. This method, which we have generally employed, will be referred to as the "extrapolation method." However, in some cases, such as those of substances undergoing slight thermal decomposition with the passage of time, better results could be obtained by making one measurement at 10–30 millimeters pressure and another at a pressure, generally about 200 millimeters, for which experience showed the gas law deviation to be within the experimental error. These pressures were about twice those for which Brockway and Coop[5] calculated a possible error of 0.002×10^{-18} in dipole moment due to gas law deviation. In general, successive measurements by the "two-point method" showed considerable variation, but, if the results of four to six such measurements were averaged at each temperature studied, the averages showed excellent agreement over a wide temperature range.

The oil-bath in which the dielectric constant cell was immersed was altered so that it could be kept constant to within 0.02° at any temperature from room temperature to 250°. A very sensitive mercury-bulb temperature regulator was made by bending ten feet of 1-cm. "Pyrex" tubing into a coil. The fixed contact was a tungsten rod sealed into the glass and the movable contact was steel piano wire, which was much more resistant than platinum to the mercury at the higher temperatures.

The calibration of the apparatus was carried out by an absolute method, for the use of which it was not necessary to rely on the purity of any compound. A system of parallel compensating and measuring condensers was so constructed that a small precision measuring condenser with a scale 2500 divisions and a variable capacity of only 7 $\mu\mu f$ could be balanced against a large precision condenser, 1000 units on the small condenser having to be successively added 128.09 times to cover 400 units on the large condenser. The large condenser was thus calibrated by comparison with the small condenser, which, in turn, was calibrated in the manner previously described[4] by successive insertions of a small unit of about 0.05 $\mu\mu f$ capacity equal to about 25 scale divisions on the small condenser. The capacity of the gas cell was measured on the large condenser and its lead capacity determined from that of a set of dummy leads. Subtraction of this fixed capacity from the total capacity of the cell gave the geometrical capacity used in calculating the dielectric constant. The total cell capacity of about 200 $\mu\mu f$ was measured frequently on the large condenser and converted into units of the small condenser by multiplying by the conversion factor 320.2. It was remeasured whenever the temperature of the oil-bath was changed more than about 10°. The cell showed a temperature coefficient of capacity of about 0.0015% per degree, superimposed on a slow continuous downward drift of capacity. As the cell had been taken apart, cleaned, and reassembled before the measurements were begun, this downward drift in capacity may have been due to the opportunity afforded by thermal expansion and contraction for the relief of strains. During twelve months of operation, the capacity of the cell decreased by 5%, showing the importance of frequent checking. Care was taken to carry out both calibration and measurements at a constant frequency of 780 ± 3 kilocycles. Under these conditions, the effects introduced by lead and condenser inductances were constant and cancelled out in the measurements.

The platinum resistance thermometer in the cell was calibrated by comparison with a Bureau of Standards calibrated platinum resistance thermometer. As the platinum wire was exposed to the vapor in the cell, it was occasionally necessary to bake out the cell at 250° for a few days to avoid adsorption effects which lowered the apparent temperature reading. Temperatures as measured are believed accurate to within 0.2°.

Three compounds were measured as calibration checks: carbon dioxide, benzene and water. Carbon dioxide was measured by the two-point method, the pressures used being about 35 and 950 millimeters. The effect of frequency drift was corrected for by repeating each measurement in the reverse direction and averaging the two figures obtained. The observed pressures were corrected by the use of van der Waals constants. The average of six successive measurements on carbon dioxide was $(\epsilon_{760} - 1) \times 10^6 = 988 \pm 2$, reduced to 0°, in excellent agreement with the values of McAlpine and Smyth,[6] 989, and Stuart,[7] 987.

Benzene was measured at 140° by the extrapolation

(7) Stuart, *Z. Physik*, **47**, 457 (1928).

method. The average of four measurements gave a polarization of 27.1 cc., in agreement with the previously determined[6] value of 27.0 cc.

The polarization of a sample of pure *n*-octane, kindly given us by Dr. C. E. Boord, was also measured. This served in a sense as a calibration check, as the expected small increase in polarization over the liquid value was observed. The average of four measurements at 160° gave a polarization of 40.1 cc. The polarization of the same material in the liquid phase was 39.7 cc., as measured by Dr. P. F. Oesper in this Laboratory.

The dipole moment of water vapor was measured, using the two-point method, over the temperature range 111 to 250°, the average moment value obtained being 1.844 Debye units. This figure is in good agreement with those reported by Sänger, Steiger and Gachter,[8] 1.852 ± 0.008, and by Groves and Sugden,[9] 1.850 ± 0.01, values which have been recalculated with the currently accepted factor, 0.01281, in the Debye equation.

Experimental Results

The results of individual runs are given in Table I for the dielectric constant ϵ minus 1 for

carbon dioxide, for the polarization P for all the substances, and for the dipole moment μ for the polar substances except the last two. For these two, a tendency toward decomposition and the consequent use of the two-point method of measurement increased the error in individual P values and made desirable an increased number of runs and the use of an average of the results, $P_{av.}$, to calculate the moment. The molar refraction for the sodium D line, MR_D, is listed in Table II for each nitro compound, together with the average of the moment values for the substance in Table I.

Discussion of Results

The results obtained for the substances measured as a test of the accuracy of the apparatus agree so well with previously published data as to indicate an absolute accuracy almost as great as the relative accuracy, about 0.01×10^{-18} in moment. The slight elevation of the polarization value found for *n*-octane vapor over that of the liquid at 25° parallels that previously observed for benzene[6] and noted again in the present measurements and similar behavior on the part of other non-polar substances previously discussed.[10] It is to be noted that Sample I of nitroethane, a material prepared commercially by vapor phase nitration of hydrocarbons, gives a moment value identical with that for Sample II, prepared by the reaction of silver nitrite with ethyl bromide, which, taken in conjunction with the accuracy established for the apparatus, seems to establish definitely the correctness of the value. The average moment, 3.70×10^{-18}, may be compared with the value of Smyth and McAlpine[11] for nitromethane, 3.50 (recalculated on the basis of MR_D) and with the value of Wiswall and Smyth[1] for 1-nitropropane, 3.72×10^{-18}. From these results it appears that the inductive effect of the nitro group is barely, if at all, detectable by dipole moments beyond the first two carbons in the chain. This conclusion is consistent with the indications of the previous measurements and the accuracy of the previously reported[1] 0.2 rise in moment caused by lengthening of the carbon chain is confirmed.

Monochloronitromethane was measured by the extrapolation method over a range of 73°. As there was some evidence of decomposition, however, it was thought best to use the two-point method for 1-chloro-1-nitroethane and 1-chloro-1-nitropropane. In this way low pressures (200 mm.) could be used, and the vapor remained in the cell at this pressure for no longer than fifteen minutes for each determination of dielectric constant. The possibility of appreciable decomposition was further minimized by limiting the temperatures used to 220° or lower.

Calculation of the moment of monochloronitromethane by vector addition of the moments of methyl chloride (1.87×10^{-18}) and nitromethane (3.50×10^{-18}), assuming tetrahedral carbon, gives a resultant moment of 3.40×10^{-18}. The observed moment, 2.91, may, for the time being, be taken to indicate that the lowering due to mutual induction between the chloro and nitro groups is 0.49. This is comparable in magnitude to the lowering observed in methylene chloride, where the moment calculated is 2.16 and the observed is 1.58,[12] so that the apparent inductive lowering is 0.58. Since the inductive lowering observed for the dichloro compound is slightly larger than that for the chloronitro compound, while the moment of nitromethane is nearly twice that of methyl chloride, it appears that the nitro group is considerably less susceptible to inductive lowering of its moment than the chlorine atom. This conclusion is consistent with the previous interpretation[13] of the moment of nitroform in carbon tetrachloride solution, which is only 0.49 lower than the solution moment of nitromethane. This lowering may be compared with that for chloroform, which has a moment 0.85 lower than that of methyl chloride.

The moment of 1-chloro-1-nitroethane, calculated by vector addition of the moments of ethyl chloride and nitroethane is 3.60×10^{-18}. The observed moment, 3.33, indicates that the apparent inductive lowering is 0.27 as compared with 0.49 for monochloronitromethane. The moment rise expected between monochloronitromethane and 1-chloro-1-nitroethane is 3.60 —

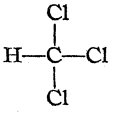
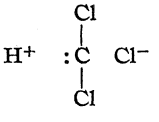
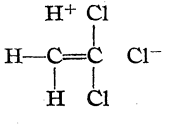
3.40 = 0.20, while the observed rise is 0.42. For the moment of 1-chloro-1-nitropropane we have: moment calculated—3.62, moment observed—3.52, apparent inductive lowering—0.10; expected rise from 1-chloro-1-nitroethane—0.02, observed rise from 1-chloro-1-nitroethane—0.19. Analogous rises are found in the values for 1,1-dichloroethane and 2,2-dichloropropane[12] and the solution value for 1,1-dichloropropane,[14] the increases again being larger than estimated. A large elevation of an apparent inductive rise was found in the difference between chloroform and methyl chloroform, which was found to be 0.77 higher.[1,12] Maryott, Hobbs and Gross[12] attribute this elevation in methyl chloroform, and, analogously, in ethylidene chloride and 2,2-dichloropropane, to "first, the transfer of charge that takes place from the methyl carbon to the other carbon atom, and second, the transfer of some of this new charge from the chloroform carbon to the chlorine atoms." A more specific mechanism may be proposed to account for the effect by assigning ionic character to the hydrogen-carbon bonds and considering the possible resonating structures. The normal covalent structure of chloroform would be

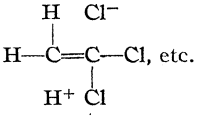


but three ionic structures of the type



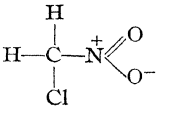
could make small contributions. Contributions from these three structures would increase the positive character of the hydrogen and probably account for its apparent ability to take part in hydrogen bonding and for its slightly tighter binding to the carbon as evidenced by Raman spectra. In methyl chloroform, instead of three such polar structures, nine can be written



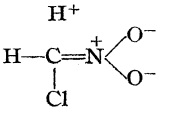


The result of small contributions from these nine structures would be an increase of moment considerably in excess of what would be expected merely from the forces exerted on the methyl group electrons by the three C–Cl dipoles. Analogous structures would contribute to the moment of ethyl chloride, but the presence of only one, instead of three, chlorines would involve a smaller accumulation of negative charge and a correspondingly smaller influence in increasing the moment. Similar considerations account for the smaller moment elevations of 1,1-dichloroethane and 2,2-dichloropropane.

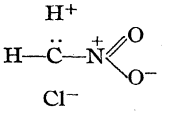
In the discussion of the chloronitroparaffins the difference between observed and calculated values, which has been referred to as the apparent inductive lowering of the moment, contains a rather large negative contribution from resonance effects similar to those just considered. The lowering of moment by mutual induction between the chlorine and the nitro group should be approximately the same in each of these three chloronitroparaffins, and the inductive effect of each of the two dipoles upon the carbon chain was taken care of approximately in calculating the moment of the chloronitro compound by using the moments of methyl chloride and nitromethane in calculating that of the disubstituted methane, of ethyl chloride and nitroethane for the disubstituted ethane, and of propyl chloride and 1-nitropropane for the disubstituted propane. The moment observed for the methane was, as previously stated, 0.49 lower than the calculated, that for the ethane, 0.27 lower than the calculated, and that for the propane 0.10 lower than the calculated. In other words, the moment of the chloronitroethane is 0.22 higher, and that of the propane 0.39 higher than would be expected on the basis of the moment of chloronitromethane and those of the monosubstituted compounds. In addition to a normal structure for chloronitromethane such as



one may write two polar structures such as



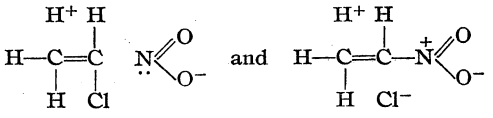
and two such as



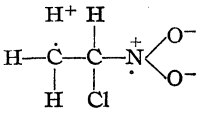
which would, by their contributions, raise the moment as in the case of analogous structures for

(14) Gross, *Physik. Z.*, **32**, 587 (1930).

chloroform. In chloronitroethane, a further increase in moment should result from contributions from structures such as



and



in addition to those from structures like those just written for the methane. For the substituted propane, analogous structures can be written, the number of possible polar structures being increased by the presence of the additional methylene group. The smallness of the increase in moment from the monosubstituted ethane to the monosubstituted propane shows that the contributions from these additional polar structures are extremely small in the monosubstituted compounds, where the concentration of negative charge on a single group would lessen the stabilities of the polar structures. In the disubstituted compounds, the distribution of negative charge between the chlorine and the nitro group would tend to stabilize the polar forms and thus increase the molecular moment. That this stabilizing effect extends, at least to a small extent, to the structures with maximum charge separation in 1-chloro-1-nitropropane is indicated by its considerable increase in moment over 1-chloro-1-nitroethane. It is to be noted that the resonance which has been proposed for these molecules gives rise to hyperconjugation.

It may be pointed out that the previously examined[11] moment of chloropicrin, 1.88, which must lie in the axis of symmetry of the Cl_3CNO_2 molecule, the C–N line, is very close to the difference between the moment of $(CH_3)_3CNO_2$ and that of Cl_3CCH_3, $3.71-1.77 = 1.94$, as it should be, while if the moment of nitromethane, 3.50, is used in the calculation, the result is 0.15 lower than the observed instead of 0.06 higher. In view of the several effects involved, neither calculated value can be regarded as far from the observed.

Summary

The dielectric constants of the vapors of nitroethane, chloronitromethane, 1-chloro-1-nitroethane and 1-chloro-1-nitropropane have been measured and used to calculate the dipole moments of the molecules. As a check on the absolute accuracy of the determination, measurements have been made upon carbon dioxide, benzene, *n*-octane and water vapor, the results obtained being in excellent agreement with those already in the literature.

The moment of nitroethane is 0.20 higher than that of nitromethane and very close to those of α- and β-nitropropane and 2-methyl-2-nitropropane, confirming the indications of their values that the inductive effect is inappreciable beyond the first two carbon atoms of the molecular chain.

The considerable increases in moment from chloronitromethane to the ethane and from the ethane to the propane are attributed to increased stabilization of resonating polar forms by the distribution of the negative charge over two groups in the disubstituted compounds instead of its localization on one group as in the monosubstituted compounds.

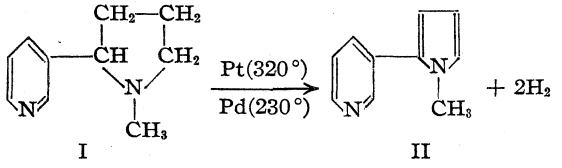
3,2′-Nicotyrine. Insecticidal Properties of Certain Azo Derivatives[1]

BY ROBERT L. FRANK, ROBERT W. HOLLEY AND DONALD M. WIKHOLM

3,2′-Nicotyrine (II)[2] can now be obtained readily from nicotine (I) by catalytic dehydrogenation. Since both of these bases possess insecticidal properties,[3] it seemed possible that dyes derived from them might also have this property and be useful as insect-proofing agents. In the present work a number of such dyes from 3,2′-nicotyrine have been prepared and tested.

The preparation of 3,2′-nicotyrine from nicotine has been accomplished by several methods. It was first carried out by Cahours and Étard[4] by oxidation of natural nicotine with calcium ferricyanide in alkaline solution. Other methods which have been used since that time are oxidation of nicotine by means of silver oxide,[5] silver acetate[6] and electrolysis,[7] but these are all unsatisfactory as preparative methods.

Wibaut and Overhoff[7] have reported yields up to 92% by means of catalytic dehydrogenation of nicotine with platinum-on-asbestos catalyst at 320° in a heated tube. The catalytic dehydrogenation of nicotine by means of palladium-on-asbestos is reported in the present communication and has been found to provide a convenient method for the preparation of 3,2′-nicotyrine. It can be carried out either in the vapor phase in an electrically heated reaction tube (Procedure 1) or more simply by refluxing nicotine containing a suspension of palladium-on-asbestos (Procedure 2). These two procedures give approximately the same yields, but the latter is the more convenient.



I II

The vapor phase dehydrogenation (Procedure 1) gives best yields, up to 41% of the nicotine which reacts, at 305–325°. Lowering the temperature lowers the yields.

In Procedure 2, on the other hand, dehydrogenation begins to take place at much lower temperatures, as evidenced by the evolution of hydrogen. Best results were obtained when nicotine and palladium-on-asbestos were heated to about 230° and the temperature was then allowed to rise gradually to 270–280°. When the reaction was carried out in this way, the yields were 30–35% and were almost as high after thirty minutes as after three hours. Very little nicotine was recovered. Several experiments were also made by this method in which lower temperatures were maintained by the addition of varying amounts of xylene to the reaction mixture. The yields were somewhat lower at temperatures varying from 185 to 230°, and the conversions were considerably lower. The yield was lowered sharply by carrying out Procedure 2 at temperatures higher than 250°.

The yields, ranging from 20 to 41% of the nicotine which reacted, are much lower than those reported by Wibaut and Overhoff, but the method should nevertheless be of value because of the rapidity of the reaction, the simplicity of the apparatus, the ready availability of nicotine, and the lower cost of palladium as compared to platinum.

In addition to 3,2′-nicotyrine and recovered nicotine, two other fractions were isolated, one boiling at 48–70° (1 mm.) and the other, approximately as large as the yield of 3,2′-nicotyrine, boiling at 210–230° (1 mm.). This is interesting in view of the fact that Wibaut and Overhoff reported that there were no side products at all in the dehydrogenation with platinum. These fractions are being further investigated.

3,2′-Nicotyrine has been found to couple readily with diazonium salts and a number of the resulting azo dyes have been prepared (III, R equals p-$C_6H_4SO_3Na$, m-$C_6H_4NO_2$, p-$C_6H_4NO_2$, p-$C_6H_4CO_2H$, β-$C_{10}H_7$). These compounds are crystalline solids ranging in color from orange to purple. They are stable in acid solution and dissolve in boiling concentrated hydrochloric acid with no apparent decomposition.

(1) Presented before the Organic Division at the Buffalo meeting of the American Chemical Society, September 7–11, 1942.

(2) This is the name adopted by Wibaut and Overhoff for *N*-methyl-(3-pyridyl)-2-pyrrole.[7] The compound is also referred to simply as nicotyrine, since it was the first of the N-methylpyridylpyrroles to be described.[5]

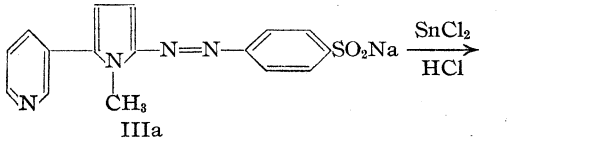
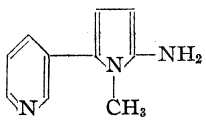
III

The coupling reaction is believed to occur at the free alpha position of the 3,2′-nicotyrine rather than at one of the beta positions since Fischer and Hepp[8] and Plancher and Soncini[9] have found that substituted pyrroles undergo coupling in one of the alpha positions unless these are blocked.

One of these azo dyes was reduced to the corresponding aminonicotyrine, which, on the basis of the above evidence, probably has the structure IV. Sodium 5′-(3,2′-nicotyrine)-azo-*p*-benzenesulfonate (IIIa) was reduced to 5′-amino-3,2′-nicotyrine (IV) in 46% yield by means of stannous chloride and hydrochloric acid. The



IIIa



IV

product, a crystalline solid melting at 86–87°, could be purified only by distillation under reduced pressure. It is stable when kept out of contact with air, but gradually becomes dark and sticky when exposed. When heated in water, alcohol, ether or chloroform, it decomposes and a dark tar separates. It was possible to form a white hydrochloride by treating the amine with gaseous hydrogen chloride in anhydrous ether, but this decomposed rapidly when isolated. The picrate was found to be a stable derivative, however, although it could not be recrystallized.

The instability of this amine parallels the findings of Fischer and Rothweiler,[10] who were unable to recrystallize 2,4,5-trimethyl-3-aminopyrrole.

Samples of wool cloth dyed with four of the compounds gave fast colors ranging from yellow to brown. These were subjected to the attack of the larvae of the black carpet beetle (*Attagenus Piceus*), and all were affected much less than a sample of undyed wool. Details are included in the experimental part.[11]

Experimental

Purification of Nicotine.—The technical product "Nicofume" of the Tobacco By-Products and Chemical Corporation of Louisville, Ky., containing 95% nicotine, was diluted with an equal volume of ethanol and refluxed over Raney nickel for three hours. The nickel was then removed by filtration and the filtrate was fractionally distilled, yielding a nicotine fraction boiling at 118–121° (18 mm.); $n^{20}D$ 1.5252.

Palladium-on-Asbestos Catalyst.—A catalyst containing 5 g. of palladium on 11 g. of asbestos wool was prepared from chloropalladic acid according to the directions of Linstead and Thomas.[12]

Dehydrogenation of Nicotine.—The dehydrogenation was carried out in two ways.

Procedure 1.—The vapor phase dehydrogenation was carried out by a procedure similar to that employed by Wibaut and Overhoff.[7] The apparatus consisted of a vertical "Pyrex" glass catalyst tube equipped with an electrically heated jacket. A thermometer was inserted in the jacket next to the tube and the open ends of the jacket were then packed with asbestos wadding. A cold-finger condenser was attached by means of a ground-glass joint to the top of the catalyst tube and a side-arm at the top of this was connected by means of glass tubing to a buret. Nicotine was allowed to drop from this buret at a rate of 0.5–0.8 cc. per hour.

The brown-colored product was collected in a filter flask attached to the bottom of the reaction tube.

It was found necessary in filling the reaction tube with catalyst to take precautions to prevent spontaneous ignition of the catalyst. A slow stream of nitrogen was passed through the tube while it was being filled; it was then put into place immediately and the nitrogen was replaced by hydrogen, which was passed in from the top by means of a three-way stopcock between the condenser and the buret. Hydrogen was passed in slowly until the tube reached the desired temperature, after which the hydrogen was shut off and the nicotine passed in.

Procedure 2.—Nicotine and palladium-on-asbestos were heated over a hot-plate in a round-bottomed flask equipped with a glass-jointed condenser and a side arm through which a thermometer was inserted. Dehydrogenation began somewhat below 230°, but became vigorous at this temperature. The evolution of hydrogen and the boiling of the liquid served to agitate the contents of the flask.

The mixture became dark in color as soon as the reaction began, and the refluxing temperature rose gradually to 270–280° (with the formation of higher-boiling products).

The reaction products were separated by slow fractional distillation in a modified Widmer column (those obtained by Procedure 2 were first filtered to remove the catalyst). A typical example using 28 g. of nicotine gave the following fractions: 2.2 g. boiling at 48–70° (1 mm.), 2.5 g. at 74–99° (1 mm.), 7.7 g. at 104–107° (1 mm.), and 7.6 g. at

(12) Linstead and Thomas, *J. Chem. Soc.*, 1127 (1940).

210–220° (1 mm.). Considerable residue was left in the distilling flask.

The fraction boiling at 74–99° (1 mm.) was mainly nicotine and that boiling at 104–107° (1 mm.) was 3,2′-nicotyrine, a colorless liquid, darkening somewhat on standing, very slightly soluble in water, soluble in alcohol and in acids, b. p. 150–152° (16 mm.); $n^{20}D$ 1.6057; d^{20}_4 1.241. A picrate melted at 168.5–169° (Wibaut and Overhoff reported 168–169°).

Sodium 5′-(3,2′-Nicotyrine)-azo-*p*-benzenesulfonate (IIIa).—Eleven grams (0.058 mole) of sulfanilic acid and 2.5 g. of sodium carbonate were dissolved in 100 cc. of water. Three and five-tenths grams (0.051 mole) of sodium nitrite dissolved in 20 cc. of water was added to the solution. After cooling to 3°, 7 cc. of concentrated hydrochloric acid was added with stirring. To the diazotized solution was added 7.8 g. (0.049 mole) of 3,2′-nicotyrine dissolved in 3 cc. of glacial acetic acid. After stirring for ten minutes, the solution was made alkaline by adding a solution of 7 g. of sodium hydroxide in 20 cc. of water. Some orange solid settled out, but the precipitation was made more nearly complete by the addition of 20 g. of sodium chloride. The orange-red solid was removed by filtration and allowed to dry. A yield of 15.0 g. (84%) was obtained.

The compound was crystallized from hot water, in which it was fairly soluble, and washed with alcohol and ether. It did not melt below 300°.

Anal. Calcd. for $C_{16}H_{13}O_3N_4SNa$: N, 15.38. Found: N, 15.35.

5′-(3,2′-Nicotyrine)-azo-*p*-nitrobenzene.—One and two-tenths grams (0.0087 mole) of *p*-nitroaniline was dissolved in 20 cc. of hot water and 3 cc. of concentrated hydrochloric acid. Twenty grams of ice was added and the solution cooled to 0°. To this was added 0.69 g. (0.01 mole) of sodium nitrite dissolved in 20 cc. of water.

One and four-tenths grams (0.0089 mole) of 3,2′-nicotyrine was dissolved in 25 cc. of alcohol and 3.0 g. of sodium acetate in 20 cc. of water was added to the alcoholic solution. The combined solution was added slowly with stirring to that of the diazonium salt. A red solid precipitated immediately. After standing thirty minutes, the solid was removed by filtration and recrystallized from hot alcohol. Two and four-tenths grams (90%) of beautiful purple-red needles was obtained. After two recrystallizations, these melted at 200–201°.

Anal. Calcd. for $C_{16}H_{13}O_2N_5$: N, 22.80. Found: N, 22.79.

Three other dyes were prepared in the same manner as 5′-(3,2′-nicotyrine)-azo-*p*-nitrobenzene from the corresponding aromatic amines. These are described as follows.

5′-(3,2′-Nicotyrine)-azo-*m*-nitrobenzene.—The same amounts were used as in the preparation of 5′-(3,2′-nicotyrine)-azo-*p*-nitrobenzene. The yield was 2.1 g. of orange-red solid (79%), which melted at 156–157° after two recrystallizations from alcohol.

Anal. Calcd. for $C_{16}H_{13}O_2N_5$: N, 22.80. Found: N, 22.95.

5′-(3,2′-Nicotyrine)-azo-*p*-benzoic Acid.—One and two-tenths grams (0.0088 mole) of *p*-aminobenzoic acid was used. The yield was 1.9 g. (71%) of orange needles. After five recrystallizations from hot alcohol, these melted with decomposition at 245–246°.

Anal. Calcd. for $C_{17}H_{14}O_2N_4$: N, 18.29. Found: N, 18.48.

β-Naphthaleneazo-5′-(3,2′-nicotyrine).—The amount of β-naphthylamine used was 2.86 g. (0.020 mole). The product crystallized from alcohol as red plates and weighed 5.2 g. (83%). After two recrystallizations, the crystals melted sharply at 148°.

Anal. Calcd. for $C_{20}H_{16}N_4$: N, 17.94. Found: N, 17.90.

5′-Amino-3,2′-nicotyrine (IV).—The reduction of sodium 5′-(3,2′-nicotyrine)-azo-*p*-benzenesulfonate was carried out according to the method of Smith, Opie, Wawzonek and Prichard.[13] Twenty grams (0.055 mole) of the azo compound was dissolved in 200 cc. of 20% hydrochloric acid and warmed on a steam-cone. To this was added a solution of 24 g. (0.127 mole) of stannous chloride in 30 cc. of concentrated hydrochloric acid. The mixture was stirred and within one minute became light tan in color. After three minutes it was poured into a cooled solution of 100 g. of sodium hydroxide in 100 cc. of water and this mixture was further cooled. The alkaline mixture was extracted with eight 50-cc. portions of ether and the extract dried with solid potassium hydroxide. The ether was then removed and the black oil remaining was distilled at 166–167° (3 mm.). The light yellow distillate (4.4 g.; 46.2%) crystallized in the receiver with the evolution of much heat of crystallization, m. p. 86–87°. It was a light yellow solid which darkened on exposure, and was soluble (with decomposition when heated) in water, alcohol, chloroform and ether. It was insoluble in benzene.

Anal. Calcd. for $C_{10}H_{11}N_3$: N, 24.28. Found: N, 24.30.

A golden-yellow picrate of 5′-nicotyrineamine was formed by the method of Shriner and Fuson,[14] with the exception that the solutions were not heated. It melted with decomposition at 173–174°.

Anal. Calcd. for $C_{22}H_{17}N_9O_{14}$: C, 41.84; H, 2.71; N, 19.97. Found: C, 42.21; H, 2.85; N, 19.89.

Azonicotyrine Dyes as Insect-Proofing Agents.—Four of the azo dyes prepared from 3,2′-nicotyrine were used for testing and the procedure with each was the same. Five-tenths of a gram of the dye was dissolved in 10 cc. of acetic acid and 25 cc. of warm water. To this solution was added 5 g. of sodium sulfate and 0.5 cc. of concentrated sulfuric acid and the combined solution was heated to 60°. A 1 × 3-inch strip of white wool cloth was then immersed in the dye solution and heated for one hour on a steam-bath. The cloth was then removed and rinsed with cold water.

The dyed strips were washed in boiling water and also in hot soapy water with no loss in color.

The wool strips, along with an undyed sample, were weighed and placed in separate cages, each containing ten larvae of the black beetle. After sixty-two days the samples were again weighed to determine the loss in weight

due to attack by the larvae, and the number of larvae still alive was also recorded, as shown in Table I.

TABLE I

ACTION OF BLACK CARPET BEETLE LARVAE ON DYED WOOL SAMPLES

Dye	Color of cloth	Mg. loss in wt. per 200 mg. cloth	% Larvae still alive
III, R = p-$C_6H_4SO_3Na$	Light yellow	21.2	80
III, R = p-$C_6H_4NO_2$	Brown	18.4	100
III, R = p-$C_6H_4CO_2H$	Tan	14.2	60
III, R = β-$C_{10}H_7$	Golden-yellow	12.2	40
Untreated sample	White	67.0	100

Summary

1. A convenient method for the preparation of 3,2′-nicotyrine from nicotine by means of palladium-on-asbestos catalyst is described.

2. 3,2′-Nicotyrine couples readily with diazonium salts to form azo dyes which show activity as insect-proofing agents.

3. Sodium 5′-(3,2′-nicotyrine)-azo-p-benzenesulfonate has been reduced to 5′-amino-3,2′-nicotyrine.

The Constitution of Arabo-galactan. IV. The Structure of the Repeating Unit

BY E. V. WHITE

In the previous papers of this series[1a,b,c] it has been shown that the water-soluble gum extracted from western larch, *Larix occidentalis*, yields the glycosides of 2,4-dimethyl-*d*-galactose (3 parts), 2,3,4-trimethyl-*d*-galactose (1 part), 2,3,4,6-tetramethyl-*d*-galactose (2 parts), and 2,3,5-trimethyl-*l*-arabinose (1 part) upon methanolysis of the methyl ether derivative[1a]). The furanopentose unit is joined by oxygen linkage through the reducing carbon to the 6-position of an adjacent galactose residue as an arabofuranosido-galactan I[1c] and this, together with the separation of two crystalline disaccharides, heptamethyl-6-*d*-galactosidogalactose II and octamethyl-6-*d*-galactosidogalactose III from the partial methanolysis

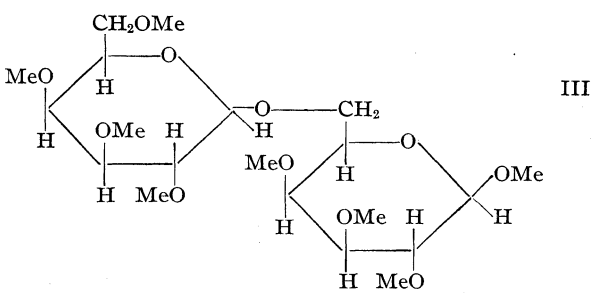
II



III

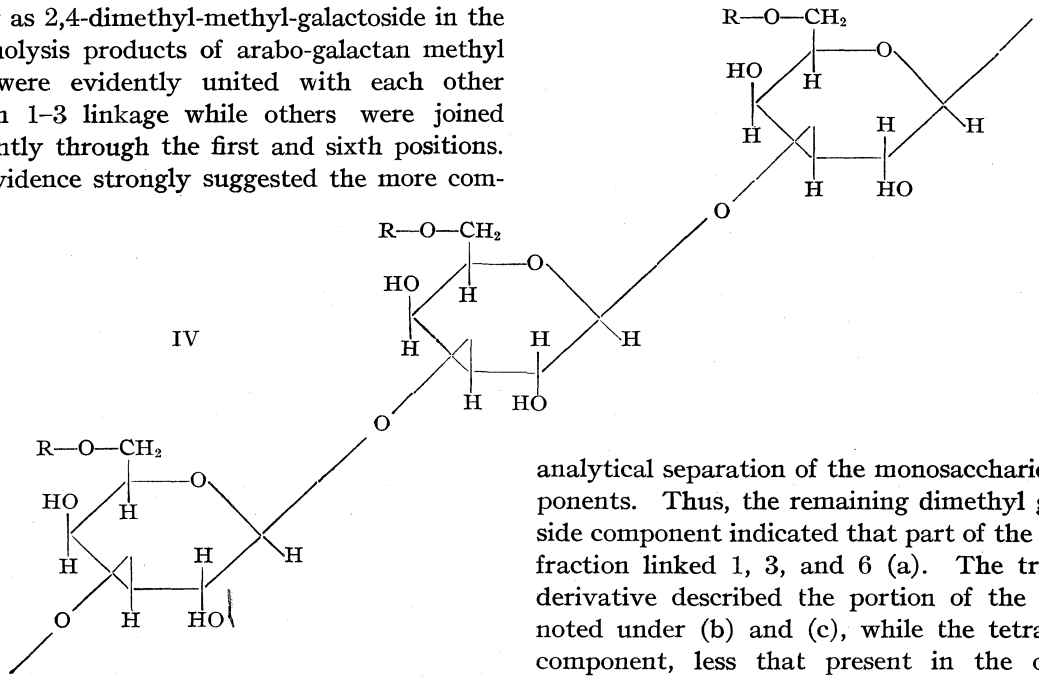
products of methylated arabogalactan[1b] establishes the position of linkage of the terminal units of the polysaccharide. It is also apparent, since two of the three 2,4-dimethyl-methyl-galactoside residues found in the complete methanolysis products are united through position 6 to terminal units in I and II, that these residues are joined by 1–3 linkage to dimethyl substituted units in the original methyl ether.

In the event that the third dimethylated residue is joined in a similar manner the repeating unit structure IV would be suggested wherein each unit of the 1–3 linked main chain galactose anhydrides is substituted in position 6 by the radicals R, respectively, *l*-arabinose, *d*-galactose, and 6-*d*-galactosidogalactose. However, if the above third residue is not part of the main chain but is located rather in a side-chain the radicals R become of polysaccharide character and the nature of the main chain linkage is open to question.

Preliminary experiments, reported in Part II, showed that some of the galactose residues oc-

(1) (a) White, THIS JOURNAL, **63**, 2871 (1941); (b) **64**, 302 (1942); (c) **64**, 1507 (1942).

curring as 2,4-dimethyl-methyl-galactoside in the methanolysis products of arabo-galactan methyl ether were evidently united with each other through 1–3 linkage while others were joined apparently through the first and sixth positions. This evidence strongly suggested the more com-



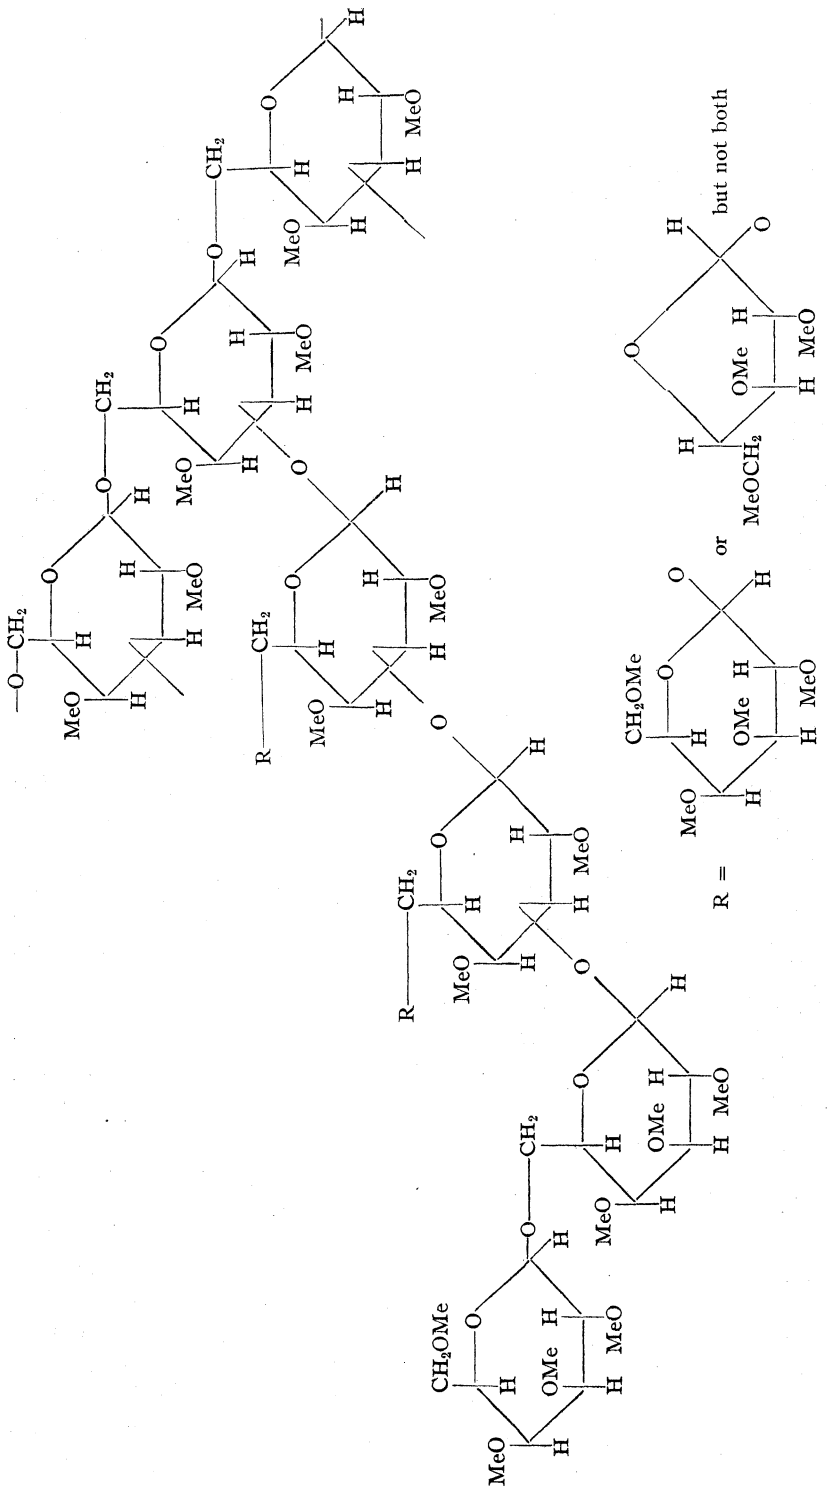
IV

plicated structure and an extension of the problem has substantiated previous indications.

The methyl ether derivative of arabo-galactan was prepared by the previously described method[1b] and subjected to partial methanolysis using anhydrous methanolic hydrogen chloride. The hydrolyzing solution contained a slightly higher concentration of hydrochloric acid than was used formerly, and a similar partition of the hydrolyzate was obtained as petroleum ether-soluble and -insoluble fractions. The latter product was separated into two components by extraction with ethyl ether. The ether-soluble portion represented approximately a methylated arabo-galactan freed from the arabinose component by hydrolysis. The ether-insoluble fraction was found to consist of dimethyl galactose anhydride residues together with a small portion of terminal tetramethyl galactose.

A theoretical analysis of the ether insoluble fraction, regardless of homogeneity, reveals that the dimethyl galactose residues can be united by oxygen linkage (a) at the 1, 3, and 6 positions, (b) at the 1 and 3 positions, a hydroxyl group occupying position 6, (c) at the 1 and 6 positions with free hydroxyl at position 3, and (d) at the 1 position only, both positions 3 and 6 being hydroxylated. A differentiation among this variety of linkage was furnished upon complete methylation of the fraction followed by methanolysis and analytical separation of the monosaccharide components. Thus, the remaining dimethyl galactoside component indicated that part of the original fraction linked 1, 3, and 6 (a). The trimethyl derivative described the portion of the original noted under (b) and (c), while the tetramethyl component, less that present in the original, allocated the proportion of dimethyl galactan hydroxylated at the 3 and 6 positions, respectively (d). A separation of the trimethyl galactoside fraction into its 2,4,6- and 2,3,4-trimethyl components furnished the ratio of 1–3 linked dimethyl galactose residues (b) to that of the 1–6 linked variety (c). On a molecular basis the decrease in dimethyl galactose anhydride resulting from etherification and, correspondingly, the sum of the tri- and corrected tetramethyl units described the over-all effect of methylation.

As a result of these experiments it was found that only a small proportion of the dimethyl galactose anhydride units present in the ether-insoluble products of partial methanolysis are united with each other through 1–3 oxygen linkage. The 1–6 linked variety, on the other hand, is relatively common and far in excess of that possibly due to the unknown character of linkage of the small tetramethylgalactose component of the fraction. Thus, since two of the three dimethyl galactose residues are known to be joined by 1–3 linkage to similar anhydrides, the conclusion is reached that the third dimethylated unit of the complete methanolysis products is joined in the original ether to other dimethyl substituted residues by 1–6 linkage. Apparently hydrolysis of arabo-galactan proceeds with removal of the labile furanopentose residue concomitant with galactan fission wherein the 1–3 linkage is somewhat more readily hydrolyzed than the 1–6 variety.



The rates of hydrolysis of the 3- and 6-galactosido-galactoses have not been evaluated for either the alpha- or beta-configurations, although the beta-methyl galactosides are known to hydrolyze more rapidly than the corresponding alpha-modifications.[2] During methanolysis of the methyl derivative there is progressively formed in the hydrolyzate 2,3,5-trimethyl-methylarabinoside, octa-methyl- and heptamethyl-6-*d*-galactosidogalactose and apparently a chain of 1–6 linked dimethyl galactose residues together with other intermediate products eventually leading to the previously described components of complete hydrolysis.[1a] The process is not in any sense stepwise in character but is controlled rather by the relative rates of hydrolysis of the variety of linkage involved.

The repeating unit of arabogalactan, which has been shown to comprise an association of six galactose residues with one unit of arabinose[3] must provide for the intermediate formation of the above products during methanolysis and must furnish upon complete reaction the glycosides of 2,4-dimethyl-*d*-galactose, 2,3,4-trimethyl-*d*-galactose, 2,3,4,6-tetramethyl-*d*-galactose and 2,3,5-trimethyl-*l*-arabinose in 3:1:2:1 molecular ratio. The difficulties involved in the investigation and correct representation of the complex polysaccharides are well known although in the present instance the evidence strongly supports a main chain structure of 1–6 linked galactose anhydride units as proposed by Hirst and co-workers.[4] Each unit of the primary chain is apparently substituted in position 3 by a secondary chain of three 1–3 linked galactose residues each in turn substituted at the 6 position by termi-

nal units. The latter are, respectively, *d*-galactose and the radicals R, *d*-galactose and *l*-arabinose, whose relative position is, of course, not known. The tentative structure proposed for the repeating unit is represented as the methyl ether derivative V and illustrates the highly branched structure of the polysaccharide. In all phases of the problem thus far investigated no evidence has been obtained relative to heterogeneity of the repeating unit. However, the number of such units comprising arabogalactan is not known and, in common with many natural polymers, the polysaccharide may prove to be polymolecular in this respect. On the basis of viscosity studies Husemann[5] limits the chain length between 180 and 280 monosaccharide units.

Experimental

Preparation of Methylated Arabo-galactan.—Larch sawdust was extracted with the minimum quantity of water and the extract purified, after filtering through norite and Super-Cel, by fractional precipitation using ethyl alcohol.[1a] The precipitate was then dissolved in water, evaporated at 50° under reduced pressure to remove residual alcohol, and methylated at 25° under nitrogen using dimethyl sulfate and 30% sodium hydroxide. After complete methylation the derivative was separated from the inorganic reaction products with chloroform. The chloroform extract, dried over magnesium sulfate and filtered, was evaporated to a sirup and extracted with petroleum ether. The residue, taken up in ethyl ether, filtered and evaporated to a sirup, was finally obtained as a light-yellow friable, glassy solid upon removal of residual solvent under reduced pressure; (Found: MeO, 44.4. Calcd. for $(C_6H_{10}O_5)_6(C_5H_8O_4)$-$(CH_2)_{20}$: MeO, 44.8). This procedure has been refined so that a relatively large quantity of uniform product can be prepared without difficulty.

Partial Methanolysis of Arabo-galactan Methyl Ether.—Ninety grams of methylated arabo-galactan was dissolved in anhydrous methyl alcohol and methanolic hydrogen chloride added together with fresh alcohol such that the total volume was 900 cc., 0.140 *N* in hydrochloric acid. The reacting solution was heated under reflux on a water-bath for twelve hours and cooled to room temperature. Excess acidity (0.076 *N*) was neutralized with silver carbonate and the solution treated with norite, filtered and evaporated to a sirup; yield, 93 g.

Separation and Analysis of the Products of Partial Methanolysis.—The sirup (93 g.) obtained upon partial methanolysis of methylated arabo-galactan was extracted thoroughly with hot ligroin. After removal of solvent by evaporation, the extract (26.0 g.) was distilled fractionally under high vacuum (0.2 mm.) yielding the portions given in Table I.

The products of Table I have been characterized previously and were not investigated further.

The residue remaining after removal of the ligroin-soluble components was extracted with ethyl ether. Upon removal of solvent the extract gave a sirup (54.2 g.). A sample of the latter in chloroform solution was precipitated into petroleum ether, dried, and analyzed; (Found: MeO, 42.0. Calcd. for methylated arabo-galactan arabinose-free MeO, 42.6). A second sample (17.0 g.) was subjected to complete methanolysis with methanolic hydrogen chloride. The product was isolated in the usual manner, distilled fractionally, and analyzed for monosaccharide components. The results are given in Table II.

Molar ratio found				1.70	1.12	3.20
Molar ratio calcd.				2.00	1.00	3.00

The ether-soluble component of the methanolysis sirup thus appears to be a methylated arabo-galactan freed from the arabinose component by hydrolysis and having simultaneously undergone a small amount of terminal galactose fission. The fraction is obviously non-homogeneous.

The final residue remaining after extraction of the methanolysis sirup with ligroin and ethyl ether was taken up in chloroform, filtered from a small amount of inorganic material, and washed thoroughly by dropping the solution into an excess of rapidly stirred ether. The residue, taken up in acetone, was obtained as a light-yellow, friable, glassy solid upon evaporation of excess solvent under reduced pressure; yield, 13 g. (Found: MeO, 34.7). A sample (3.2 g.) subjected to complete methanolysis in the usual manner gave a sirup; yield, 3.64 g. (Found: MeO, 45.0). Fractional distillation of the sirup gave only tetramethyl-methyl-galactoside, 13.9 molar per cent., and 2,4-dimethyl-methyl-galactoside, 86.1 molar per cent.

Methylation and Alcoholysis of the Ether-Insoluble Residue.—The remainder of the ether-insoluble residue (9.0 g.) dissolved in 25 cc. of acetone was methylated at 30° under nitrogen using 50 cc. of methyl sulfate and 150 cc. of 30% sodium hydroxide for each methylation. The reagents were added dropwise and simultaneously over a period of three hours and the methylation was complete after three such treatments. The product was separated from the reaction mixture with chloroform, purified and isolated as a friable solid by the procedure described for the methylation of arabo-galactan; yield, 8.0 g. (Found: MeO, 44.8).

The methylated product was subjected to methanolysis in a sealed tube using 2% methanolic hydrogen chloride at

(5) Husemann, *J. prakt. Chem.*, **155**, 13 (1940).

105° for five hours. The reaction products were separated in the usual manner and distilled fractionally under high vacuum (0.2 mm.). The results are given in Table III.

TABLE III

ANALYSIS OF METHANOLYSIS PRODUCTS FROM THE ETHER-INSOLUBLE RESIDUE AFTER METHYLATION

Fraction	Temp., °C.	Yield, g.	MeO	"Tetra"	"Tri"	"Di"
1	80– 90	3.50	61.5	3.50		
2	90–105	1.25	52.9	0.05	1.20	
3	105–115	1.60	46.5		0.94	0.56
4	115–130	1.85	41.9			1.85
Total grams				3.55	2.14	2.41
Molar per cent.				41.5	26.5	31.8

Analysis of Trimethyl-methyl-galactoside Sirup and Identification of the Components.—The combined intermediate fractions (2.85 g.) from the above distillation were dissolved in 25 cc. of *N* sulfuric acid and heated on a boiling water-bath for twelve hours. The hydrolysis product was separated in the usual manner, extracted with chloroform, and fractionally distilled under high vacuum. The trimethyl-galactose portion, 1.60 g. (Found: MeO, 41.8), was dissolved in 10 cc. of pyridine and treated with 2.1 g. of trityl chloride. After two days at room temperature a small quantity of water was added to dissolve pyridine hydrochloride and the reaction poured into rapidly stirred ice water. Following two days in the ice box and occasional stirring, the flocculent precipitate was removed by filtration, washed with ice water, and dissolved in acetone. After drying and removal of solvent, a sirup was obtained from which triphenylcarbinol crystallized slowly in the presence of acetone. The non-crystallizable residue, Fraction I, (2.09 g.) comprising triphenylcarbinol and the tritylated galactose derivative, upon treatment with aniline (0.75 g.) in the usual manner gave the anilide of 2,3,4-trimethyl-6-trityl galactose after removal of solvent; m. p. 152°, recrystallized from ethyl alcohol. By calculation on the basis of yield and methoxyl content the 2,3,4-trimethyl-galactose equivalent of Fraction I was determined.

The filtrate from the tritylation reaction was neutralized with silver carbonate and filtered. Silver ion was removed as sulfide and the filtered solution, after treatment with norite, evaporated to dryness. The sirup was taken up in chloroform, filtered, and excess solvent evaporated yielding Fraction II (0.45 g.). Upon treatment with aniline in the usual manner Fraction II gave the crystalline anilide of 2,4,6-trimethyl-galactose; m. p. 178°, recrystallized from ether–ethanol.

The results of the separation are given in Table IV.

TABLE IV

ANALYSIS OF TRIMETHYL-METHYL-GALACTOSIDE SIRUP

Fraction	Yield	MeO	2,3,4-Trimethyl-galactose, g.	2,4,6-Trimethyl-galactose, g.
I	2.90	15.6	1.08	
II	0.45	41.8		0.45
Per cent.			70.6	29.4

Summary

1. Partial hydrolysis of arabo-galactan methyl ether yields a variety of fission fragments including 2,3,5-trimethyl-methyl-*l*-arabinoside, octamethyl- and heptamethyl-6-*d*-galactosidogalactose, and a residue comprising mainly 2,4-dimethyl galactose anhydride units.

2. The individual dimethylated residues are shown to be united with each other through the first position, through the first and third positions, through the first and sixth positions, and through the first, third, and sixth positions, respectively.

3. The proportion of 2,4-dimethyl galactose anhydride linked through the first and sixth positions is considerably in excess of that joined at the first and third positions.

4. A tentative structure is presented to represent the repeating unit of arabo-galactan.

MOSCOW, IDAHO RECEIVED AUGUST 3, 1942

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY OF THE UNIVERSITY OF ROCHESTER]

Attempted Asymmetric Syntheses Involving the Grignard Reagent in Optically Active Solvents

BY D. S. TARBELL AND MARK C. PAULSON

In a recent article, it was reported[1] that the Grignard reaction between methylmagnesium iodide and benzaldehyde in dimethylbornylamine as solvent gave optically active methylphenylcarbinol. The same result was obtained using phenylmagnesium bromide and acetaldehyde. This reaction interested us as an example of a new type of asymmetric synthesis,[2] and it suggested the possibility of obtaining optically active secondary and tertiary alcohols by a synthetic method. We have been unable, however, to obtain optically active carbinols by this reaction under a variety of conditions, using dimethylbornylamine, *d*-methyl *s*-butyl ether, or methyl menthyl ether as solvent for the Grignard reagent.

Attempts to duplicate the preparation of methylmagnesium iodide using dimethylbornylamine as a solvent, as reported by Betti and Lucchi,[1] failed. In all cases the quaternary am-

(1) Betti and Lucchi, *Boll. sci. facoltà chim. ind. Bologna*, No. 1–2, 2 (1940) (*C. A.*, **34**, 2354 (1940)).

(2) *Cf.* Ritchie, "Asymmetric Synthesis and Asymmetric Induction," Oxford University Press, London, 1933.

monium salt precipitated almost immediately and the magnesium remained unattacked even after days of standing in the reaction mixture.[3] When methylmagnesium iodide was prepared in ethyl ether, the displaceable ether removed by heating with benzene, and dimethylbornylamine and benzaldehyde added, a poor yield of inactive methylphenylcarbinol was produced. A similar run, (one-tenth mole) in which benzene was omitted and the ether was removed by a water pump, yielded 4 g. of inactive carbinol and 1.4 g. of a heavy straw-colored oil, b. p. 200–210° (20 mm.), m. p. 60–62° after solidification. The oil gave an observed reading of +0.75° at 25° in a polarimeter (0.44 g. diluted to 10 cc. with ethyl alcohol, 1-dm. tube). Later experiments revealed oxidation and reduction occurring in Grignard runs in the absence of ether and led to the identification of this substance as benzalacetophenone, which was doubtless formed by condensation of acetophenone (from the oxidation of methylphenylcarbinol) and benzaldehyde. The rotation of the benzalacetophenone is undoubtedly due to the by-product described in the following paragraph.

In some runs, the methylphenylcarbinol obtained showed a slight positive rotation. That this was due to an optically active by-product from the dimethylbornylamine was shown by blank runs carried out as before, except that the benzaldehyde was omitted; a neutral substance, an amorphous, soft, white solid with a marked terpene-like odor, m. p. *ca.* 110–120°, was isolated. The small quantity obtained from a one-tenth molar blank run produced a reading of +2.39° (diluted to 10 cc. with ether, 1-dm. tube). The amount isolated was so small that identification was not attempted.

Phenylmagnesium bromide was successfully prepared by heating a flask containing magnesium turnings, dimethylbornylamine and bromobenzene in an oil-bath at 130–140° for four hours, as described by Betti and Lucchi.[1] This was treated with paraldehyde and heated to 110–120° for one hour; fair yields of methylphenylcarbinol (45–60%) were obtained. Optical activity was not consistently produced; in some runs a positive rotation (as high as +0.26°, 4 g. dil. to 10 cc. with 50–50 alcohol–benzene, 1-dm. tube), in others, no rotation was observed. Since careful purification of the product appeared to eliminate the activity, it is believed that the by-product above caused the rotation.

A much more straight-forward reaction was obtained when *d*-methyl *s*-butyl ether (which does not seem to have been reported in the active form previously) was used as the solvent for the Grignard reaction. Completely inactive methylphenylcarbinol was obtained in 60–68% yield, using either methylmagnesium iodide or phenylmagnesium bromide with the proper aldehyde. The product in each case was checked by preparation of the 3,5-dinitrobenzoate, m. p. 90°, and mixed melting point of this derivative with that of an authentic sample.

It seemed desirable to try another optically active ether with a higher rotation than the *s*-butyl ether, and methyl menthyl ether, $[\alpha]^{25}D$ −95.6°, was prepared and studied. In this connection, it is interesting to note that Wegler and Ruber[4] found that in the preferential esterification of *d,l*-methylphenylcarbinol by acetic anhydride in the presence of optically active bases, the activity of the ester mixture varied greatly with the base used.

Methyl menthyl ether proved to be an unsuitable solvent for the Grignard reaction. When magnesium was treated with methyl or ethyl iodide in this ether, the magnesium quickly became coated with an insoluble white material which prevented further reaction. The coating formed by ethyl iodide gave a positive Gilman Grignard color test with Michler ketone. The Grignard reagents were better prepared in diethyl ether, which was then removed *in vacuo* in a nitrogen atmosphere with a capillary to prevent bumping. When most of the ether had been removed, methyl menthyl ether was added (75 to 100 cc. for tenth-molar runs) and the vacuum (water pump) again applied for several hours. Usually after the first half-hour, the entire contents of the flask solidified to a white solid. This was probably the Grignard etherate involving the optically active ether. Methylmagnesium iodide prepared in this manner reacted with *n*-butyraldehyde to produce, instead of the expected *s*-amyl alcohol, *n*-butyl alcohol and methyl *n*-propyl ketone. The alcohol was identified by preparation of its 3,5-dinitrobenzoate and a mixed melting point with the corresponding derivative of an authentic sample; the ketone in like fashion through its

(3) This agrees with the observations of Stadnikoff and Weizmann, *J. prakt. Chem.*, **112**, 177 (1926), who attempted to prepare Grignard reagents in dimethylaniline solution.

(4) Wegler and Ruber, *Ber.*, **68**, 1055 (1935).

2,4-dinitrophenylhydrazone. The *n*-butyraldehyde is evidently reduced by the magnesium halide alkoxide of *s*-amyl alcohol which is formed by primary addition of the Grignard.

The failure to get an asymmetric synthesis in the reaction with *d*-methyl *s*-butyl ether, at least, is rather surprising. A possible explanation is that the organomagnesium compound is coordinated with two molecules of the ether in such a way that the complex has a plane of symmetry.[5]

Preparation of Materials

Bornylamine (a mixture of the diastereoisomers, bornylamine and neobornylamine, hereafter referred to as the former) was prepared from *d*-camphor in 83% yield (crude) using Ingersoll's modification[6] of the Leuckart method. The crude product was used in the preparation of dimethylbornylamine, since the latter product is much easier to purify.

Dimethylbornylamine was prepared by adding dimethyl sulfate to a vigorously stirred mixture of the crude bornylamine, aqueous sodium hydroxide and benzene. A Schotten-Baumann reaction employing benzoyl chloride effectively separated the mixture of secondary and tertiary amines; the organic material was isolated in ether and the tertiary amine extracted from the benzamide by dilute hydrochloric acid; yield 44.5% (purified amine); b. p. 92° (13 mm.). *Rotation.* α −1.01° (0.525 g. dil. to 25 cc. with dry benzene, 1-dm. tube), $[\alpha]^{24}D$ −48.1°. No gas was evolved when this product was treated with methylmagnesium iodide.

Hydrolysis of the N-methyl-N-bornylbenzamide proved too difficult to make the recovery of the secondary amine practicable.

Optically Active Methyl *s*-Butyl Ether.—*s*-Butyl alcohol was partially resolved by the method of Pickard and Kenyon,[7] using the modification of Sprung and Wallis and of Viditz.[8] The ether[9] was prepared by the Williamson synthesis, treating the alkoxide (prepared from 42 g. of *s*-butyl alcohol and 8 g. of sodium) with 52 g. of methyl iodide; yield, 83%, b. p. 59–60°, alcohol of rotation α_D +7.5° (homogeneous, 1-dm. tube) produced an ether of α_D +12.19° (homogeneous, 1-dm. tube).

Methyl Menthyl Ether.—Sodium (24 g.) was added in approximately 1-g. portions to 172 g. of *l*-menthol dissolved in 175 cc. of dry toluene. The mixture was heated on a steam-bath for twenty-seven hours. At the end of this time, 4.1 g. of unreacted sodium was removed from the flask. The solution was cooled and 128 g. of methyl iodide was added dropwise. After the initial reaction had subsided the flask was warmed in an oil-bath at 75° for four hours. Most of the toluene was then removed under diminished pressure; the residue of sodium iodide was filtered off and was washed with ether to remove any reaction product. The product was fractionated twice under diminished pressure. Thirty-seven grams of menthol was recovered from the first fractionation. The second fractionation was carried out in the presence of a few small pieces of sodium to aid in removal of traces of menthol; yield, 109.5 g. (74%); b. p. 83° (12 mm.); b. p. 197° (uncor. 736.5 mm.); $n^{23}D$ 1.4427; $[\alpha]^{25}D$ −95.6°; d^{25}_{25} 0.8584; homogeneous rotation, −82.06°, 1-dm. tube. *Anal.*[10] Calcd. for $C_{11}H_{22}O$: C, 77.56; H, 13.03. Found: C, 77.56; H, 12.91.

Summary

1. Methylphenylcarbinol prepared by the Grignard reaction in optically active methyl *s*-butyl ether is optically inactive. The carbinol prepared in dimethylbornylamine is also inactive, although a neutral optically active impurity is formed in the reaction.

2. Methyl menthyl ether is not a suitable solvent for the Grignard reaction; *n*-butyl alcohol and methyl *n*-propyl ketone were obtained when methylmagnesium iodide was treated with *n*-butyraldehyde.

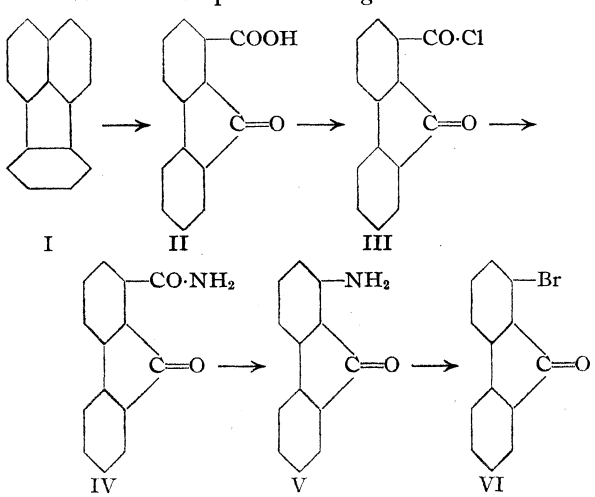
Fluorenones and Diphenic Acids. IX.[1] Establishment of Authentic 1-Bromo- and 4-Bromofluorenones

BY ERNEST H. HUNTRESS, KARL PFISTER, 3RD,[2] AND K. H. T. PFISTER

Of the four isomeric monobromofluorenones predicted by the structure theory, the 2-bromofluorenone[3] and 3-bromofluorenone[3b,4] have been well established. Data regarding the other two isomers, however, are inadequate for 1-bromofluorenone and contradictory for the 4-bromofluorenone. The present paper confirms and expands our knowledge of the first, and resolves the prior contradictions for the second.

Previous to this work, 1-bromofluorenone had been reported only once.[4a] It had been obtained by dehydrobromination of 2,6-dibromobenzophenone under conditions so drastic (heating at its boiling point for several days) as to leave some doubt as to the ultimate location of the residual bromine atom, particularly in view of previously unsuccessful attempts in this Laboratory to repeat this method of preparation and of the alleged existence of two 4-bromofluorenones discussed later in this paper.

We have, therefore, prepared authentic 1-bromofluorenone by an independent sequence of conventional reactions not involving drastic conditions. This sequence is diagrammed as follows

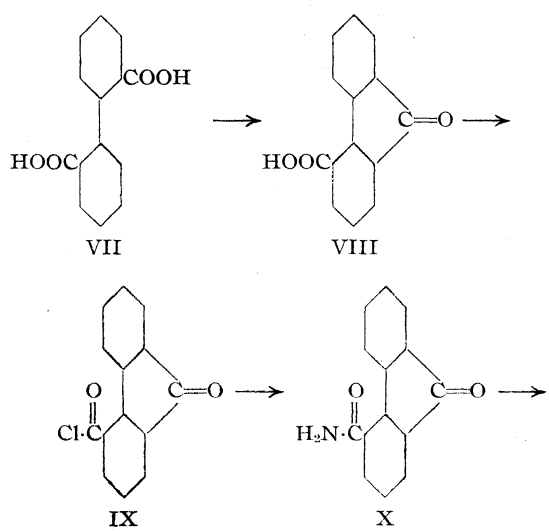


The properties of the resultant 1-bromofluorenone are in excellent agreement with those described for the original method[4a] and this result provides for the first time not only convincing evidence of the stability of the bromoketone toward heat but also a much improved method of preparation.

The structure of our product is supported not only by analysis, but also by conversion of its precursor (1-aminofluorenone) to 1-cyanofluorenone and thence to fluorenone-1-carboxylic acid whose structure has already been definitely established.[5]

Two distinctly different compounds both claimed to be 4-bromofluorenones are recorded. The higher melting compound was reported[4b,c] as the product of three independent processes. The lower melting substance was independently obtained[6] by a fourth method. Despite the marked difference of their product from that originally described by Miller and Bachman[4b,c] these authors made no reference in their paper to any of the preceding work.

We have prepared 4-bromofluorenone by a different series of reactions as follows



(1) For Article VIII of this series see Huntress and Seikel, THIS JOURNAL, **61**, 1358–1364 (1939).

(2) This paper is in part constructed from a thesis submitted in May, 1940, by K. Pfister to the Faculty of the Massachusetts Institute of Technology in partial fulfillment of the requirements for the degree of Bachelor of Science.

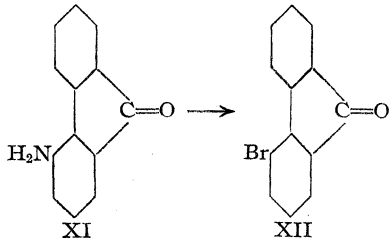
(4) (a) Montagne and van Charante, *Rec. trav. chim.*, **32**, 164–173 (1913); (b) Miller and G. B. Bachman, THIS JOURNAL, **57**, 2443–2446 (1935); (c) **57**, 2447–2450 (1935).

(5) (a) Mayer and Freitag, *Ber.*, **54**, 347 (1921); (b) Sieglitz, *ibid.*, **57**, 316 (1924); (c) von Braun and Anton, *ibid.*, **62**, 145 (1929).

(6) France, Heilbron and Hey, *J. Chem. Soc.*, 1364 (1938).

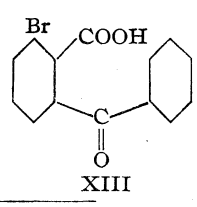


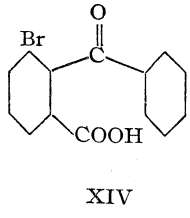
By this sequence the position of the bromine in the ultimate ketone is unequivocally established since there can be no ambiguity regarding the structure of fluorenone-4-carboxylic acid (VIII). The melting point of our 4-bromofluorenone so prepared proved to be in accord with that observed by France, Heilbron and Hey[6] and confirms the identity of their product. Since the numerical magnitude of this melting point is not very different from that of 1-bromofluorenone we have also shown that the melting point of a mixture of authentic 1-bromofluorenone with authentic 4-bromofluorenone is substantially depressed.

The results described above left seriously in doubt the identity of the bromofluorenone originally reported by Miller and Bachman as the 4-bromo isomer. We have, therefore, attempted to repeat their three syntheses. We were unable, however, to duplicate their results by the method starting with methyl *o*-iodobenzoate and made several unsuccessful efforts to employ their oxidation[4c] of supposed 4-bromofluorene from the mercuration of fluorene. Extensive experimentation with their method from 3-bromophthalic anhydride, however, led to the discovery that it yielded to us 1-bromofluorenone identical with our authentic material described above and definitely depressing the melting point of the true 4-bromofluorenone.

The error into which the American workers fell in this last case is attributable to their acceptance without further corroboration of the structure assigned by Stephens[7] to an acid resulting from the interaction of 3-bromophthalic anhydride with benzene in the presence of aluminum chloride.

From its method of preparation Stephens' acid could have had only one or the other of two structures (XIII or XIV).

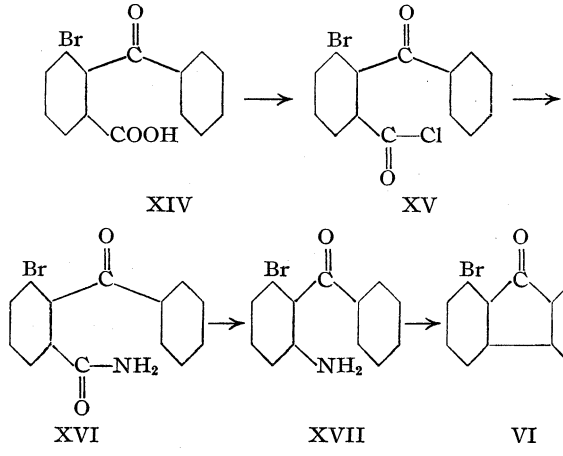




(7) Stephens, THIS JOURNAL, **43**, 1950–1956 (1921).

Upon what now seems like extremely meager evidence Stephens assigned to his product structure XIII. This evidence consisted of the observation that when his product was subjected to fusion with potassium hydroxide benzoic acid and *o*-bromobenzoic acid were isolated. Stephens appears not to have considered the possibility that both of these products might equally well have resulted from structure XIV by loss of carbon dioxide and fission of the resultant *o*-bromobenzophenone in both possible senses.

We have prepared Stephens' acid and carried it through the Miller and Bachman series of reactions to the resultant bromofluorenone. Contrary



to the results of Miller and Bachman this turned out to be 1-bromofluorenone identical with the authentic product prepared by us by a series of reactions starting with fluoranthene. This work thus serves not only to correct the errors of Miller and Bachman, but also establishes the structure of Stephens' acid and represents a third and independent preparation of 1-bromofluorenone.

Experimental Work

The melting points reported below were taken with a 360° rod form melting point thermometer by the Berl–Kullmann copper block method and are uncorrected.

Fluorenone-1-carboxylic Acid (II).—Pure fluoranthene (m. p. 109–110°) was oxidized to fluorenone-1-carboxylic acid substantially according to the directions of Fieser and Seligman[8]; yield 55%, m. p. 188.5–190.5°. Repeated recrystallization from dilute alcohol gave long orange-red needles, m. p. 191–192°.

Fluorenone-1-carboxylic Acid Amide (IV).—The acid was converted to the acid chloride by brief boiling with twice its weight of thionyl chloride. After cooling the clear light-red solution the precipitated yellow solid was filtered off and washed with petroleum ether (b. p. 35–60°). The finely powdered acid chloride was then allowed to

(8) Fieser and Seligman, *ibid.*, **57**, 2175 (1935).

stand overnight with excess concentrated ammonium hydroxide, the resultant amide filtered off, washed with water and dried; yield 95%, m. p. 222.5–225°. Recrystallization of the acid chloride from petrolum ether prior to ammonia treatment gave a crude amide of m. p. 224.5–227°. Recrystallization of the amide from 95% alcohol yielded long deep yellow needles, m. p. 226.5–227°.

Fluorenoneanil-1-carboxylic Acid Anilide.—This product was obtained from fluorenone-1-carboxylic acid chloride by warming for a few minutes with aniline. Evaporation of excess amine left a brown residue which upon recrystallization from 95% alcohol gave long yellow needles, m. p. 184.7–185°.

Anal. Calcd. for the anil-anilide ($C_{26}H_{18}ON_2$): N, 7.50. Found: N, 7.62. (Calcd. for fluorenone-1-carboxylic acid anilide ($C_{20}H_{13}O_2N$): N, 4.68.)

1-Aminofluorenone (V).—To fluorenone-1-carboxylic acid amide (2.0 g. = 0.009 mole) finely powdered in water (3 ml.) was added in one batch the hypobromite solution prepared by adding bromine (1.4 g. = 0.009 mole) to water (15 ml.) and then adding dropwise an ice-cold solution of potassium hydroxide (3.0 g. = 0.054 mole) in water (25 ml.). The resultant mixture was warmed gently for a few minutes until a homogeneous brown gel had formed, then allowed to stand for two hours. Finally the mixture was heated for half an hour at 100°, a solution of potassium hydroxide (4.5 g. = 0.08 mole) in water (4.5 ml.) added and heating at 100° continued for forty-five more minutes. After cooling, the resultant yellow-brown solid was filtered off and extracted four successive times with 25-ml. portions of boiling 6 *N* hydrochloric acid, refluxing fifteen minutes with each portion before filtration. The amine hydrochloride which separated from these extracts on cooling was collected, washed with 6 *N* hydrochloric acid and converted to 1-aminofluorenone with concentrated ammonium hydroxide. The resultant 1-aminofluorenone, m. p. 114.5–116.5°, was obtained in 56% yield. After vacuum sublimation (140–150° at 2 mm. bath temperature) and several recrystallizations from dilute alcohol the aminoketone formed beautiful long yellow needles, m. p. 118–118.5° (only previously recorded[9] m. p. 110°).

1-Acetylaminofluorenone.—1-Aminofluorenone boiled for one minute with acetic anhydride and a trace of concd. sulfuric acid gave on cooling a solid, which after recrystallization from 95% alcohol and from ligroin (b. p. 90–100°) separated as yellow needles (75% yield) m. p. 138–138.3°.

Anal. Calcd. for $C_{15}H_{11}O_2N$: N, 5.90. Found: N, 6.13, 6.28.

1-Benzoylaminofluorenone.—1-Aminofluorenone dissolved in pyridine and shaken with equivalent benzoyl chloride, then diluted with water gave a yellow precipitate of benzoyl derivative. After washing with water, dilute aqueous sodium carbonate and recrystallization from 95% alcohol and from ligroin, it was obtained (75% yield) as long silky yellow needles, m. p. 149–149.8°.

Anal. Calcd. for $C_{20}H_{13}O_2N$: N, 4.68. Found: N, 4.75.

1-Chlorofluorenone.—To 1-aminofluorenone (0.976 g. = 0.005 mole) was added concentrated hydrochloric acid (2.92 ml. = 0.035 mole) and from the resultant solution the free base was reprecipitated in finely divided form by addition of water (25 ml.) and cooling to 10–15°. The resulting suspension was diazotized by addition of sodium nitrite (0.35 g. = 0.005 mole) in water (10 ml.), stirring for ten minutes. After removing excess nitrous acid by addition of urea, the filtered solution was added in a fine stream to a boiling solution of cuprous chloride (0.6 g. = 0.006 mole) in 6 *N* hydrochloric acid (30 ml.). Five minutes at 100° served to coagulate the yellow precipitate which was filtered off after standing for several hours. This crude product was washed with 1 *N* sodium hydroxide, then extracted with hot glacial acetic acid (15 ml.) and the crude 1-chlorofluorenone precipitated from the filtrate by addition of water. Distillation under reduced pressure (2 mm. at 175–185° bath temperature) gave 40% yield, m. p. 134.0–135.5°; two recrystallizations from 95% alcohol raised the melting point of the yellow needles to 137–137.8°.

Anal. Calcd. for $C_{13}H_7OCl$: Cl, 16.52; Found: Cl, 16.5, 16.3.

1-Bromofluorenone (from 1-Aminofluorenone).—To 1-aminofluorenone (0.976 g. = 0.005 mole) was added 40% hydrobromic acid (5.13 ml. = 0.035 mole) and the diazotization carried through as for the preceding case. The cold diazonium solution was added in a thin stream to a gently boiling solution of cuprous bromide (0.86 g. = 0.006 mole) in 40% hydrobromic acid (50 ml.). After ten minutes digestion at 100° the reaction product was cooled, the solid filtered off and washed with 1 *N* sodium hydroxide, extracted with hot alcohol, and reprecipitated by dilution. After being dried and vacuum distilled (2 mm. at 170–180° bath temperature) the yield of 1-bromofluorenone was 42%. Two recrystallizations from 95% alcohol gave stubby yellow needles, m. p. 134–134.3°. (The only other recorded value is 135°.[4a])

Anal. Calcd. for $C_{13}H_7OBr$: C, 60.26; H, 2.73; Br, 30.84. Found: C, 60.1, 60.2; H, 2.85, 2.92; Br, 29.8, 30.0.

1-Iodofluorenone.—1-Aminofluorenone hydrochloride (1.16 g. = 0.005 mole) in a mixture of concentrated hydrochloric acid (2.5 ml. = 0.030 mole) with water (25 ml.) was diazotized as above. Particular care that every trace of excess nitrous acid should be removed by the urea treatment was found essential. To the cold filtered diazonium solution was added potassium iodide (1.0 g. = 0.006 mole) in water (15 ml.) and after heating at 100° for five minutes, the resulting suspension stood several hours. After the usual alkali washing and vacuum distillation (2 mm. at 180–190° bath temperature) the 1-iodofluorenone was obtained (48% yield) as yellow needles, m. p. 144–145°. Two recrystallizations from 95% alcohol raised the value to 146.5–147°.

Anal. Calcd. for $C_{13}H_7OI$: I, 41.46. Found: I, 41.4, 41.2.

1-Cyanofluorenone.—The diazotized solution prepared from 1-aminofluorenone exactly as for 1-chlorofluorenone (above) was added in a fine stream to the hot solution from copper sulfate crystals (1.25 g. = 0.005 mole) and potassium cyanide (1.40 g. = 0.020 mole) in water (15 ml.). After standing several hours, the solid was filtered off, washed with alkali, dried and distilled (2 mm. at bath temperature of 220°). After recrystallization from alco-

(9) Goldschmiedt, *Monatsh.*, **23**, 893–895 (1902).

hol, the resulting 1-cyanofluorenone (14% yield) melted at 174–175.5°.

This nitrile was also obtained from fluorenone-1-carboxylic acid amide (0.25 g. = 0.0011 mole) by warming with phosphorus pentachloride (0.23 g. = 0.0011 mole). After the initial rapid reaction the mixture was heated at 200° for one and one-half hours (48% yield). One recrystallization from dilute acetic acid gave a product of m. p. 172–173.2°. Since this material did not depress the melting point of the product from the Sandmeyer method, all the corresponding materials were combined and several times recrystallized from dilute acetic acid. The 1-cyanofluorenone was then obtained in short deep yellow rods, m. p. 177.2–177.8°.

Anal. Calcd. for $C_{14}H_7ON$: N, 6.83. Found: N, 6.74.

Further confirmation of the identity of this nitrile was obtained by its hydrolysis with hot 50% sulfuric acid to fluorenone-1-carboxylic acid. After crystallization from 95% alcohol the small orange-red needles (80% yield) showed m. p. 190–192° and did not depress the melting point of an authentic sample (m. p. 191–192°) from the oxidation of fluoranthene.

Fluorenone-4-carboxylic Acid (VIII).—Diphenic acid (5 g. = 0.021 mole) was added to concentrated sulfuric acid (23 g. = 0.45 mole) during the two minutes required to bring the mixture to 140 ± 5°. The red solution was held at this temperature with constant shaking for twelve minutes, then poured into water (150 ml.). The yellow precipitate was boiled gently for an hour, then filtered hot and washed with a large volume of hot water. The yield of crude keto acid was 82%; m. p. 216–218°. After recrystallization from 50% alcohol it was obtained in yellow needles, m. p. 220–221°.

Fluorenone-4-carboxylic Acid Amide (X).—The keto acid (1.0 g.) was added slowly to thionyl chloride (5 ml.). After refluxing the clear but dark colored solution for a few minutes, the excess thionyl chloride was evaporated in a dry air blast and the crude dry keto acid chloride allowed to stand for an hour in excess (5 ml.) concentrated ammonium hydroxide. The solid was then filtered, washed with water and recrystallized from 95% alcohol from which on cooling beautiful cream-colored needles, m. p. 223–224°, separated in 82% yield.

4-Aminofluorenone (XI).—Fluorenone-4-carboxylic acid amide (1 g. = 0.0045 mole) ground to a fine slurry with water (15 ml.) was added to an alkaline hypobromite solution prepared by adding to bromine (0.7 g. = 0.0045 mole) in water (5 ml.) at 0° a solution of potassium hydroxide (1.5 g. = 0.027 mole) in water (10 ml.). The amide dissolved almost immediately and the resultant orange solution was left at room temperature for two hours. After removing a dark colored high melting residue by suction filtration, the filtrate was heated at 100° for seventy-five minutes to cause precipitation of the aminoketone. After cooling the orange needles were filtered, washed with ice water and dried, yield 74%, m. p. 138–139°.

4-Bromofluorenone (XII).—The above 4-aminofluorenone (1 g. = 0.005 mole) was diazotized in the usual way using 40% hydrobromic acid (5.25 ml. = 0.036 mole), sodium nitrite (0.36 g. = 0.005 mole) and a total of 35 ml. of water. The resultant filtered solution was poured in a fine stream into a boiling solution of cuprous bromide (0.88 g. = 0.06 mole) in 40% hydrobromic acid (50 ml.). After heating at 100° for five to ten minutes the resultant light orange precipitate was filtered off, ground up with excess 1 *N* sodium hydroxide solution, filtered and washed. The undissolved bromoketone was then distilled at reduced pressure (2 mm. at bath temperature of 105–115°) giving 45% yield, m. p. 124.5–125.5°. Recrystallization from dilute acetic acid and from 95% alcohol gave 4-bromofluorenone as small yellow needles, m. p. 125–126°.

Anal. Calcd. for $C_{13}H_7OBr$: Br, 30.84. Found: Br, 30.7, 30.8.

The melting point of a mixture of this 4-bromofluorenone with authentic 1-bromofluorenone was depressed more than 25°.

2-Benzoyl-3-bromobenzoic Acid (XIV) **(Stephens' Acid).**—This compound was prepared from 3-bromophthalic anhydride, benzene and aluminum chloride precisely according to Stephens' directions; yield 83%, m. p. 226–227°. After recrystallization from 50% aqueous acetone our melting point was 227–228° (Stephens gave 231.5° but did not state whether this value was corrected or not).

Anal. Calcd. for $C_{14}H_9O_3Br$: neut. eq., 305.1; C, 55.11; H, 2.97; Br, 26.19. Found: neut. eq., 304.0, 304.7; C, 55.1, 54.9; H, 3.00, 3.12; Br, 26.0, 26.0.

Methyl 2-Benzoyl-3-bromobenzoate.—This ester (not previously recorded) was prepared via the diazomethane method. It formed colorless flat rectangular prisms, m. p. 136.7–137.5°.

Anal. Calcd. for $C_{15}H_{11}O_3Br$: Br, 25.04. Found: Br, 25.0, 24.9.

2-Benzoyl-3-bromobenzoyl Chloride (XV).—The above acid (Stephens') was converted to the acid chloride with phosphorus pentachloride in benzene precisely according to Miller and Bachman,[4c] except that not until the amount of benzene had been reduced to one-half their quantity and petroleum ether substituted for their ligroin did we obtain their yield. They described their acid chloride as light brown prisms, m. p. 119–120°. Our product, however, was perfectly white and showed m. p. 121–122°.

2-Benzoyl-3-bromobenzamide (XVI).—Many attempts to follow the Miller and Bachman procedure for conversion of the acid chloride from Stephens' acid to the corresponding amide gave only mixtures of compounds which obstinately resisted separation. By the following modification, however, we obtained the amide easily and in good yields.

A citrate of magnesia bottle was charged with two dozen small quartz pebbles and concentrated ammonium hydroxide (120 ml.) and chilled in an icebox overnight. To it was then added freshly prepared 2-benzoyl-3-bromobenzoyl chloride (14.5 g. = 0.045 mole) and the mixture tumbled for six hours. The flask contents were then diluted with water, the pebbles screened out, the solid filtered off with suction, washed thoroughly with dilute ammonium hydroxide (1 volume concd. NH_4OH: 2 water), and dried. The yield was 12.7 g. (93%). Recrystallization from toluene gave m. p. 202–202.5° (somewhat higher melting points were, however, sometimes obtained).

Anal. Calcd. for $C_{14}H_{10}O_2NBr$: N, 4.61; Br, 26.28. Found: N, 4.64, 4.66; Br, 26.2, 26.3.

In one experiment where the flask containing both crystals and mother liquor was allowed to stand for several

days the bulky needles were replaced by an entirely different appearing mass of intensely glittering prisms. These, however, showed the same melting point as the usual needles, and reverted to the latter upon recrystallization.

2-Benzoyl-3-bromoaniline (XVII).—The above amide (7.5 g. = 0.025 mole) was added to an alkaline hypobromite solution prepared from bromine (1.3 ml.) and potassium hydroxide solution (12.5 ml. of 1:1 solution plus 20 ml. water) and the mixture kept at 0° for half an hour with occasional stirring. The resulting white pulp was dissolved in water (60 ml.) and poured into a boiling mixture of water (400 ml.) and alcohol (50 ml.). After refluxing for an hour most of the alcohol was distilled off.

A heavy brown oil which had then separated was solidified by transferring it to a mortar, washing with a little 5% potassium hydroxide solution and then triturating with 5% hydrochloric acid (50 ml.). The resultant brown powder was filtered off, washed, dried, dissolved in ether (50 ml.), the ether solution filtered and treated with 72% perchloric acid (2.5 ml.). The amine perchlorate precipitated leaving the colored impurities behind in the mother liquor. After washing the perchlorate salt with ether it was decomposed with dilute ammonium hydroxide and the free amine washed and dried. The yield was 3.2 g. (46%). For further purification it was dissolved in ligroin (250 ml. of b. p. 60–90°), boiled with Norit, filtered and cooled. The amine separated as clusters of yellowish prisms, m. p. 84.5–85.5°.

Anal. Calcd. for $C_{13}H_{10}ONBr$: N, 5.07; Br, 28.94. Found: N, 5.45, 5.51; Br, 28.9, 29.1.

The aqueous alkaline solution decanted from the above amine (original crude oil) gave upon acidification an ample white precipitate indicating considerable hydrolysis of the original amine back to its acid as is often the case in Hofmann reactions.

1-Bromofluorenone (VI) from 2-Benzoyl-3-bromoaniline (XVII).—Preliminary experiments showed that this very weakly basic aminoketone does not readily lend itself to ring closure by elimination of the amino group *via* decomposition of the diazonium salt. The reaction tends to take a more complicated course leading largely to mixtures of resinous matter and amorphous dark-colored pigments. There is also formed a considerable amount of an alkali soluble product. However, a satisfactory result was finally obtained by the following procedure.

The aminoketone (3.5 g. = 0.0127 mole) dissolved in concentrated sulfuric acid (28 ml.) at 0° was treated at one time with finely powdered 97% sodium nitrite (0.014 mole) with constant shaking. As soon as a clear solution resulted, it was mixed with anhydrous sodium sulfate (100 g.), transferred to a large porcelain dish resting on a boiling water-bath, and constantly stirred for twenty minutes. After treatment with alkali (80 ml. 40° Baumé sodium hydroxide plus 1000 ml. water) the undissolved residue was filtered, washed and dried: weight 1.5 g.

This greyish-brown solid was mixed with Norit (3 g.), then refluxed with ligroin (400 ml., b. p. 60–90°) for one hour. After cooling and filtering, evaporation of the solvent yielded 0.4 g. of long lemon-yellow spears, m. p. 134.5–135°. From the Norit a second lot (0.4 g.) of equally pure material was obtained. The total yield was approximately 25% of the theoretical.

Anal. Calcd. for $C_{13}H_7OBr$: C, 60.26; H, 2.73; Br, 30.84. Found: C, 60.3, 60.0; H, 2.90, 3.15; Br, 30.8, 31.1.

This product (m. p. 134.5–135°) did not depress the melting point (134.0–134.3°) of 1-bromofluorenone prepared from fluorenone-1-carboxylic acid, but did depress that (125–126°) of 4-bromofluorenone obtained from fluorenone-4-carboxylic acid.

Summary

1. 1-Bromofluorenone has been prepared from fluorenone-1-carboxylic acid by a series of reactions leaving no doubt as to its structure. Our results confirm the work of Montagne and van Charante, who prepared it by another method.

2. 4-Bromofluorenone has been prepared from fluorenone-4-carboxylic acid by a series of reactions leaving no doubt as to its structure. Our product confirms the properties previously reported by France, Heilbron and Hey.

3. The series of reactions by which Miller and Bachman reported to have obtained from 3-bromophthalic anhydride a product claimed to be 4-bromofluorenone yielded in our hands only authentic 1-bromofluorenone. This discovery resolves the serious contradictions in the previous literature of this compound.

4. As a result of the establishment of the true 1-bromo- and 4-bromofluorenone it was found that the bromobenzoylbenzoic acid resulting from the reaction of 3-bromophthalic anhydride with benzene in the presence of aluminum chloride is in fact 2-benzoyl-3-bromobenzoic acid and not the alternative 2-benzoyl-6-bromobenzoic acid erroneously inferred by previous workers.

5. The above discoveries bring in question the true nature of the Miller and Bachman supposed "4-bromofluorenol" and "4-bromofluorene," the mercuration of fluorene in the 4-position, and their supposed "4-bromo-9-chlorofluorene" and "4,9-dibromofluorene." They also render very doubtful the structure proposed by Stephens for the diphenyl bromophthalide prepared from 3-bromophthalic anhydride.

6. During the course of the above work the following previously unreported compounds were characterized: 1-chloro-, 1-iodo-, 1-cyano-, 1-acetamino-, and 1-benzoylamino fluorenones; 2-benzoyl-3-bromobenzoic acid, methyl 2-benzoyl-3-bromobenzoate, 2-benzoyl-3-bromobenzoyl chloride, 2-benzoyl-3-bromobenzamide, 2-benzoyl-3-bromoaniline, and fluorenone-anil-1-carboxylic acid anilide.

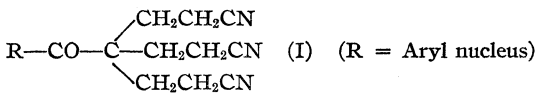
The Chemistry of Acrylonitrile. II. Reactions with Ketones

BY HERMAN ALEXANDER BRUSON AND THOMAS W. RIENER

The powerful cyanoethylating action of acrylonitrile in the presence of strong bases upon organic compounds possessing labile hydrogen atoms[1] is strikingly evident with various types of ketones.

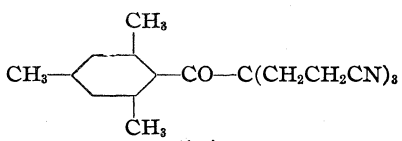
Aromatic methyl ketones of the type R—CO—CH_3 as exemplified by acetophenone, *p*-methylacetophenone, *p*-methoxyacetophenone, *p*-chloroacetophenone, *p*-bromoacetophenone, *p*-acetyldiphenyl, and 2-acetylnaphthalene readily took up three molecular equivalents of acrylonitrile in the presence of strong alkali catalysts such as trimethylbenzylammonium hydroxide or potassium hydroxide to form crystalline *tri*-cyanoethylation products (I).



(I) (R = Aryl nucleus)

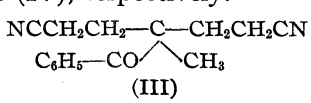
These are listed in Table I together with their physical and analytical data. Upon hydrolysis with aqueous sodium hydroxide or potassium hydroxide these tri-(cyanoethyl)-methyl aryl ketones yielded the corresponding aryl keto tricarboxylic acids R—CO—$C(CH_2CH_2COOH)_3$. These are listed in Table II.

Even acetomesitylene which because of steric hindrance reacts sluggishly, gave a small yield (30%) of the *tri*-cyanoethylation product (II).

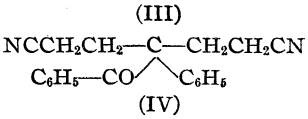


(II)

Propiophenone and desoxybenzoin which possess only two active hydrogen atoms contiguous to the carbonyl group, each took up two molecular equivalents of acrylonitrile to form γ-benzoyl-γ-methylpimelonitrile (III) and γ-benzoyl-γ-phenylpimelonitrile (IV), respectively.



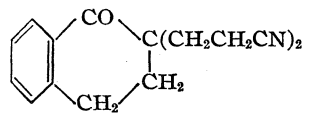
(III)



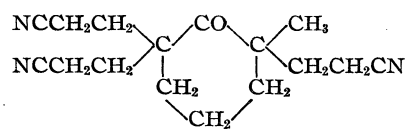
(IV)

Upon hydrolysis with aqueous sodium hydroxide, compounds III and IV yielded γ-benzoyl-γ-methylpimelic acid and γ-benzoyl-γ-phenylpimelic acid, respectively.

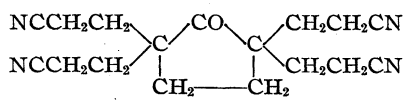
In a similar manner acrylonitrile reacted with α-tetralone, *o*-methylcyclohexanone and cyclopentanone to form compounds V, VI and VII, respectively.



(V)

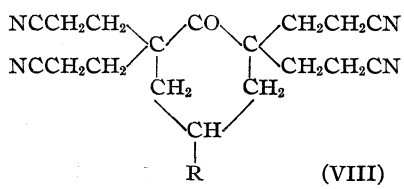


(VI)



(VII)

Cyclohexanone itself as well as *p*-methylcyclohexanone, *p*-*t*-amyl cyclohexanone, *p*-(α,α,γ,γ-tetramethylbutyl)-cyclohexanone and *p*-cyclohexylcyclohexanone each took up four moles of acrylonitrile to yield crystalline 2,2,6,6-tetracyanoethylation products of the general type (VIII) in 80–95% yields (Table III).



(R = H, alkyl, or cycloalkyl)

(VIII)

Upon alkaline hydrolysis compounds VI, VII, and VIII were converted into the corresponding ketonic polycarboxylic acids. The tetra-carboxylic acids derived from (VIII) are listed in Table IV.

When cyclohexanone reacted with only one or two molecular equivalents of acrylonitrile, it was possible to isolate a mono-cyanoethylation product, 2-(β-cyanoethyl)-cyclohexanone, and a dicyanoethylation product, very probably 2,2-di-(β-cyanoethyl)-cyclohexanone, from the reaction mixture in addition to considerable tetra-cyanoethylation product.

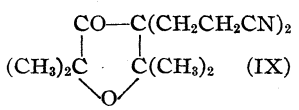
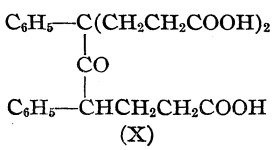
In an analogous manner, the heterocyclic ketone 2,2,5,5-tetramethyltetrahydrofuranone-3 reacted with acrylonitrile to yield the crystalline dicyanoethylation product (IX).



(IX)

Upon alkaline hydrolysis it formed the corresponding 4,4-di-(β-carboxy-ethyl)-2,2,5,5-tetramethyltetrahydrofuranone-3.

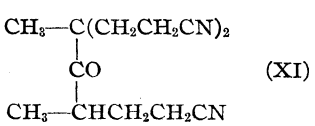
An attempt was made to *tetra*-cyanoethylate dibenzyl ketone but the only product that could be isolated after saponification, from the resinous mixture obtained, was a crystalline tricarboxylic acid (X).



(X)

instead of the expected tetra-carboxylic acid.

In a similar manner, an attempt to *tetra*-cyanoethylate diethyl ketone gave a resinous product from which a crystalline *tri*-cyanoethylation product (XI) could be isolated by vacuum distillation.



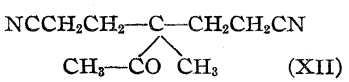
(XI)

Upon alkaline saponification (XI) yielded the corresponding 2,4,4-tri-(β-carboxyethyl)-pentanone-3.

In all of the above examples, the positions occupied by the entering cyanoethyl groups can hardly be other than those indicated since these are established by the only available active hydrogen atoms in the ketones employed.

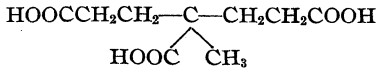
However, in the case of the saturated aliphatic methyl ketones of the type CH_3—CO—CH_2—alkyl, such as methyl ethyl ketone, methyl propyl ketone, methyl iso-butyl ketone, methyl *n*-amyl ketone, and methyl *n*-hexyl ketone, which could presumably react on either the —CH_2— group, or the CH_3—group, or both, it was of interest to determine the exact location of the entering cyanoethyl groups and also the maximum number that could be introduced.

Methyl ethyl ketone reacted with acrylonitrile to first take up two cyanoethyl radicals on the methylene group and give 4-acetyl-4-methylpimelonitrile (XII) in yields up to 90%.



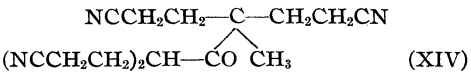
(XII)

The structure of this compound was established by saponifying it to the corresponding γ-acetyl-γ-methylpimelic acid, and subjecting the latter in alkaline hypochlorite solution to the haloform reaction, whereby chloroform was evolved and the new tricarboxylic acid XIII isolated.



(XIII)

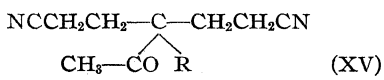
Upon treating 4-acetyl-4-methylpimelonitrile with one molecular equivalent of acrylonitrile in an attempt to cyanoethylate one of the hydrogen atoms of the remaining active methyl group, a resin was obtained from which a crystalline tetracyanoethylation product (XIV) could be distilled under high vacuum.



(XIV)

Acrylonitrile also combined with methyl propyl ketone to give a crystalline di-cyanoethylation product, which by conversion to the corresponding dicarboxylic acid and subjection of the latter to the haloform reaction, was shown to have both cyanoethyl groups on the methylene group. It was also possible to isolate a crystalline *tri*-cyanoethylation product, namely, 1,3,3-tri-(β-cyanoethyl)-pentanone-2 from the original di-cyanoethylation reaction mixture.

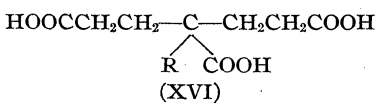
In the same manner methyl isobutyl ketone, methyl *n*-amyl ketone and methyl *n*-hexyl ketone gave crystalline γ-acetyl-γ-alkyl pimelonitriles (XV) upon treatment in alkaline solution with two moles of acrylonitrile.



(XV)

R = (Isopropyl, *n*-butyl, *n*-amyl)

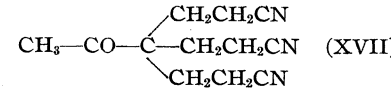
The above γ-acetyl-γ-alkyl pimelonitriles were saponified to the corresponding γ-acetyl-γ-alkyl-pimelic acids, which were isolated in the pure form. The latter in turn were each oxidized by means of alkaline hypochlorite solution to chloroform and the γ-alkyl-γ-carboxypimelic acids (XVI).



(XVI)

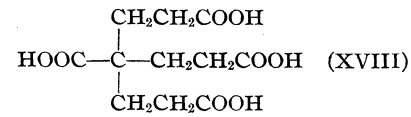
The positions taken by the two entering cyanoethyl radicals in the homologs of methyl ethyl ketone having thus been established as being on the —CH_2— group, it was of interest to study the cyanoethylation of acetone itself since this possesses two active methyl groups of equal value and might perhaps distribute the cyanoethyl radicals between both of them.

Upon treating acetone with three moles of acrylonitrile in the presence of potassium hydroxide as the catalyst, a crystalline *tri*-cyanoethylation product was obtained in 75–80% yield. This compound is 1,1,1-tri-(β-cyanoethyl)-acetone (XVII).



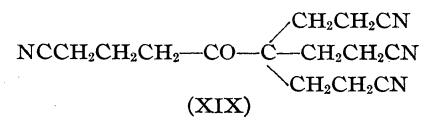
(XVII)

Upon alkaline hydrolysis it yielded the corresponding 1,1,1-tri-(β-carboxyethyl)-acetone which, upon oxidation with alkaline hypochlorite solution, gave chloroform and the tetra-carboxylic acid (XVIII).



(XVIII)

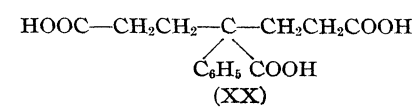
The *tri*-cyanoethylation of acetone therefore takes place first on one methyl group. Upon further cyanoethylation of the 1,1,1-tri-(β-cyanoethyl)-acetone, a crystalline *tetra*-cyanoethyl acetone could be isolated from the resinous residue, and consequently must possess formula (XIX).



(XIX)

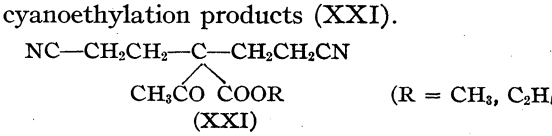
It is highly probable that the resinous residue contains a *penta*- or a *hexa*-cyanoethylation product, but the purification offers considerable difficulty.

In the case of phenylacetone, which also possesses two possible points of reaction, di-cyanoethylation took place on the methylene group to give the crystalline γ-acetyl-γ-phenylpimelonitrile in 86% yield. Upon saponification it yielded γ-acetyl-γ-phenylpimelic acid which upon oxidation with alkaline hypochlorite solution cleaved to give chloroform and γ-carboxy-γ-phenylpimelic acid (XX).



(XX)

Finally, acrylonitrile was condensed with acetoacetic esters. Both methyl acetoacetate and ethyl acetoacetate gave good yields of crystalline di-cyanoethylation products (XXI).



(XXI)

From the foregoing it appears therefore that with aliphatic or arylaliphatic ketones possessing the reactive grouping —CH_2—CO—CH_3 cyano-

ethylation first occurs on the —CH_2— group and after this has been satisfied further cyanoethylation can occur on the remaining methyl radical.

In conclusion it may be said that certain methylene ketones were incapable of being cyanoethylated by the method here described, namely, camphor, iso-phorone, and di-isobutyl ketone. Furthermore, attempts to utilize α-methyl acrylonitrile or crotononitrile in place of acrylonitrile were unsuccessful.

Experimental

R—CO—C(CH_2CH_2CN)$_3$ (R = Aryl).—The general method of condensing aryl alkyl ketones with acrylonitrile consisted in dissolving the ketone R—CO—CH_3 (R = aryl) in dioxane or in tertiary butyl alcohol so as to form a 25–50% solution, adding a small quantity of aqueous 40% trimethylbenzylammonium hydroxide[2] corresponding to about 5–10% on the weight of the ketone, and then adding *dropwise* three molecular equivalents of acrylonitrile to the stirred reaction mixture while maintaining the temperature of the mixture between 25 and 40° by means of external water cooling and by regulating the rate of addition of the acrylonitrile. The mixture was then usually stirred for two to four hours longer at room temperature, and the tricyanoethylation product separated either by filtration or by neutralizing the alkali with dilute hydrochloric acid, evaporating off the solvent under reduced pressure on a steam-bath, and crystallizing the residue from a suitable solvent.

A typical procedure using acetophenone, for example, is as follows:

To a solution of 60 g. of acetophenone (0.50 mole) in 60 g. of dioxane and containing 5 g. of "Triton B," was added 79.5 g. of acrylonitrile (1.5 mole) dropwise during a period of two hours while the mixture was stirred and maintained between 30 and 40° by external water cooling. During the addition crystals separated. After all the acrylonitrile had been added, the mixture was stirred for one hour and then filtered by suction. The pinkish crystalline product weighed 79 g., corresponding to a 57% yield of 1,1,1-tri-(β-cyanoethyl)-acetophenone. After recrystallization from glycol monoethyl ether ("Cellosolve") it formed colorless crystals melting at 128–129°.

In Table I are given the physical and analytical data of the various homologs of acetophenone prepared in the above manner. All of the melting points given in this paper are uncorrected for stem exposure.

R—CO—C(CH_2CH_2COOH)$_3$, R = Aryl.—The general method of hydrolyzing the cyanoethylated ketones consisted in boiling the tricyanoethylation products given in Table I with an excess of sodium hydroxide or potassium hydroxide in aqueous solution for a period of from four to twelve hours until all the product had dissolved and evolution of ammonia had ceased. The solution was then clarified with charcoal, filtered, and the filtrate acidified with concentrated hydrochloric acid. The tricarboxylic acids usually precipitated first as viscous oils or dough-like masses which gradually solidified to a crystalline product. After recrystallization from hot water, or from a mixture of water–dioxane (4:1), they were obtained in pure form as colorless crystals.

A typical procedure using 1,1,1-tri-(β-cyanoethyl)-acetophenone is as follows:

A mixture consisting of 400 g. of water, 39 g. of potassium hydroxide and 55.8 g. of 1,1,1-tri-(β-cyanoethyl)-acetophenone was stirred rapidly and boiled under reflux for six hours. The solution was clarified with charcoal, filtered, and the filtrate acidified with concentrated hydrochloric acid. The 1,1,1-tri-(β-carboxyethyl)-acetophenone separated as a white, resinous mass which soon became crystalline. It was purified by recrystallization from hot water, yield 58 g. or 80%.

In Table II are given the physical and analytical data of the various 1,1,1-tri-(β-carboxyethyl)-methyl aryl ketones prepared in the above manner. The yields of pure product were between 80 and 85%.

III. γ-Benzoyl-γ-methylpimelonitrile.—To a solution of 26.9 g. of propiophenone (0.2 mole), 50 g. of dioxane and 2 g. of "Triton B" there was added dropwise 21.2 g. of acrylonitrile (0.4 mole) during the course of twenty minutes while the reaction mixture was stirred and maintained between 25 and 30° by external water cooling. The mixture was stirred for five hours longer, then neutralized with dilute hydrochloric acid and poured into 300 cc. of water. The oil layer was separated, taken up in ethylene dichloride, washed thoroughly with water, and the ethylene dichloride layer evaporated under reduced pressure on a steam-bath. The residual oil (48 g.) was mixed with an equal weight of ethanol and chilled whereupon the product crystallized. After recrystallization from ethanol the γ-benzoyl-γ-methylpimelonitrile formed colorless crystals m. p. 66°. *Anal.* Calcd. for $C_{15}H_{16}N_2O$: C, 74.96; H, 6.72; N, 11.66. Found: C, 75.10; H, 6.65; N, 11.71.

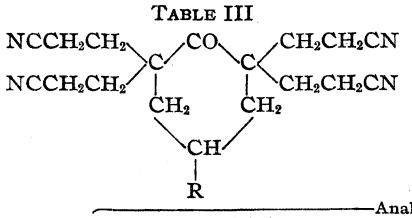
γ-Benzoyl-γ-methylpimelic Acid.—A mixture of 150 g. of water, 10 g. of sodium hydroxide, and 16.5 g. of III was boiled under reflux for six and one-half hours, treated with charcoal and the clear filtrate acidified with concentrated hydrochloric acid. The precipitated product was crystallized from hot water; m. p. 166–167°. *Anal.* Calcd. for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52. Found: C, 64.50; H, 6.29.

IV. γ-Benzoyl-γ-phenylpimelonitrile.—Acrylonitrile (13.5 g.) was added dropwise to a stirred solution of 50 g. of dioxane, 25 g. of desoxybenzoin and 2 g. of "Triton B" while the reaction temperature was maintained at 30–35° by external cooling. After all the acrylonitrile had been added, the mixture was stirred for three hours at 45° to complete the reaction. It was then cooled, acidified with dilute hydrochloric acid, taken up in ethylene dichloride and washed with water. The ethylene dichloride layer was evaporated to dryness under reduced pressure on a steam-bath and the residual crystalline product (38 g.) washed with a little alcohol and purified by recrystallization from ethanol. The yield of pure product melting at 149–150°, was 31 g. *Anal.* Calcd. for $C_{20}H_{18}N_2O$: N, 9.27. Found: N, 9.06.

γ-Benzoyl-γ-phenylpimelic Acid.—A mixture of 12 g. of IV, 150 g. of water and 6 g. of sodium hydroxide was boiled under reflux for twenty-one hours. The solution was treated with charcoal, filtered and the filtrate acidified with

(2) Available commercially as "Triton B."

TABLE III



Value of R	M. p., °C.	Formula	Analyses, % Calcd. C	Calcd. H	Calcd. N	Found C	Found H	Found N

hydrochloric acid. The product precipitated as a white solid. Upon repeated recrystallization from water and drying in an oven at 70° for twenty-four hours the analytical sample melted at 172–173°. *Anal.* Calcd. for $C_{20}H_{20}O_5$: C, 70.55; H, 5.93. Found: C, 70.21; H, 5.85.

V. 2-Di-(β-cyanoethyl)-tetralone-1.—Acrylonitrile (21.2 g.) was added at room temperature to a mixture of 29.2 g. of α-tetralone, 50 g. of dioxane, and 4 g. of "Triton B." The mixture was stirred for twenty-four hours, then neutralized with dilute hydrochloric acid, washed well with water and distilled under reduced pressure at 1 mm. The fraction boiling at 250–260° (1 mm.) formed a pale yellow oil which gradually solidified to a waxy, crystalline mass. After recrystallization from ethanol, the product formed colorless crystals melting at 80°. *Anal.* Calcd. for $C_{16}H_{16}N_2O$: C, 76.15; H, 6.39; N, 11.10. Found: C, 76.59; H, 6.05; N, 11.09.

VI. 2,2,6-Tri-(β-cyanoethyl)-6-methyl-cyclohexanone.—Acrylonitrile (63.5 g.) was added dropwise to a stirred solution of 44.8 g. of *o*-methylcyclohexanone, 200 g. of benzene, and 5 g. of "Triton B" while maintaining the reaction temperature at 30–40°. The mixture was then stirred at room temperature for eighteen hours and, after neutralization with hydrochloric acid and thorough washing with water, was filtered to remove some polyacrylonitrile which was present. The filtrate was evaporated to dryness under reduced pressure on a steam-bath and the residual oil (103 g.) distilled under high vacuum. The product (41 g.) came over at 270–285° (1–2 mm.) as a viscous, amber-colored sirup which gradually crystallized on long standing. Upon recrystallization from ice-cold methanol it was obtained in the form of colorless crystals melting at 69–70°. *Anal.* Calcd. for $C_{16}H_{21}N_3O$: C, 70.82; H, 7.79; N, 15.49. Found: C, 71.00; H, 7.49; N, 15.86.

VII. 2,2,5,5-Tetra-(β-cyanoethyl)-cyclopentanone.—To a solution of 42 g. of cyclopentanone (0.5 mole) in 200 g. of benzene, there was added 5 g. of "Triton B." The mixture was stirred rapidly and cooled to 35–45° while 106 g. of acrylonitrile (2 moles) was added dropwise during two hours. Crystals began to separate within a few minutes after the addition was begun. As the reaction proceeded it was necessary to add 200 cc. of benzene to prevent clogging the stirrer by the crystalline mass. The mixture was allowed to stand for eighteen hours before the crystals were filtered by suction. The yield was 144 g. or 97%. The product can be recrystallized from hot methyl ethyl ketone or glycol monoethyl ether, from which it separates in colorless crystals, m. p. 175°. *Anal.* Calcd. for $C_{17}H_{20}N_4O$: N, 18.90. Found: N, 18.93.

VIII. 2,2,6,6,-Tetra-(β-cyanoethyl)-cyclohexanone.—To 935 g. of tertiary butyl alcohol there was added 15 g. of aqueous 40% potassium hydroxide solution and 294 g. of cyclohexanone (3 moles). The solution was stirred rapidly in a three-neck flask surrounded by running tap water, and 636 g. of acrylonitrile (12 moles) added dropwise thereto during one and one-half hours, while the temperature of the reaction mixture was maintained between 35 and 45°. During the addition crystals separated. The mixture was stirred for an additional fifteen hours at room temperature and the crystalline product filtered off by suction, washed with water, and dried; yield 820 g. of faintly yellow crystals, or 88%. Upon recrystallization from acetone it formed colorless fine needles, melting at 165°.

In Table III are given the physical and analytical data of the various 2,2,6,6-tetra-(β-cyanoethyl)-cyclohexanones of type VIII prepared in the above manner. The *p*-*t*-octylcyclohexanone used was obtained from *p*-(α,α,γ,γ-tetramethylbutyl)-phenol by catalytic hydrogenation with Raney nickel to *p*-(α,α,γ,γ-tetramethylbutyl)-cyclohexanol and oxidation of the latter with potassium dichromate–sulfuric acid mixture.[3]

Tetra-(β-carboxyethyl)-cycloalkanones.—The general method of hydrolysis used consisted in boiling the tetracyanoethylated cycloalkanones given in Table III with an excess of potassium hydroxide or sodium hydroxide in aqueous solution for a period of from four to eight hours until ammonia ceased to be evolved, then treating the hot solution with Norite decolorizing charcoal, filtering, and acidifying the filtrate with concentrated hydrochloric acid. The crude tetra-carboxylic acids precipitated in crystalline form and were then recrystallized from appropriate solvents.

The following procedures were typical:

2,2,5,5-Tetra-(β-carboxyethyl)-cyclopentanone.—A mixture of 600 g. of water, 80 g. of sodium hydroxide and 95 g. of 2,2,5,5-tetra-(β-cyanoethyl)-cyclopentanone (VII) was stirred and boiled under reflux for twenty-three hours. The clear, amber-colored solution was treated with charcoal, filtered and acidified with concentrated hydrochloric acid. The clear solution obtained was cooled in an ice-bath to 10–15° whereupon it set to a white crystalline magma, which after filtration and drying at room temperature weighed 108 g.

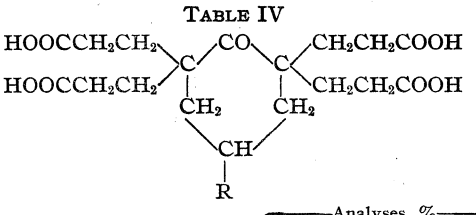
(3) Niederl, *Ind. Eng. Chem.*, **30**, 1270 (1938).

Upon recrystallization from water the product formed colorless crystals melting at 173°, containing one mole of water of crystallization. *Anal.* Calcd. for $C_{17}H_{24}O_9 \cdot H_2O$: C, 52.28; H, 6.72. Found: C, 52.20; H, 6.78.

2,2,6,6-Tetra-(β-carboxyethyl)-cyclohexanone.—A mixture consisting of 1900 g. of water, 196 g. of potassium hydroxide and 217 g. of 2,2,6,6-tetra-(β-cyanoethyl)-cyclohexanone was stirred and boiled under reflux for five hours. The clear solution was acidified with 350 g. of concentrated hydrochloric acid, and cooled to 15–20° whereupon the product crystallized. It was filtered off and washed with a little ice water; yield 199 g. of air-dried, white crystals. Upon recrystallization from water the compound formed colorless needles melting at 179–180°.

In Table IV are given the physical and analytical data of various tetra-(β-carboxy-ethyl)-cyclohexanones prepared in the above manner from the tetra-cyanoethylation products of cyclohexanone, *p*-methylcyclohexanone, *p*-*t*-amylcyclohexanone, *p*-(α,α,γ,γ-tetramethylbutyl)-cyclohexanone, and *p*-cyclohexylcyclohexanone, respectively.

TABLE IV



Value of R	M. p., °C.	Formula	Analyses, % Calcd. C	Calcd. H	Found C	Found H
H	179–180	$C_{18}H_{26}O_9$	55.93	6.79	56.30	6.59
Methyl	205–206	$C_{19}H_{28}O_9$	56.96	7.05	57.01	7.10
t-amyl	205	$C_{23}H_{36}O_9$	60.49	7.95	60.89	7.94
t-Octyl	185–186	$C_{26}H_{42}O_9$	62.60	8.49	61.90	8.49
Cyclohexyl	205–206	$C_{24}H_{36}O_9$	61.50	7.74	61.61	7.40

2-(β-Cyanoethyl)-cyclohexanone.—To a stirred mixture of 98 g. of cyclohexanone (1 mole) and 5 g. of "Triton B," was added dropwise 53 g. of acrylonitrile (1 mole) at 30–35° during the course of eighty minutes. The mixture was stirred at 35–40° for one hour thereafter and finally for eighteen hours at room temperature. The partially crystalline mixture was acidified with dilute hydrochloric acid and the crystalline tetracyanoethylation product (30 g.) was filtered off by suction. The filtrate was washed with water and distilled in vacuum. About 31 g. of unchanged cyclohexanone was recovered.

The 2-(β-cyanoethyl)-cyclohexanone distilled over at 138–142° (10 mm.) as a colorless oil; yield 16.5 g. *Anal.* Calcd. for $C_9H_{13}NO$: N, 9.27. Found: N, 9.03.

The fraction boiling at 195–198° (1 mm.) was a viscous yellow oil; yield 12.5 g. On standing it gradually crystallized. After recrystallization from benzene it formed colorless crystals melting at 69°, the analysis of which corresponds to a di-cyanoethylation product of cyclohexanone. *Anal.* Calcd. for $C_{12}H_{16}N_2O$: C, 70.54; H, 7.90; N, 13.71. Found: C, 70.90; H, 7.85; N, 13.78.

IX. 4,4-Di-(β-cyanoethyl)-2,2,5,5-tetramethyltetrahydrofuranone-3.—Acrylonitrile (24.4 g.) was added dropwise to a stirred solution consisting of 50 g. of dioxane, 3 g. of aqueous 40% Triton B, and 33 g. of 2,2,5,5-tetramethyltetrahydrofuranone-3 while the reaction temperature was maintained at 35–40° by external cooling. The mixture was then stirred three hours longer at 25°. During the addition crystals separated. The mixture was neutralized with dilute hydrochloric acid, the white crystalline product filtered off, and washed with a little ethanol; yield 41 g. After recrystallization from ethanol, the product formed colorless needles melting at 153°. *Anal.* Calcd. for $C_{14}H_{20}N_2O_2$: N, 11.28. Found: N, 11.16.

4,4-Di-(β-carboxy-ethyl)-2,2,5,5-tetramethyltetrahydrofuranone-3.—A mixture of 120 g. of water, 12 g. of sodium hydroxide and 27 g. of compound IX was boiled under reflux for eight hours. The solution was treated with charcoal, filtered and the filtrate acidified with concentrated hydrochloric acid. The product crystallized on cooling; yield 18 g. Upon recrystallization from water it formed colorless crystals, m. p. 170–171°. *Anal.* Calcd. for $C_{14}H_{22}O_6$: C, 58.70; H, 7.75. Found: C, 58.61; H, 7.57.

X. 1,3-Diphenyl-1,1,3-tri-(β-carboxyethyl)-propanone-2.—Acrylonitrile (21.2 g.) was added dropwise during forty minutes to a stirred mixture of 21 g. of dibenzyl ketone, 50 g. of dioxane and 2 g. of "Triton B" at 30–35°. The mixture was allowed to stand eighteen hours at room temperature. It was then acidified with dilute hydrochloric acid and taken up in ethylene dichloride. The solution was washed thoroughly with water and evaporated to dryness *in vacuo* at 30 mm. on a steam-bath. The residue was a viscous, sticky sirup weighing 42 g. which could not be made to crystallize. It was therefore saponified directly by boiling 36 g. of it with a solution of 200 g. of water and 18 g. of sodium hydroxide for eight and one-half hours under reflux. The product was treated with charcoal and filtered. Upon acidifying the clear filtrate with hydrochloric acid, the product separated as a dough-like material which solidified to a hard mass. Upon recrystallization from a mixture of dioxane–water (30:70), with Norite to remove the color, the product was obtained in colorless crystals, m. p. 205° after drying at 60° for twenty-four hours. *Anal.* Calcd. for $C_{24}H_{26}O_7$: C, 67.57; H, 6.15. Found: C, 68.18; H, 6.15.

XI. 2,4,4-Tri-(β-cyanoethyl)-pentanone-3.—To a stirred solution of 34.4 g. diethyl ketone (0.4 mole), 35 g. of tertiary butyl alcohol, and 4 g. of "Triton B," there was added dropwise 84.8 g. of acrylonitrile (1.6 mole) at 30–40° during the course of two hours. The reaction mixture was allowed to stand for twenty-four hours at room temperature. It was then acidified with dilute hydrochloric acid, taken up in ethylene dichloride, and washed thoroughly with water. The solvent was removed *in vacuo* on a steam-bath and the residual oil weighing 123 g. was distilled in high vacuum. The fraction boiling at 280–300° (2 mm.) was a viscous sirup (45 g.) which crystallized from methanol in colorless crystals melting at 90–91°; yield 30 g. pure product. *Anal.* Calcd. for $C_{14}H_{19}N_3O$: C, 68.55; H, 7.79; N, 17.14. Found: C, 68.80; H, 7.60; N, 17.38.

2,4,4-Tri-(β-carboxyethyl)-pentanone-3.—A mixture of 21 g. of compound XI, 150 g. of water and 32 g. of sodium hydroxide was boiled under reflux for fourteen and one-half hours, then treated with carbon black and filtered. Upon acidifying the clear filtrate with concentrated hydrochloric acid an oil separated on cooling. The water layer was poured off and the oil layer was dissolved in 60 cc. of warm water and allowed to crystallize in a refrigerator for

about a week. The air-dried crystalline product weighed 21 g. Upon recrystallization from nitromethane it formed colorless crystals melting at 116°. *Anal.* Calcd. for $C_{14}H_{22}O_7$: C, 55.59; H, 7.34. Found: C, 55.55; H, 7.35.

XII. 4-Acetyl-4-methylpimelonitrile.—A solution consisting of 160 g. of acrylonitrile and 100 g. of tertiary butyl alcohol was added dropwise during the course of three hours, to a rapidly stirred, ice-cold solution of 144 g. of methyl ethyl ketone, 200 g. of tertiary butyl alcohol, and 10 g. of methanolic potassium hydroxide (30% solution) care being taken that the reaction temperature did not exceed 5°. During the addition a crystalline solid separated. After all the acrylonitrile had been added, the mixture was stirred for two hours longer at 5–10°, then filtered by suction while still cold. After air-drying for twenty-four hours the product was obtained as an almost white crystalline material; yield 239 g. or 89%. Upon recrystallization from benzene it forms colorless crystals, m. p. 67°. *Anal.* Calcd. for $C_{10}H_{14}N_2O$: C, 67.37; H, 7.92; N, 15.72. Found: C, 67.80; H, 7.82; N, 15.90.

γ-Acetyl-γ-methylpimelic Acid.—A mixture of 50 g. of compound XII, 400 g. of water, and 39.2 g. of potassium hydroxide was gradually heated to boiling under reflux (exothermal reaction). Boiling was continued for three hours. The product was then evaporated to expel the ammonia and acidified with hydrochloric acid. The mixture was evaporated to dryness on a steam-bath and the powdered residue extracted with boiling ethylene dichloride. Upon chilling the extract, 38 g. of colorless crystals was obtained. After recrystallization from ethylene dichloride the product melted at 125°. *Anal.* Calcd. for $C_{10}H_{16}O_5$: C, 55.52; H, 7.46. Found: C, 55.70; H, 7.46.

XIII. γ-Carboxy-γ-methylpimelic Acid.—A solution of alkaline potassium hypochlorite was prepared by stirring at 50° a solution of 660 g. of water and 165 g. of calcium hypochlorite ("HTH" containing 70% available Cl) with a solution of 115 g. of anhydrous potassium carbonate, 33 g. of potassium hydroxide and 330 g. of water for about ten minutes and filtering off the precipitate of calcium carbonate. The clear filtrate was stirred and to it was added dropwise a solution of 71 g. of γ-acetyl-γ-methylpimelic acid in 200 g. of 20% sodium hydroxide solution, while maintaining the reaction mixture between 60 and 70° by external cooling. Chloroform was evolved. After all had been added, the mixture was stirred for one hour longer at 60–70° and any excess hypochlorite destroyed by adding a solution of sodium bisulfite. The product was then acidified with hydrochloric acid and the clear solution evaporated to dryness on a steam-bath, under reduced pressure. The solid residue was extracted with hot acetone. Upon evaporation of the acetone from the extract, 64 g. of a viscous sirup was obtained which gradually set to a solid mass. Upon recrystallization from nitromethane it separated in colorless crystals. The analytical sample was dried in a vacuum desiccator over phosphorus pentoxide for several, days. It melted at 111°. *Anal.* Calcd. for $C_9H_{14}O_6$: C, 49.51; H, 6.47. Found: C, 49.21; H, 6.33.

XIV. 1,1,3,3-Tetra-(β-cyanoethyl)-butanone-2.—To a solution of 100 g. of dioxane, 53.4 g. of compound XII (0.3 mole) and 3 g. of "Triton B," there was added 15.9 g. (0.3 mole) of acrylonitrile while stirring at 25–40°. The reaction mixture was then allowed to stand for forty-eight hours at room temperature. The product was acidified with dilute hydrochloric acid, taken up in ethylene dichloride, washed thoroughly and dried *in vacuo* at 90°. The residual oil weighing 62 g. was then distilled under high vacuum. About 40 g. of unchanged XII boiling at 180–200° (2 mm.) was recovered. The fraction boiling at 345–355° (2 mm.) distilled as a thick oil (11 g.) which crystallized when stirred with ethanol. After several recrystallizations from ethanol it was obtained as colorless crystals, m. p. 84–85°; yield 4 g. *Anal.* Calcd. for $C_{16}H_{20}N_4O$: C, 67.57; H, 7.09; N, 19.70. Found: C, 67.40; H, 6.97; N, 19.79.

4-Acetyl-4-ethylpimelonitrile.—To a stirred solution of 60 g. of methyl *n*-propyl ketone, 10 g. of tertiary butyl alcohol and 1 g. of "Triton B," there was added dropwise 74 g. of acrylonitrile during the course of one and one-half hours while maintaining the reaction temperature at 10–15° by means of an ice-bath. The mixture was stirred for one hour longer at 15° after all the acrylonitrile had been added. It was then made slightly acid with dilute hydrochloric acid, and the crystalline precipitate filtered off and washed with a little ethanol; yield 57 g. Upon recrystallization from ethanol the compound formed colorless crystals, m. p. 109°. *Anal.* Calcd. for $C_{11}H_{16}N_2O$: C, 68.70; H, 8.39; N, 14.57. Found: C, 68.50; H, 8.15; N, 14.49.

1,3,3-Tri-(β-cyanoethyl)-pentanone-2.—The filtrate from the above preparation was mixed with ethylene dichloride and washed thoroughly with water. The ethylene dichloride was evaporated off under reduced pressure on a steam-bath and the residual oil (67 g.) distilled in high vacuum. The fraction boiling at 200–270° (1 mm.) amounting to 10 g. was crystalline and consisted almost entirely of 4-acetyl-4-ethylpimelonitrile. The fraction boiling at 270–285° (1 mm.) amounted to 26 g. and consisted almost entirely of 1,3,3-tri-(β-cyanoethyl)-pentanone-2. Upon recrystallization from ethanol it melted at 90–91°. *Anal.* Calcd. for $C_{14}H_{19}N_3O$: C, 68.53; H, 7.81; N, 17.13. Found: C, 68.51; H, 7.61; N, 17.27.

γ-Acetyl-γ-ethylpimelic Acid.—A mixture of 400 g. of water, 88 g. of sodium hydroxide, and 192 g. of 4-acetyl-4-ethylpimelonitrile was boiled under reflux for five hours. The clear solution was treated with "Norite," filtered, and acidified with 210 g. of concentrated hydrochloric acid while it was cooled and stirred. The product separated as a white crystalline mass (yield 170 g.) which, upon recrystallization from hot water, melted at 112–113°. *Anal.* Calcd. for $C_{11}H_{18}O_5$: C, 57.36; H, 7.88. Found: C, 57.70; H, 7.83.

γ-Carboxy-γ-ethylpimelic Acid.—To a stirred filtered solution of potassium hypochlorite made from 250 g. of calcium hypochlorite, 1500 g. of water, 175 g. of potassium carbonate and 50 g. of potassium hydroxide, there was added gradually at 60–70°, 115 g. of γ-acetyl-γ-ethylpimelic acid in 300 g. of 20% sodium hydroxide solution. Chloroform was evolved. The product was worked up as described for compound XIII. Upon evaporation of the acetone, 105 g. of crystalline product was obtained. Upon recrystallization from water or nitromethane it melted at 172°. *Anal.* Calcd. for $C_{10}H_{16}O_6$: C, 51.69; H, 6.95. Found: C, 51.30; H, 6.51.

γ-Acetyl-γ-alkyl-pimelonitriles (Alkyl = Isopropyl, *n*-butyl, *n*-amyl).—In Table V are given the physical and

analytical data of various dicyanoethylated homologs of methyl propyl ketone, prepared, respectively, from methyl isobutyl ketone, methyl *n*-amyl ketone, and methyl *n*-hexyl ketone. These dinitriles were prepared in the same manner as compound XII, but since they did not separate as solids from the reaction mixture, they were isolated by vacuum distillation after neutralizing the alkaline catalyst with dilute hydrochloric acid. The distilled products were then crystallized from ethanol to constant melting point. The yields of dicyanoethylation product were 50 to 60% in the case of methyl *n*-amyl ketone and methyl *n*-hexyl ketone, but only about 20% in the case of methyl isobutyl ketone, which reacted very sluggishly.

γ-Acetyl-γ-alkylpimelic Acids (Alkyl = Isopropyl, *n*-butyl, *n*-amyl).—These were obtained by saponification of the dinitriles of Table V, by boiling with an excess of aqueous sodium hydroxide solution, bleaching the resulting solution with charcoal, filtering, and acidifying the filtrate with concentrated hydrochloric acid, by the method described in the preparation of γ-acetyl-γ-ethylpimelic acid. They are listed in Table VI.

TABLE VI

$$HOOC{-}CH_2CH_2{-}C(R)(CO{-}CH_3){-}CH_2CH_2COOH$$

[a,b] Recrystallized from *a* water; *b* benzene.

γ-Alkyl-γ-carboxypimelic Acids (Alkyl = Isopropyl, *n*-butyl, *n*-amyl).—These were prepared by treating the above γ-acetyl-γ-alkylpimelic acids dissolved in aqueous sodium hydroxide solution with an excess of potassium hypochlorite solution containing free potassium hydroxide at 60–70°, destroying the excess hypochlorite after eight hours of reaction, by means of sodium bisulfite, acidifying the solution with hydrochloric acid and evaporating the mixture to dryness, by exactly the same procedure as described above in the preparation of γ-carboxy-γ-ethylpimelic acid. The dried residue was extracted with acetone, and the acetone extract evaporated to dryness in vacuum on a steam-bath. The resulting crude tri-carboxylic acids were each recrystallized from water or nitromethane and dried over phosphorus pentoxide for analysis. These are listed in Table VII.

TABLE VII

$$HOOC{-}CH_2CH_2{-}C(R)(COOH){-}CH_2CH_2COOH$$

[a,b] Recrystallized from *a* nitromethane; *b* water.

XVII. 1,1,1-Tri-(β-cyanoethyl)-acetone.—To a solution of 29 g. of acetone, 30 g. of tertiary butyl alcohol and 2.5 g. of ethanolic 30% potassium hydroxide solution, cooled to 0° there was added dropwise, with rapid mechanical stirring, a solution consisting of 80 g. of acrylonitrile and 37 g. of tertiary butyl alcohol during a period of one and one-half hours while the reaction mixture was maintained between 0 and 5° by an ice–salt cooling bath. The mixture was stirred thereafter for two hours at 5° and the crystalline product filtered off by suction; yield 84 g. After recrystallization from hot water or from glycol monoethyl ether it formed colorless crystals; m. p. 154°. *Anal.* Calcd. for $C_{12}H_{15}N_3O$: C, 66.32; H, 6.96; N, 19.34. Found: C, 66.80; H, 6.91; N, 19.40.

1,1,1-Tri-(β-carboxyethyl)-acetone.—A mixture consisting of 140 g. of potassium hydroxide, 800 cc. of water, and 120 g. of XVII was boiled under reflux for four hours. The solution was treated with "Norite," cooled to 50° and filtered. The filtrate was acidified to congo red indicator with concentrated hydrochloric acid, and then evaporated to dryness under reduced pressure on a steam-bath. The residue was extracted with hot acetone. Upon cooling the hot filtered acetone extract, tri-(carboxyethyl)-acetone separated in colorless crystals; yield 80 g. More can be obtained from the mother liquor. The compound forms colorless needles from acetone melting at 149–150°. It is readily soluble in water or in ethanol. *Anal.* Calcd. for $C_{12}H_{18}O_7$: C, 52.53; H, 6.62. Found: C, 52.30; H, 6.68.

XVIII. Tri-(β-carboxyethyl)-acetic Acid.—To a stirred filtered solution of potassium hypochlorite prepared from 85 g. of calcium hypochlorite ("HTH" containing 70% available chlorine), 59.5 g. of anhydrous potassium carbonate, 17 g. of potassium hydroxide and 510 g. of water, there was added dropwise at 60–70° a solution of 136 g. of 20% sodium hydroxide solution and 46.5 g. of 1,1,1-tri-(β-carboxyethyl)-acetone. Chloroform was evolved. The mixture was stirred for two hours after reaction had apparently ceased. The product was worked up as described for compound XIII. The acetone extract upon evaporation yielded a white powdery residue which after several recrystallizations from water melted at 192° after softening at 182°. *Anal.* Calcd. for $C_{11}H_{16}O_8$: C, 47.80; H, 5.84. Found: C, 47.70; H, 5.67.

XIX. 1,3,3,3-Tetra-(β-cyanoethyl)-acetone.—A solution of 43.4 g. of 1,1,1-tri-(β-cyanoethyl)-acetone in 150 g. of acetonitrile was prepared by warming at 50°. To this stirred solution, 5 g. of "Triton B" was added. Acrylonitrile (31.6 g.) was then added dropwise during twenty

minutes, while stirring and maintaining the temperature at 40–42°. The mixture was stirred for two hours longer, then cooled, acidified with dilute hydrochloric acid, poured into water, and the oil taken up in ethylene dichloride. The ethylene dichloride solution was washed with water and dried in vacuum on a steam-bath. The residual oil weighed 53 g. Upon distillation in high vacuum, 27 g. of material distilled over up to 320° (1–3 mm.) This was mostly tri-(cyanoethyl)-acetone. The fraction which came over at 320–340° (1–3 mm.) weighed 7 g. Upon recrystallization from methanol it formed colorless needles, m. p. 121–122°. *Anal.* Calcd. for $C_{15}H_{18}N_4O$: C, 66.63; H, 6.71; N, 20.73. Found: C, 66.04; H, 6.63; N, 20.39.

γ-Acetyl-γ-phenylpimelonitrile.—Acrylonitrile (53 g.) was added dropwise to a stirred solution of 100 g. of tertiary butyl alcohol, 67 g. of phenylacetone, and 5 g. of "Triton B" while the reaction mixture was stirred and maintained at 20–25° by cooling. After one hour of additional stirring the almost solid mixture of crystalline product was filtered off and washed with about 50 cc. of methanol; yield 104 g. of colorless crystals. Upon recrystallization from ethanol it melted at 109–110°. *Anal.* Calcd. for $C_{15}H_{16}N_2O$: C, 74.95; H, 6.71; N, 11.66. Found: C, 74.70; H, 6.67; N, 11.63.

γ-Acetyl-γ-phenylpimelic acid.—A mixture of 40 g. of sodium hydroxide, 400 g. of water, and 87 g. of γ-acetyl-γ-phenylpimelonitrile was boiled under reflux for nine hours, treated with "Norite," filtered, and acidified with concentrated hydrochloric acid. The product separated as a thick oil which rapidly solidified. After recrystallization from water, the analytical sample melted at 171–172°. *Anal.* Calcd. for $C_{15}H_{18}O_5$: C, 64.72; H, 6.52. Found: C, 64.85; H, 6.64.

XX. γ-Carboxy-γ-phenylpimelic Acid.—To a stirred filtered potassium hypochlorite solution made from 50 g. of calcium hypochlorite ("HTH" containing 70% available Cl), 35 g. of anhydrous potassium carbonate, 10 g. of potassium hydroxide and 300 g. of water, there was added dropwise at 60–70° a solution of 27.8 g. of γ-acetyl-γ-phenylpimelic acid in 60 g. of aqueous 20% sodium hydroxide, while stirring. Chloroform was evolved. The mixture was stirred for one hour after reaction had ceased, and worked up as described for compound XIII. Upon evaporation of the acetone, 19 g. of resin-like material was obtained. Upon crystallization of the resin from nitromethane the product separated in the form of colorless crystals melting at 154°. *Anal.* Calcd. for $C_{14}H_{16}O_6$: C, 59.97; H, 5.76. Found: C, 59.67; H, 5.85.

XXI. α,α-Di-(2-cyanoethyl)-acetoacetic Methyl Ester.—(a) To a solution of 58 g. of methyl acetoacetate, 100 g. of dioxane and 7 g. of "Triton B," there was added 53 g. of acrylonitrile while the solution was stirred and cooled to 30–40°. After stirring for one hour the crystalline product was filtered off; yield 55 g. After recrystallization from acetone it formed colorless crystals melting at 154°. A further quantity can be obtained from the original filtrate on addition of water. *Anal.* Calcd. for $C_{11}H_{14}N_2O_3$: C, 59.43; H, 6.35; N, 12.60. Found: C, 59.80; H, 6.29; N, 12.59.

(b) The ethyl ester can be obtained in the same manner by using 65 g. of ethyl acetoacetate in the above procedure. The crude reaction product was poured into one liter of ice water whereupon the compound separated in crystalline form. After recrystallization from ethanol it melts at 82°. *Anal.* Calcd. for $C_{12}H_{16}N_2O_3$: C, 60.98; H, 6.83; N, 11.85. Found: C, 61.60; H, 6.88; N, 11.84.

Acknowledgment.—The analyses of the above products were performed by the semi-micro method by Mr. C. W. Nash of these laboratories.

Summary

1. Acrylonitrile condenses in the presence of aqueous trimethylbenzylammonium hydroxide or other strong alkali as a catalyst, with reactive ketones having a —CH—, —CH_2—, or CH_3— group adjacent to the carbonyl, so as to replace one or more of the reactive hydrogen atoms thereof by β-cyanoethyl radicals. The reaction furnishes a simple method for preparing a wide variety of ketonic polynitriles and polycarboxylic acids.

2. Acetophenone and its aryl substituted derivatives gave tri-cyanoethylation products R—CO—$C(CH_2CH_2CN)_3$; cyclopentanone, cyclohexanone and para-substituted cyclohexanones gave tetra-cyanoethylation products; *o*-methylcyclohexanone gave a tri-cyanoethylation product, and α-tetralone gave a dicyanoethylation product.

3. Acetone gave a crystalline tri-cyanoethylation product, $CH_3CO—C(CH_2CH_2CN)_3$. Substituted acetones of the type R—CH_2—CO—CH_3 (R is alkyl or aryl) reacted first on the —CH_2— group to give dicyanoethylation products. These products are cyanoethylated further on the residual CH_3 group.

4. Acetoacetic esters similarly gave crystalline dicyanoethylation products.

Phenethylamines. IV. Dimethoxy and Dihydroxyphenyl-*n*-propylamines (β-Methyl-β-phenethylamines)[1]

BY E. H. WOODRUFF

It was desired to have available for the purpose of pharmacological study a series of compounds possessing the phenethylamine skeleton in which all possible mono and disubstituted isomers were represented. This communication reports the preparation of all possible nuclear dimethoxy and dihydroxy-β-phenyl-*n*-propylamines. In conjunction with work already published[2] the first such complete series of isomers is available for pharmacological comparison, the results of which will appear elsewhere.

The general outline for the preparation of the amines described in the experimental section follows that previously used in this Laboratory.[3,4] The appropriately substituted cinnamic acid was reduced to the hydrocinnamic acid, the amide prepared from the acid chloride and the amine then obtained from the amide by means of sodium hypobromite.

When possible it was found to be more convenient to prepare the β-methylcinnamic acids having an ortho methoxyl group by the hydrolysis and methylation of a hydroxy-4-methylcoumarin. This method gave uniformly the *trans* or high melting form of the cinnamic acid in contrast to the mixture of isomers obtained by the dehydration and saponification of a hydroxy ester.[4,5] No satisfactory method for the preparation of 8-hydroxy-4-methylcoumarin was found so the 2,3-dimethoxy-β-methylcinnamic acid as well as those not containing an ortho methoxyl were obtained through the Reformatsky reaction on the appropriate ketone followed by dehydration and saponification.

The preparation of 2,6-dimethoxy-β-methylcinnamic acid from the 5-hydroxy-4-methylcoumarin gave an 80% yield of the *trans*-form melting at 185°,[6] None of the low melting (148–150°) form previously reported[7] as being obtained from this coumarin was found. However, when the acid was prepared through the Reformatsky reaction after repeated crystallizations an acid melting at 143–144° was obtained. These two acids on further treatment gave identical products.

In an early attempt to prepare 3,5-dihydroxyacetophenone, the alkali fusion of the supposed acetophenone 3,5-disulfonyl chloride of Riesz and Frankfurter[8] was tried. *m*-Hydroxybenzoic acid m. p. 201–202° and *m*-methoxybenzoic acid m. p. 102–108° from the methylation of the hydroxy acid were obtained. This confirms the statement of Suter and Weston[9] that only one sulfonyl group had entered the ring.

The 2,3- and 3,5-dimethoxyacetophenones were prepared from the corresponding benzoyl chlorides and dimethylcadmium.[10] This method is satisfactory for aromatic acid chlorides with dimethylcadmium to give methyl ketones but the yields are lower when used to prepare higher members of a series.

The reduction of the cinnamic acids by sodium amalgam as previously used[4] was replaced early in this investigation by electrolytic reduction using a lead anode and a mercury cathode.[11] This method is as efficient as sodium amalgam in the reduction of cinnamic acids with the possible exception of the 2,6-dimethoxy derivative and is more convenient when large amounts of the amalgam must be prepared.

Experimental

Preparation of Coumarins.—7-Hydroxy-[12,13] and 6-hydroxy[14]-4-methylcoumarins were prepared as described in the literature. For the preparation of 5-hydroxy-4-methylcoumarin the condensation of methyl β-resorcylate with acetoacetic ester by means of anhydrous aluminum chloride in nitrobenzene was carried out according to Sethna, Shah and Shah.[7] After the removal of the nitrobenzene the product was boiled twice with 200-cc. portions of methyl alcohol, filtering hot and discarding the filtrate. The intermediate crude methyl 5-hydroxy-4-methylcoumarin-6-carboxylate melting at 175–182° was obtained

3,5-	197–203	11	75	123.5–124.5	88	64.83	64.79	6.35	6.28

[a] From ester before crystallization. [b] *Anal.* Calcd. for $C_{14}H_{18}O_4$: C, 67.17; H, 7.20. Found: C, 67.11; H, 7.09. [c] Yield 48% allowing for recovered ketone. [d] From Reformatsky reaction. An 80% yield of acid melting at 185–185.5° was obtained by hydrolysis of 6-hydroxy-4-methylcoumarin. [e] M. p. 138–140°, ref. 34.

in 47% yield. The hydrolysis of the ester was accomplished by refluxing with 73% sulfuric acid instead of heating in a sealed vessel with a mixture of hydrochloric and acetic acids. The product so obtained was heated to 300° and after decarboxylation was distilled at 10 mm. The crude 5-hydroxy-4-methylcoumarin was obtained in 57.5% yield and melted when crystallized once from alcohol at 260°.

Preparation of Ketones.—2,3-Dimethoxybenzoic acid[15,16] was prepared in 85% yield by the oxidation of 2,3-dimethoxybenzaldehyde[17] with potassium permanganate.[18] Oxalic acid was used to remove the manganese dioxide prior to the precipitation of the acid. The acid was converted to the chloride (94%)[19] using a sixfold excess of thionyl chloride. Twice the calculated amount of thionyl chloride was consumed, the remainder being recovered. 3,5-Dimethoxybenzoic acid[20] was obtained by methylating 3,5-dihydroxybenzoic acid.[21] The acid was converted to the acid chloride (90%) using phosphorus pentachloride and carbon tetrachloride.[22] The 2,3- (71%) and 3,5- (84%)-dimethoxyacetophenones[23,24] were obtained from the acid chlorides by the procedure of Gilman and Nelson.[10] The ketone so prepared was always contaminated with ester. This was removed by refluxing the crude product with alcoholic alkali. The yields given deduct for the recovered acid. 3,4-Dimethoxyacetophenone[25] was prepared by the reaction of veratrole with acetyl chloride and anhydrous aluminum chloride below +10°, using twice the quantity of solvent used in the previous preparation. After filtration from the insoluble complex (20% loss) the solvent may be reused without purification. 2,6-Dimethoxyacetophenone[26] was obtained by methylating 2,6-dihydroxyacetophenone.[13]

Preparation of Cinnamic Acids.—The cinnamic acids were prepared in two ways as previously mentioned. For a discussion of the Reformatsky reaction a recent review by Shriner[27] is recommended. In two instances the presence of *o*-methoxy groups caused a considerable lowering of the yield. This was so great in the case of the 2,6-dimethoxyacetophenone as to render this method unsuitable for the preparation of suitable quantities of the acid. The dehydration of the hydroxy esters was accomplished with a minimum of side reactions by heating to 250–300° at atmospheric pressure. The hydrolysis and methylation of a hydroxycoumarin is illustrated by the following example: 35.2 g. (0.2 mole) of 6-hydroxy-4-methylcoumarin was shaken with 25 cc. of dimethyl sulfate and 28 cc. of 33% potassium hydroxide solution. After the reaction had subsided the solution was cooled and again shaken with alkali and methyl sulfate. While hot, 50 cc. of 33% potassium hydroxide was added and the reaction refluxed one hour. The methylation treatment was repeated and after the addition of excess alkali the solution was refluxed to hydrolyze any methyl ester formed. The solution was diluted to one liter and boiled with decolorizing charcoal and filtered. When cold, hydrochloric acid was added, the precipitated acid collector on a Büchner funnel, washed with water and dried. Crystallization is best from a benzene–skelly-solve B mixture although alcohol–water may be used. The 2,5-dimethoxy-β-methylcinnamic acid (81%) so obtained melted at 119–120°.[28] In a similar manner 2,4-dimethoxy-β-methylcinnamic acid (76% yield) melting at 148° was obtained.[29]

Hydrocinnamic Acids.—The cinnamic acids were reduced electrolytically.[11] 2,6-Dimethoxy-β-methylhydrocinnamic acid was also prepared by the reduction of 5-hydroxy-4-methylcoumarin[30] followed by the hydrolysis and methylation of the dihydrocoumarin.

Seventeen and six-tenths grams (0.1 mole) of 5-hydroxy-4-methylcoumarin, 200 cc. of alcohol and 6 cc. of Raney nickel catalyst were reduced at 60° and 60 pounds hydrogen pressure in an Adams hydrogenator. After seven hours, the theoretical amount of hydrogen was absorbed. The catalyst was filtered and the solvent removed. The residue was crystallized from alcohol–water or benzene–skelly solve B.

Fourteen and six-tenths grams (82%) of 5-hydroxy-4-methyl-3,4-dihydrocoumarin b. p. 214° at 5 mm., m. p. 160° was obtained. *Anal.* Calcd. for $C_{10}H_{10}O_3$: C,

3,4-	180 –181	53.07	52.92	6.93	7.17				
3,5-	164 –166	53.07	52.99	6.93	7.20	6.88	6.98	17.41	17.14

67.40; H, 5.66. Found: C, 67.10; H, 5.85. The hydrolysis to the hydrocinnamic acid was carried out as previously given. A yield of 91% was obtained. After two crystallizations from a dilute solution in skelly-solve B, crystals m. p. 78.5–79° were obtained identical with those obtained by the reduction of the cinnamic acid.

Dimethoxy-β-methylhydrocinnamides.—The amides were prepared as previously reported.[3] They were crystallized from alcohol–water or benzene–skelly solve B.

Dimethoxyphenyl-*n*-propylamines.—The amines were prepared by the action of sodium hypobromite on the finely divided (to pass a 40-mesh screen) amide.[3] The ease of solution of the amide appears to vary with the ring substituents. The presence of a *m*-methoxy group confers increased ease of solubility. The 2,4-dimethoxy amide was the least soluble. The hydrochlorides were best prepared by adding a weighed amount (10% over the molecular quantity) of dry hydrogen chloride to absolute ethyl alcohol. The alcoholic hydrogen chloride was added to the amine and the hot solution is diluted with anhydrous ether until a faint cloudiness just fails to persist. On cooling, the amine hydrochloride precipitates in a crystalline condition. The direct addition of dry hydrogen chloride to an anhydrous ether solution of the amine often gave a gummy precipitate which later solidified. This was more difficult to purify. Recrystallization was carried out from an absolute alcohol–ether mixture.

Dihydroxyphenyl-*n*-propylamine Hydrochloride.—Demethylation was accomplished by heating in a sealed tube with concentrated hydrochloric acid for two hours at

160°.[3,4] The dihydroxyamine hydrochlorides are more hygroscopic and difficult to crystallize than the methoxy amines. The crystalline condition of the hydrochloride has much to do with its deliquescence. When alcohol–ether cannot be used for crystallization, alcohol–benzene, alcohol–toluene, or ethyl–acetate–alcohol may be used. The usefulness of the solvent varies with the amine hydrochloride even in such a closely related group of isomers as reported here.

The author wishes to thank Dr. Earl Pierson, Dr. John P. Lambooy and Dr. William E. Burt for their assistance while holders of Kalamazoo College Fellowships and Mr. Harold Emerson and Mr. William A. Struck for the micro analyses.

Summary

All of the nuclear dimethoxy- and dihydroxy-β-phenyl-*n*-propylamines and their hydrochlorides have been prepared. The properties are reported for the cinnamic acids, hydrocinnamic acids and hydrocinnamides used in the preparation of these amines as well as the syntheses of many of the intermediates used in their preparation. The hydrolysis and methylation of an hydroxy-4-methylcoumarin always gave the *trans* form of the resulting dimethoxy-β-methylcinnamic acid.

KALAMAZOO, MICHIGAN RECEIVED AUGUST 1, 1942

[CONTRIBUTION FROM THE SANDERS LABORATORY OF CHEMISTRY, VASSAR COLLEGE]

The Reaction of *n*-Butylmagnesium Bromide with Some Aromatic Ketones[1,2]

BY H. MARJORIE CRAWFORD, MARY ELIZABETH SAEGER[3] AND FLORENCE E. WARNEKE[4]

Since *n*-butyl bromide can be prepared by students in good yield and reacts readily with magnesium to give a Grignard reagent, we had hoped to work out a series of student preparations by adding this Grignard reagent to a ketone and dehydrating the resulting tertiary alcohol to the corresponding unsaturated compound. This purpose was not achieved, but several new compounds were prepared in the course of the studies. Four ketones were selected for study: acetophenone, benzophenone, benzil and desoxybenzoin.

A. Acetophenone.—The reaction of acetophenone and *n*-butylmagnesium bromide gave good yields (72–80%) of the expected tertiary alcohol, 2-phenylhexanol-2 (I). This tertiary alcohol was very resistant to complete dehydration, but was finally transformed into the unsaturated hydrocarbon, 2-phenylhexene-2 (II), by heating with Lucas reagent. The position of the double bond was established by oxidation to acetophenone and *n*-butyric acid. The same results were obtained whether the oxidizing agent was potassium permanganate in sulfuric acid or chromium trioxide in acetic acid.

B. Benzophenone.—The reducing action of aliphatic Grignard reagents on benzophenone has been studied by several workers.[5] Schlenk and Bergmann[6] obtained impure diphenyl-*n*-butylcarbinol by the reaction of phenylmagnesium bromide on ethyl *n*-valerate. It was mixed with the dehydration product and was easily converted into the unsaturated hydrocarbon. The two reactions which we carried out gave no tertiary alcohol and no unsaturated hydrocarbon. Benzohydrol (17 and 30%) was obtained. The remaining oils were distilled under reduced pressure and a yield of 5.6% of dibenzylhydryl ether separated from the residue (above 270°, 42 mm.). Analyses of this compound agreed closely with the calculated values. Dibenzhydryl ether had previously been reported by Kharasch and Weinhouse[5] as resulting from the reaction of allylmagnesium bromide on benzophenone.

C. Benzil.—The reaction of *n*-butylmagnesium bromide on benzil gave small yields of solid products regardless of the variations in procedure. Both addition and reduction occurred. The reduction product, benzoin, was obtained in seven of the ten reactions in yields varying from 0.5 to 13.0%. The mono-addition product 1,2-diphenylhexanol-2-one-1 (II) was obtained in all ten reactions in yields varying from 0.5 to 5.6%. A solid which was possibly the di-addition product (V) was obtained twice in very small yields. Benzoic acid was obtained after the oily

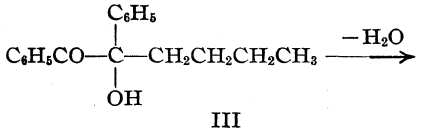
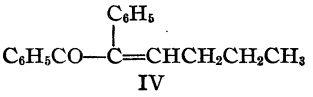
(6) Schlenk and Bergmann, *Ann.*, **479**, 42 (1930).

mixtures were exposed to the light for some time. Under these conditions benzil decomposes to form benzoic acid.[7] The only generalization which can be drawn from the results of the ten reactions is that the yield of mono-addition product (III) was smaller when a large excess of *n*-butylmagnesium bromide was used. The highest yields were obtained when 0.2 mole of benzil was added to 0.5 mole of *n*-butylmagnesium bromide.

Dehydration of the mono-addition product (III) by refluxing with Lucas reagent gave a liquid unsaturated ketone (IV) whose structure was established by oxidation to benzil and *n*-butyric acid.



III



IV

Attempts to prepare the di-addition product by the reaction of *n*-butylmagnesium bromide on the mono-addition product were not successful.

D. Desoxybenzoin.—No addition products were obtained from the reaction of *n*-butylmagnesium bromide on desoxybenzoin, but various reduction products were isolated in very small yields. The product obtained in the largest amounts was stilbene, which would result from reduction of the desoxybenzoin followed by the loss of a molecule of water. It was obtained in three of the four reactions in yields of 2.5, 5.3 and 7.4%. Desoxybenzoin pinacol (m. p. 175°) was obtained in two reactions, but the total yield was only 0.3 g. It was identified by a mixed melting point with a known sample of the pinacol. A compound thought to be the pinacolone (VI) was obtained in two reactions, the total yield being 1%. All attempts to rearrange the pinacol were unsuccessful and the amount of the compound VI available was too small to make structure proof possible. The formation of a pinacolone would be interesting, for, although the pinacol has been known since 1870, no mention of the pinacolone could be found. Orechoff[8] dehydrated the pinacol by boiling it with acetyl chloride, a treatment known to rearrange many pinacols, and recorded the formation of 1,2,3,4-tetraphenylbutadiene-1,3 and other products.

(8) Orechoff, *ibid.*, **47**, 91 (1914).

Experimental

General Procedure.—Since the variations in length of time of heating the reaction mixtures, variations in the kind and amount of solvent used to dissolve the ketones and decomposition of the magnesium complex with dilute sulfuric acid or with ammonium chloride solution seemed to have no effect on the kind or amount of resulting products, the individual experiments will not be described.

n-Butylmagnesium bromide was prepared in the usual way from 0.5 mole of *n*-butyl bromide. Slightly less than the calculated amount of the ketone was dissolved in either benzene or ether and dropped slowly into the Grignard solution. After standing or being heated for varying lengths of time the magnesium complex was decomposed, the organic material was extracted with ether, and most of the solvent was removed on the steam-bath. If solid separated on standing, it was filtered and recrystallized from appropriate solvents. When no more solid formed, the oils were distilled under reduced pressure. Solid which formed in any of the fraction was then removed and recrystallized. Many of the fractions have not solidified after standing for over a year.

2-Phenylhexanol-2, I.—One refractionation gave the pure alcohol, b. p. 123–124° (9 mm.); d^{25} 0.954. It was colorless and decomposed partially when distilled at atmospheric pressure.

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.85; H, 10.18; mol. wt., 178. Found: C, 80.67; H, 10.15; mol. wt., 178.

2-Phenylhexene-2, II.—Many attempts were made to dehydrate 2-phenylhexanol-2 and none of them were entirely successful. Distillation at atmospheric pressure resulted in the partial decomposition of the alcohol. Samples of the alcohol (20–25 g.) were refluxed for two hours with 75 ml. of 20% sulfuric acid and with 20 g. of fused potassium bisulfate, for four hours with 10 g. of fused zinc chloride and with 50 g. of acetic anhydride, and for eight hours with a trace of iodine. The alcohol was dropped on anhydrous cupric sulfate at 230°. Analyses of the products from all of these reactions showed a percentage of carbon intermediate between the values calculated for the alcohol and for the unsaturated hydrocarbon. The best results were obtained by refluxing the alcohol with an equal weight of Lucas reagent for thirty minutes. After separation, washing with water and drying, the product boiled 210–230° with the main fraction at 223–226°. It decolorized bromine readily.

Anal. Calcd. for $C_{12}H_{16}$: C, 89.94; H, 10.06; mol. wt., 160. Found: C, 87.13; H, 9.87; mol. wt., 161.

1,2-Diphenylhexanol-2-one-1, III.—This compound is a white solid melting at 124°. When crystallized from a benzene–petroleum ether mixture or from 50% alcohol it forms long fine needles. The dehydration is described below. The starting material was recovered unchanged after attempts to prepare the di-addition product by treating 0.004 mole of this mono-addition product with 0.04 mole of *n*-butylmagnesium bromide. The reaction was forced by refluxing the reactants in *n*-butyl ether for five hours.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.56; H, 7.51; mol. wt., 268. Found: C, 80.13; H, 8.44; mol. wt., 273.

1,2-Diphenylhexene-2-one-1, IV.—This compound was prepared by the dehydration of 1,2-diphenylhexanol-2-

one-1. Treatment of the alcohol with gaseous hydrochloric acid and refluxing it with a trace of iodine in glacial acetic acid failed to bring about the expected dehydration. After repeated trials had failed to produce any solid material from the products of the reaction of the alcohol with Lucas reagent, the resulting liquid was distilled at atmospheric pressure. In an actual preparation of the unsaturated compound, 2 g. of the alcohol was boiled for six hours with 30 ml. of Lucas reagent. After washing with water and drying, the yield was almost 2 g. of a liquid boiling 288–290°. It decolorized bromine readily.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.36; H, 7.25. Found: C, 86.28; H, 7.23.

5,6-Diphenyldecandiol-5,6, V.—A total of about 0.5 g. of solid thought to be this di-addition product was obtained in two of the ten reactions between *n*-butylmagnesium bromide and benzil. It was only slightly soluble in benzene but after recrystallization from alcohol it melted at 184°.

Anal. Calcd. for $C_{22}H_{30}O_2$: C, 80.93; H, 9.26; mol. wt., 326. Found: C, 81.87, 81.49; H, 6.24, 5.79; mol. wt., 339, 318.

Preparation of Desoxybenzoin Pinacol.—A very small yield (5%) of the pinacol was obtained by the reduction of benzoin by the method of Ballard and Dehn,[9] and no pinacol was obtained by the method of Wislicenus and Blank.[10] Desoxybenzoin pinacol was obtained in 97% yield by exposing a solution of 6 g. of desoxybenzoin in 50 ml. of isopropyl alcohol to the sunlight for several days. This is an adaptation of the method described by Fieser[11] for the preparation of benzopinacol from benzophenone. The pinacol melted at 172° and was identical with the small amount of material obtained from the reaction of *n*-butylmagnesium bromide on desoxybenzoin. Molecular weight determinations and analyses for carbon and hydrogen agreed well with the calculated values.

Attempts to Rearrange the Pinacol to the Pinacolone.—When 2 g. of the pinacol was refluxed for five minutes with a few crystals of iodine in 15 ml. of glacial acetic acid, only starting material was recovered. Increasing the time of heating to one and one-half hours caused no rearrangement and the pinacol was recovered. When the time of heating was increased to eight hours, dark gummy material was formed which would not crystallize. Refluxing for six hours with hydriodic acid in glacial acetic acid gave dark non-crystalline material. Two grams of the pinacol was added to 70 ml. of cold, concd. sulfuric acid and the resulting bright green solution was poured over ice after standing for two hours at room temperature. The pinacol was recovered. Refluxing for two hours with dilute sulfuric acid caused no rearrangement and the pinacol was recovered. Finally, *n*-butylmagnesium bromide was prepared from 5 g. of *n*-butyl bromide and 1 g. of the pinacol was added to the Grignard reagent. The ether was refluxed for one hour, then the solvent was removed and the mixture was heated overnight on the steam-bath. After decomposition with ice and ammonium chloride solution, the pinacol was recovered.

Desoxybenzoin Pinacolone, VI.—The compound thought to be the pinacolone was obtained in one reaction from a fraction boiling 242–252° (53 mm.) and from the residue, above 226° (64 mm.), in another reaction. It was crystallized from alcohol and melted at 133°. The amount available was too small to determine whether the phenyl or the benzyl group had migrated.

Anal. Calcd. for $C_{26}H_{24}O$: C, 89.32; H, 6.42; mol. wt., 377. Found: C, 89.23, 89.21; H, 6.07, 6.19; mol. wt., 376.

Summary

1. The reaction of *n*-butylmagnesium bromide on acetophenone resulted in addition to form a new tertiary alcohol. This alcohol was dehydrated to form the corresponding new olefin.

2. Benzophenone was reduced by *n*-butylmagnesium bromide to form benzohydrol and dibenzhydryl ether.

3. The reaction of *n*-butylmagnesium bromide on benzil resulted in reduction to benzoin and addition to form a new hydroxy ketone. The hydroxy ketone was dehydrated to form the corresponding unsaturated ketone.

4. Desoxybenzoin was reduced by *n*-butylmagnesium bromide to form stilbene, desoxybenzoin pinacol and a compound thought to be desoxybenzoin pinacolone.

The Ionic Nature of the Grignard Reagent

BY WARD V. EVANS AND RALPH PEARSON[1]

Work has been done in this Laboratory for the past nine years on various phases of the electrolysis of organo-magnesium halides, in ethyl ether.[2] The products of electrolysis are magnesium metal at the cathode, various hydrocarbons at the anode and magnesium halide formed in solution. Since the magnesium halide was believed to form at the anode,[3] several equations were suggested to represent the electrode reactions[4]

(a) at the cathode: $Mg^{++} + 2e^- \longrightarrow Mg$
at the anode: $R_2MgX_2^{=} - 2e^- \longrightarrow 2R\cdot + MgX_2$

(b) at the cathode: $2RMg^+ + 2e^- \longrightarrow Mg + R_2Mg$
at the anode: $2RMgX_2^- - 2e^- \longrightarrow 2R\cdot + 2MgX_2$

The symbol R· stands for an alkyl or aryl free radical that immediately underwent coupling, disproportionation or other reactions.

Because of the very great interest in the Grignard reagent in synthetic work and the need to understand its method of operation, it was thought desirable to do further work to prove or disprove the suggested electrode reactions and to investigate more fully the ionic equilibria involved in ether solutions of the Grignard reagent. This was done by means of transference studies, conductance data and chemical evidence. New light is also thrown upon the equilibrium

$$2RMgX \longrightarrow R_2Mg + MgX_2$$

known to be present in solutions of the Grignard reagent.[5]

Transference Studies

Experimental.—An H-tube transference cell with large internal bore in order to reduce resistance was used. Three glass stopcocks were provided for draining out the anode, cathode and middle portions. Circular platinum electrodes mounted horizontally so that no potential drop existed along their length were used. Rubber stoppers freed from sulfur, one of which was fitted with a glass tube connected to two mercury traps to allow for expansion and contraction, supported the glass tubing holding the electrodes. The whole cell was immersed almost completely in a large jar and surrounded by a mixture of ice and water. Voltages used were from 90 to 180, current was from 0.03 to 0.04 ampere filtered through a no. 80 Radiotron tube. A copper coulometer in series was used to measure the total number of coulombs. Runs were from eight to twelve hours. Sampling before and after electrolysis was by means of 25-cc. washout pipets in a hood of nitrogen to prevent decomposition by air and moisture. The anode, cathode and middle portions were weighed to the closest 0.01 g., cooled in an ice-bath, samples withdrawn, and then reweighed to get weight of sample. In this way the loss of ether by evaporation was at a minimum. Each sample was hydrolyzed with excess standard nitric acid and then back-titrated using sodium hydroxide and methyl orange indicator. This gave the equivalents of R present. Then eosin and dextrin were added to the neutral or slightly basic sample and the total halogen was titrated with standard silver nitrate. The equivalents of magnesium were then equal to the sum of R and X, where R is the alkyl group and X the halogen. In many cases this was confirmed by determining the magnesium separately as the pyrophosphate.

Results.—The only Grignards tried were ethylmagnesium bromide, *n*-butylmagnesium bromide and phenylmagnesium bromide. The ethylmagnesium bromide was found to be unsuitable for transference study as the tabulated results of Table I show. There was a considerable transport of matter to the anode portion, indicating a large, mobile anion. Since the cathode portion did not gain by transport, it became more dilute and solute diffused from the middle portion into the cathode portion. Hence a true middle portion could not be obtained. This difficulty could have been avoided by using a vertical transference cell with the cathode on top and the anode on the bottom so that diffusion to the cathode would be prevented by gravity. However, instead of changing the cell, the Grignard reagent was changed, one being chosen that would possess a larger, heavier alkyl radical both to slow down the anion and to decrease its coördinating power by virtue of its

bulk. *n*-Butylmagnesium bromide was selected and as the data of Table II show, fairly good results were obtained. The total loss of R agreed with the number of faradays passed through the cell to within one or two milliequivalents, excellent agreement considering the great reactivity of the RMgX compounds and the volatility of the solvent. Other workers have previously shown that for the aliphatic Grignards one equivalent of magnesium is plated out per faraday of electricity.[6] It was also known that the amount of gaseous hydrocarbons formed in the electrolysis of simple aliphatic Grignards corresponds closely to 100% current efficiency.[7] All calculations were made on a weight basis making due allowance for the weight of solution due to the solute.

Although the data of Table II are not suitable for quantitative calculations, a number of interesting observations can be made from them:

1. All of the losses occur in the cathode portion. The anode portion shows a gain in solute at all times even after losing an equivalent amount of R by electrolysis.

2. The relative amounts of R and X gained by the anode portion are not constant but depend upon the ratio of R to X in the original solution, that is, upon the concentration of MgX_2 present. When the MgX_2 concentration is low, R_2Mg or RMgX is transported to the anode so that the anode gains in R. When the MgX_2 concentration is high, MgX_2 is transported to the anode and the anode gains in X.

(6) Konduirev, *J. Russ. Phys.-Chem. Soc.*, **60**, 545 (1928).

(7) Braithwaite, Ph.D. Thesis, Northwestern University, 1940.

3. The net migration of magnesium to the anode shows that it is present in the anion as well as in the cation.

4. The cathode losses show that MgX_2 is always gained since the loss of R is always greater than the loss of X. However, this gain is probably due to two factors, a real gain in MgX_2 as a product of electrolysis and an apparent gain in MgX_2 because of the loss of R_2Mg from the cathode portion by transference.

The behavior of phenylmagnesium bromide in a transference cell is unusual. After several hours of running all of the Grignard reagent settles out at the anode and the cathode, leaving a clear supernatant liquid that has no RMgX in it and only a little MgX_2. This appears to be an electrophoretic effect. The colloidal nature of the aromatic Grignards is further shown by the dark color of their ether solutions and their pronounced Tyndall effect. The aliphatic C_2H_5MgBr and *n*-C_4H_9MgBr solutions were water white, optically clear liquids after settling and filtering through glass wool. The conclusion is that while the aliphatic Grignards form true solutions, the aromatic Grignards are in part colloidal. The difference may be due to the greater coördinating power of the benzene ring. Benzene, for example, forms complexes with aluminum chloride.[8] With ions for nuclei, large complexes could be formed in ether, so large as to be of colloidal dimensions. This colloidal nature does not affect the reactivity of the aromatic Grignards, which behave in general like the aliphatic Grignards in synthesis. Nor is the molecular weight as measured by boiling point rise any different from the aliphatics, both C_6H_5MgBr and C_2H_5MgBr being approximately $(RMgX)_2$ in half molar solution.[9] Presumably because of the low ionic concentration only a small percentage of the Grignard molecules are involved in the colloidal complexes. In an electrolysis, however, as the ions were continuously discharged leaving the rest of the particle neutral and free to settle out, more ions would form and new complexes build up until the solution was exhausted of ArMgX.

Conductance Data

The conductances of several Grignards in ethyl ether have been reported.[10] The form of

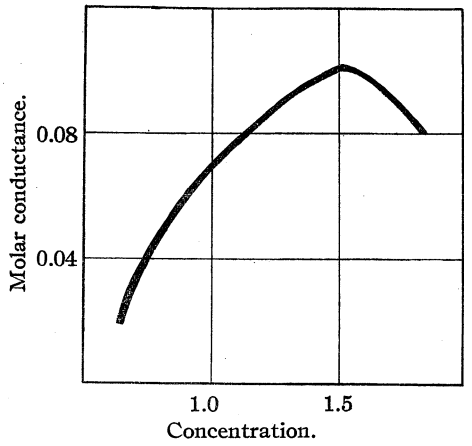

Fig. 1.—Molar conductance of ethylmagnesium iodide plotted against molar concentration.

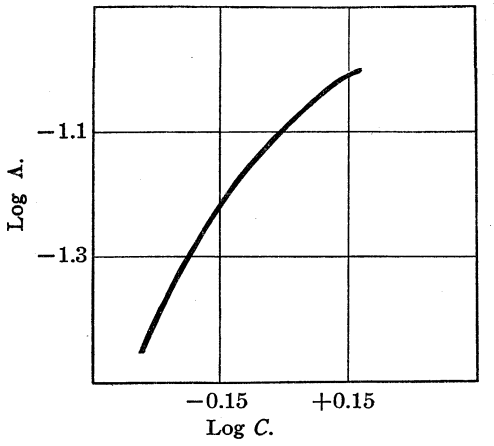

Fig. 2.—Log molar conductance of ethylmagnesium iodide plotted against log molar concentration.

the conductance–concentration curves for ethyl magnesium iodide is shown in Fig. 1. The molar conductance increases rapidly with the concentration, a general phenomenon in solvents of low dielectric constant. A maximum is reached at about 1.5 molar concentration, then the molar conductance falls off rapidly. This decrease in conductance is not surprising since the solvent is no longer ether but is 30% MgX_2 and RMgX by weight. In addition to changes in the dielectric constant and nature of the medium, the viscosity has changed from that of a mobile liquid to a sirupy solution. The great decrease in conductance could be explained by the change in viscosity alone. If the log of the molar conductance is plotted against the log of the concentration up to 1.5 molar, a curve is obtained (Fig. 2) that is not a straight line but falls off as log c increases. The slope of the straightest portion of the curve varies from 0.75 to 1.5. The interpretation of this according to the Kraus–Fuoss theory of multiple ions[11] is that the over-all formula for the ionization involves not one molecule of RMgX but from three to five. Accordingly, the ions formed are not simple but complex. This is in accordance with the size of the ions as indicated by the transference studies of ethylmagnesium bromide, where several times as many equivalents of R and X are transported as faradays of electricity are used.

Measurement of the gross conductance of RMgX does not give any information as to the contribution to the total of the conductances of R_2Mg, MgX_2, and RMgX. Consequently the conductances of several organometallic compounds in ether have been measured and compared with the conductance of ethylmagnesium bromide and magnesium bromide in ether. The results are included in Table III and for comparison the amounts of ionic character in the various bonds as calculated from the electronegativities of the elements according to the method of Pauling[12] are also presented. There is good agreement between the specific conductance and the amount of ionic character expected for each bond. The prediction of almost as much ionic character in the C-Mg bond as in the Mg-Br bond as predicted by Pauling's table of electronegativities is confirmed by the fair conductance of magnesium diethyl, prepared by the method of Noller.[13]

TABLE III

SPECIFIC CONDUCTANCE OF HALF MOLAR SOLUTIONS IN ETHYL ETHER AT 20°

		Bond	% Ionic character
$MgBr_2$	2.0×10^{-5}		
C_2H_5MgBr	1.6×10^{-5}	Mg-Br	47
$(C_2H_5)_2Mg$	1.0×10^{-5}	Mg-C	34
$(C_2H_5)_2Zn$	5×10^{-6}	Zn-C	24
$(C_2H_5)_2Hg$	0	Hg-C	10

A specific conductance of zinc diethyl in ether was reported as 10^{-4} by Rodebush.[14] The conductance of a half molar solution is somewhat less than this. The conductance of magnesium bromide at half molar concentration was extrapolated from lower concentrations since the limiting solubility of $MgBr_2$ in ether alone is only 0.15 molar.[10a] The presence of RMgX greatly increases the solubility of MgX_2 in ether as was

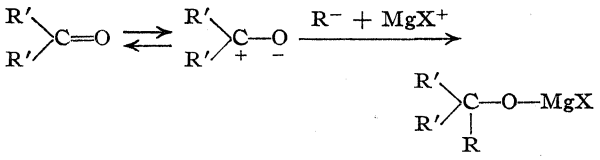
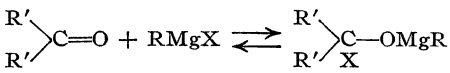
shown by Doering and Noller.[15] The actual concentration of MgX_2 in the Grignard solution may easily be half molar or above depending on the total concentration of RMgX. The total conductance of a Grignard is then due to the ionization of R_2Mg, MgX_2, and RMgX, with the R_2Mg contributing almost as much as the MgX_2. The conductance of RMgX alone cannot be measured since disproportionation to R_2Mg and MgX_2 always occurs. However, it seems reasonable to believe that the molar conductance of RMgX lies between those of R_2Mg and MgX_2 and that the ionic character of one bond does not greatly affect the ionic character of another bond in the same molecule.

Chemical Evidence

In the majority of its reactions the Grignard reagent behaves as an R^- anion and a MgX^+ cation. The anion with its unshared pair of electrons goes on an atom with an open sextet and the cation adds on to an atom with an unshared pair of electrons. The reaction with a ketone may be taken as illustrative



Instead of an atom with an open sextet, an ionizable hydrogen may furnish the necessary orbital for the unshared pair of the anion which in this sense acts as a base. The hydrogen ion may come from OH, NH, SH, or activated CH. The behavior of the Grignard reagent in enolization and condensation is due to this reaction. The reducing effect of Grignard reagents is particularly noticed in the case of highly branched R^- anions and branched chain carbonyl compounds.[16] Here, due to steric factors, a hydride ion, H^-, adds to the carbonyl group, giving a reduction product and an olefin. In other cases, as in the reaction with allyl bromide, the R^- behaves like any other anion, pushing out the Br^- by the usual displacement reaction. In all of these cases the reaction is carried to completion by the irreversibility of the formation of the carbon–carbon or carbon–hydrogen bond. Because of this only the R^- seems to react. Actually the X^- must be undergoing the same reactions but to a lesser degree because of the lower basicity of the halide ion as compared with an alkide ion



But in such cases the reaction is readily reversible because of the lability of the carbon halogen bond alpha to an oxygen atom. Similarly, if HX were formed from an ionizable hydrogen, it would react further to give RH. In cases where the carbon–halogen bond is not easily broken, stable halogenated products can be formed from the Grignard reagents or simply magnesium halide in ether. For example, ethylene oxide reacts with RMgX to give both RCH_2CH_2OH and XCH_2CH_2OH.[17]

The nature and extent of the reaction $2RMgX \rightarrow R_2Mg + MgX_2$ has been the subject of numerous papers.[18] It has been shown that the dioxane precipitation of the halogen compounds does not give true values for the position of equilibrium nor for the time necessary to reach equilibrium.[19] Some speculation can be made on the subject with the aid of a study on a related reaction, the exchange between anhydrous zinc chloride and ethylmagnesium bromide in ether. When equal volumes of molar solutions of these two substances were mixed, white fumes of zinc oxide were given off immediately and a precipitate of magnesium chloride and ethylmagnesium chloride was formed. The fuming is typical of organo-zinc compounds. The mixture was treated with dioxane at once to precipitate all the halogen and then centrifuged. The clear solution, free from halogen, was analyzed for zinc and magnesium. It was found that 95% of the ethyl radical present was zinc diethyl and less than 5% was magnesium diethyl. Allowing the solution to stand overnight before precipitating with dioxane did not change the per cent. conversion from RMgX to R_2Zn. The exchange was evidently instantaneous. Reasoning by analogy, if MgX_2 were added to a solution containing R_2Mg the exchange would be instantaneous and equilibrium reached in a very short time. Such rapid reaction in a solution of as low dielectric constant as ether cannot proceed by a purely ionic mechanism since the concentration of ions is

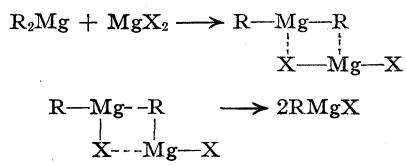
probably too small. The most likely method is a collision leading to an association of these highly polar molecules and a dissociation with the groups interchanged.



The ease with which the groups are lost by one atom and gained by another suggests strongly that primarily ionic linkages are involved and that the molecules can be considered to a first approximation as being simply ion pairs held together by coulombic forces. This is not strictly true, of course, since the physical properties, especially of R_2Mg, suggest a considerable amount of covalent character in the bonds. There is, unfortunately, no direct evidence as to the position of equilibrium above, but if the undissociated molecules are considered as ion pairs, it seems likely that only statistical factors will determine the relative numbers of R_2Mg, MgX_2 and RMgX molecules. In such case the equilibrium constant $K = [R_2Mg][MgX_2]/[RMgX]^2$ should be unity. Actually the constants calculated by the dioxane method are of this order of magnitude for most Grignards. The dioxane constants cannot be regarded as more accurate than an order of magnitude since undoubtedly as the least soluble component, presumably MgX_2, is precipitated first the reaction is dragged to the direction that causes the formation of more MgX_2. The chloride always gives a greater percentage of R_2Mg than the bromide, and the bromide gives a greater percentage of R_2Mg than the iodide.[18b] This is the same order as increasing solubility of the magnesium halides. The iodide should give the most nearly correct results, though even here the values are doubtful because the concentration of R_2Mg changes with rate of addition of the dioxane and the time and intimacy of contact of the mother liquor with the precipitate.[19] That the yields of R_2Mg are increased by shaking the precipitate with the mother liquor indicates that R_2Mg is coprecipitated with the halogenated compounds to a considerable extent. Since the Grignard reagents are undoubtedly associated, such coprecipitation is not surprising and invalidates the quantitative value of the dioxane precipitation as a means of comparing various Grignard reagents.

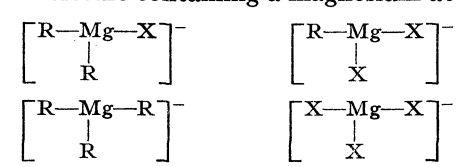
Discussion

Taking into account the foregoing evidence, a fairly lucid picture of the ionization and electrode reactions of the aliphatic Grignard reagents in ethyl ether can now be given. The specific properties of the four types of molecules present must be first taken into account. The ether molecule is strictly an electron donor molecule by virtue of the unshared pairs on the oxygen atom. The R_2Mg, RMgX and MgX_2 molecules are all acceptor molecules because of the two stable unfilled orbitals of the magnesium atom. The RMgX and MgX_2 molecules are also donor molecules because of the unshared pairs of the halogen atoms, but the donor power of a halogen atom is much less than that of oxygen atoms. The following ionic ruptures undoubtedly all occur

$$RMgX \rightleftharpoons R^- + MgX^+ \text{ or } X^- + RMg^+$$
$$R_2Mg \rightleftharpoons R^- + RMg^+$$
$$MgX_2 \rightleftharpoons X^- + MgX^+$$

The presence of Mg^{++} is unlikely in view of the low dielectric constant of the medium. As is true in any solution, ionization only occurs because the energy of solvation is great enough to overcome the coulombic attraction. The positively charged cation must be strongly solvated by the ether molecules. Since the cation MgX^+ has at least three stable orbitals, more than one molecule of ether is coördinated with it. This is of importance in determining the mobility of the cation since it eliminates the possibility of its jumping from one ether molecule to the next and possessing a high mobility analogous to the proton in water solution.

The anion having an unshared pair of electrons is but weakly attracted to the ether molecules, or repelled, and is coördinated instead with an acceptor molecule containing a magnesium atom



It is unlikely that the process stops at this point since the negative charge makes the anion a stronger base than the ether molecule. Consequently the ether molecules are displaced from other magnesium atoms and an anion involving several molecules of RMgX or R_2Mg or MgX_2 may be built up. This is in accordance with the conductance data in that several molecules of Grignard are necessary for the ionization re-

action to occur. We have then a small, highly solvated cation which is not mobile because of its attraction for the solvent and a large anion which is mobile because it has little attraction for the electron donating solvent. This is in accordance with the transference data where, especially with ethylmagnesium bromide, there is a large transference of matter to the anode. Even with the butylmagnesium bromide there are more equivalents of R plus X transferred to the anode than faradays of electricity used. More R is transferred to the anode than X, probably because R_2Mg is a better electron acceptor than MgX_2 and coördinates with the anion more readily. If the MgX_2 concentration is high, however, more of it is carried to the anode in place of R_2Mg, since the concentration of the latter must be small and the difference in concentration balances the difference in acceptor power.

The cation upon reaching the electrode is discharged to give an RMg· or MgX· free radical which reacts in pairs to give magnesium plus MgX_2 or R_2Mg

$$2RMg^+ + 2e^- \longrightarrow Mg + R_2Mg$$
$$2MgX^+ + 2e^- \longrightarrow Mg + MgX_2$$

The anion upon reaching the electrode is discharged in such a way that the R or X group having the lowest discharge potential is liberated as a free atom or radical. In the case of the aliphatic Grignards, and the aromatic Grignards at low current density, the R group is most easily discharged[2]

$$R_2MgX^- \longrightarrow R\cdot + RMgX + e^-$$
$$\text{or } R_3Mg^- \longrightarrow R\cdot + R_2Mg + e^-$$
$$\text{or } RMgX_2^- \longrightarrow R\cdot + MgX_2 + e^-$$

However, under certain circumstances the halide ion may be discharged

$$R_2MgX^- \longrightarrow X\cdot + R_2Mg + e^-$$
$$\text{or } MgX_3^- \longrightarrow X\cdot + MgX_2 + e^-$$
$$\text{or } RMgX_2^- \longrightarrow X\cdot + RMgX + e^-$$

The following series of reactions would then occur

$$2X\cdot \longrightarrow X_2$$
$$X_2 + RMgX \longrightarrow RX + MgX_2$$
$$RX + Mg \longrightarrow RMgX$$

In the electrolysis of phenylmagnesium bromide, for example, it was shown that bromobenzene formed at the anode and, unless prevented from diffusion, would migrate to the cathode and react with the magnesium plated out there.[2] That the halogen molecule is an intermediate is shown by the electrolysis of phenethinylmagnesium iodide, $C_6H_5C{\equiv}C{-}MgI$. In this electrolysis the $C_6H_5{-}C{\equiv}C^-$ ion is not discharged but the iodide ion is. Since iodine reacts only slowly with this particular Grignard, a mass of crystalline iodine collects upon the anode and can be readily identified.

The discharge of halogen instead of the alkyl or aryl radical is favored by several factors: high electronegativity of the radical, low electronegativity of the halogen, and high voltages. Aryl radicals are more electronegative than alkyl radicals and the electrolysis of aromatic Grignards gives current efficiencies, based upon the amount of hydrocarbons formed, that are very much lower than for the aliphatic Grignards.[2] Among the several halogens the order of increasing current efficiency is iodide, bromide, and chloride in accordance with increasing decomposition potentials for these ions.[20] High voltages favor the release of halogen and lower the current efficiency because a saturation current due to anions containing the alkyl or aryl group is reached. Anions such as MgX_3^- are then discharged because the source of more easily discharged ions is momentarily exhausted.

The necessity for having both electron donors and electron acceptors present to promote ionization in solutions of low dielectric constant is shown by several other organo-metallic compounds in solution. Zinc diethyl and magnesium diethyl etherate are non-conductors in benzene, while magnesium bromide etherate and ethylmagnesium bromide etherate in benzene conduct fairly well.[21] The explanation is in the low electron donating power of benzene compared to ether which leaves the zinc and magnesium diethyl with no means of solvating the cation. Magnesium bromide and ethylmagnesium bromide have the halogen atom to serve as electron donor and coordinate the cation. Zinc diethyl by itself is known to be a non-conductor, but in ether it conducts because the ether solvates the RZn^+ cation. Sodium ethyl conducts in zinc diethyl and Hein showed that the anion was $Zn(C_2H_5)_3^-$ with the zinc atom acting as the acceptor molecule.[22] There is no molecule present to solvate the sodium ion, but solvation other than that furnished by the negative end of the zinc–carbon dipole is not necessary for the sodium ion, which has a low coördinating power at all times. The organolithium compounds, C_2H_5Li, C_6H_5Li and n-C_4H_9Li in ethyl ether solution have been tested in this

(20) Evans and Field, THIS JOURNAL, **58**, 2284 (1936).
(21) Unpublished work in this Laboratory.

Laboratory and found to be non-conductors.[21] This non-conductance is due in part to a high amount of covalent character in the lithium–carbon bond as shown by the much lower conductance of lithium ethyl in zinc diethyl than the corresponding sodium and potassium compounds.[22] It is probably due more to the inability of the lithium atom to serve as an acceptor atom for the unshared pair of the alkide ion in comparison with the high coördinating power of the zinc and magnesium atoms.

Summary

Transference studies of *n*-butylmagnesium bromide and ethylmagnesium bromide in ether are reported.

The conductances of magnesium diethyl and zinc diethyl in ether have been measured.

The exchange reaction between zinc chloride and ethylmagnesium bromide in ether has been found to be instantaneous.

From a consideration of all available data a theory is proposed for the ionization of the aliphatic Grignard reagents and for the electrode reactions in their electrolysis.

Both the halogen and the alkyl group can ionize. The cation is coördinated with ether and is small and slow. The anion is coördinated with RMgX, MgX_2 and R_2Mg and is large and mobile.

The importance of having both molecules with electron donor properties and molecules with electron acceptor properties to promote ionization in solvents of low dielectric strength is brought out.

The Stability of β-Methylmaltoside toward Hot Alkali

BY THOMAS JOHN SCHOCH, E. JUSTIN WILSON, JR., AND C. S. HUDSON

In connection with studies on the decomposition of starch in alkaline medium, it was desirable to establish whether the 1,4-α-glucosidic linkage is susceptible to direct hydrolytic scission by hot aqueous alkali. Evans and Benoy[1] have shown that the action of hot alkali upon maltose results primarily in a rapid enediol splitting. If this reaction could be prevented by blocking the aldehyde group against enolization, as in β-methylmaltoside, then any acids developed during hot alkali digestion could be attributed to direct hydrolysis of the disaccharide linkage, and subsequent enolic splitting of the former glucosido portion of the maltoside molecule. β-Methylglucoside is known to be fully resistant to hot aqueous alkali.

β-Methylmaltoside and calcium maltobionate have been so tested, by dissolving 0.5 g. in 100 ml. of 0.1 *N* sodium hydroxide, heating at 100° for one, two and five hour periods, and then back-titrating the unconsumed alkali. Except for the use of longer heating periods, the technique is identical with that described by Schoch and Jensen[2] for alkali number evaluation of starches; in their method the time of heating is one hour. Production of acidity is similarly expressed, as the number of milliliters of 0.1 *N* sodium hydroxide consumed per gram of carbohydrate. Each value in Table I represents the average of three to five determinations; blank runs (without carbohydrate) showed negligible loss of alkali. As an additional check on the results obtained, beta-methylcellobioside was tested in the same manner.

TABLE I

ALKALI CONSUMPTION AT 100°

Digestion time, hr.	β-Methyl-maltoside	β-Methyl-cellobioside	Calcium maltobionate	Calcium gluconate
1[a]	0.32 ± 0.04	0.10 ± 0.05	0.72 ± 0.06	0.76 ± 0.03
2	.24 ± .04	.13 ± .05	.99 ± .06	.93 ± .08
5	.16 ± .04	.08 ± .05	1.60 ± .09	1.78 ± .11

[a] Starches give alkali numbers of about 4 (waxy maize), 7 (potato) and 11 (corn).

Since the alkaline decomposition of 1 g. of anhydrous glucose consumes 85.2 ml. of 0.1 *N* sodium hydroxide,[2] it may be calculated that β-methylmaltoside hydrate and calcium maltobionate would consume 41.0 ml. and 40.7 ml., respectively, if the disaccharide bond were completely hydrolyzed. The very slight consumption by the two glycosides is barely detectable and is not progressive, which leads us to believe that it is caused by traces of impurities which recrys-

(1) Evans and Benoy, THIS JOURNAL, **52**, 294 (1930).
(2) Schoch and Jensen, *Ind. Eng. Chem., Anal. Ed.*, **12**, 531 (1940).

tallization failed to remove. From the experimental data we conclude that β-methylmaltoside may be regarded as stable against hot alkali; a similar conclusion applies to β-methylcellobioside, containing the 1,4-β-glucosido linkage. While calcium maltobionate undergoes a slight progressive decomposition, this is of the same order of magnitude as for calcium gluconate, and therefore cannot be attributed to glycosidic hydrolysis. In all probability this decomposition follows the mechanism previously given by Upson and co-workers[3] as accounting for the action of 4 *N* barium hydroxide at 140° upon the aldonic acids. The results are in agreement with the theory of alkaline oxidation of carbohydrates, as developed by Evans and his co-workers.

We assume from the present data, in agreement with Evans' views, that alkali attacks starch only at a terminal aldehydo glucose, and this must undergo enolic splitting before the second glucose can in turn be attacked. Admittedly, this does not take into account the possibility of linkages other than 1,4-α-glucosidic bonds, which might be susceptible to direct alkaline hydrolysis since definite data to the contrary are not known.

It seems worthy of mention that what is commonly called the 1,4-α-glycosidic linkage that is present in maltose is not precisely the 1,4-linkage that is postulated as the main linkage in the starch structure or in the Schardinger dextrins. If the linkage in maltose be used as a definition of the true 1,4-α-linkage, the attachment of a substituent glucose molecule to carbon atom 4 changes the type of this linkage in chains made up of glucose units. The change may have great effect upon the character of enzyme actions on starch, and an alteration of the speed of acid hydrolysis is a possibility.

Experimental Part

Calcium Maltobionate.—The calcium maltobionate here employed was prepared by the method of Glattfeld and Hanke,[4] with subsequent purification through the basic lime compound.[5] The product contained 7.53% calcium oxide; theory 7.43%.

β-Methylcellobioside.—The heptaacetate of this substance was prepared according to the directions of Pacsu.[6] The β-methylcellobioside was obtained by deacetylation, using the method of Zemplén and Pacsu[7]; the substance melted at 190–193° (cor.) and rotated $[\alpha]^{20}D$ −19.7° in water (c = 3), in agreement with recorded values.[8]

Improved Preparation of β-Methylmaltoside.—Previously, β-methylmaltoside has been obtained in pure form only with considerable difficulty and in low yields.[9] The following procedure has been found to give readily excellent yields of the pure crystalline substance. Thirty grams of β-octaacetylmaltose (m. p. 157–159°) was converted to acetobromomaltose by the method of Brauns.[10] The resulting sirup was dissolved with gentle warming in 400 ml. of absolute methanol and the solution shaken with 20 g. of silver carbonate. It was then heated under reflux for one hour, filtered through Darco, and concentrated *in vacuo*. Fine needles separated on cooling; one recrystallization from absolute ethanol gave 20.6 g. of nearly pure heptaacetyl-β-methylmaltoside, melting at 126–128.5° as compared with the recorded value of 128–129° for the pure substance.[9] Deacetylation was effected by the procedure of Zemplén and Pacsu.[7] Twenty grams of the heptaacetate was dissolved in 120 ml. of absolute methanol, and the solution was boiled for one hour with 5 ml. of 0.2 *N* sodium methylate. The slight yellow color was removed by filtration with Darco, and the filtrate evaporated to dryness *in vacuo*. The resulting sirup was taken up in hot 95% ethanol, and the product crystallized as long needles on cooling. The yield was 10.8 g. (94%), melting at 111–113° (cor.), with $[\alpha]^{20}D$ +84.6° in water (c = 1.7) as compared with the recorded m. p. of 110–111° and $[\alpha]_D$ of +83.9° in water (c = 1).[9] Recrystallization gave no further change in the constants. The product was isolated as the monohydrate.

One of the authors (E. J. W., Jr.) expresses his thanks to the Corn Industries Research Foundation for a fellowship.

Summary

The 1,4-α-glucosidic linkages in β-methylmaltoside and calcium maltobionate do not undergo direct hydrolysis in hot alkali. The 1,4-β-glucosidic linkage in β-methylcellobioside is likewise stable to alkali.

It appears probable that alkali can attack starch only at the terminal aldehydo glucose, which must undergo enolic splitting before the second glucose can in turn be attacked. The present results agree with Evans' views on the degradation of starch by alkali.

Some Allyl Nitrophenyl Thiosemicarbazides and their Analytical Properties

BY ALFRED W. SCOTT AND J. T. ANDREWS[1]

Thiosemicarbazide and allyl groups have been present in a number of organic compounds which gave precipitates or color reactions with aqueous solutions of certain inorganic cations. While these groups together would appear to be the reactive part of the compound, both the selectivity and sensitivity of the reagent would seem to be affected by the constitution of the remainder of the molecule.

The purpose of this investigation was to study the effect on the selectivity and sensitivity of a related series of reagents which contained both the thiosemicarbazide and allyl groups. For this purpose 1-allyl-4-phenyl thiosemicarbazide[2,3] was selected as the reference compound and a nitro group was successively introduced into the phenyl group in the ortho, meta and para positions. In addition to the selectivity and sensitivity possibilities mentioned above, the results of a study of this series of compounds might add to our information upon the effect of ortho, meta and para substitution in organic analytical reagents.

Distilled water solutions (0.1 *N*) of the metallic nitrates of most of the cations usually encountered in elementary qualitative analysis were tested. Each of the four reagents gave tests with silver, mercurous, mercuric and copper ions. Therefore, the nitro group had no effect upon the selectivity of the reactive group. The sensitivity of the four reagents, however, varied widely. The para nitro compound was by far the most sensitive in every instance, and the ortho nitro compound was next, while the meta nitro compound and the reagent without any nitro group present, were found to be the least sensitive and about equally poor.

1-Allyl-4-(*p*-nitrophenyl) thiosemicarbazide gave a red precipitate upon standing with mercuric mercury solutions of one part in a million and a slight color reaction with one part in ten million. Several attempts were made to use this reagent in a gravimetric quantitative determination of mercury, but the results obtained were unsatisfactory.

(3) Avernarius, *Ber.*, **24**, 268 (1891).

Experimental

1-Allyl-4-phenyl thiosemicarbazide was prepared according to Avernarius.[2,3] It melted at 119° (uncor.) and agreed in all other respects to the compound described in the literature. An excess of the compound was added to water, heated to 90°, agitated for some time, and allowed to cool to 25°. Ten ml. of this saturated solution was pipetted into a tared dish, evaporated and dried in an oven at 90° and weighed. The result in grams times ten was taken as the water solubility of the compound in 100 ml. of water. Duplicate results gave the solubility as 0.118 g. at 25°. An alcoholic solution of the compound added to aqueous solutions of the cations gave a white precipitate with silver, a gray precipitate with mercurous mercury, a yellow precipitate with mercuric mercury, and a blue color with copper.

1-Allyl-4-(*o*-nitrophenyl) thiosemicarbazide was prepared according to Guha.[4] The purified needles melted at 166° (uncor.). There was 0.029 g. found to be soluble in 100 ml. of water at 25°. An alcoholic solution of the compound added to aqueous solutions of the cations gave orange precipitates with both mercurous and mercuric mercury, a red precipitate with silver, and a green precipitate with copper.

1-Allyl-4-(*m*-nitrophenyl) Thiosemicarbazide.—To an alcohol solution of 10 g. of *m*-nitrophenylhydrazine was added 7 g. of allyl isothiocyanate. This solution was heated for five minutes and allowed to cool. The thick oil which separated was dissolved in hot 50% alcohol and allowed to cool. The yellow crystals obtained were soluble in acetone, bases (turning orange red), and very slightly soluble in water. Their m. p. was 120° (uncor.). The yield was 90% of the theoretical.

Anal. Calcd. for $C_{10}H_{12}N_4O_2S$: N, 22.21; S, 12.71. Found: N, 22.14; S, 12.63.

The solubility in 100 ml. of water at 25° was 0.033 g. An alcoholic solution of the compound added to aqueous solutions of the cations gave a cream colored precipitate with silver, a grayish-black precipitate with both mercurous and mercuric mercury, and a blue color with copper. It was not very sensitive with any of these.

1-Allyl-4-(*p*-nitrophenyl) Thiosemicarbazide.—To a solution of 8 g. of *p*-nitrophenylhydrazine dissolved in 95% alcohol was added 4.6 g. of allyl isothiocyanate. This mixture was heated for five minutes and allowed to cool. The yellow needles obtained were recrystallized from 95% alcohol until pure. They were very soluble in acetone, soluble in alcohol, slightly soluble in water and soluble in bases (turning a red color). At 25°, 3.273 g. of the compound was soluble in 100 ml. of 95% alcohol. At 25°, 0.031 g. of the compound was soluble in 100 ml. of water. The compound melted at 188° (uncor.), with some decomposition. The yield was 76% of the theoretical.

TABLE I

Concn., γ/l. (mcg.)	Reagent A	Reagent B	Reagent C
		Sensitivity for Cu^{++}	
1×10^7	Dark blue color	Black-green ppt.	Black ppt.
1×10^6	Blue color	Black-green some ppt.	Black-green ppt.
1×10^5	Blue color	Dark green colored soln.	Gray ppt.
1×10^4	Blue color	Light green color	Brown-red color, brown ppt. after standing
1×10^3	Slight blue color	No reaction	Very slight color
		Sensitivity for Ag^+	
1×10^7		Brown ppt.	Orange ppt.
1×10^6		Brown-purple ppt.	Orange-red ppt.
1×10^5		Purple ppt.	Crimson ppt.
1×10^4		No color or ppt.	Light red soln., ppt. after standing
1×10^3		No reaction	Slight color
		Sensitivity for Hg^{++}	
1×10^7		Yellow ppt.	Orange ppt.
1×10^6		Red ppt.	Red ppt.
1×10^5		Purple red ppt.	Red ppt.
1×10^4		Red color	Red ppt.
1×10^3		Slight color	Some ppt. after standing
2.5×10^2		No reaction	Red color that can be seen clearly
1×10^2		No reaction	Slight change in color

Anal. Calcd. for $C_{10}H_{12}N_4O_2S$: N, 22.21; S, 12.71. Found: N, 22.26; S, 12.66.

An alcoholic solution of the compound when added to aqueous solutions of the cations gave an orange precipitate with both mercurous and mercuric mercury, a red precipitate with silver, and a dark green precipitate with copper.

Sensitivities.—The tests for the sensitivities of the compounds were made in the following way. A solution containing 1×10^7 mcg. per liter of the ion to be tested was prepared and diluted to other concentrations in volumetric flasks. A saturated alcohol solution of each reagent was used in the tests. When eight drops of this alcohol solution of the reagent were added to five ml. of water or to five ml. of dilute nitric acid, and allowed to stand overnight, no precipitation resulted. When eight drops of the reagent were added to 5 ml. of concentrated nitric acid and allowed to stand overnight, a slight precipitation occurred. The sensitivity of 1-allyl-4-(*m*-nitrophenyl) thiosemicarbazide was not determined since it affected the mercurous, mercuric, silver and copper ions in fairly concentrated solutions only. For the same reason, the sensitivity of 1-allyl-4-phenyl thiosemicarbazide (Reagent A) was only tested for copper. The sensitivities of 1-allyl-4-(*o*-nitrophenyl) thiosemicarbazide (Reagent B) and 1-allyl-4-(*p*-nitrophenyl) thiosemicarbazide (Reagent C) are shown in the table.

Summary

1. Neither the presence of a nitro group, nor its position, affected the selectivity of the reactive group, but did materially affect the sensitivity of the compounds.

2. 1-Allyl-4-(*p*-nitrophenyl) thiosemicarbazide is a very sensitive reagent for mercuric mercury.

ATHENS, GA. RECEIVED APRIL 21, 1942

Mechanism of the Reaction between Hindered Carbonyl Compounds and the Grignard Reagent. II[1]

BY RICHARD T. ARNOLD AND R. WINSTON LIGGETT[2]

In the first paper of this series[1] it was shown that esters of the type $R-C(=O)-O-R'$ are cleaved abnormally by the Grignard reagent if in R— there are substituents which sterically hinder additions to the carbonyl group of the ester, and if R'— is of such a nature that it has considerable thermodynamic stability as a cation (R'+). The general reaction between such an ester and the Grignard reagent can be expressed by the equation

$$R-C(=O)-O-R' + R''MgX \longrightarrow R-C(=O)-O-MgX + R'R'' \quad (1)$$

If on the other hand, R'— has little tendency to form a cation and the group —OR' readily forms an anion (*i. e.*, Cl^-, $-OC_6H_5$, or $R_1CO_2^-$) then an entirely different reaction takes place and ketones are produced[3,4,5,6]

$$R-C(=O)-O-R' + R''MgX \longrightarrow R-C(=O)-R'' + R'O-MgX \quad (2)$$

The present paper deals with a study of the cleavage reaction (Eq. 1). As indicated earlier,[1] when the magnitude of the steric factors about the carbonyl group is small, then simple allyl esters of carboxylic acids react normally with the Grignard reagent to produce tertiary alcohols.[7]

If the steric factors in R— are sufficiently great to prevent or decidedly inhibit the addition of R''MgX to the carbonyl group, then allyl esters react entirely according to Equation (1). Obviously there must be some point between these two extremes where the rates of the normal ester-Grignard reaction and the cleavage reaction are alike. This midpoint has now been roughly determined by a systematic study in which the steric effects in group R— have been varied over a wide range of values.

R = I = triphenylmethyl
II = diphenylmethylcarbinyl
III = 2,3-dimethylnaphthyl
IV = benzylethylmethylcarbinyl
V = 3-heptyl
VI = 3-pentyl
VII = cyclohexyl
VIII = 1-ethylcyclohexyl

The element of steric hindrance is pronounced enough when R = I, II, III, or IV that the corresponding allyl esters undergo complete cleavage with phenylmagnesium bromide. When R = V or VI, the cleavage and normal reactions proceed simultaneously and at comparable rates. The marked increase in steric properties observed when one passes from a methyl to an ethyl group is usually attributed to the large effective volume swept out by the freely rotating methyl component of the ethyl group. We have found additional confirmation for this explanation in the fact that when R = VII or VIII only the normal reaction takes place between the allyl esters and phenylmagnesium bromide. In these two cases, free rotation is prevented by the rigidity of the ring structures.

A later report will discuss the effects of changes in the nature of groups R' and R'' on the allyl ester–Grignard reaction.

Experimental

1-Bromo-2,3-dimethylnaphthalene.—To a cooled solution of 200 g. of 2,3-dimethylnaphthalene in 500 cc. of chloroform in an ice-bath, 215 g. of bromine in 200 cc. of carbon tetrachloride was added over a two-hour interval with stirring. After three additional hours at room temperature the solution was thoroughly washed with dilute alkali, the solvent distilled off and the residue crystallized from 400 cc. of hot ethanol; yield, 250 g.; m. p. 62–63°; after recrystallization, m. p. 63–64°.

Anal. Calcd. for $C_{12}H_{11}Br$: C, 61.3; H, 4.72. Found: C, 60.4; H, 4.72.

2,3-Dimethyl-1-naphthoic Acid.—Fifty-seven grams of 1-bromo-2,3-dimethylnaphthalene in 150 cc. of ether was converted to the Grignard reagent with 11.8 g. of magnesium and two drops of ethylmagnesium bromide solution. Carbonation was effected by dropping the Grignard solution slowly into dry ether through which passed a vigorous stream of anhydrous carbon dioxide. After

(6) Fuson, Corse and Rabjohn, *ibid.*, **63**, 2852 (1941).
(7) The one general exception to this rule is the case in which group R' has an extreme tendency to form a cation (*i. e.*, triphenylmethyl acetate); here only cleavage occurs [Fieser and Heymann, THIS JOURNAL, **64**, 376 (1942)].

decomposition there was obtained 36–40 g. of crude acid. Recrystallization from methanol–water mixtures gave a product melting at 167–168°.

Anal. Calcd. for $C_{13}H_{12}O_2$: C, 78.0; H, 6.04. Found: C, 77.4; H, 6.13.

Allyl 2,3-Dimethyl-1-naphthoate.—Fifty grams of 2,3-dimethyl-1-naphthoic acid was treated with a sodium ethoxide solution prepared from 6 g. of sodium and 100 cc. of ethanol. The alcohol was removed by vacuum distillation and to the residue was added 32 cc. of allyl bromide in 200 cc. of xylene. The mixture was effectively stirred at the reflux temperature for eight hours. Extraction of the xylene solution with dilute alkali followed by drying and fractionation gave 37.5 g. of ester; b. p. 155–160° (2 mm.). The distillate was taken up in low boiling petroleum ether and cooled. The ester appeared as a white solid; m. p. 33–34°.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.78; H, 6.70. Found: C, 79.79; H, 6.13.

Reaction of Allyl 2,3-Dimethyl-1-naphthoate with Phenylmagnesium Bromide.—The Grignard solution was prepared from 13.0 cc. of bromobenzene and 3.2 g. of magnesium in 75 cc. of ether. To this in one portion was added 15.1 g. of the crystalline ester dissolved in 50 cc. of ether. Refluxing was continued for two hours and the solution stood at room temperature for an additional twenty-four hours. Alkali extraction of the ether layer after decomposition yielded 12.2 g. of 2,3-dimethyl-1-naphthoic acid (97%). Fractionation of the ether layer gave 6 g. of allylbenzene (82.4%); b. p. 155–157°.

Allyl Triphenylacetate.—The anhydrous salt from 6.4 g. of triphenylacetic acid was heated under reflux for ten hours with 20 cc. of allyl bromide and 50 cc. of toluene. After filtration, the toluene was removed by distillation and the oily residue taken up in ether and extracted with dilute alkali. Evaporation of the ether solution gave a solid ester which on recrystallization from alcohol melted at 85–85.5°.

Anal. Calcd. for $C_{23}H_{20}O_2$: C, 84.14; H, 6.14. Found: C, 84.18; H, 6.16.

Cleavage of Allyl Triphenylacetate.—To a solution of phenylmagnesium bromide prepared from 2.6 g. of bromobenzene was added 3.8 g. of the ester dissolved in 50 cc. of ether. After standing overnight the solution was decomposed with dilute hydrochloric acid in the usual way. There was obtained 3.1 g. (93%) of triphenylacetic acid.

Ethyl Benzylmethylethylacetate.—The enolate of ethyl methylethylacetate was formed by the use of triphenylmethylsodium according to the procedure of Hudson and Hauser.[8] Because of the unexpected violent reaction which ensued during the benzylation with benzyl bromide, a slight accident occurred and only 44.5 g. of ethyl benzylmethylethylacetate was obtained from 61 g. of the starting ester. The product boiled at 127–130° (9–10 mm.).

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15. Found: C, 76.47; H, 9.12.

Allyl Benzylmethylethylacetate.—The ethyl ester (28 g.) was saponified by refluxing for ten hours with 25 g. of potassium hydroxide in 50 cc. of absolute alcohol. After adding 250 cc. of water and extracting with ether, the aqueous solution was neutralized to congo red with hydrochloric acid. The free acid was extracted with ether and purified by distillation; yield 24 g. From this acid the anhydrous sodium salt was prepared with sodium ethoxide and converted to the ester by heating with 20 cc. of allyl bromide and 150 cc. of xylene for ten hours. The allyl ester weighed 23 g. (80%) and distilled at 139–140° (8 mm.).

Anal. Calcd. for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68. Found: C, 77.66; H, 8.51.

Cleavage of Allyl Benzylmethylethylacetate.—The ester (20 g.) was added in one portion to a Grignard solution prepared from 21 cc. of bromobenzene in the usual manner. After an induction period of a few minutes the reaction became quite violent and had to be cooled periodically. The reaction mixture was decomposed after standing two hours with dilute hydrochloric acid. There was obtained 14.5 g. (87%) of benzylmethylethylacetic acid and 7.0 g. (70%) of allylbenzene.

Allyl α,α-Diphenylpropionate.—Fifteen grams of α,α-diphenylpropionic acid[9] was converted to its sodium salt by treatment with 1.7 g. of sodium in 50 cc. of absolute ethanol. The ethanol was removed by distillation under diminished pressure, and the residual salt refluxed with allyl bromide (10 cc.) in 100 cc. of dry xylene for thirty hours. The ester (b. p. 175–177° (8 mm.)) was isolated in the usual manner.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.11; H, 6.82. Found: C, 81.19; H, 6.75.

Reaction of Phenylmagnesium Bromide with Allyl α,α-Diphenylpropionate.—To a Grignard solution prepared from 5.25 cc. of bromobenzene in 50 cc. of ether there was added 5.07 g. of the allyl ester in one portion. The solution was refluxed gently for four hours. After decomposition of the reaction mixture there was obtained 3.8 g. (88%) of α,α-diphenylpropionic acid.

Allyl 2-Ethylcaproate.—One hundred grams of commercial 2-ethylhexanal was placed in a large gas drying tower with a trace of manganese dioxide. Air was bubbled through vigorously for four hours at 90°. Basic extraction of the acid from the mixture and purification by distillation resulted in a yield of 58 g.; b. p. 118–120° (8–10 mm.). The acid was converted to the pure acid chloride; yield 56 g. To a solution of 50 g. of pyridine and 25 g. of allyl alcohol in 100 cc. of chloroform, the acid chloride dissolved in 50 cc. of chloroform was added slowly. The mixture was cooled at all times to prevent the temperature from rising above 15°. After addition, the solution was kept at 4° overnight.[10] The mixture was washed once with normal hydrochloric acid, twice with water, and then extracted with dilute sodium bicarbonate solution. The chloroform layer was dried and distilled. The allyl ester (45 g.) boiled at 79–79.5° (8 mm.).

Anal. Calcd. for $C_{11}H_{20}O_2$: C, 71.67; H, 10.94. Found: C, 71.44; H, 10.87.

Phenylmagnesium Bromide Reaction with Allyl 2-Ethylcaproate.—Treatment of the allyl ester (31.5 g.) with a Grignard solution prepared from 36.6 g. of bromobenzene in 100 cc. of ether yielded after decomposition 2-

ethylcaproic acid (30%), allylbenzene (26%) and a mixture recognized as carbinol (about 49%) containing the olefin as impurity.

Allyl Diethylacetate.—This ester was prepared from the dry sodium salt (from 160 g. of acid), allyl bromide and xylene as described above. The reflux time employed was forty-eight hours; yield 65 g.; b. p. 165–167°.

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.3; H, 10.3. Found: C, 69.9; H, 10.3.

Reaction of Allyl Diethylacetate with Phenylmagnesium Bromide.—The Grignard solution was prepared from 45 cc. of bromobenzene in 200 cc. of ether. To this was added slowly 25.3 g. of allyl diethylacetate in 50 cc. of ether. A violent reaction ensued and the mixture was decomposed after thirty minutes. There were obtained 4.5 g. of diethylacetic acid, 9.0 g. of allylbenzene, and 10.3 g. of carbinol boiling at 170–175° (8 mm.). The carbinol was identified by dehydration with formic acid to an olefin having the correct composition for 1,1-diphenyl-2-ethylbutene-1.

Anal. Calcd. for $C_{18}H_{20}$: C, 91.5; H, 8.5. Found: C, 91.3; H, 8.5.

Allyl Hexahydrobenzoate.—This ester was prepared from 50 g. of the acid chloride, 25 g. of allyl alcohol, 100 cc. of chloroform and 40 g. of pyridine by the method described above; yield 44 g.; b. p. 103–104° (18 mm.).

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.35; H, 9.58. Found: C, 71.15; H, 9.48.

Diphenylcyclohexylidenemethane.—Treatment of allyl hexahydrobenzoate with two moles of phenylmagnesium bromide in the usual manner gave a carbinol as the sole product. Dehydration of the carbinol with formic acid (85%) gave the expected olefin; m. p. 82–83°.[11]

Ethyl 1-Ethyl-2-ketocyclohexanecarboxylate.—Dry sodium ethoxide was prepared in xylene solution from sodium (13.5 g.) and ethanol. The excess ethanol was removed by distillation. To this suspension was added 100 g. of ethyl 2-ketocyclohexanecarboxylate in 100 cc. of xylene. After stirring at reflux temperature for three hours, 110 g. of ethyl benzenesulfonate was added and the mixture was refluxed for fifteen hours. The precipitate was filtered and the filtrate was carefully fractionated. The desired alkylated β-ketoester (86 g.) was obtained; b. p. 125–130° (15–18 mm.). Its semicarbazone melted at 156.5–157°.

Anal. Calcd. for $C_{12}H_{21}O_3N_3$: C, 56.44; H, 8.30. Found: C, 56.69; H, 8.05.

Allyl 1-Ethylcyclohexanecarboxylate.—As preliminary tests at each stage showed that purification of the intermediates was unnecessary and wasteful, the following series of reaction was carried out without purifying at each step. Forty-one grams of ethyl 1-ethyl-2-ketocyclohexanecarboxylate was reduced with Raney nickel at 175–200° and 2000 lb. pressure of hydrogen. The product after removing the catalyst was dissolved in dry benzene and 30 g. of phosphorus pentoxide was cautiously added. The solution was refluxed for two hours. The benzene solution was poured from the tarry residue and the solvent was removed; 25 g. of oil remained. The oil was reduced with Raney nickel at 150° and 1800 pounds pressure of hydrogen. The reduced material (12 g.) distilled at 100–110° (10–15 mm.). Saponification with methanolic potassium hydroxide yielded 7.5 g. of crude acid. This was converted through its acid chloride and allyl alcohol to the allyl ester; yield 4.7 g.; b. p. 97–98° (8 mm.).

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.4; H, 10.3. Found: C, 73.4; H, 10.7.

Reaction of Allyl 1-Ethylcyclohexanecarboxylate with Phenylmagnesium Bromide.—A Grignard solution (30 cc.) prepared from 5 cc. of bromobenzene was treated with 3 g. of the allyl ester. A rather violent reaction ensued and after standing overnight the mixture was decomposed with dilute acid. No fatty acid or allylbenzene could be detected. The highly viscous product was obviously the normally expected carbinol.

Summary

1. A number of allyl esters have been prepared which have varying degrees of steric hindrance about the carbonyl group.

2. It has been shown that the magnitude of these steric factors determines very largely whether the allyl esters are cleaved by the Grignard reagent or undergo the well-known reaction to produce tertiary alcohols.

Preparation of Mixed, Secondary Aliphatic Amines, RR'NH[1,2]

BY HENRY R. HENZE AND DAVID D. HUMPHREYS[3]

In connection with a program of synthesis of pharmaceutical products, a number of mixed, secondary amines were needed. Compounds of the type HNRR' in which one group is aryl and the other alkyl are obtainable fairly readily by standard methods of synthesis, but those possessing two different alkyls are not so easily obtained. For production of this type three methods, perhaps, are used more commonly.

(1) The Hinsberg[4] method leads to the preparation of a pure mixed secondary amine but the procedure is somewhat involved, is not rapid and frequently the over-all yield is low.

(2) Stepwise alkylation of aniline with a subsequent nitrosation and alkaline hydrolysis[5] leads to the formation of a mixed, secondary amine in a state of purity dependent upon that of the mixed dialkyl aniline used.

(3) Interaction of a primary amine and a carbonyl compound with subsequent reduction of the imine.

(a) Reduction by means of sodium and alcohol[6] requires a separation and purification of the imine with a consequent loss of time and product.

(b) As reported by Skita and Keil,[7] reduction with colloidal platinum and hydrogen at room temperature and three atmospheres pressure for two to three hours produced, in satisfactory yield, several secondary amines of carbon content between C_9 and C_{15}.

(c) Mailhe[8] stated that catalytic reduction of the imine derived from isovaleraldehyde and ethylamine, by passing its vapors over finely divided nickel in the presence of hydrogen at a temperature of 190–200°, yielded N-ethyl-isoamylamine as the principal product together with some diethylamine and triethylamine.

In all probability the infrequency of reference in the chemical literature to the use of mixed, secondary aliphatic amines is highly indicative of the fact that these methods are neither very simple, rapid, nor productive of wholly satisfactory yields.

Because of the success in this Laboratory[9] in obtaining mixed secondary amines by reduction in the presence of Raney nickel catalyst of the Schiff bases formed by the interaction of benzaldehyde, or a derivative, with a primary amine, it was decided to study the analogous synthesis of mixed, secondary aliphatic amines in a similar manner.

It has been found that without preliminary isolation or purification, the products formed from the interaction of primary amines and simple aldehydes, except formaldehyde, or ketones in a hydrocarbon solvent can be hydrogenated in the presence of Raney nickel catalyst to produce mixed, secondary aliphatic amines in satisfactory yield.

In the preparation of seven of the mixed amines obtained during this investigation, *n*-butylamine was allowed to react with the appropriate carbonyl compound. However, in the case of N-methyl-*n*-butylamine the reactants were methylamine and *n*-butyraldehyde and here a significant amount of N-methyl-di-*n*-butylamine was formed also. The other preparations yielded various amounts of high boiling basic mixtures of indefinite composition.

In order to characterize them further and at the same time obtain substances useful for other syntheses, the amines were condensed with bromoacetone to form aminoacetones. The latter are colorless or faintly yellow, slightly viscous liquids having a characteristic odor and when impure they acquire a red color very rapidly. However, when pure they remain essentially colorless for long periods of time. They are quite soluble in the usual organic solvents, but are insoluble in water. The molecular refractions and parachors calculated from the densities, refractive indices, and surface tensions check quite closely with the sum of the atomic refractions[10] and the atomic parachors.[11] All attempts to form picrates of the aminoacetones resulted in the formation of oils which could not be solidified. Treatment of anhydrous ether

solutions of these ketoamines with dry hydrogen chloride yielded no solid hydrochloride.

Where high pressure hydrogenation apparatus is available it is our belief that the method to be described below represents a simpler and more rapid procedure for preparing mixed, secondary, aliphatic amines in satisfactory yields than the older methods.

Experimental

Aldimines.—Half-mole quantities of amine and aldehyde are separately dissolved in 25-cc. portions of Skellysolve. The solutions are chilled in a salt–ice mixture (except that of methylamine which is chilled to −15° with a bath of acetone chilled with solid carbon dioxide) and the solution of aldehyde is added slowly to that of the amine while shaking the mixture. Water begins to separate after approximately one-half of the aldehyde has been added. The reaction mixture is allowed to stand for one hour in the ice box and the water is separated. The hydrocarbon solution is dried over anhydrous potassium carbonate or sodium sulfate before hydrogenation.

Ketimines.—Half-mole quantities of amine and ketone are mixed with 50 cc. of Skellysolve and the clear, homogeneous solution is hydrogenated without any attempt at dehydration.

Hydrogenation.—The Skellysolve solutions as prepared above are hydrogenated at 75° in the Adkins apparatus using 10 g. of Raney nickel catalyst, and an initial hydrogen pressure of 3000 lb./sq. in. Separation of water occurs during the hydrogenation of the ketone–amine solution. The hydrogenation of the aldimines is practically complete within three hours, but that of the ketimine solutions requires three to four times that period.

Isolation of the Amines.—The hydrogenation solution is filtered from the catalyst and the amine is extracted with a slight excess of 6 *N* hydrochloric acid. After washing the acid solution with ether, it is made strongly alkaline with 40% sodium hydroxide and ether extracted. The ether solution of basic material is dried with anhydrous potassium carbonate, and after removal of the ether the crude amine is partially purified by distillation. The distillate is dried over sodium and fractionated to obtain the pure amine.

The N-alkyl-*n*-butylamines prepared by this procedure are the methyl, ethyl, *n*-propyl, isopropyl, isobutyl, sec-butyl, *n*-amyl and isoamyl compounds. In this series, synthesis of the methyl,[12] ethyl,[13] *n*-propyl,[14] *n*-amyl[15,16] and iso-amyl[15] members has been reported previously, but their characterization is incomplete.

Preparation of Aminoacetones.—The conversion of the amines to aminoacetones is accomplished by one of the methods used by Magee,[9] namely, the condensation of two-tenths mole of amine dissolved in 200 cc. of anhydrous ether with one-tenth mole of bromoacetone dissolved in 25 cc. of ether. The amine precipitated as hydrobromide is recovered and treated with another portion of bromoacetone until three reaction mixtures have been obtained. The combined ether solutions are washed with water, then the basic material is extracted with a slight excess of 6 *N* hydrochloric acid solution. The acid solution is washed with ether, then made alkaline with a considerable excess

of 40% sodium hydroxide solution. The basic material is extracted with ether and after drying over anhydrous potassium carbonate or sodium sulfate the ether is removed leaving the crude aminoacetone to be purified by fractional distillation. When the aminoacetones are not to be used for synthesis immediately they should be stored in a desiccator over potassium carbonate.

In Table I are included data for certain physical properties, values derived from them by calculation, and the results of analyses of the N-alkyl-*n*-butylamines.

Data for the new aminoacetones prepared in this investigation are tabulated in Table II, and for the semicarbazones of these ketones in Table III.

Summary

1. A simple, rapid method of preparing mixed, secondary aliphatic amines in satisfactory yield has been tested by synthesizing eight examples of N-alkyl-*n*-butylamines. The method involves high pressure hydrogenation of aldimines or ketimines in the presence of Raney nickel.

2. These amines have been converted into eight new disubstituted aminoacetones of the type CH_3COCH_2NRR'.

5,5-Dimethylhydantoins Containing a —NRR′ Substituent. II

BY HENRY R. HENZE AND DAVID D. HUMPHREYS[1,2]

About four years ago there was reported[3] from this Laboratory the synthesis of a series of 5,5-dimethylhydantoins containing a dialkylamino substituent in which the two alkyls were alike. More recently,[4] was recorded the preparation of another series of 5,5-dimethylhydantoins, these, however, containing a —NRR′ substituent in which R represented a normal alkyl group or phenyl and R′ phenyl or benzyl. Intermediate between these two series would be that containing a —NRR′ substituent in which R and R′ represent different alkyl groups.

As a result of another investigation[5] there were available eight N-alkyl-*n*-butylaminoacetones. Each of these has been converted into the corresponding hydantoin derivative by reaction with ammonium carbonate and potassium cyanide. Through the courtesy of Parke, Davis and Company, six of these hydantoins have received preliminary testing on mice intraperitoneally for toxicity and possible hypnotic action. The N-methyl and N-ethyl members of the series produced slight analgesia in nearly fatal doses. None exhibited any appreciable hypnotic activity.

Experimental

The dialkylaminoacetones were readily converted into substituted hydantoins by the Bucherer[6] procedure. In general, 0.1 mole of the N-alkyl-*n*-butylaminoacetone was dissolved in 75 cc. of ethyl alcohol; then a solution of 0.11 mole of potassium cyanide dissolved in 60 cc. of water was added. Ammonium carbonate (0.3 mole) was crushed to a coarse powder and added to the ketone–cyanide mixture. Now, 60% alcohol solution was added until only one liquid phase existed in the reaction mixture at 55–60°; the ammonium carbonate was completely in solution after a few hours. The warming continued at 55–60° under a reflux condenser for ten to twelve hours. The light yellow solution was chilled causing virtually complete separation of the hydantoin. The latter was recrystallized from diluted alcohol; in some instances addition of petroleum ether to a benzene solution of the hydantoin proved to be an efficacious method for purification. Data concerning certain physical properties for and analyses of the eight hydantoins have been placed in Table I.

Keto Ethers. X. 1-Methoxyethyl Alkyl Ketones

BY WINSTON PAUL WALLACE[1] AND HENRY R. HENZE

In connection with two other problems being investigated in this Laboratory, namely, the extension of the Pfitzinger procedure to the synthesis of alkoxyalkylquinolines[2,3] and to the preparation of hydantoin derivatives[4] possessing therapeutic activity, a number of alkyl 1-methoxyethyl ketones were needed. Methyl and ethyl members of this series had previously been prepared by Gauthier[5] who reported, however, no data other than boiling points for their physical properties. These two keto ethers, together with eight additional examples of this type, have now been prepared.

Experimental

1-Chloroethyl Methyl Ether.[6]—Henry's[7] method was utilized through condensation of methyl alcohol (10 moles) with an equivalent amount of paraldehyde by means of dry hydrogen chloride. A yield of 810 g. (95% of the theoretical) of crude material was obtained; by fractionation 485 g. was collected; b. p. 70–72° (746 mm.); d^{20}_4 0.9909; $n^{20}D$ 1.3969; *MR* calcd. 22.56; *MR* found 22.96.

α-Methoxypropionitrile.[8]—In resynthesizing this compound, because of unsatisfactory yields, various diluents were used; dry ether proved best, but with it only a 36% yield was obtained; b. p. 117–119° (740 mm.); d^{20}_4 0.8928; $n^{20}D$ 1.3818; *MR* calcd. 22.13; *MR* found 22.17.

Alkyl 1-Methoxyethyl Ketones.—After preparing the necessary alkylmagnesium bromide in the usual way, the ether solution of α-methoxypropionitrile was added slowly at such a rate that there was rapid refluxing of the solvent. Usually the reaction product stood for twelve to eighteen hours before being decomposed by addition of ice-cold dilute hydrochloric acid. The ether layer was separated and combined with the ether extract of the neutralized acidic layer. After washing with sodium bicarbonate solution and with water, the ether extract was dried over anhydrous calcium chloride and fractionally distilled; the first three members were fractionated at atmospheric pressure and the remainder under reduced pressure. The keto ethers are mobile liquids which frequently required repeated distillation in order to be obtained water white and of pleasant ester-like odor.

The data determined for physical properties of the keto ethers, together with results obtained from their analysis, are reported in Table I. Although excellent agreement between the calculated and found values for molecular refraction was obtained, and despite the fact that in all cases save one combustion analyses yielded satisfactory values for hydrogen content, the values found for percentage of carbon were uniformly high. Only a poor yield of *t*-butyl ketone was obtained using *t*-butylmagnesium chloride; no yield resulted from attempted use of the corresponding bromide or iodide.

In order to further characterize the keto ethers, they were converted into semicarbazones which could be recrystallized from benzene to sharp melting points. The data for these derivatives are recorded in Table I.

[a] Gauthier, ref. 5, reported b. p. 114° (727 mm.); Diels and Pflaumer [*Ber.*, **48**, 230 (1915)] recorded b. p. 113° (759 mm.). [b] Gauthier, *ibid.*, reported b. p. 133° (729 mm.).

Summary

1. The series of alkyl 1-methoxymethyl ketones has been extended, by the synthesis of eight additional members, to include branched as well as normal groupings. The methyl and ethyl members have been resynthesized and characterized more fully.

2. Semicarbazones, useful in identification of these keto ethers, have been prepared for each member.

Quassin. IV. A Minor Constituent of Jamaica Quassia Wood*

BY E. P. CLARK

In the preparation of crude quassins from Jamaica quassia wood,[1] the mother liquors consistently yielded a small quantity of a fairly soluble material which, in the crude state, melted at about 150°. It was readily purified to a constant melting point of 166–167° by recrystallization from 16% methanol and as such had the physical characteristics of a pure compound. Analyses of several specimens gave fairly consistent values for carbon, hydrogen, methoxyl, and molecular weight, but they failed to harmonize with any possible formula. These facts indicated that if the material was an individual substance it was impure, but since its purification was complete as established by physical standards, the only conclusion tenable was that it was a complex of two or more substances which separated as mixed crystals.

With this as a working hypothesis, resolution was attempted by methods other than fractional crystallization. Selective adsorption upon aluminum oxide was the most successful in that the material was roughly separated into neoquassin, unchanged material, and a fraction which would not crystallize. The first two fractions could be readily purified, but all attempts to isolate the material in the last fraction failed.

The facts here recorded are presented for record in order to describe an unreported constituent of quassia wood and to call attention to the unique properties of the substance. Further work upon the material is not contemplated, because the small yield (0.015% of the wood) precludes any possible importance of the substance as an insecticide, the original object of the study.

Experimental

The aqueous-methanolic mother liquors from the crystallization of crude quassins from 200 kg. of Jamaica quassia wood were concentrated under reduced pressure until a resinous material began to separate. The liquid was then filtered through norit and set aside to crystallize. A product slowly separated as long, thin, slightly colored hexagonal plates, which melted unsharply at 150°. Reworking the mother liquors gave more material, the total quantity being 30 g. A solution of 5 g. of the crystals in 15 cc. of hot methanol was diluted with 90 cc. of hot water. The liquid was immediately filtered through norit and allowed to crystallize. The product was further purified by repeating the process three times. It then had a melting point of 166–167°, which further recrystallization failed to change. The crystals were long, colorless rods and hexagonal plates. In parallel polarized light (crossed nicols) the extinction was parallel and the elongation was negative. Many of the rods did not extinguish sharply and low polarization colors were characteristic. In convergent polarized light (crossed nicols) biaxial interference figures were rarely observable, but when they were the acute bisectrix was nearly vertical. The apparent optic axial angle in air was very small. The indices of refraction were η_α, 1.557, usually lengthwise; η_β, indeterminate; η_γ, 1.559, usually crosswise; both ± 0.002.[2]

The substance contained only carbon, hydrogen, and oxygen, and analyses of three different preparations are as follows:

Anal. Found: C, 66.14, 65.11, 65.63; H, 7.83, 7.78, 7.59; OCH_3, 11.69, 11.79, 11.79; mol. wt., 410.

Chromatographic Separation of Neoquassin.—A solution of 1 g. of the purified material in 30 cc. of ethyl acetate was passed through a 12 × 200 mm. column of aluminum oxide, and the chromatogram was developed with the same solvent. The eluate was collected to 50-cc. fractions, each evaporated under reduced pressure to dryness, and the residues were dissolved from the flask with small quantities of methanol. These liquids were evaporated to a small volume, diluted with 6 to 7 volumes of water, and allowed to crystallize. Five main fractions were obtained: I, m. p. 195–205°; II, m. p. 185–190°; III, m. p. 165°; IV, m. p. 155–160°, and V, m. p. 145–147°. The first two fractions contained most of the neoquassin, the third contained practically pure starting material, and the fourth and fifth fractions consisted of impure starting material. Fractions I and II were further purified by repeating the process with chloroform as a solvent. Impure neoquassin, m. p. about 215°, was obtained from the first fractions of this operation, and unchanged material in rather impure condition was obtained in the last fractions. Two recrystallizations of the impure neoquassin (solvent 35% methanol) gave a pure product, m. p. 226°. It was identified by its characteristic crystal habit and its failure to depress the melting point of an authentic sample of neoquassin. The last fractions from both the ethyl acetate and chloroform extractions were recrystallized from 16% methanol, which gave a preparation that melted at 166–167° and did not depress the melting point of the starting material.

The columns, after having been exhausted with either chloroform or ethyl acetate, were eluted with methanol. An appreciable quantity of sirupy, water-soluble material was thus obtained, but all efforts to crystallize it failed. It is impossible to state that this represents the material

(1) E. P. Clark, THIS JOURNAL, 59, 927 (1937).

(2) The crystallographic data here recorded were determined by George L. Keenan, of the Food and Drug Administration, Federal Security Agency, Washington, D. C.

associated with neoquassin in the original substance, for it may represent a decomposition product resulting from the operation involved, or it is possible the unknown component was not eluted from the adsorbent. Both considerations seem doubtful, for a methanolic solution of the original material was rapidly and quantitatively passed through a column of aluminum oxide without separation or apparent change. However, a solution of neoquassin added to a solution of the uncrystallizable material failed to effect a synthesis of the original substance.

Summary

A hitherto unrecorded constituent of Jamaica quassia wood is described. It has the physical properties of an individual compound, but in reality consists of a complex of neoquassin and one or more unknown materials, which apparently separate as mixed crystals.

Local Anesthetics. II. Alkoxybenzoates of 2-Monoalkylamino-2-methyl-1-propanols and 2-Monoalkylamino-1-butanols[1,2]

BY J. STANTON PIERCE, J. M. SALSBURY, WALTER W. HADEN AND L. H. WILLIS

In a recent paper from this Laboratory,[3] the preparation of β-monoalkylaminoethanol esters of alkoxybenzoic acids was described. Goldberg, Ringk and Spoerri[4] reported aminobenzoates of β-monoalkylaminoethanols in which branching occurs on the alpha carbon of the amino alcohol.

We have mono-alkylated 2-amino-2-methyl-1-propanol and 2-amino-1-butanol, which are now on the market, and have been engaged in the preparation of esters of these amino alcohols with alkoxybenzoic, alkoxycinnamic, alkoxynaphthoic, diphenylacetic, acetyltropic, acetylmandelic and *p*- and *m*-nitrobenzoic acids, with the expectation of reducing the latter to the aminobenzoate esters. The recent report of Kremer and Waldman[5] on *p*-nitrobenzoic and *p*-aminobenzoic esters of 2-monoalkylamino-2-methyl-1-propanols makes it desirable to report the results thus far obtained. This paper takes up the preparation of 2-monoalkylamino-2-methyl-1-propanols, 2-monoalkylamino-1-butanols and the alkoxybenzoates of these amino alcohols.

Alkylation of 2-amino-2-methyl-1-propanol and 2-amino-1-butanol with the lower alkyl halides usually was carried out by heating equimolar quantities of the amino alcohol and alkyl bromide in a sealed tube or under reflux at 100° for two hours. For the introduction of the amyl, hexyl, heptyl, allyl and benzyl radicals, usually the molar quantity of amino alcohol was doubled and in the introduction of the latter two groups, chlorides were used instead of bromides. The reaction product was dissolved in dilute hydrochloric acid, separated from unchanged alkyl halide, in case the reaction was not complete, and treated with excess concentrated sodium hydroxide. The alkylation product rose to the surface of the hot solution as an oil. The oil was vacuum distilled and the distillate redistilled at atmospheric pressure. The 2-monoalkylamino-2-methyl-1-propanols except the allyl, solidified on cooling. Several of the 2-monoalkylamino-1-butanols showed a tendency to crystallize, reaching a maximum in the case of 2-monobenzylamino-1-butanol. The crystals of this compound, on separation, reverted to a mixture of liquid and crystals.

In a previous paper from this Laboratory,[3] the preparation and isolation of β-monoalkylaminoethyl alkoxybenzoate hydrochlorides was described. The same general procedure, with some modifications, was used to obtain hydrochlorides of alkoxybenzoates of 2-monoalkylamino-2-methyl-1-propanols and 2-monoalkylamino-1-butanols.

Experimental

Examples are given of the preparation of 2-*n*-amylamino-2-methyl-1-propanol and of the condensation of this amino alcohol with *p*-ethoxybenzoyl chloride.

2-*n*-Amylamino-2-methyl-1-propanol.—A mixture of 113 g. (0.75 mole) of *n*-amyl bromide and 134 g. (1.5 moles) of 2-amino-2-methyl-1-propanol was heated in two sealed tubes for two hours at 100°. The contents of the tubes were combined and dissolved in 500 ml. of water and 80 ml. of concentrated hydrochloric acid. No oil remained undissolved. To the acid solution was added a solution of 100 g. of sodium hydroxide in 100 ml. of water. The oil which rose to the surface was vacuum distilled, yielding

[a] The melting points of the distilled amino alcohols were taken without recrystallization of the products, since it was found that recrystallization raised the melting point only slightly. [b] Also prepared by Kremer and Waldman.[5]

Hydrochloride of *p*-Ethoxybenzoate of 2-Mono-*n*-amylamino-2-methyl-1-propanol.—To 15.9 g. (0.1 mole) of 2-mono-*n*-amylamino-2-methyl-1-propanol was added 12.5 ml. (0.15 mole) of concentrated hydrochloric acid. The excess hydrochloric acid was removed by vacuum evaporation. To the solid hydrochloride of 2-mono-*n*-amylamino-1-propanol was added 18.4 g. (0.1 mole) of *p*-ethoxybenzoyl chloride. The reaction mixture was heated, with occasional shaking, in an oil-bath at 100° for thirty minutes, at 130° for thirty minutes, and at 150° for fifteen minutes. The reaction mixture was dissolved in 60 ml. of 95% ethanol, poured into 800 ml. of *N* sodium hydroxide solution, and extracted with 125 ml. of isopropyl ether. The ether solution was extracted with 1500 ml. of 0.4 *N* hydrochloric acid. The acid solution was made basic with sodium hydroxide and the free base of the amino alcohol ester was extracted with 150 ml. of isopropyl ether. The isopropyl ether solution was saturated with dry hydrogen chloride, yielding 23 g. (67%) of an oily precipitate of the hydrochloride of β-mono-*n*-amylamino-β,β-(dimethyl)-ethyl *p*-ethoxybenzoate, which solidified within a few minutes. On two crystallizations from acetone, this product melted at 127–129°.

In this study, approximately sixty alkoxybenzoates of 2-monoalkylamino-2-methyl-1-propanols and 2-monoalkylamino-1-butanols were prepared, that their anesthetic activity might be tested. In some runs in which very insoluble ester hydrochlorides were formed, the products were isolated by precipitation with a large excess of hydrochloric acid and by filtration. Table II gives the melting points and chloride analyses of the hydrochlorides of the above alkoxybenzoates which were most readily crystallized.

The β-monoalkylaminoalkyl alkoxybenzoate hydrochlorides reported in this paper are being tested pharmacologically by Dr. C. C. Haskell. The results will be reported elsewhere.

Summary

A series of hydrochlorides of alkoxybenzoates of 2-monoalkylamino-2-methyl-1-propanols and of 2-monoalkylamino-1-butanols is described.

RICHMOND, VA. RECEIVED SEPTEMBER 1, 1942

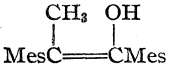
Vinyl Alcohols. IV.[1] Oxidative Cleavage

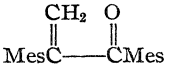
BY REYNOLD C. FUSON, D. J. BYERS,[2] A. I. RACHLIN AND P. L. SOUTHWICK[3]

The vinyl alcohol, 1,2-dimesityl-1-propen-1-ol (I),[4] was observed to undergo slow deterioration in contact with the air.[5] In the absence of air, however, it has proved to be stable. Samples of this remarkable enol, kept in sealed tubes under nitrogen, show no change after eighteen months.

The oil produced by the action of oxygen on the enol was found to contain acetomesitylene and mesitoic acid, evidently produced by oxidative cleavage. Subsequent study of this cleavage has shown acetomesitylene to occur invariably as a principal product whereas mesitoic acid is generated only in small amounts or not at all. Another product, isolated in traces, proved to be



I



II

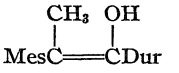
mesityl α-mesitylvinyl ketone (II). Its formation is to be ascribed to 1,4-dehydrogenation of the enol, a reaction that had been brought about earlier by the use of permanganate, chromic anhydride[6] and chloranil.

It remained to discover the moiety sheared off in the production of acetomesitylene. By suitable modification of the procedure it was an easy matter to isolate in quantity a low-melting, volatile solid, which proved to be *mesitol*. The amount corresponded roughly to that of acetomesitylene. Attempts to write an equation, however, revealed that a carbon atom was yet to be accounted for. Tests for formaldehyde and carbon dioxide showed that neither was produced in appreciable amounts. Analysis of the exit gas, however, provided the answer; carbon monoxide was present and in amounts proportional to those of acetomesitylene and mesitol. The production of a mole of carbon monoxide for every mole of oxygen absorbed explains the observation that there was no change in pressure during the reaction. The oxidative degradation can accordingly be represented by the following equation

Two additional products were detected in small amounts. One of these was hydrogen, which was found in the exit gases from the oxidation chamber. Its origin is not apparent. The other by-product was a phenolic compound melting at 169.5–171.5°. Its properties indicate that it may be made up of two mesitol residues but this surmise has not been verified.

It seems probable that a peroxide is formed which then breaks down to yield the three products shown in the equation. The peroxide could decompose in an alternative manner to yield mesitoic acid and acetomesitylene. The chief reaction, however, is that leading to the production of mesitol, carbon monoxide and acetomesitylene. It is a new type of oxidative cleavage. There is a possibility that it is related to the well-known Dakin cleavage of certain types of aromatic aldehydes and ketones to the corresponding phenols.[7]

The new reaction has been used to degrade several enols, structurally similar to I, and appears to be generally applicable to compounds of this type. For example, 1-duryl-2-mesityl-1-propen-1-ol (III)[1] yielded acetomesitylene, durenol, carbon monoxide and smaller amounts of 2,3,5,6-tetramethylbenzoic acid and duryl α-mesitylvinyl ketone. It is interesting that in this cleavage no



III

high-melting phenol was detected. Results similar to the foregoing have been obtained in structure studies of other vinyl alcohols described elsewhere.[8]

Experimental

Cleavage of 1,2-Dimesityl-1-propen-1-ol

The cleavage is readily accomplished by bubbling oxygen through a solution of the enol in an organic solvent such as acetone, or a mixture of ether and petroleum ether. However, to facilitate collection of the gaseous products of the reaction it was found convenient to make use of a Parr

low-pressure hydrogenation machine of the Adams type.[9] The reaction was carried out by shaking acetone solutions of the enol with oxygen in this apparatus. Various procedures for separating and identifying the products of the cleavage were tried. The following is the description of a run in which the most satisfactory procedure was used.

Treatment with Oxygen.—A solution of 8.4 g. (0.029 mole) of the enol in 250 cc. of acetone was placed in the shaker bottle and treated with oxygen for three days at a gage pressure of 14.75 lb. per sq. in. The drop in pressure during this time was negligible.

Analysis of Gases.—Gas samples were taken from the shaker bottle by means of an exit tube provided in the stopper, and from the tank through the outlet valve. The gases were passed through sulfuric acid to remove acetone vapors and samples were collected by displacement of water from sample tubes of 300 cc. capacity.

The presence of carbon monoxide was detected by the palladium chloride test.[10] Quantitative analysis[11] of the gas samples was carried out with an apparatus of the Orsat type. Carbon dioxide was determined by absorption in 33% potassium hydroxide solution, and oxygen by absorption in a 10% solution of pyrogallol in 33% potassium hydroxide. After removal of carbon dioxide and oxygen, the gases were scrubbed with 90% sulfuric acid and then passed over cupric oxide at 250°. Hydrogen was then estimated from the decrease in the volume of the sample upon condensation of the water formed. Carbon monoxide was determined by absorption of the resulting carbon dioxide in 33% potassium hydroxide solution.

The sample from the shaker bottle contained 56.1 mole per cent. of carbon monoxide, and the sample from the tank 4.8 mole per cent. An estimate based on the capacity of the bottle and of the tank indicated the formation of approximately 0.028 mole of carbon monoxide in the reaction. No carbon dioxide was found in the gases produced in this run, although minute quantities were found in another run by passing the entire gaseous mixture through a saturated barium carbonate solution. Hydrogen was found to the extent of 2.6 mole per cent. in the sample from the bottle, and 0.6 per cent. in the sample from the tank.

The solution was taken from the shaker bottle, and the acetone removed by distillation from a steam-cone. The acetone distillate was refluxed for four hours while a slow stream of carbon dioxide was bubbled through it, and the exit gases were passed through 150 cc. of water kept at 0°. At the end of that time no formaldehyde could be detected in the water by the fuchsin test. In another run a fuchsin test which could not be decolorized by sulfuric acid was obtained from the acetone distillate, but the methone test was negative.

Acidic Components

The oil remaining after removal of the acetone was taken up in a very small amount of ether and extracted repeatedly with a 10% potassium hydroxide solution. Acidification of the alkaline extracts yielded 4.2 g. of a solid precipitate. This material was dissolved in ether, and the solution was extracted twice with a 10% solution of potassium bicarbonate. Acidification of the extracts precipitated 0.2 g. of a white solid melting at 151–153°. No depression of the melting point was observed when this compound was mixed with an authentic sample of mesitoic acid.

The ether solution of the acidic components, which now contained only the phenolic fraction, was evaporated, and the residual solids were subjected to steam distillation. Two and four-tenths grams of a white solid melting at 67–69° was obtained by cooling and filtering the distillate. Crystallization from low-boiling petroleum ether gave white needles melting at 71–72° which did not depress the melting point of a known sample of mesitol.

The solid remaining in the steam-distillation flask was collected on a filter and dissolved in 10% potassium hydroxide solution. The solution was filtered free of a small amount of insoluble solid material, and acidified with hydrochloric acid. Five-tenths of a gram of a tan solid was precipitated. After repeated crystallization from glacial acetic acid, white crystals melting at 169.5–171.5° were obtained.

Anal.[12] Calcd. for $C_{18}H_{22}O_2$: C, 79.95; H, 8.28. Found: C, 79.60; H, 8.13.

Approximately 0.2 g. of the high-melting phenol was heated for a few minutes with 5 cc. of acetic anhydride and one drop of concentrated sulfuric acid. Excess acetic anhydride was decomposed by heating with water, and the resulting solid product was crystallized four times from high-boiling petroleum ether. White needles melting at 148–149° were obtained.

Anal. Calcd. for $C_{22}H_{26}O_4$: C, 74.53; H, 7.40. Found: C, 74.71; H, 7.75.

Neutral Components.—After extraction with 10% potassium hydroxide, the ether solution containing the neutral components was washed with water, and the ether was removed by distillation. Distillation of the residual oil yielded 3.2 g. of a liquid boiling at 85–90° at 3 mm. A 0.5-g. portion of this oil was treated with 10 cc. of fuming nitric acid at 0°, and the nitration mixture was poured on ice. The precipitated white product melted at 135–137° after crystallization from ethanol, and did not depress the melting point of a known sample of dinitroacetomesitylene.

A small amount of methanol was added to the viscous red oil remaining in the distilling flask after removal of the acetomesitylene, and a crystalline precipitate formed immediately. About 0.3 g. of this material was obtained by cooling and filtering the solution. After crystallization from ethanol, it melted at 132–133° and was shown to be mesityl α-mesitylvinyl ketone by the mixed melting point test.

Cleavage of 1-Duryl-2-mesityl-1-propen-1-ol

The cleavage was brought about by shaking a solution of 8.5 g. of the enol in 250 cc. of acetone with oxygen for three days at a gage pressure of 10 lb. per sq. in.

A gas sample from the bottle contained 39.4 mole per cent. of carbon monoxide, no appreciable carbon dioxide and 1.2 mole per cent. of hydrogen.

(11) The gas analyses were carried out by Mr. Robert S. Hanmer.

(12) Microanalyses by Miss Theta Spoor.

Acidic Components.—The procedure was very similar to that described above for 1,2-dimesityl-1-propen-1-ol. Acidification of the bicarbonate extract yielded 0.5 g. of a white solid melting at 176.5–178.5° after crystallization from high-boiling petroleum ether. It did not depress the melting point of an authentic sample of 2,3,5,6-tetramethylbenzoic acid.

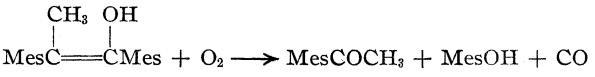
The remainder of the acidic fraction was dissolved in 10% potassium hydroxide solution, filtered free of insoluble material, and precipitated by acidification. One and four-tenths gram of a product melting at about 110° was obtained. Crystallized twice from low-boiling petroleum ether, it melted at 117–118° and did not depress the melting point of a known sample of durenol.

Neutral Components.—After extraction of the acidic components, the oil was washed with water and allowed to stand; a small amount of a crystalline product separated and was removed by filtration. Distillation of the filtrate yielded 1.5 g. of an oil boiling at 93–95° at 5 mm. Nitration of this oil as described above converted it to dinitroacetomesitylene.

Methanol was added to the viscous residue in the distilling flask, and the yellow solid which separated was filtered and crystallized from ethanol. It melted at 156.5–157.5° and did not depress the melting point of a sample of duryl α-mesitylvinyl ketone. The solid mentioned above, which crystallized from the oily mixture, was crystallized from ethanol, and likewise proved to be duryl α-mesitylvinyl ketone. A total of 0.8 g. of this compound was isolated.

Summary

It has been found that treatment with oxygen causes the vinyl alcohol, 1,2-dimesityl-1-propen-1-ol, to undergo cleavage to acetomesitylene, mesitol and carbon monoxide according to the equation



Small amounts of mesityl α-mesitylvinyl ketone, mesitoic acid, hydrogen and an unidentified phenol were also detected among the reaction products.

Similar results were obtained with 1-duryl-2-mesityl-1-propen-1-ol.

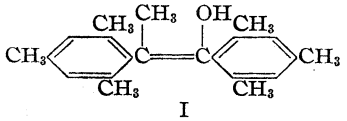
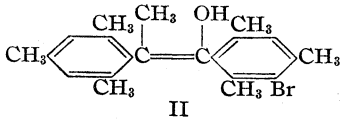
Vinyl Alcohols. V.[1] Isomeric Bromo-1,2-dimesityl-1-propen-1-ols

BY REYNOLD C. FUSON, R. V. LINDSEY, JR., AND P. BURKE WELLDON

In an effort to relate the remarkable stability of 1,2-dimesityl-1-propen-1-ol[2] (I) to structural features, a number of similar enols were prepared. The method in every case involved the corresponding desoxybenzoin as a starting material. One of the most interesting of these syntheses was that of the bromo derivative (II) of the original enol. It was made from 3′-bromodesoxymesitoin (III),

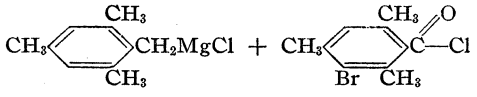


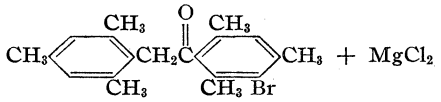
I



II

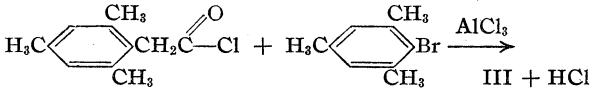
which in turn was prepared by condensing 3-bromomesitoyl chloride with α[2]-isodurylmagnesium chloride.





III

Because the yields of the bromodesoxymesitoin (III) were low, an effort was made to find a better method of synthesis. The most promising alternative appeared to be the Friedel–Crafts reaction between mesitylacetyl chloride and bromomesitylene.



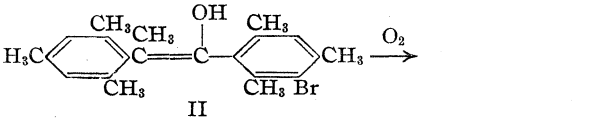
The result was, however, very surprising. The condensation proceeded smoothly to yield a compound of the expected composition and similar melting point. But a mixed melting point determination showed it to be different from the desired 3′-bromodesoxymesitoin.

(1) For the preceding article in this series, see Fuson, Byers, Rachlin and Southwick, THIS JOURNAL, **64**, 2886 (1942).

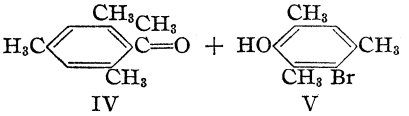
(2) (a) Fuson, Corse and McKeever, *ibid.*, **62**, 3250 (1940); (b) Fuson, Byers and Rabjohn, *ibid.*, **63**, 2639 (1941).

That we were dealing with isomeric bromodesoxymesitoins became clear when it was found that each compound, when condensed with formaldehyde, yielded an unsaturated ketone that could be converted by hydrogenation to a vinyl alcohol. Both vinyl ketones melted at 150°, but a mixed melting point determination showed a 20° lowering. The new vinyl alcohols were considerably less permanent than the parent enol, 1,2-dimesityl-1-propen-1-ol (I); they were isolated only as unstable solids. Enol II was converted to the methyl ether.

Fortunately, the newly discovered oxidative cleavage[1] of such enols offered a simple method of structure determination. The vinyl alcohol (II) derived from 3′-bromodesoxymesitoin (III) yielded acetomesitylene (IV) and 3-bromomesitol (V), as was expected.

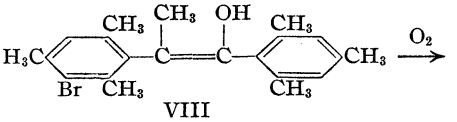


II

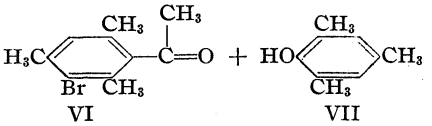


IV V

The enol from the new desoxy compound was oxidized to 3-bromoacetomesitylene (VI) and mesitol (VII).

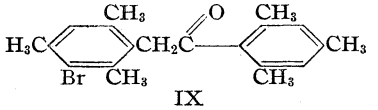


VIII



VI VII

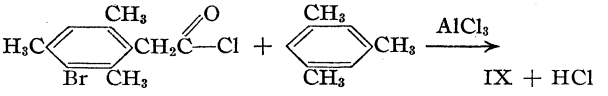
It must, therefore, have the structure, VIII. As a consequence, the desoxy compound from the Friedel–Crafts synthesis can be assigned the structure of 3-bromodesoxymesitoin (IX). Its



IX

formation involves the transfer of the bromine atom from one ring to the other. This remarkable migration must occur at some intermediate point in the condensation, for the 3′-bromodesoxymesitoin did not undergo isomerization when treated with aluminum chloride. Although halogen migrations during the Friedel–Crafts reaction are well-known,[3] this one seems noteworthy for the selectivity with which it proceeds. The yields ranged from 40 to 90%.

The structure of 3-bromodesoxymesitoin was confirmed by an independent synthesis. This compound was obtained in satisfactory yields by condensing 3-bromomesitylacetyl chloride with mesitylene.



Experimental

3-Bromomesitoic Acid.—Mesitoic acid was brominated by the method of Shildneck and Adams[4]; omission of the iron catalyst gave consistently higher yields. There was obtained 288 g. (74% yield) of 3-bromomesitoic acid, m. p. 162–165°, from 260 g. of mesitoic acid.

The acid was converted to the *acid chloride* (b. p. 175–178° (28 mm.)) in 97% yield by the action of thionyl chloride at room temperature.

Condensation of 3-Bromomesitoyl Chloride with α^2-Isodurylmagnesium Chloride.—A solution of 8.4 g. of α^2-chloroisodurene in 350 cc. of dry ether was added over one and one-half hours to 10 g. of magnesium in 150 cc. of dry ether at 0°. The temperature of the mixture was allowed to rise to room temperature; stirring was continued for thirty minutes, after which a solution of 13 g. of 3-bromomesitoyl chloride in 25 cc. of dry ether was added dropwise. Stirring was continued for one hour; the reaction mixture was then decomposed with cold, dilute hydrochloric acid. The ether layer was extracted with dilute alkali, washed with water and evaporated. The residue was crystallized from absolute alcohol; 8 g. (45% yield) of 3′-bromodesoxymesitoin was obtained as white plates melting at 91–92°.

Anal. Calcd. for $C_{20}H_{23}OBr$: C, 66.85; H, 6.40. Found: C, 67.00; H, 6.42.

Repetition of this preparation gave yields of less than 10%; the product was contaminated with large amounts of 1,2-dimesitylethane (m. p. 115–116°) from the coupling of the Grignard reagent and could be obtained pure only by repeated fractional crystallization from low-boiling petroleum ether.

Condensation of Mesitylacetyl Chloride with Bromomesitylene.—A solution of mesitylacetyl chloride (20 g.) and bromomesitylene (25 g.) in carbon disulfide (30 cc.) was added over forty-five minutes to a stirred mixture of bromomesitylene (20 g.), aluminum chloride (30 g.) and carbon disulfide (80 cc.) at 0°. Stirring was continued at 0° for three hours, and for an additional three hours at 0–17°. The reaction mixture was decomposed with ice and hydrochloric acid; the organic layer was diluted with 200 cc. of ether and washed thoroughly with 10% sodium hydroxide solution and water. Exhaustive steam distillation removed the solvents and excess bromomesitylene; the

(3) Thomas, "Anhydrous Aluminum Chloride in Organic Chemistry," Reinhold Publishing Corp., New York, N. Y., 1941, p. 692.

(4) Shildneck and Adams, THIS JOURNAL, **53**, 349 (1931).

last portion of the distillate yielded 1 g. of a white solid mixture from which was isolated tribromomesitylene.[5] The viscous residue was crystallized from absolute alcohol; there was obtained 33.4 g. of white solid melting at 90–93°. A mixture of this solid and 3′ bromodesoxymesitoin melted at 71–75°. Recrystallization first from petroleum ether and then from methanol yielded white crystals melting at 98–99°. This compound was subsequently shown to be 3-bromodesoxymesitoin; yield, 90%.

Anal. Calcd. for $C_{20}H_{23}OBr$: C, 66.85; H, 6.40. Found: C, 66.91; H, 6.31.

3-Bromomesityl α-Mesitylvinyl Ketone.—The procedure was that described for the preparation of α-mesitylvinyl mesityl ketone.[2b] From 8 g. of 3′-bromodesoxymesitoin there was obtained 6.84 g. of the vinyl ketone, melting at 150–151°; yield, 83%.

Anal. Calcd. for $C_{21}H_{23}OBr$: C, 67.92; H, 6.24. Found: C, 68.06; H, 6.32.

Mesityl α-(3-Bromomesityl)-vinyl Ketone.—The same procedure[2b] was followed, except that the time of stirring was reduced to seventeen hours. Addition of a second portion of paraformaldehyde was unnecessary. From 12 g. of 3-bromodesoxy-mesitoin there was obtained 12.2 g. of mesityl α-(3-bromomesityl)-vinyl ketone, melting at 149–150°; yield, 98%.

Anal. Calcd. for $C_{21}H_{23}OBr$: C, 67.92; H, 6.24. Found: C, 67.82; H, 6.37.

A mixture of this compound and 3-bromomesityl α-mesitylvinyl ketone melted at 131–134°.

The Methyl Ether of 1-(3-Bromomesityl)-2-mesityl-1-propen-1-ol.—3-Bromomesityl α-mesitylvinyl ketone (15 g.) in glacial acetic acid (150 cc.) was subjected to one and one-half atmospheres pressure of hydrogen in the presence of platinum oxide catalyst. One mole of hydrogen was absorbed per mole of ketone. The solution was filtered into water; the enol was obtained as a white precipitate which became gummy after short exposure to air. It was dissolved in benzene; the solution was washed with dilute potassium bicarbonate solution and water. The benzene solution was partially distilled to dry it, and then was stirred and heated with 2.3 g. of finely divided sodium for one and one-half hours. Excess methyl sulfate was added, and the treatment continued for two hours. The benzene solution was warmed with dilute alkali, washed with water, and evaporated to dryness. Crystallization of the residue from ethanol yielded 12.5 g. of the enol ether, melting at 117.5–119°; yield, 80%.

Anal. Calcd. for $C_{22}H_{27}OBr$: C, 68.22; H, 6.98. Found: C, 68.22; H, 6.99.

Oxidative Cleavage of 1-(3-Bromomesityl)-2-mesityl-1-propen-1-ol.—3-Bromomesityl α-mesitylvinyl ketone (5.5 g.) in ether (50 cc.) was reduced to the enol. The solution was filtered, diluted with acetone and treated with oxygen for three days by the procedure of Fuson, Byers, Rachlin and Southwick.[1] Extraction of an ethereal solution of the residue with alkali followed by acidification yielded 2.24 g. of a solid which was sublimed *in vacuo* to give white needles, m. p. 81–82°. A mixture of this compound and an authentic sample of 3-bromomesitol (prepared by the method of Jacobsen[6]) melted at 81–82°.

(5) Fittig and Storer, *Ann.*, **147**, 8 (1868).

(6) Jacobsen, *ibid.*, **195**, 270 (1879).

Distillation of the neutral residue yielded 1.4 g. of acetomesitylene, which was identified by conversion to the dinitro derivative as previously described.[2b]

Oxidative Cleavage of 1-Mesityl-2-(3-bromomesityl)-1-propen-1-ol.—When mesityl α-(3-bromomesityl)-vinyl ketone was reduced in methanol by the usual procedure, the resulting enol was again a white solid which became gummy after short contact with air. Treatment of this unstable enol with cold potassium permanganate in acetone[2b] dehydrogenated it to regenerate the vinyl ketone.

A solution of the enol (formed by reduction of 5.6 g. of mesityl α-(3-bromomesityl)-vinyl ketone) in an ether–acetone mixture was treated with molecular oxygen[1] for three days. The phenolic product obtained (1.4 g.) was shown to be mesitol by a mixed melting point determination. Distillation of the neutral residue gave 2.4 g. of 3-bromoacetomesitylene, b. p. 110–115°(3 mm.). The identity of this compound was established by use of the procedure of Adams and Miller.[7] By treatment with phosphoric acid the ketone was cleaved to bromomesitylene, which was identified as the dinitro derivative.

Attempted Isomerization of 3′-Bromodesoxymesitoin.—Efforts to transform the 3′-bromo ketone to the isomeric 3-bromodesoxymesitoin by the influence of aluminum chloride were unsuccessful. Conditions of the original Friedel–Crafts reaction were duplicated. If excess bromomesitylene was added, the products were tribromomesitylene, starting material and some intractable oil.

3-Bromomesitylmethyl Chloride.—Gaseous hydrogen chloride was passed for eight hours into a violently agitated mixture of bromomesitylene (50 g.), paraformaldehyde (25 g.), zinc chloride (2 g.) and concentrated hydrochloric acid (250 cc.) at 65–70°. The cooled mixture was extracted with benzene; the benzene solution was washed with alkali and water, dried (calcium chloride) and distilled. Seven grams of unchanged bromomesitylene was recovered; the chloromethyl compound was obtained as white needles; m. p. 44–45°; b. p. 126–129° (2 mm.); weight, 45 g. (84% yield).

Anal. Calcd. for $C_{10}H_{12}BrCl$: C, 48.51; H, 4.89. Found: C, 48.72; H, 5.00.

3-Bromomesitylacetonitrile.—3-Bromomesitylmethyl chloride (24.75 g.) was added over five minutes to a mixture of sodium cyanide (8.4 g.), alcohol (28 cc.) and water (20 cc.) at 55–60°; stirring and heating were continued for three hours. The cooled mixture was extracted with benzene; the benzene solution was washed with water, dried (calcium chloride) and evaporated on the water-bath. The residue was crystallized from high-boiling petroleum ether, yielding white needles melting at 113–114°; weight, 19.6 g. (82% yield).

Anal. Calcd. for $C_{11}H_{12}NBr$: C, 55.48; H, 5.08. Found: C, 55.49; H, 4.94.

3-Bromomesitylacetic Acid.—3-Bromomesitylacetonitrile (11.9 g.) was hydrolyzed by refluxing and stirring with 104 cc. of 55% sulfuric acid for ten hours. The acid was obtained as white, fluffy needles after crystallization from benzene–high-boiling petroleum ether; m. p. 168.5–169.5°; weight, 10.06 g. (78% yield).

Anal. Calcd. for $C_{11}H_{13}O_2Br$: C, 51.36; H 5.09. Found: C, 51.43; H, 5.23.

(7) Adams and Miller, THIS JOURNAL, **62**, 53 (1940).

3-Bromomesitylacetamide (0.38 g.) was obtained as alkali-insoluble residue. After crystallization from benzene–high-boiling petroleum ether, it formed white, fluffy needles melting at 231–232°.

Anal. Calcd. for $C_{11}H_{14}ONBr$: C, 51.58; H, 5.51. Found: C, 51.78; H, 5.49.

The acid was converted to the *acid chloride* (b. p. 146–148° (4 mm.)) in 85% yield by the action of thionyl chloride at room temperature.

3-Bromodesoxymesitoin.—A solution of 3-bromomesitylacetyl chloride (3.25 g.) in mesitylene (5 cc.) was added over fifteen minutes to a stirred mixture of mesitylene (15 cc.), aluminum chloride (2 g.), and carbon disulfide (40 cc.) at 0°. Over one hour, the mixture was gradually warmed to 50°, at which temperature it refluxed gently for fifteen minutes. It was decomposed with ice and hydrochloric acid; the organic layer was diluted with 100 cc. of ether and washed with dilute alkali and water. Steam distillation removed the solvents and excess mesitylene; the residue was dried and crystallized from absolute alcohol. The white solid product melted at 97–99°; a mixture with the product of the Friedel–Crafts reaction between mesitylacetyl chloride and bromomesitylene melted at 97–99°.

Summary

Isomeric bromo 1,2-dimesityl-1-propen-1-ols have been prepared; they are very unstable compared to similar vinyl alcohols containing no halogen substituent.

The Friedel–Crafts reaction of mesitylacetyl chloride and bromomesitylene has been shown to yield 3-bromodesoxymesitoin instead of the expected 3′-bromo compound.

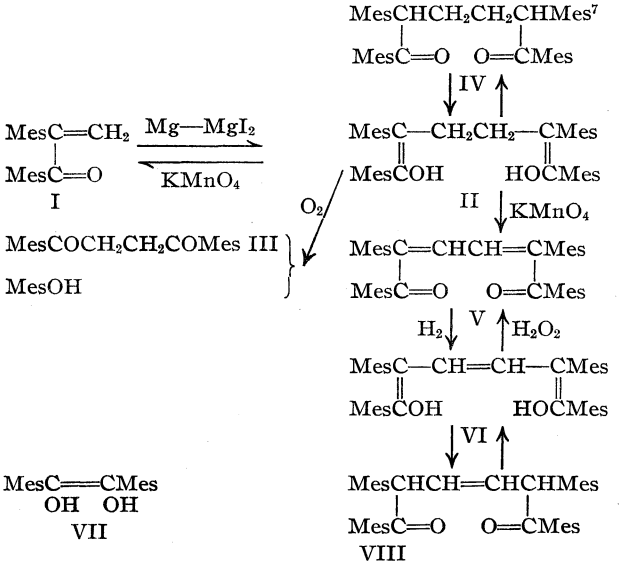
Enediols. XI.[1] Vinylogs of Ethylene and Acetylene Glycols

BY REYNOLD C. FUSON, D. J. BYERS[2] AND A. I. RACHLIN

The production of a stable vinyl alcohol by the hydrogenation of mesityl α-mesitylvinyl ketone (I)[3] suggested that the corresponding dienol (II) might be formed if the reduction could be caused to take place bimolecularly. Experiment has shown that this type of reduction can be accomplished readily and in high yield by use of the binary mixture, Mg-MgI_2.[4]

The structure of the dienol, 1,2,5,6-tetramesityl-1,5-hexadien-1,6-diol (II), was established by use of the cleavage described recently for enols of this type.[5] Treatment with oxygen converted it to mesitol and 1,2-dimesitoylethane (III).

The dienol exhibited chemical properties similar to those of the monoenol. It could be ketonized by long treatment with hot alcoholic hydrogen chloride to yield 1,2,5,6-tetramesityl-1,6-hexanedione (IV). The dienol was regenerated by use of ethylmagnesium bromide. Oxidation with permanganate brought about cleavage, giving the parent vinyl ketone (I). This remarkable reaction resembles the cleavage of 1,2-glycols by lead tetraacetate[6]; it was found that cleavage to the vinyl ketone could be effected with this reagent.



This scission of a 1,6-glycol with lead tetraacetate is in accord with the vinylogous relationship between this glycol and ethylene glycol. It is particularly interesting from a theoretical point of view, since the formation of a cyclic intermediate seems unlikely.[8]

The principal product of the oxidation, however, was not the vinyl ketone but the doubly unsaturated diketone, 1,2,5,6-tetramesityl-2,4-hexadien-

1,6-dione (V). This compound underwent 1,8 hydrogenation to yield what was perhaps the most remarkable compound of the entire series—the dienol, 1,2,5,6-tetramesityl-1,3,5-hexatriene-1,6-diol (VI). It is a vinylog of the enediol, 1,2-dimesitylacetylene glycol (VII). Like the acetylene glycol, it can be ketonized by treatment with alcoholic hydrogen chloride. From the resulting diketone (VIII) the dienol can be regenerated by the use of ethylmagnesium bromide.

Experimental[9]

1,2,5,6-Tetramesityl-1,5-hexadiene-1,6-diol (II).—To a well-stirred mixture of 1.92 g. of magnesium, 40 cc. of dry ether and 80 cc. of dry benzene was added 9.8 g. of iodine. When the iodine color had disappeared, 11.68 g. of solid α-mesitylvinyl mesityl ketone was added within one minute. The solution was stirred and heated at the refluxing temperature for three hours. The reaction mixture was cooled, decomposed with iced hydrochloric acid and washed once with water. The aqueous layer was extracted with ether, and the combined organic solution was dried over calcium chloride. It was then concentrated to a volume of 25 cc. and cooled in an ice-bath. The product which precipitated weighed 11 g. (94%) and melted at 203–205°. The pure compound, recrystallized from benzene, melted at 207–208°.

Anal. Calcd. for $C_{42}H_{50}O_2$: C, 85.95; H, 8.60; mol. wt., 586. Found: C, 86.08; H, 8.69; mol. wt. (ebullioscopic in chloroform), 605.

1,2,5,6-Tetramesityl-1,5-hexadiene-1,6-diol Diacetate.—A solution of 2.0 g. of the diol (II) in 15 cc. of acetic anhydride was heated at the refluxing temperature for two hours. The reaction mixture was cooled and poured into water. The white diacetate, recrystallized from benzene, weighed 1.95 g. and melted at 217.5–218.5°.

Anal. Calcd. for $C_{46}H_{54}O_4$: C, 82.34; H, 8.11. Found: C, 82.72; H, 8.23.

Ketonization of 1,2,5,6-Tetramesityl-1,5-hexadiene-1,6-diol.—A solution of 2.0 g. of the diol in 200 cc. of absolute ethanol, which had previously been saturated with dry hydrogen chloride, was refluxed for twelve hours. The solid diketone started to separate from the hot solution. The mixture was cooled and filtered. The product weighed 1.5 g., and melted at 250–255°. A second crop of crystals weighing 0.4 g. was obtained. Recrystallized from benzene, the diketone (IV) melted at 259–261°.

Anal. Calcd. for $C_{42}H_{50}O_2$: C, 85.95; H, 8.60. Found: C, 86.04; H, 8.83.

Enolization of 1,2,5,6-Tetramesityl-1,6-hexanedione (IV).—To a Grignard solution made from 11 g. of ethyl bromide, 2.4 g.of magnesium and 50 cc. of ether was added a solution of 1 g. of the diketone (IV) in 50 cc. of dry benzene. The mixture was stirred and refluxed for twelve hours, cooled and decomposed with iced ammonium chloride solution. The aqueous layer was extracted with benzene, and the benzene solution was dried over calcium chloride and concentrated to a volume of 10 cc. Cooling caused the separation of 0.8 g. of a solid, which, after recrystallization from benzene, melted at 207–208° alone or mixed with a sample of the diol obtained by the other method.

Reaction of 1,2,5,6-Tetramesityl-1,5-hexadiene-1,6-diol with Oxygen.—Oxygen was bubbled through a solution of 4 g. of the diol in 300 cc. of acetone for seventy-two hours. The solvent was removed by distillation and the residue was dissolved in ether. The ether solution was extracted three times with 10% potassium bicarbonate solution. Acidification of the combined bicarbonate solutions failed to cause the precipitation of an insoluble acid. The ether solution was then extracted with several portions of 10% sodium hydroxide solution. Acidification of the combined alkaline solutions caused the precipitation of 0.9 g. of mesitol. A sample, purified by sublimation, melted at 70° and did not depress the melting point of a known sample of mesitol.

The ether solution was washed with water and the residue, after removal of the ether, weighed 2.2 g. The crude solid was recrystallized from methanol. The first crop of crystals weighed 1.2 g. and melted at 136–137° alone or when mixed with an authentic sample of 1,2-dimesitoylethane.

Reaction of 1,2,5,6-Tetramesityl-1,5-hexadiene-1,6-diol (II) with Potassium Permanganate.—A solution of 1.9 g. of potassium permanganate in 250 cc. of acetone was added over a period of one-half hour to a well-stirred solution of 5 g. of the diol in 160 cc. of acetone. The manganese dioxide was gathered on a filter and extracted in a Soxhlet apparatus with acetone until the solvent was no longer yellow. The solutions were combined and concentrated to a volume of 150 cc. The excess permanganate was removed by filtration as manganese dioxide and the clear yellow solution was concentrated to 25 cc. Cooling caused the separation of the canary yellow diketone (V) which weighed 2.2 g. and melted at 279–282°. After recrystallization from benzene, it melted at 282–284°.

Anal. Calcd. for $C_{42}H_{46}O_2$: C, 86.53; H, 7.97. Found: C, 86.73; H, 8.13.

The mother liquor was evaporated to dryness and subjected to fractional crystallization from methanol. In this manner there was isolated 0.2 g. of the diketone and 1.1 g. of a white compound identified as α-mesitylvinyl mesityl ketone; m. p. 131–132°.

Reaction of 1,2,5,6-Tetramesityl-1,5-hexadiene-1,6-diol (II) with Lead Tetraacetate.—To a hot well-agitated solution of 5 g. of the diol in 100 cc. of benzene was added 10.5 g. of lead tetraacetate. The mixture was stirred and refluxed for fourteen hours. It was filtered and the clear solution was concentrated to a volume of 20 cc. Cooling caused the separation of 2.5 g. of the yellow diketone (V), m. p. 279–282°. Further investigation of the mother liquor resulted in the isolation of 0.3 g. of α-mesitylvinyl mesityl ketone, m. p. 129–131°. The residue was a dark tar.

When the reaction mixture was heated for five hours, there was produced 2.4 g. of the yellow diketone (V) and 0.8 g. of α-mesitylvinyl mesityl ketone.

1,2,5,6-Tetramesityl-1,3,5-hexatriene-1,6-diol (VI).—**A.** A solution of 0.2 g. of the diketone (V) in 150 cc. of

(9) Microanalyses by Miss Mary S. Kreger, Miss Margaret McCarthy, Miss Theta Spoor and Mr. L. G. Fauble.

benzene (thiophene-free) was shaken with a platinum oxide catalyst and hydrogen at atmospheric pressure until the yellow color had disappeared. The catalyst was removed by filtration and the solution was concentrated to a small volume and cooled. The resulting white diol melted to a yellow liquid at 252–253°.

Anal. Calcd. for $C_{42}H_{48}O_2$: C, 86.24; H, 8.28. Found: C, 86.14; H, 8.22.

When it was exposed to the atmosphere, the pure diol gradually assumed a brownish color. After two days it was brownish-yellow and the melting point was 235–240°.

B. To a solution of 0.5 g. of the diketone in 75 cc. of hot glacial acetic acid was added 3 g. of zinc dust. The mixture was heated on a steam-bath for one hour, after which time the zinc was removed by filtration. Cooling caused the separation of 0.45 g. of a brownish crystalline solid which melted, after washing with water, at 235–240°. Recrystallized from ethanol, the diol was white and melted to a yellow liquid at 252–253° alone or mixed with a sample of the diol obtained by method A.

1,2,5,6-Tetramesityl-1,3,5-hexatriene-1,6-diol Diacetate.—A. A solution of 0.5 g. of the diol (VI) in 25 cc. of acetic anhydride was heated at the refluxing temperature for ninety minutes. Cooling caused the separation of 0.5 g. of white needles, m. p. 271–273°. Recrystallized from glacial acetic acid, the diacetate melted at 273–274°.

Anal. Calcd. for $C_{46}H_{52}O_4$: C, 82.59; H, 7.83. Found: C, 82.63; H, 8.03.

B. To a solution of 0.18 g. of the diketone (V) in acetic anhydride was added 0.3 g. of fused zinc chloride and 3 drops of concentrated hydrochloric acid.[10] The mixture was shaken for twenty minutes with 10 mg. of platinum oxide catalyst and hydrogen at atmospheric pressure. At the end of this time the solution was colorless and the product separated as white needles. It weighed 0.15 g. Recrystallized from glacial acetic acid, it melted at 273–274° alone or mixed with the diacetate obtained by method A.

Oxidation of 1,2,5,6-Tetramesityl-1,3,5-hexatriene-1,6-diol with Hydrogen Peroxide.—A solution of 0.28 g. of the yellow diketone (V) in 60 cc. of benzene (thiophene-free) was shaken with hydrogen at atmospheric pressure over platinum until the color had disappeared. The catalyst was removed by filtration and the benzene solution was shaken for ten minutes with 5 cc. of 30% hydrogen peroxide and 25 cc. of water. The benzene solution turned yellow. After removal of the solvent the yellow residue weighed 0.19 g. Recrystallized from benzene, the product melted at 282–284° alone or when mixed with another sample of the yellow diketone.

Ketonization of 1,2,5,6-Tetramesityl-1,3,5-hexatriene-1,6-diol.—Two grams of the yellow diketone (V) was reduced by the zinc and acetic acid method. The resulting trienediol (1.8 g.) was transferred to a flask containing 500 cc. of absolute ethanol which had previously been saturated with dry hydrogen chloride. The solution was refluxed on a steam-bath for twelve hours. After cooling, this product (1.25 g.) was separated by filtration; m. p. 170–185°. The pure diketone (VIII) obtained by fractional crystallization from methanol melted at 201° and weighed 0.8 g.

Anal. Calcd. for $C_{42}H_{48}O_2$: C, 86.24; H, 8.28. Found: C, 86.00; H, 8.38.

Enolization of 1,2,5,6-Tetramesityl-3-hexene-1,6-dione (VIII).—To a Grignard solution made from 11 g. of ethyl bromide, 2.5 g. of magnesium and 25 cc. of ether was added a solution of 1.5 g. of the diketone (VIII) in 10 cc. of ether and 25 cc. of benzene. The mixture was stirred and refluxed for five hours. It was cooled and poured into iced ammonium chloride solution. The aqueous layer was extracted with 50 cc. of ether. The ether solution was dried over calcium chloride and evaporated to dryness on a steam-bath. Treatment of the residue with cold ethanol caused the separation of 0.8 g. of the diol (VI), m. p. 235–240°. Recrystallized from ethanol, it melted to a yellow liquid at 252–253° alone or mixed with a sample of the compound obtained by another method.

Summary

Bimolecular reduction of mesityl α-mesitylvinyl ketone yields 1,2,5,6-tetramesityl-1,5-hexadien-1,6-diol, a vinylog of ethylene glycol. Oxidation of the diol produces chain cleavage analogous to that of 1,2-glycols, regenerating the parent vinyl ketone.

A second product of oxidation is 1,2,5,6-tetramesityl-2,4-hexadien-1,6-dione. This ketone undergoes 1,8 addition of hydrogen to yield 1,2,5,6-tetramesityl-1,3,5-hexadien-1,6-diol, a vinylog of acetylene glycol.

The new dienols can be ketonized by long treatment with alcoholic hydrogen chloride. The dienols can be regained by treating the resulting diketones with the Grignard reagent.

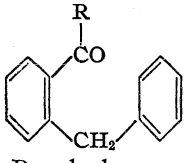
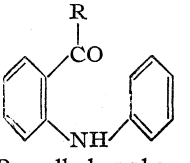
The Mechanism of Cyclization Reactions

BY ERNST BERLINER

Following the observation of E. Bergmann[1] that the acetal of *o*-benzylbenzaldehyde (I) yields a certain amount of anthracene when hydrolyzed with hydrochloric acid in acetone, Bradsher[2] worked out a convenient method of synthesizing 9-substituted anthracenes and 1,2-benzanthracenes in excellent yield by refluxing ketones of the type II with 34% hydrobromic acid and acetic acid. The synthesis of naphthalene by the cyclization of β-styrylaldehyde is considered by Bradsher[3] the simplest cyclodehydration reac-



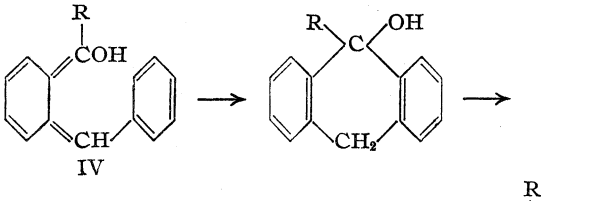
I R = hydrogen
II R = alkyl or phenyl



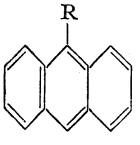
III R = alkyl or phenyl

tion of this type and similar to the formation of β-phenylnaphthalene from two molecules of phenylacetaldehyde observed by Zincke.[4]

A reaction analogous to the above hydrocarbon synthesis has been known in the acridine series for a long time and a number of acridines have been prepared[5] from the corresponding aldehydes or phenylketones (III) (in one case a methyl ketone). As far as the mechanism of the hydrocarbon synthesis is concerned, Bergmann suggested a similarity to the Elbs pyrolysis assuming enolization as the first step. Bradsher[6] pointed out

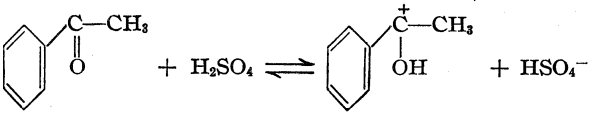


IV



that the reaction is more like a Friedel–Crafts condensation than an Elbs pyrolysis, and proposed enolization as the first step followed by cyclization and subsequent loss of water.

The following alternate explanation is based upon the behavior of carbonyl compounds in strongly acidic media and upon the concept of cyclodehydration as essentially an internal aromatic substitution. It is believed that the neutral enol (IV), even if it were formed by an acid-catalyzed enolization of the type proposed, would hardly undergo cyclization. It is now generally believed that ionic fragments play an important role as reaction intermediates, even in cases where the initial and final products are non-ionic in character and where the concentration of the ions is not great enough to be detected.[7] Thus in most aromatic substitution reactions, a positive fragment attacks a position of high electron density in the benzene ring, which loses a proton to the acid residue (base), after the intermediate complex is formed.[8] In order to satisfy these requirements, a mechanism is proposed on the basis of an addition of a proton to the carbonyl oxygen followed by an electrophilic substitution reaction. Addition compounds of the carbonyl group with acids and salts have long been known,[9] but their nature was not clearly understood until the work of Hantzsch, and later Hammett[10] showed that the solubility of carbonyl compounds in sulfuric acid depends on salt formation, as illustrated for the case of acetophenone



A proton is transferred from the acid to the carbonyl group and the conjugate acid of the ketone is positively charged. The first step in the cyclization reaction thus may be the formation of the conjugate acid (V), which is a hybrid of the

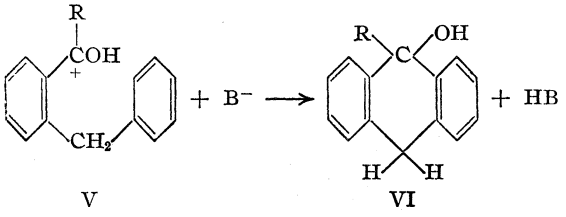
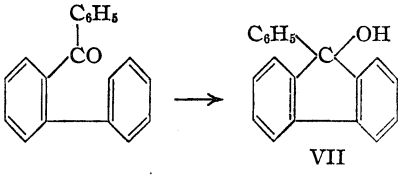
two resonant forms  , the positive charge being distributed between the oxygen and carbon atoms. The ring closure is an electrophilic attack by the carbon atom on the opposite ortho position forming the dihydroanthranol (VI), which readily suffers dehydration.



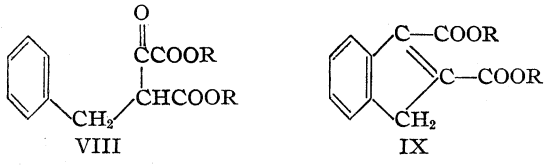
V VI

This mechanism does not require enolization as the first step and no active hydrogen is necessary. This concept is substantiated by the present observation that a similar cyclization can be accomplished with a compound which has no hydrogen available for enolization. When 2-phenylbenzophenone[11] was treated according to the procedure of Bradsher a mixture was obtained from which 9-phenylfluorenol and its acetate were isolated. Furthermore, when the same ketone was treated with sulfuric acid and acetic anhydride, a substance was obtained identical with a polymer of 9-phenylfluorenol obtained by treating the carbinol (VII) with the same reagents.[12] A reaction



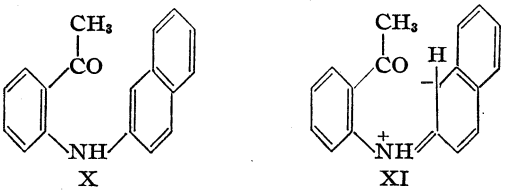
VII

very similar to the one considered was discovered by Bougault,[13] who found that the ester of the keto acid (VIII) undergoes ring closure under the



VIII IX

influence of sulfuric acid to give the indene dicarboxylic ester IX. The reaction was studied by Auwers and Moeller[14] and has proved useful in synthesis.[15] Auwers and Moeller regarded the enol form of the ketone as reaction intermediate, but here again the neutral enol, although it certainly could be present in this case, is not likely to enter into the substitution reaction for reasons given above. The first step in the proposed mechanism is the same as in the mechanism for acid-catalyzed enolization.[16] After the positively charged conjugate acid is formed, the ketone which is about to enolize, attacks the ring before the neutral enol is formed, and while it still carries the positive charge.



X XI

The cyclization proceeds with greater ease in the acridine series. If the secondary amine (X) is dissolved in glacial acetic acid and a few drops of concentrated sulfuric acid are added the reaction is completed after short heating, whereas much longer periods are necessary in the case of the hydrocarbons. The amino group (X) is much stronger ortho-directing than the methylene group, and an equivalent structure (XI) can be written with a true negative charge in the ortho position.[17]

The cyclization reaction has been utilized further for the synthesis of three higher benzologs of 9-methylacridine, namely, the 1,2-benz-, 3,4-benz- and 1,2,3,4-dibenz- derivatives. Since dibenzacridines have been shown to possess carcinogenic properties it seemed of interest to test these meso-substituted derivatives for comparison with the potent isolog 9-methyl-1,2-benzanthracene.

Another cyclodehydration reaction, where ionic fragments appear to be the intermediates, is the formation of 9-phenylfluorenes from triarylcarbinols.[18,19] The reaction proceeds with surprising ease and is accompanied by a remarkable color change. Thus when the carbinol (XII) is

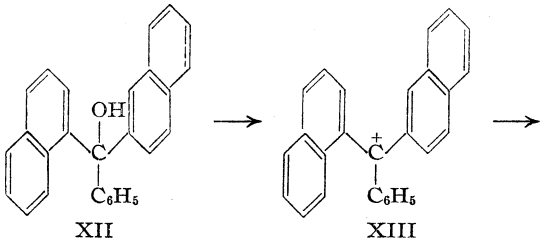
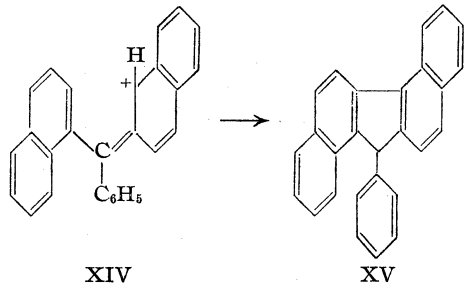
dissolved in acetic acid and heated to the boiling point, the solution is but slightly colored. If a few drops of hydrochloric acid are added at the boiling point a deep green color appears for a few seconds, water is given off as the green color disappears, and a reddish-brown color results. The reaction is over and another drop of hydrochloric acid does not produce any further color change. The fluorene, XV, crystallizes from the cooled solution and the whole reaction resembles those with inorganic ions. The carbinol itself dissolves in sulfuric acid with the same green color. In all observed cases the transient color was identical with the color of the carbinol in sulfuric acid. It is generally accepted that the color which is obtained when triarylcarbinols are dissolved in sulfuric acid, or when they are treated with different inorganic salts, is due to the color of the positive carbonium ion. Therefore, it seems justifiable to assume that the first step in the cyclodehydration is the formation of the carbonium ion (XIII).



XII XIII



XIV XV

The positive charge is distributed on the ortho and para postions, accounting for the stability of these ions. If the charge moves to the nearest ortho position, an equivalent structure (XIV) is obtained which allows substitution on the opposite ring. This is followed by aromatization. If the initial step consists in the formation of the carbonium ion and not in the loss of water, any electrophilic reagent other than strong mineral acids should bring about the cyclization. This was confirmed by dissolving the carbinol (XII) in an inert solvent and adding different salts which are known to effect ionization of the triarylcarbinols. In each case a complex precipitated immediately which had the color of the carbinol in sulfuric acid, and the fluorene was obtained after decomposition with water. This explains why it is so difficult to prepare stable salts or the chlorides of the higher benzologs of triphenylcarbinol.[18,19] Two fluorene derivatives, 1,2,5,6- and 1,2,7,8-dibenz-9-phenylfluorene were synthesized by the above reaction. The intermediate carbinols were prepared by the Grignard action of a naphthyl halide and a naphthyl phenyl ketone. The possibility of reaction in the phenyl instead of the naphthyl group to form the 9-naphthyl-benzfluorene is less likely because of the relative inertness of the phenyl group. Furthermore, Schoepfle[19] and Ullmann[18] prepared similar compounds by the dehydration of the carbinols, as well as by the action of phenylmagnesium bromide on the corresponding fluorenones and obtained identical compounds. It can be assumed, therefore, that the above compounds have the structure assigned to them.

Acknowledgment.—I wish to express my sincere thanks to Professor L. F. Fieser, Harvard University, under whom I have the privilege to work and without whose generous help and kind interest this work would not have been accomplished. I also thank Mrs. L. F. Fieser for her help in preparing the manuscript.

Experimental[20]

o-(α-Naphthyl)-aminoacetophenone.—A mixture of 2.4 g. of *o*-aminoacetophenone,[21] 4 g. of α-bromonaphthalene, 5 g. of potassium carbonate and 0.3 g. of copper powder was heated in refluxing nitrobenzene (50 cc.) in an all glass apparatus. The solution became dark and carbon dioxide was evolved. After three hours the reaction mixture was steam-distilled to remove the solvent and excess reagents, and the residue was taken up in ether–benzene, and dried with sodium sulfate. After evaporation, a brown oil remained which could be used for cyclization without further purification. The oil crystallized upon the addition of alcohol and 3.9 g. was obtained as small yellow prisms after several recrystallizations from alcohol and a little benzene, m. p. 96.4–97.2°.

Anal.[22] Calcd. for $C_{18}H_{15}NO$: C, 82.73; H, 5.78. Found: C, 83.00; H, 5.65.

9-Methyl-3,4-benzacridine.—Three grams of the above oil was dissolved in 25 cc. of glacial acetic acid, 3 cc. of concentrated sulfuric acid was added, and the flask was placed on the steam-bath. The yellow sulfate of the acridine precipitated immediately and was filtered after ten minutes' heating. It was suspended in water, and the base (2.5 g.) which precipitated on addition of concentrated ammonia, was filtered and dried. It formed yellow needles from alcohol, m. p. 111.6–112.2°.

(20) All melting points are corrected.

(22) Microanalyses by Miss E. Werble.

Anal. Calcd. for $C_{18}H_{13}N$: C, 88.86; H, 5.38. Found: C, 88.91; H, 5.33.

The **picrate** (fine yellow needles) is sparingly soluble in the common solvents. Higher boiling solvents (toluene, dioxane) dissolve it, but with decomposition. The picrates of the other acridines show the same properties. It was crystallized from acetone; m. p. 251–255° (dec.).

Anal. Calcd. for $C_{24}H_{16}N_4O_7$: N, 11.86. Found: N, 11.83.

***o*-(β-Naphthyl)-aminoacetophenone** (X) was prepared in the same way as the other isomer from 3.1 g. of *o*-aminoacetophenone, 5.2 g. of β-bromonaphthalene, 6 g. of potassium carbonate and 0.3 g. of copper powder in 50 cc. of boiling nitrobenzene. The remaining oil was distilled at 6 mm. and 195–196°. In an attempt to prepare the picrate, a precipitate was formed after short boiling with picric acid which proved to be the picrate of the cyclized product.

Anal. Calcd. for $C_{18}H_{15}NO$: N, 5.36. Found: N, 5.4.

9-Methyl-1,2-benzacridine.—Four grams of the oil was heated on the steam-bath in 25 cc. of glacial acetic acid and 4 cc. of concentrated sulfuric acid. After fifteen minutes it was poured on ice and filtered. The filtrate was treated with ammonia and the acridine which precipitated (3.7 g.) was dried and recrystallized repeatedly from benzene–ligroin. It forms yellow, shining plates, m. p. 145–145.2°.

Anal. Calcd. for $C_{18}H_{13}N$: C, 88.86; H, 5.38. Found: C, 88.87; H, 5.1.

The **picrate** forms small yellow needles from acetone, m. p. 245–248° (dec.).

Anal. Calcd. for $C_{17}H_{16}N_4O_7$: N, 11.86. Found: N, 11.56.

9-Methyl-1,2,3,4-dibenzacridine.—A mixture of *o*-aminoacetophenone (1.5 g.), 9-bromophenanthrene (3 g.), potassium carbonate (4 g.) and copper powder (0.3 g.) was heated in 40 cc. of nitrobenzene as described for the other isomers. The remaining oil was taken up in glacial acetic acid (20 cc.) and after the addition of 3 cc. of concentrated sulfuric acid heated for twenty-five minutes on the steam-bath. Part of the sulfate precipitated and was filtered off and treated with ammonia. This was combined with the precipitate obtained after adding ammonia to the filtrate, and crystallized from a little alcohol and benzene, as straw-like needles (3 g.), m. p. 121.4–122.4°.

Anal. Calcd. for $C_{22}H_{15}N$: C, 90.07; H, 5.1. Found: C, 90.05; H, 4.9.

The picrate forms yellow needles from acetone; m. p. 206–208° (dec.).

Anal. Calcd. for $C_{18}H_{18}N_4O_7$: N, 10.72. Found: N, 10.44.

β-Benzoylnaphthalene.—A Grignard solution prepared from 18 g. of bromobenzene and 2.8 g. of magnesium turnings was treated with 12 g. of β-naphthonitrile in absolute ether; a crystalline precipitate separated after short boiling. Refluxing and stirring was maintained for five hours, after which time the mixture was decomposed with ammonium chloride solution. The ether layer was evaporated and the remainder refluxed with 50 cc. of water, 16 cc. of acetone, and 25 cc. of concentrated hydrochloric acid. After three hours the cooled solution was extracted with ether and the ketimide hydrochloride, which was not hydrolyzed, was treated once more with acid to which 30 cc. of benzene was added. The combined organic layers were dried and the solvents evaporated. The remaining solid was crystallized from alcohol: (15 g., 82.5%), m. p. 81–82°.[23]

α,β-Dinaphthylphenylcarbinol (XII).—A Grignard solution was prepared from 8 g. of α-bromonaphthalene and 0.94 g. of magnesium turnings in absolute ether. About 0.5 cc. of α-bromonaphthalene was added at the end of the reaction to take care of the unreacted magnesium. Eight grams of β-benzoylnaphthalene was added over a period of twenty-five minutes, and stirring and refluxing was maintained for two hours after which the complex was decomposed with ice-cold 25% ammonium chloride solution. The organic layer was separated, dried over sodium sulfate and the oil remaining after evaporation crystallized readily upon the addition of ether–ligroin (9 g., 72%). The carbinol crystallizes with benzene or alcohol when in contact with these solvents. The addition products are very stable and melt between 195–205° with loss of solvent. The carbinol was recrystallized from ether–ligroin as small white prisms; m. p. 168–169°. It dissolves in concentrated sulfuric acid with a dark green color and appears red in transmitted light.

Anal. Calcd. for $C_{17}H_{20}O$: C, 89.97; H, 5.59. Found: C, 90.09; H, 5.84.

1,2,5,6-Dibenz-9-phenylfluorene (XV).—Four grams of the crude carbinol was dissolved in 15 cc. of glacial acetic acid, heated to the boiling point and a few drops of hydrochloric acid added. The solution turned green and then reddish. An oil separated which solidified on cooling. It was crystallized repeatedly from acetic acid and forms white needles, m. p. 219–219.5°. It is soluble in ether, warm benzene, hot acetic acid, sparingly soluble in alcohol and ligroin.

Anal. Calcd. for $C_{27}H_{18}$: C, 94.7; H, 5.3. Found: C, 94.67; H, 5.3.

The following experiments were carried out with 100 mg. of the carbinol. It was dissolved in benzene (5 cc.) and a spatula full of aluminum chloride, aluminum bromide, iodine, phosphorus pentachloride, or a few drops of stannic chloride was added. In each case the green complex separated immediately. The mixture was heated for about five minutes on a steam-bath, and then decomposed with water until it had all dissolved. The fluorene was isolated from the benzene layer. No fluorene was obtained by heating the carbinol in refluxing xylene or acetonitrile.

β,β-Dinaphthylphenylcarbinol was prepared in the same way as the other isomer from 9 g. of β-bromonaphthalene and 1.1 g. of magnesium to which 9 g. of β-benzoylnaphthalene was added in ether and benzene. The reaction mixture was worked up as usual and a quantity of small white needles (2 g.) separated from the ether–benzene solution after drying and concentrating. A further quantity (3 g.) was obtained on concentrating the solution but about half of the carbinol remained in an oily condition and crystallized only very slowly in the ice chest. Recrystallized from benzene–ether (very little soluble in

(23) Kollarits and Merz, *Ber.*, **6**, 543 (1873), give 82°.

ether) it melts at 216.5–217.5°. A dilute solution of the compound in concentrated sulfuric acid looks green when viewed through a thin layer, but red in more concentrated solutions.

Anal. Calcd. for $C_{27}H_{20}O$: C, 89.97; H, 5.59. Found: C, 90.17; H, 5.52.

1,2,7,8-Dibenz-9-phenylfluorene.—The cyclization was carried out on the oil. Three grams in 30 cc. of glacial acetic acid and 3 cc. of hydrochloric acid were refluxed for twenty minutes. An oil and a solid separated, which were filtered off and extracted with boiling acetic acid without further drying. This removed an unidentified by-product which, when not removed, made the purification of the fluorene very difficult. The white compound which was obtained after cooling the solution was recrystallized several times by suspending it in hot ligroin and adding just enough benzene to bring it into solution, small white needles arranged in rosets resulted; m. p. 148.5–149.5°.

Anal. Calcd. for $C_{27}H_{18}$: C, 94.7; H, 5.3. Found: C, 94.6; H, 5.15.

α,α-Dinaphthylphenylcarbinol.—This compound was first made by Elbs[24] from benzoic ester and α-bromonaphthalene and later by Schoepfle who used toluene to improve the yield. We prepared it by the above general method using 11 g. of bromonaphthalene, 1.3 g. of magnesium and 11 g. of α-benzoylnaphthalene[25] (64% yield). In order to obtain crystals, the ether solution was concentrated to a small volume and ligroin was added until no more of the light oil separated. The supernatant layer which contained the by-products was disregarded. The carbinol crystallized in the desiccator after a few cc. of benzene was added, m. p. 169–170°.

3,4,5,6-Dibenz-9-phenylfluorene was prepared as above, the transient color is purple; m. p. 275° (as given by Schoepfle).

Cyclization of 2-Phenylbenzophenone, 1.—One gram of 2-phenylbenzophenone was dissolved in 10 cc. of glacial acetic acid and 10 cc. of 34% hydrobromic acid was added at the boiling point. Five more cc. of acetic acid was added to keep all in solution. After twenty-four hours a yellow oil separated and boiling was continued for two more days. The oil solidified on cooling and crystallized on rubbing. The crude product softened between 105–107° and melted between 150–160°. It was extracted with hot ether and the ether soluble product recrystallized three times from acetic acid. Twenty mg. of white needles was obtained, m. p. 169–171°. Kliegl[26] gives 169–169.5° for 9-phenylfluorenol acetate.

The compound apparently contained some of the polymerization product which is difficult to remove. The combined mother liquors were boiled with sodium acetate in acetic acid to hydrolyze the acetate still present and a white compound, m. p. 106–107°, precipitated on pouring on ice[26] (given for 9-phenylfluorenol 107–108°). This crude product was reduced with zinc, hydrochloric acid and acetic acid and the obtained hydrocarbon (about 50 mg.) recrystallized once from alcohol in which it is soluble with a distinct blue fluorescence, m. p. 142.8–144.6° (lit. 145–146°[27]); mixed m. p. 142.4–144.4.

2. Five hundred mg. of the ketone was dissolved in 10 cc. of acetic anhydride and heated on the steam-bath. One cc. of concentrated sulfuric acid was added. The yellow compound which separated melted over the wide range of 260–300° and had the properties of the polymer of 9-phenylfluorenol. It was dissolved in chloroform and reprecipitated with alcohol, as suggested by Kliegl.[26] It darkens at about 250° and melts between 300–330°. The cyclization of the ketone with hydrobromic acid is of no preparative value for making the carbinol because the polymer is always formed along with it. This makes the yield low and the carbinol hard to purify.

Summary

9-Methyl-1,2-benzacridine, 9-methyl-3,4-benzacridine, 9-methyl-1,2,3,4-dibenzacridine as well as 9-phenyl-1,2,5,6-dibenzfluorene and 9-phenyl 1,2,7,8-dibenzfluorene were synthesized by cyclizing the corresponding methyl ketones or dinaphthylphenylcarbinols, respectively. A mechanism for the cyclodehydration reaction is suggested which involves as the first step the formation of a positively charged fragment followed by an electrophilic aromatic substitution reaction.

The Reaction of Formaldehyde with 1(−)-Asparagine[1]

BY D. C. CARPENTER AND F. E. LOVELACE

The action of formaldehyde on various amino acids has been investigated by numerous workers. Much of the older work was concerned with the isolation and analysis of compounds.[1a] More recently the reactions have been followed by measurements of the unreacted amino groups and hydrogen-ion concentrations and various constants evaluated.[2] Lately measurements of the optical rotation have been used in a study of the reaction between formaldehyde and 1(−)-proline.[3]

In the present paper studies of the latter sort have been employed in indicating the progress of the reaction and the compounds formed. Under the experimental conditions we have used, methylene-1(−)-asparagine is formed which reacts further with a second mole of formaldehyde. The latter compound has not been isolated because of its ease of decomposition. The existence of these compounds is a valuable clue in interpreting the reaction of formaldehyde with proteins in the manufacture of plastics, etc.

Preparation of Materials

1(−)-Asparagine.—A commercial sample of 1(−)-asparagine was recrystallized twice from hot water as the monohydrate, m. p. 225° (cor.), and its moisture content determined by drying to constant weight *in vacuo* at 61° over phosphorus pentoxide (H_2O, 12.18; calcd., 11.99%). The amino nitrogen was determined by the Van Slyke method (amino N, 9.30; calcd., 9.33%).

Formaldehyde.—A very pure concentrated formaldehyde solution was brought to exactly *p*H 7.0 against the glass electrode by the addition of sodium hydroxide solution and the formaldehyde content of this stock solution determined by the sodium bisulfite method of Kleber.[4]

Experimental

Into each of a series of 50-ml. volumetric flasks exactly 0.02 mole of 1(−)-asparagine was weighed out (corrected for water content) and 0.02 mole of carefully standardized sodium hydroxide solution added and the mixture shaken until all the 1(−)-asparagine was in solution. Various amounts of the stock formaldehyde solution were added from a micro-buret to each flask and the volume of each solution made up to the 50-ml. mark with water and well shaken. Part of each solution was transferred to a 2-dm. polarizing tube and the reserve solutions and those in the polarizing tubes were kept at 20° in a constant temperature bath and the rotation of the latter read periodically in the polariscope with the sodium arc as a light source. In solutions containing small amounts of formaldehyde, equilibrium was attained very slowly (thirty-four days for solution 5 containing 0.02 mole of formaldehyde per 0.02 mole of 1-asparagine); however, equilibrium was reached in a much shorter period when higher aldehyde concentrations were employed. The angular rotations at equilibrium for a 2-dm. tube are recorded in Table I. When equilibrium was attained, the hydrogen-ion concentrations of the reserve solutions were measured with a standardized glass electrode against a saturated calomel half-cell.

[a] In this column the angular rotation of solutions containing 0.02 mole of 1-asparagine with equivalent of base (Na) and designated moles of formaldehyde are reported for 2-dm. tube length after reaching equilibrium.

For estimating the uncombined formaldehyde in the solutions, appropriate aliquots of the reserve solutions were taken and caused to react with dimethyldihydroresorcinol as described by Vorländer.[5] The crystalline methylene derivative was filtered off after three hours of interaction at room temperature onto fritted glass crucibles, washed several times with water, dried at 110° and weighed.

The solubility of methylene-(bis)dimethyldihydroresorcinol in a saturated aqueous solution of dimethyl

dihydroresorcinol was found to be 0.0025 g. per liter and 0.0050 g. per liter in water at 20°. The weights of methylene-(*bis*)dimethyldihydroresorcinol reported have been corrected for the above respective solubilities. One gram of methylene-(*bis*)dimethyldihydroresorcinol is equivalent to 0.1027 g. of formaldehyde.

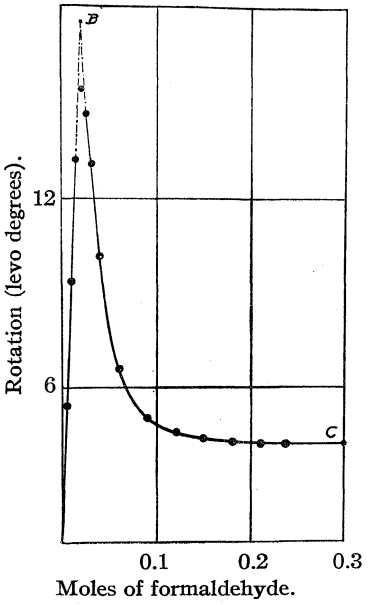

Fig. 1.—Effect of added formaldehyde on angular rotation (2 dm.) of 0.02 mole of sodium 1(−)-asparaginate in 50 ml. of solution: B, sodium salt of methylene-1(−)-asparagine; C, same with additional mole of formaldehyde forming unstable compound.

We have found it unnecessary to add acetic acid to effect the precipitation of the resorcinol derivative as was recommended by Wadsworth and Pangborn.[2] The addition of acid produces decomposition of methylene-1-asparagine and consequent liberation of formaldehyde and is to be avoided. In our experience the methylene-1-asparagine compound with one additional mole of formaldehyde is so unstable that, in the presence of an excess of dimethyldihydroresorcinol as is used in the precipitation, it decomposes giving formaldehyde and methylene-1-asparagine. The aldehyde so liberated reacts with dimethyldihydroresorcinol in addition to any free aldehyde remaining in the solution at equilibrium.

The results of the analyses for free formaldehyde are given in Table II. The optical rotation and hydrogen-ion concentrations are shown graphically in Figs. 1 and 2.

Discussion

It is clear from the results of the optical rotation work (Fig. 1) that a definite compound having a maximum levo rotation is formed when the mole ratios of asparagine and formaldehyde are 0.02 and 0.02, respectively. The compound formed is methylene - 1 - asparagine, inasmuch as we have obtained 6-oxy-5-bromopyrimidine 4-carbonic acid (m. p. 206–7° (cor.) with decomposition) therefrom by the action of sodium hypobromite, the same compound previously described by Cherbuliez and Starvitch.[6] From Fig. 2 it is clear that the maximum rate of change of hydrogen-ion concentration produced

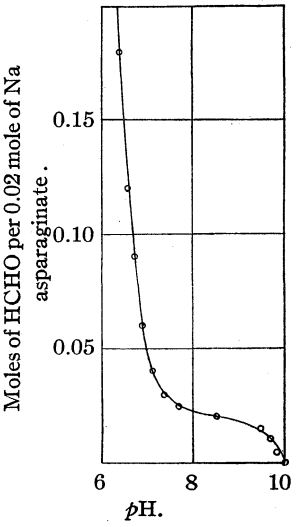

Fig. 2.—Effect of added formaldehyde on *p*H of 0.02 moles of sodium 1-asparaginate in 50 ml. of solution.

.50	10.82	.342	.200	.142	.142	1.00	0	−0.848
.60	9.49	.455	.240	.215	.143	0.67	−0.176	.667
.70	8.16	.590	.280	.310	.133	.43	.368	.508
.80	6.82	.761	.320	.441	.110	.25	.602	.355

by adding formaldehyde is achieved in the region where 0.02 mole of formaldehyde reacts with 0.02 mole of asparagine. To this maximum we give the usual interpretation of compound formation in equimolecular proportions. That compound formation has been with the α-amino group rather than the amide group is confirmed from Fig. 2 by the rapid increase in acidic properties.

With regard to the further reaction of methylene-1-asparagine with additional formaldehyde (B-C section of Fig. 1), we have approached the problem from the basis of the equilibrium constant. If the concentrations of formaldehyde, methylene-1-asparagine and the reaction product be represented by C_F, C_A and C_{AF_n}, respectively, and n moles of formaldehyde take part in the reaction, then at equilibrium $(C_A \times C_F^n)/C_{AF_n} = k$, where k is the equilibrium constant. On the assumption that the optical rotation of substances A and AF_n are of different magnitude and each proportional to its concentration and further that the presence of neither species has an influence on the rotation of the other, we may calculate k from the rotation data. From examination of the first few experimental points it is clear that n cannot be greater than unity. In evaluating k we have employed the extrapolated values −17.50 and −4.15° for the maximum and minimum ends, respectively, of the curve. Points where the reaction is 0.20, 0.30, 0.40, etc., complete have been chosen and the respective formaldehyde concentrations read off from the curve. It is difficult to estimate the aldehyde concentrations near the beginning of the curve on account of its steepness and likewise near the end on account of its flatness, and partly for this reason only the central section has been employed in the calculations, which latter are carried out on a moles per liter basis. These data are given in Table III. In the column headed Total Formaldehyde, the 0.40 mole of formaldehyde required to form 0.40 mole of methyleneasparagine has been subtracted from the total formaldehyde in the system as read from the graph. The equilibrium constant k shows a fair constancy in the region 0.14.

The equilibrium constant may also be evaluated from the logarithmic form of the equilibrium equation log (C_A/C_{AF}) + log C_F = log k as employed by Frieden, Dunn and Coryell,[3] in which a graph of log (A/AF) plotted against log F should give a straight line. This relation is given in Fig. 3. A straight line can be drawn through several of the points, which gives a graphical solution for k of 0.142 in reasonable agreement with the foregoing treatment.

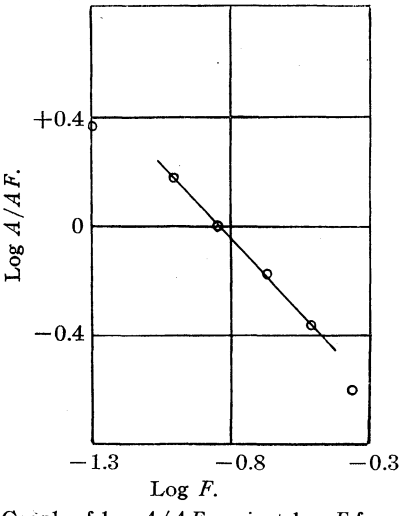

Fig. 3.—Graph of log A/AF against log F for unstable compound of methylene-1(−)-asparagine with formaldehyde.

While the data show that methylene-1-asparagine binds an additional mole of formaldehyde to form an unstable compound, evaluation of the data depends on the validity of the assumptions mentioned earlier, of which the lack of constancy of rotation of the two species with respect to concentration seems to be the main disturbing feature for the compounds under consideration.

There can be little doubt that the first mole of formaldehyde reacts with the α-amino group of

asparagine to give a methylene derivative. One might expect that the second mole of formaldehyde reacts with the amide group forming a methylol derivative. In support of this view it may be said that many methylol compounds of acid amides and formaldehyde have been reported in the literature, and in common with our second asparagine compound all are unstable and give off formaldehyde. Further work is in progress in this Laboratory to ascertain the formaldehyde binding of 1(+)-aspartic and 1(+)-glutamic acids, in an effort to elucidate the point of attachment of the second mole of formaldehyde.

In 6.64% aqueous solution $[\alpha]^{20}D$ is $-116.04°$ for the sodium salt of methylene-1(−)-asparagine and $-23.06°$ for the sodium salt of the methylene-1(−)-asparagine compound with one additional mole of formaldehyde, the latter concentration being 9.04% and dissolved in 14.4% formaldehyde solution. For sodium 1(−)-asparaginate $[\alpha]^{20}D$ is $-7.28°$ for a 6.16% solution in water. Clough[7] records for the latter a value of $-7.53°$ for a 14.51% solution at 25° and Becker[8] a value of -7.42 for a 11.68% solution at 20°. Clough notes that the rotation becomes more negative as the temperature is raised and hence our value compares well with the older data.

Summary

1. The reaction between solutions of (1−)-asparagine containing an equivalent of sodium hydroxide and various amounts of formaldehyde was followed by polariscopic and hydrogenion measurements, and estimation of unreacted aldehyde.

2. 1(−)-Asparagine reacts with formaldehyde, mole per mole, to form methylene-1(−)-asparagine. The latter reacts further with one additional mole of formaldehyde to form an unstable compound of unestablished constitution which readily loses aldehyde.

GENEVA, N. Y. RECEIVED AUGUST 17, 1942

[CONTRIBUTION FROM THE STAMFORD RESEARCH LABORATORIES OF THE AMERICAN CYANAMID COMPANY]

Studies in Chemotherapy. VI. Sulfanilamido Heterocycles[1]

BY GEORGE W. ANDERSON, H. ELDRIDGE FAITH, HARRY W. MARSON, PHILIP S. WINNEK AND RICHARD O. ROBLIN, JR.

On the basis of our present knowledge, N^1-heterocyclic substituted sulfanilamide derivatives still appear to offer the greatest possibilities for therapeutically effective sulfanilamide type compounds. Continuing our investigations in this field,[2] we have prepared a number of new derivatives of this type. These compounds, together with pertinent data concerning them, are listed in Table I. Several of the amino heterocycles required as intermediates have not been reported previously. The syntheses and properties of these substances are described in the Experimental part.

Most of the sulfanilamide derivatives were prepared by the standard procedure. In a few cases, such as the conversion of 2-aminoöxazole to the corresponding sulfanilamido compound, it was necessary to use *p*-nitrobenzenesulfonyl chloride. Even this method was hardly satisfactory, since in this particular case, the over-all yield, including the synthesis of the amino heterocycle, was only about 0.2%. Numerous attempts to prepare an unsubstituted sulfanilamido triazine from 2-amino-1,3,5-triazine were unsuccessful. Under all of the conditions employed, this intermediate appeared to be unstable in the presence of sulfonyl chlorides. Both sulfanilamide and sulfaguanidine were isolated as final products of the various reactions.

Some of the sulfanilamido derivatives are of interest because of their chemical relationship to well-known sulfonamides. For example, 2-sulfanilamidoöxazole is the oxygen analog of sulfathiazole, and 3-sulfanilamidopyridazine is an isomer of sulfadiazine and sulfapyrazine. The imidazole derivative corresponds to sulfadiazine in the five-membered ring series. 4-Sulfanilamido-1,2,4-triazole represents a somewhat different type of heterocyclic derivative, in that the sulfanilamido group is joined to the ring through one of the hetero-atoms rather than through a carbon atom.

In vitro bacteriostatic tests against *E. coli* are included in Table I for comparison with the results in experimental animals.[3] None of the new sulfanilamido heterocycles showed much *in vivo* activity. All of them, however, showed some degree of bacteriostasis, including two compounds (2-sulfanilamidoöxazole and 3-sulfanilamidopyridazine) which were as active as sulfathiazole. In spite of high blood levels, these two derivatives were without activity in experimental mouse infections. This phenomenon has been encountered previously.[2,4] It was suggested that some of the discrepancies between *in vitro* and *in vivo* results, where lack of absorption could be ruled out, might be due to the formation of less active substances in the animal body.[4c] On the other hand, all cases of this type may not be explainable on the basis of a breakdown to less active products.

Davis[5] has suggested that the *in vivo* activity of sulfonamides may be influenced by the binding effect of serum proteins. Based on preliminary bacteriostatic experiments, he also suggested the possibility that the bound form might be inactive. Since the degree of binding appeared to be a function of the particular sulfonamide, it is possible that such a phenomenon may explain some of the differences between *in vitro* and *in vivo* activity. In any event, it is evident from the data in Table I that factors other than bacteriostasis, absorption and generally recognized variables are important to the chemotherapeutic activity of sulfonamides against experimental animal infections. These observations emphasize again the number of variables, both known and unknown, which may complicate any attempts to correlate *in vivo* activity with chemical structure.

(3) The pharmacological and bacteriological studies were carried out in these Laboratories under the direction of Dr. W. H. Feinstone.

Experimental

Aminoheterocycles, in general, were prepared by methods which have been described in the literature (see references in Table I). Several of these intermediates have not been described previously, and the data for these compounds are recorded in Table II. The following is a description of the procedures employed for the synthesis of the new aminoheterocycles.

2-Aminoöxazole was prepared by one of the standard methods for the synthesis of the analogous thiazole derivative,[6] substituting urea for thiourea. In spite of the numerous modifications tried, the yields were much poorer when urea was used. 379 g. (2.65 moles) of α,β-dichlorodiethyl ether, 800 cc. of water and 318 g. (5.3 moles) of urea were refluxed gently, with stirring, for five and one-half hours. After standing overnight, the clear solution was

TABLE II

AMINOHETEROCYCLES

Compound	M. p., °C. (cor.)	Yield,[a] %	Analyses, % Calcd. C	Calcd. H	Calcd. N	Found C	Found H	Found N
2-Aminoöxazole	96– 98	4.4	42.9	4.8	33.3	43.0	4.9	33.1
3-Amino-5-methyl-1,2,4-oxadiazole	117–119	9.8	36.4	5.1	42.4	36.4	5.3	42.2
3-Aminopyridazine	168– 70	58	50.5	5.3	44.2	50.5	5.1	44.5
2-Amino-4-diethylaminopyrimidine	86– 88	59	57.8	8.5	33.7	58.2	8.7	33.3

[a] Yield of material suitable for conversion to the corresponding sulfanilamido derivative. In several cases samples were further purified before analysis; the melting point is that of the analyzed sample.

extracted with 200 cc. of ether, in two portions, to remove any chloroacetaldehyde. A solution of 240 g. (6 moles) of sodium hydroxide in 320 cc. of water was added with cooling. The strongly basic solution was then extracted with 1.3 liters of ethyl ether in five portions. After drying over flake sodium hydroxide and distilling to dryness, a residue of 2-aminoöxazole remained. Recrystallization from octanes gave 7.6 g. of the compound, m. p. 93–96°; 2.8 g. more was obtained by continuous extraction of the mother liquor (4.4% total yield, based on the α,β-dichlorodiethyl ether used). This product was suitable for the coupling reaction. A sample recrystallized from heptane had a m. p. of 96°–98°. Variations in the proportions of urea used and the time of reflux did not improve the yield. The reaction of bromoacetaldehyde and urea in water[7] gave similar yields.

3-Amino-5-methyl-1,2,4-oxadiazole was obtained by a procedure analogous to the preparation of 3-amino-5-phenyloxadiazole by Wieland and Bauer.[8] To a solution of 50 g. (0.29 mole) of dioxyguanidine hydrobromide in 135 cc. of glacial acetic acid was added 65 g. (0.65 mole) of acetic anhydride with cooling so that the temperature did not rise above 25°. Then 23.5 g. (0.29 mole) of sodium acetate was added and the mixture stirred overnight at room temperature. The insoluble salts were filtered off and washed with glacial acetic acid. Vacuum distillation of the filtrate left a viscous residue containing diacetoxyguanidine. Addition of 40% sodium hydroxide with cooling caused an evolution of gas. The alkaline solution was heated to 70–80° for twenty minutes to cyclize the diacetyl derivative. After cooling, 2.4 g. of 3-amino-5-methyloxadiazole was obtained by repeated ether extractions. It was purified by recrystallization from toluene, using activated alumina.

For the preparation of 3-aminopyridazine, 10.7 g. (0.093 mole) of 3-chloropyridazine[9] dissolved in 30 cc. of absolute alcohol and 30 cc. of anhydrous ammonia were heated at 175° in a steel autoclave for three hours, with shaking. The cooled reaction mixture was removed, heated to boiling while nitrogen was bubbled through, and filtered. The filtrate was evaporated to dryness under a reduced pressure of nitrogen. 3-Aminopyridazine was extracted from the residue with hot ethyl acetate, from which it crystallized as a light yellow solid; yield 5.1 g. It was then recrystallized from ethyl acetate.

2-Amino-4-diethylaminopyrimidine was prepared by heating 9 g. (0.07 mole) of 2-amino-4-chloropyrimidine[2] with 35 g. (0.49 mole) of diethylamine in a bomb-tube at 110°–120° for three hours. The product was dissolved in water, made alkaline with sodium hydroxide and extracted with ether. The ether was distilled off and the residue extracted with hot hexane. Cooling gave a crystalline precipitate of 9.8 g. of 2-amino-4-diethylaminopyrimidine. This was recrystallized from hexane.

Sulfanilamidoheterocycles (Table I) were prepared, in general, by the reaction of the aminoheterocycle with acetylsulfanilyl chloride in dry pyridine followed by hydrolysis.[4a] Dioxane was used as a reaction solvent for the preparation of 2-(N[4]-acetylsulfanilyl)-4-aminopyrimidine and *t*-butanol for 2-(N[4]-acetylsulfanilyl)-4-diethylaminopyrimidine. No rigid proof of structure for the former compound was attempted. The position of the sulfanilamido group on the pyrimidine ring was inferred from the instability of 4-(N[4]-acetylsulfanilamido)-pyrimidine to hydrolysis.[2,4c] If the acetylsulfanilyl chloride reacted with the 4-amino group, it was assumed that the 4-(N[4]-acetylsulfanilyl)-2-aminopyrimidine would have been decomposed in the subsequent hydrolysis.

2-(*p*-Nitrobenzenesulfonamido)-oxazole was prepared by refluxing 42.8 g. (0.19 mole) of *p*-nitrobenzenesulfonyl chloride with 16.2 g. (0.19 mole) of 2-aminoöxazole and 23.7 cc. (0.3 mole) of dry pyridine in 200 cc. of dry acetone for thirty minutes. The acetone was distilled off, and the gummy residue extracted with dilute ammonium hydroxide. Careful neutralization of the extracts with hydrochloric acid gave a first precipitate which was a sticky gum. This was removed and the desired compound was precipitated as a solid by further addition of acid. After recrystallization from water, 4.7 g. (9.0% of the theoretical) of *p*-nitrobenzenesulfonamidoöxazole was obtained. The m. p. of a further recrystallized sample was 175–177°.

Reduction by ferrous sulfate and ammonium hydroxide[10] gave 2-sulfanilamidoöxazole. Recrystallization from water did not improve the melting point. By dissolving in dilute hydrochloric acid, stirring with decolorizing carbon, filtering and precipitating by neutralization with ammonium hydroxide, colorless crystals of pure 2-sulfanilamidoöxazole were obtained. The yield of pure compound in the reduction step was 45% of the theoretical.

3-Sulfanilamido-1,2,4-triazole and 2-sulfanilamido-4,6-diamino-1,3,5-triazine were prepared by treating *p*-nitrobenzenesulfonyl chloride with the appropriate amine and then reducing with iron dust in dilute acetic acid.

Summary

The preparation and properties of a number of new sulfanilamido heterocycles are described.

Several of these compounds are closely related chemically to well-known sulfanilamido derivatives of the same type.

All of the sulfonamides showed some degree of bacteriostatic activity, but very little effect on experimental animal infections. Two compounds, in particular, were highly active *in vitro* and well absorbed. Possible explanations for these discrepancies and their bearing on the relation of molecular structure to chemotherapeutic activity, are discussed.

Studies in Chemotherapy. VII. A Theory of the Relation of Structure to Activity of Sulfanilamide Type Compounds[1]

BY PAUL H. BELL AND RICHARD O. ROBLIN, JR.

For the past three years we have been trying to find some relationship between the molecular structure and the chemotherapeutic activity of sulfanilamide type compounds. In spite of the many hundreds of derivatives which have been prepared and tested, no adequate explanation for the profound changes in therapeutic effect resulting from variations in structure has been proposed. Our approach to this problem has been through an attempt to utilize a fundamental physical property related to both structure and activity.[2] The present theory is based on the experimental observation that acid dissociation constants, which can be correlated with the structure of sulfanilamide derivatives, are also related to their bacteriostatic activity. The following is a description of this theory and a discussion of its implications.

I. Chemotherapeutic Activity and Mode of Action.—Before attempting to correlate the structure of sulfonamides with their chemotherapeutic activity, a reasonably accurate method for the determination of relative effectiveness is essential. Experimental animal tests for activity are frequently misleading because of the many factors, such as lack of absorption, rapid excretion, effect of diet and possible chemical changes in the compounds, as well as other less obvious variables,[3] which may affect the results. To a lesser degree, *in vitro* tests carried out in complex media are also somewhat confusing. In this investigation the term activity is used to indicate bacteriostatic activity against *E. coli* when the organisms are grown in a synthetic medium. This method of testing provides a more consistent and reproducible basis for the determination of relative activities by reducing the number of variables to a minimum. The relation of *in vitro* to *in vivo* results,[4] and the lack of any great degree of specificity among sulfanilamide derivatives,[5] appear to warrant this method of evaluation.

Another important prerequisite to this type of work is at least a partial understanding of the mechanism by which the compounds exert their bacteriostatic effects. None of the hypotheses advanced in recent years appeared to offer a very useful or convincing explanation, until Woods[6] demonstrated that *p*-aminobenzoic acid prevents the bacteriostatic action of sulfanilamide and sulfapyridine. This observation has since been extended by other investigators[7] to include sulfanilamide type compounds in general. Woods and Fildes[8] postulated that *p*-aminobenzoic acid is an essential metabolite associated with one or more of the enzymatic processes involved in bacterial growth. They pointed out the close structural relationship between the sulfonamides and this acid, and suggested that the former may act by blocking the enzyme system or systems with which *p*-aminobenzoic acid is involved and on which many bacteria depend for normal growth and development. Subsequent investigations have confirmed the essential nature of *p*-aminobenzoic acid,[9] and have shown experimentally

that the type of inhibition produced by sulfanilamide derivatives is competitive with respect to *p*-aminobenzoic acid.[10]

If the bacteriostatic action of the sulfanilamide type compounds is due to a competition with the required *p*-aminobenzoic acid for an essential enzyme system, then the more closely the competitor compound resembles this acid, the greater should be its blocking or bacteriostatic effect. The characterizing groups in *p*-aminobenzoic acid are the carboxyl group and the aromatic amino group para to it. Aside from geometric configuration, probably the most important property of a group is its positive or negative character. This is reflected in an amino group by its basic, and in a carboxyl group by its acidic, properties. Since many of the sulfanilamide derivatives contain both an acidic sulfonamide, and a basic para amino group, this work was undertaken to compare their physical properties with the corresponding groups in *p*-aminobenzoic acid. Dissociation constants were selected because they provide a readily measurable property which furnishes a direct indication of the positive or negative character of the groups.

II. Acid and Base Dissociation Constants (Qualitative Discussion).—During this investigation, the acid and base constants of over one hundred sulfonamides and related compounds were determined. A number of the values obtained are recorded in Table I. To conserve space, only a fraction of the total number of compounds studied is listed in this table. The results on the derivatives which are not recorded confirmed the conclusions drawn from the reported data. Methods employed for the determination of acid and base constants are described under Experimental. For convenience, the compounds are listed according to the classification of Northey.[11] The term C_R in Table I represents the minimum molar concentration necessary to cause bacteriostasis of *E. coli* in a buffered (*p*H 7) synthetic medium under standardized condition; thus, the smaller the number, the greater the activity. It is difficult to obtain a high precision in such tests, and small differences in bacteriostatic activity (factor of 2) are within experimental error.

Only brief consideration need be given to the base constants. The range of basic strength of the aromatic para amino group of practically all the sulfonamides studied was small [$(0.5\text{–}2.3) \times 10^{-12}$]. However, in order to establish this small range, it was necessary to make base constant determinations on nearly all the compounds studied. Several of the first base dissociation constants listed in Table I are greater than 2.3×10^{-12}. In these cases it is possible to show, by comparing the basic strength of the corresponding acetyl and benzene sulfonamide derivatives, that the first base constant probably does not represent the aromatic para amino group. Neither is the second base constant for these compounds a true measure of the basic strength of the aromatic amino group, because of the presence of the ion resulting from the determination of the first base constant (see Experimental).

The ionization constant for the basic amino group in *p*-aminobenzoic acid is approximately 2.6×10^{-12}.[12] To the extent that all the active sulfanilamide derivatives have identical unsubstituted para amino groups with constants which are close to this value, the base constants may be an important factor in bacteriostatic activity. But due to the very small variations in basic strength, no relation between these constants and bacteriostatic activity could be found.

Acid dissociation constants, which vary over a wide range ($< 10^{-11}$–10^{-3}), present an entirely different picture. The relationship between the *in vitro* activity of N^1-substituted sulfanilamide derivatives and their acid strength is shown in Fig. 1 (data from Table I). For convenience in plotting the curve, log $1/C_R$ is used rather than C_R. An examination of this figure indicates that as the pK_a of the sulfonamides increases, the bacteriostatic activity passes through a maximum and then decreases. In order to account for this phenomenon, several factors must be considered.

p-Aminobenzoic acid has been shown to be in the "non-zwitter ion" form in solution.[13] Never-

theless, it is a sufficiently strong acid so that in dilute solution in a medium buffered at *p*H 7, the carboxyl group is better than 99% ionized. The neutral solution is particularly important, since the form in which the compounds exist in bacterial culture media or in body fluids is of primary interest. Under these conditions, *p*-aminobenzoic acid consists of a benzene ring containing an NH_2 group, para to which is an ionic group having two very negative oxygens. Geometrically, these two oxygens are about 2.3 Å. apart,[14] while sulfones and sulfonamides both have a group similar to the CO_2 ion, namely, an SO_2 group, containing two negative oxygens[15] with an oxygen–oxygen distance of approximately 2.4 Å.[16] In general, the *p*-aminobenzene sulfonyl groups of the sulfones and sulfonamides are geometrically very similar in dimensions to the *p*-aminobenzoic ion as illustrated in Fig. 2.

Nearly all the amino groups of (a), (b) and (c), Fig. 2, have been shown to have base constants of the same order of magnitude. Consequently, the differences in the SO_2 groups of the various sulfonamides, compared with the CO_2 ion, must now be considered as a possible determining factor in the relative bacteriostatic activity of these compounds. Dipole moment studies have shown the SO_2 to be a relatively negative group.[15] However, the CO_2^- should be more negative than the SO_2, because the ion actually carries an electronic charge. It seems logical then, that the more negative the SO_2 group, the more closely it will resemble the CO_2 ion. On the basis of this reasoning, the theory which we shall attempt to develop may be stated as follows: *the more negative the SO_2 group of a sulfanilamide type compound, the greater the bacteriostatic activity of the compound.*

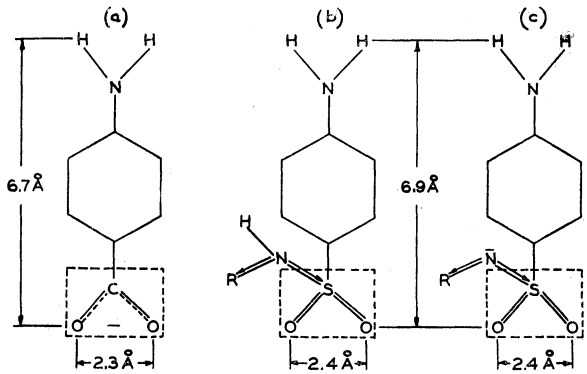

Fig. 2.—Geometric configurations.

The problem now becomes one of evaluating the relative negative character of the SO_2 group of the various sulfonamides in terms of their acid constants, to determine to what extent this property is related to bacteriostatic activity. Since the R group (Fig. 2) is the only variable involved in the N^1-substituted derivatives, it must be the factor controlling the acid constants of these compounds. For R to be acid strengthening, it must be an electronegative (electron attracting) group.[17] Under these conditions, R attracts electrons from the adjacent amide nitrogen so that the hydrogen can escape as a proton in solution, leaving the anion represented by form (c). The acid constants furnish an excellent indirect measure of the relative electronegative character of R, because any change in the acid strength of the sulfonamides should be proportional to the change in the electronegativity of the R group.

Since we are concerned with the form of the sulfanilamide type compounds in a medium buffered at *p*H 7, the effect of acid strength (as regulated by the properties of the R group) on the quantities of the molecular and ionic forms ((b) and (c), Fig. 2) existing at this *p*H must be considered. The fraction ionized, x, for any acid is given by the equation

$$x = \frac{K_a}{K_a + [H^+]} \text{ or at } p\text{H } 7 \quad x = \frac{K_a}{K_a + 10^{-7}} \qquad (1)$$

Using this equation, a plot of pK_a *versus* the fraction ionized may be made (Fig. 3). At *p*H 7, compounds which are strong acids (pK_a up to

(17) The term electronegative refers throughout to the electron attracting power of a group.[16] Negative is used to indicate the relative electron density or negative charge around a group.

5–6) are practically completely ionized, weaker acids (pK_a = 6–12) are partly ionized, and the very weak acids (pK_a > 12) are almost entirely in the un-ionized form.

With the amounts of the molecular and ionic forms of any given sulfonamide known, the relative activities of the two species must be considered on the basis of the assumption that the bacteriostatic activity is proportional to the negative character of the SO_2 group. The ionic form has an electronic charge on the amide nitrogen, as shown in (c) (Fig. 2). This electronic (negative) charge *increases greatly* the negative character of the adjacent SO_2, since the SO_2 group is also electron attracting and acquires part of the ionic charge from the amide nitrogen. Consequently, *the SO_2 group of any sulfanilamide derivative in the ionized form (c) is much more negative than the SO_2 of the same compound in the un-ionized form (b). Therefore, the ionic form of any sulfonamide should be much more active than the molecular form.*[18]

The effect of the R group (Fig. 2) on ionization, and the relative activity of the ionic and molecular forms, have been discussed. Remaining to be considered is the effect of different R groups on the negative character of the SO_2 group. Consider first the ionic form (c). As the electron attracting power of R increases, the SO_2 group should become less negative because, under these conditions, a greater part of the ionic charge of the amide nitrogen will be taken by the R group which will be competing more strongly with the SO_2 for the ionic charge. The arrows in Fig. 2 illustrate the competition between the attracting forces of these two groups for the ionic charge on the adjacent amide nitrogen. As the SO_2 becomes less negative, its ion should be less active than an ion whose R is a weaker electron attracting group. Applying the same reasoning to the molecular form (b), we arrive at similar conclusions concerning the relative negativity of the SO_2 groups. Since the electron attracting power of R is proportional to the acid strength, it follows that, *the more acidic the sulfonamide, the less negative the SO_2 group of the ionic and molecular forms and the less the bacteriostatic activity of either form.* It should be recalled here that up to a certain point this decrease in activity with increasing acid strength is more than compensated for by the increasing proportion of highly active ions. Because the ions are much more active than the corresponding molecules, the over-all effect of increasing acid strength produces an increase in activity up to the point where the sulfonamides are largely ionized. Further increases in acid strength are not accompanied by a proportionate increase in the number of ions. The predominant effect beyond this point should be the decreasing negative character of the SO_2 group, accompanied by decreasing activity. Consequently, a maximum would be expected in the curve relating pK_a to bacteriostatic activity (compare Fig. 1).

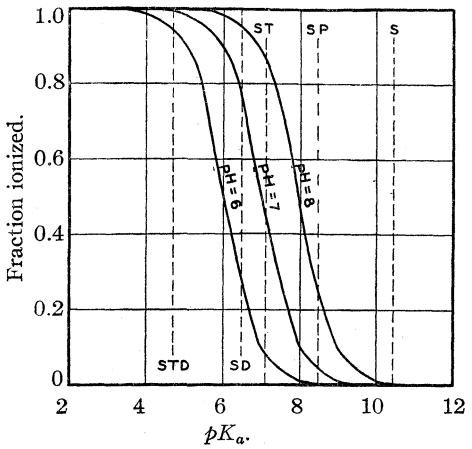

Fig. 3.—Acid ionization in buffers (nos. from Table I): S, sulfanilamide (2); sulfapyridine (15); ST, sulfathiazole (34); SD, sulfadiazine (23); STD, sulfathiadiazole (38).

It is also possible for the electron attracting power of R to change until it is actually an electron donor group. Under these conditions, R should repulse electrons toward the SO_2 group. As a result, the SO_2 group would become more negative. The acid strength also reflects the electron donor power of R. However, these compounds can become such weak acids that the effect of the highly active ions is negligible, and as a result the bacteriostatic effect should be of a lower order of magnitude. Even so, as pointed out above, the activity of the un-ionized forms should show a continuous increase as the acid strength

(18) During the preparation of this manuscript, two papers appeared in which experimental evidence supporting this conclusion is reported. See Fox and Rose, *Proc. Soc. Exptl. Biol. Med.*, **50**, 142 (1942); Schmelkes, Wyss, Marks, Ludwig and Sandskov, *ibid.*, **50**, 145 (1942). However, the present theory is not in accord with the conclusions of these authors that the ionic form of sulfanilamide derivatives is the only active form. For example, such a conclusion fails to account for the activity of sulfones, sulfaguanidine and N^1-disubstituted sulfanilamide derivatives, none of which exist as ions in solution, although they are also inhibited by *p*-aminobenzoic acid. Furthermore, we do not agree with Fox and Rose that the ions of different derivatives are equally active. Actually, the experimental data in both of these papers appear to support the view that the ions of the stronger acids are less active. Moreover, the idea of equal activity for all ions obviously is not in agreement with the experimental data for strong acids as shown in Fig. 1. This phase of the problem is considered in the subsequent discussion.

decreases. Thus, when the ionic form can be neglected, the curve relating pK_a to bacteriostatic activity should pass through a minimum and then increase as the acid strength decreases. Because compounds in which R is an electron donor group are extremely weak acids, it is not possible to determine their dissociation constants in aqueous solution. Evidence such as the relatively high bacteriostatic activity of sulfaguanidine, too weak an acid to be measured in aqueous solution, strongly suggests that a minimum may also be found in the experimental curve. Possibly studies in a basic solvent such as liquid ammonia would furnish quantitative data with which to fit these sulfonamides into this general picture.

III. Acid Constants (Quantitative Discussion).—In order to obtain optimum activity among acidic sulfanilamide derivatives, the problem is apparently one of obtaining a proper balance between the acid strengthening effect of the R group (Fig. 2) and the formal ionic charge on the sulfonamide nitrogen to give the maximum over-all negative character to the SO_2 group. Branch and Calvin[19] have shown that the dissociation constant of an organic acid can be predicted quantitatively by an equation of the type

$$\log K = \log K_a + \Sigma I_R \alpha^i \qquad (2)$$

where K_a is the acid constant of the parent acid, I_R the inductive constants for each atom or group other than hydrogen, α the fraction that reduces the inductive effect for the transmission across each bond, and i the number of bonds through which the effect must be transmitted. I_R multiplied by 2.3 RT then becomes a potential and has the units of free energy.

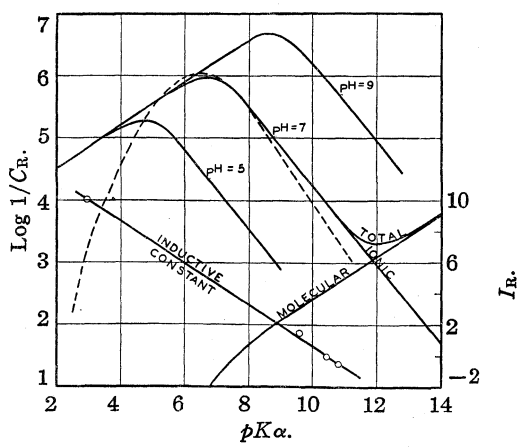

Fig. 4.—Theoretical activity *versus* pK_a: dotted line represents experimental activity from Fig. 1.

(19) Branch and Calvin, "The Theory of Organic Chemistry," Prentice-Hall, Inc., New York, N. Y., 1941.

Assuming that bacteriostatic activity is proportional to the potential of the SO_2 group, then, when the total activity is due almost entirely to the highly active ions (pK_a 2–11)

$$2.303\ RT \log (k/xC_R) = 2.303\ RT\ [\alpha(12.3 - I_R\alpha) - I_R\alpha^2] \qquad (3)$$

where C_R = minimum molar concentration of a sulfonamide required to exhibit a given bacteriostatic activity, attributing all activity to the ions, x = fraction of the total concentration of the compound in ionic form, k = proportionality constant (determined experimentally), to adjust the potential energy of the SO_2 to experimental conditions, I_R, α, as defined for equation (2), $(12.3 - I_R\alpha)$ = inductive effect of the ionic charge reduced by the effect of I_R on it, $I_R\alpha^2$ = inductive effect of R on SO_2 directly.

As a first approximation, resonance and polarization effects were neglected, and α was taken as $1/2.3$ (the value of Branch and Calvin for a covalent bond); then

$$\log \frac{k}{xC_R} = 4.04 - 0.255\ I_R \qquad (4)$$

Using Branch and Calvin's inductive constants for various radicals, it was found that I_R was a linear function of the pK_a values of the corresponding sulfanilamides.

From Fig. 4

$$I_R = -1.33\ pK_a + 13.88 \qquad (5)$$

also, for any acid at pH 7 (where the *in vitro* tests were made)

$$pK_a = 7 - \log x/(1 - x) \qquad (6)$$

Substituting (5) and (6) in equation (4), we have

$$\log 1/C_R + \log k = 3.23 + 0.661 \log x + 0.339 \log (1 - x) \qquad (7)$$

at conditions of maximum activity ($\log 1/C_R$ = max.)

$$\frac{d \log 1/C_R}{dx} = 0 = \frac{0.661}{x} - \frac{0.339}{1 - x}$$

$x = 0.661$ at maximum activity

This corresponds to a sulfanilamide derivative with a pK_a of 6.7 as calculated by equation (6), and agrees very well with the experimentally observed maximum (Fig. 1). This pK_a value of maximum activity is independent of the *in vitro* tests and depends only on the inductive effects of the R groups.

Using the experimental maximum activity, $\log 1/C_R = 6.1 \pm 0.3$, k may be evaluated by substi-

tuting $\log 1/C_R = 6.1$ and $x = 0.661$ in equation (7), and solving for k.

The final ion activity equation is then

$$\log 0.001/C_R = 3.23 + 0.661 \log x + 0.339 \log (1 - x) \quad (8)$$

A similar equation may be derived for the activity of the un-ionized form

$$\log \frac{0.001}{(1 - x)C_R} = -1.3\alpha - 2 I_R \alpha^2 \quad (9)$$

from which it can be shown that its contribution toward activity will be small except for very large pK_a values.

Combining equations (9) and (4) we may show that

$$\log \frac{(1 - x)\ C_R\ \text{(un-ionized)}}{x\ C_R\ \text{(ionized)}} = 4.85 \quad (10)$$

which means that any ion is approximately $10^{4.85}$ times more active than the corresponding molecule. Now, if C_R (un-ionized) = C_R (ionized)

$$\log (1 - x)/x = 4.85$$

and pK_a must be 11.85 to fulfil this condition. At this pK_a, log 2.0 should be added to $\log 1/C_R$ from equation (7). In this way the ion activity curve was corrected for the molecular activity at pK_a's greater than 10, and the total activity curve drawn as shown in Fig. 4.

The theoretical curves of Fig. 4 at pH 5 and 9 show how the pK_a of maximum activity may shift if the pH of the medium changes. At pH 7 the experimental and theoretical curves are in very good agreement from pK_a 10–5, but at lower pK_a values the compounds are less active than predicted. Probably the most important factor contributing to this deviation is the limitations in the development of the theory. As pointed out by Branch and Calvin, an exact equation of the type of equation (2) should contain summation terms for the polarization and resonance, as well as the inductive effect. While polarization is probably a function of pK_a, the relationship cannot be readily established experimentally. On the other hand, resonance is probably dependent on the specific character of the R group, and no general relationship between resonance and inductive effect can be established. In equation (3) polarization and resonance have been neglected, and therefore α is not equal to 1/2.8 (the simple covalent bond value) unless these effects are small. Where R is not too electronegative (weaker acids) the value for α probably is a good approximation; however, as R becomes strongly electronegative, the SO_2–N–R bonds should become more ionic, and α should be greater than 1/2.8. Such an increase in α would give better agreement between the theoretical and experimental curves in the low pK_a range.

This treatment also takes no account of the inductive effects on the p-amino group. The very acid compounds, in general, have less basic p-amino groups. In the extreme cases there appears to be considerable "zwitterion" formation, as indicated in the case of sulfanilylcyanamide by titrations in formaldehyde solution. Any large variation in the character of the p-amino group compared with the corresponding group in p-aminobenzoic acid may be expected to result in a decrease in activity.

IV. Relation of Structure to Activity.—The preceding discussion has been concerned primarily with an attempt to show how both structure and activity can be related to a common denominator, namely, the negative character of the SO_2 group, and how acid dissociation constants can be used to evaluate the relative negativity of the SO_2 group. Of necessity, this discussion has been limited largely to N^1-monosubstituted sulfanilamide derivatives, since they are the only active compounds on which measurements of the acid strength of the sulfonamide group can be made. Nevertheless, we believe that the principles outlined above apply to any substance of the type  , provided its bacteriostatic activity is inhibited by p-aminobenzoic acid. If the properties of the NH_2 are constant, the activity should depend on the relative negative character of the XO_2 group. In addition to sulfonamides and sulfones, the type formula should include compounds in which X is phosphorus, arsenic, selenium, or other elements.

The term "sulfanilamide type compounds," as used throughout this paper, is limited to derivatives of the type shown above. This limitation, of course, excludes N^4-substituted compounds; orthanilamide, metanilamide and their derivatives; nuclear substituted compounds; and substances in which the NH_2 or XO_2 groups are separated from the benzene ring by an alkyl, aryl or other radical. N^4-Substituted compounds have not been considered because it now appears to be generally accepted that these derivatives are active chemotherapeutic agents only after the N^4-substituent has been removed by some bio-

chemical process. First demonstrated by the Tréfouël's and their co-workers[20] for the original "Prontosil," this process has since been confirmed many times for a number of different N^4-substituents.

The mode of action of sulfanilamide type compounds proposed by Woods[5] and Fildes[8] should exclude all the types of compounds listed above on the basis of steric effects. The high degree of specificity of enzyme systems is well recognized. If the action of sulfonamides is based on the competitive inhibition of an enzyme system normally requiring *p*-aminobenzoic acid, then in order to be effective, a compound should have a spacial configuration as closely resembling that of the normally required substance as possible. Obviously, a substituted amino group no longer resembles a free NH_2 from this standpoint.[21] Similarly, orthanilamide and metanilamide derivatives, nuclear substituted compounds, and substances in which the groups are separated from the benzene ring, are much less closely related sterically to *p*-aminobenzoic acid than the compounds formulated above. Perhaps the most convincing argument in favor of this hypothesis is the experimental evidence that up to the present, so far as we are aware, no compounds of the types excluded have been reported to show bacteriostatic activity *per se*. In general, compounds not inhibited by *p*-aminobenzoic acid are considered to be outside the scope of the present theory.[22]

It should now be possible to generalize on the effects of various types of N^1-substituents on bacteriostatic activity, using sulfanilamide as the basis for comparison. Among these compounds all degrees of potency may be found, although none of them appears to be completely inactive. In the following discussion groups are referred to hydrogen which is considered as neutral. An electronegative substituent is one which tends to acquire electrons at the expense of the group to which it is attached. Such a group makes the resulting sulfanilamide derivative a stronger acid. By the same criterion, an electropositive substituent tends to donate electrons and form less acidic sulfonamides.

(20) Tréfouël, Tréfouël, Nitti and Bovet, *Compt. rend. soc. biol.*, **120**, 756 (1935).

(21) This effect is in contrast to an N^1-substituent which in most cases probably has very little influence on the spacial configuration of the SO_2 group.

(22) For example, *p,p'*-diaminodiphenyl sulfide has bacteriostatic activity, but its mode of action evidently is quite different since it is not inhibited by *p*-aminobenzoic acid (W. H. Feinstone, personal communication).

Alkyl groups are slightly electropositive and acid weakening. Hence, their effect in the region of weak acids should be to reduce the activity slightly (see Table I, nos. 3 and 5). Chain length should not alter the effect appreciably, as evidenced by the nearly constant acidities of the fatty acids. From a practical standpoint, of course, long chains may reduce solubility to a point where the bacteriostatic power can no longer be demonstrated. Introducing a strong electron attracting radical on the α-carbon atom of an aliphatic acid makes the group more electronegative, while further along the chain such a substituent has a much smaller effect.[19] Thus, an electronegative group (*e. g.*, halogen) in the α-position of an N^1-alkylsulfanilamide derivative should increase activity, but the effect in any other position should be relatively weak.

A second N^1-alkyl group should not exert much influence, since the monosubstituted compounds are too weakly acidic to ionize appreciably (*cf.* nos. 3 and 4). The effect of an alkyl group on another substituent such as a heterocyclic ring is also slightly acid weakening (*cf.* nos. 23, 24 and 25). For the purposes of this discussion, saturated rings (carbocyclic or heterocyclic) would be classified as alkyl substituents. Similarly, from the standpoint of their slightly electropositive character, aromatic or heterocyclic groups separated from the N^1-nitrogen by one or more methylene radicals should be considered as substituted alkyl groups (*e. g.*, no. 14).

Aromatic rings are slightly electronegative. Consequently, the activity of these derivatives, in general, should be somewhat greater than that of sulfanilamide, because they are relatively stronger acids. Moreover, since the electron attracting power of the ring may be increased or decreased considerably by substituents, the N^1-aromatic substituted compounds show rather large variations in bacteriostatic power. As might be anticipated, substituents in the ortho and para positions exert a more pronounced influence than in the meta position. For example, the electronegative sulfonamide group in N^4-sulfanilylsulfanilamide (no. 12) increases the activity over that of the unsubstituted phenyl, while in the meta position (no. 11) the effect is smaller. On the other hand, the electropositive amino group in the para position (no. 13) reduces activity.

Heterocyclic substituents show by far the greatest variation in electronegativity. As a result,

the potency of the N^1-heterocyclic sulfanilamide derivative varies widely. The bacteriostatic activity of this class of compounds increases to a maximum and then falls off as the acidity of the compounds increases (see Fig. 1). As demonstrated in Part II above, the effect of increasing ionization appears to be more than counterbalanced by a decrease in the negative character of the SO_2 group, when the sulfonamides become too strongly acidic. Consequently, compounds such as nos. 36 and 38 are stronger acids, but less potent than derivatives containing two hetero-atoms (nos. 32 and 34). Conversely, derivatives with only one hetero-atom are too weakly acidic, and again show less activity. In most cases, two hetero-atoms in the ring appear to promote optimum bacteriostatic power. Introducing substituents in the heterocyclic nucleus affects the activity differently, depending on the acidity of the unsubstituted derivative. If the compounds are too weakly acidic, an electronegative group (*e. g.*, halogen, as in the bromopyridines, nos. 17 and 18) increases their potency. But, an electropositive amino group in the pyridine ring reduces activity (nos. 19 and 20). On the other hand, when the unsubstituted N^1-heterocyclic derivatives are too strongly acidic, the presence of an electron donor group increases bacteriostasis (no. 39), while an electronegative group should cause the activity to decrease.

The carbonic acid derivatives such as sulfanilylurea (no. 41) and sulfaguanidine (no. 42) present interesting differences. The urea derivative is quite acidic, whereas sulfaguanidine is too weak an acid to be measured in aqueous solution. Sulfanilylurea is considered in the discussion of exceptions below. At first, the guanidines may also appear to be out of line with the theory. But, guanidine should be an electron donor group, since it is a very strong base. Consequently, this compound and others of the same type should fit somewhere beyond the minimum point on the high pK_a side of the total activity curve of Fig. 4.

Acyl and sulfonyl groups are strongly electronegative. Practically all of the sulfanilamide derivatives of this class are too acidic to show maximum bacteriostatic power. An electron attracting group in the α-position further reduces the activity (*cf.* nos. 44 and 45). The sulfonyl group, being more strongly electronegative than the acyl group, has an even greater tendency to reduce the bacteriostatic effect (*cf.* nos. 47 and 49).

A second N^1-substituent of any type, on a sulfanilamide derivative which is capable of appreciable ionization, should cause a pronounced decrease in the activity. Introducing such a group completely blocks the formation of the more potent ionic form, which in turn should result in a considerable reduction in the total activity. The *in vitro* data available in the literature appear to support this conclusion.[4,11]

A certain number of exceptions to any theory relating to biological phenomena which involve unknown variables are to be expected. So little is known about the mechanism of the inhibition of enzyme systems, that all the factors cannot be evaluated with our present knowledge. Considering the large group of compounds studied, the exceptions are not sufficiently numerous to detract from the general trend. Moreover, while positive exceptions (*i. e.*, compounds more active than predicted) would invalidate the preceding discussion, negative exceptions are less disconcerting. In Fig. 1 there is one point (a) which falls outside the possible limits of experimental error for the bacteriostatic tests. The compound sulfanilylurea (no. 41) is considerably more active during the first part of the test period than at the standard end-point. A plausible explanation for the low activity of the urea derivative is that it may be slowly broken down by the bacteria to sulfanilamide or some other less active substance. The fact that there is a biological mechanism for the breakdown of urea supports this supposition.

There are two other compounds listed in Table I (nos. 6 and 31) which, although definite values for bacteriostatic activity were not obtained, appear to be negative exceptions to the theory. In the case of sulfanilylglycine (no. 6), the first acid constant undoubtedly represents the carboxyl group. The second constant, which should correspond to the sulfonamide group, is too weak to be measured in aqueous solution. In general, it is possible that compounds with amino and carboxyl substituents may be less active than predicted. These substituents, in particular, may cause an improper orientation of the molecule in an enzyme system, due to their identity with the groups in *p*-aminobenzoic acid. No adequate explanation for the low activity of 4-sulfanilamido-1,2,4-triazole (no. 31) can be given at present. Undoubtedly there are other exceptions in addition to the ones encountered in this investigation, but it seems possible that practically all negative ex-

ceptions might find simple explanations if one could account for all the factors involved.

V. Implications of the Proposed Theory.—An example illustrates to what extent the proposed theory enables one to make predictions. When the curve in Fig. 1 was first plotted, there were no compounds available with a pK_a of approximately 4. Since there were fewer points on this side of the curve, it seemed desirable to strengthen the evidence by the preparation of a sulfonamide of this type. From the well-known electronegative character of the chloroacetyl group, it was possible to predict, before the compound had been synthesized, that N^1-chloroacetylsulfanilamide[23] would have a pK_a of about 4, and consequently a bacteriostatic activity of approximately 10×10^{-5} (*cf.* Table I).

In general, we believe that sufficient data are now available so that, without the aid of physical measurements, the relative electronegativity of any substituent group can be approximated from its molecular structure. Thus, for the first time, a relationship between structure and activity is established which enables one to predict the bacteriostatic effect of any new N^1-substituted sulfanilamide derivative. Furthermore, it is possible that the approach used in this study may find application to similar investigations among other types of chemotherapeutic agents, particularly those depending on enzyme inhibitions for their activity as proposed by Fildes.[8]

From the biological standpoint, a number of interesting implications are evident. It should be possible, for instance, to show a reversal in the order of activity of a selected series of compounds with changes in *p*H. This effect would be predicted on the basis of the relative change in the proportion of ions to molecules. In going from a lower to a higher *p*H this ratio does not change appreciably for a strong acid, while a weaker acid shows an appreciable increase in the ratio of ions to molecules. Conversely, passing to a lower *p*H has the opposite effect on this ratio. If organisms such as *E. coli* can be grown from *p*H 5–9 on a synthetic medium, it is possible to design an experiment to test this prediction. The relative activity of the three compounds, sulfathiadiazole (no. 38, $pK_a = 4.77$), sulfathiazole (no. 34, $pK_a = 7.12$) and sulfapyridine (no. 15, $pK_a = 8.44$), at *p*H 7 is in the order sulfathiazole > sulfathiadiazole = sulfapyridine (Table I). But at *p*H 5 the relative activities should change so that sulfathiadiazole > sulfathiazole > sulfapyridine, and at *p*H 9 the order should be sulfapyridine > sulfathiazole > sulfathiadiazole (Fig. 4). Smaller *p*H ranges probably would not be sufficient to overcome the rather large limits of error inherent in the bacteriostatic tests.[24]

Perhaps the most important implication based on both experimental and theoretical considerations is that the optimum in bacteriostatic activity of N^1-substituted sulfanilamide derivatives appears to have been reached. The maximum in the experimental curve, and the limitations on the negative character of the SO_2 group imposed by the conflicting effects of increasing acidity, both point to such a conclusion. This, of course, does not mean that better chemotherapeutic agents of this type, from the standpoint of lower toxicity or differences in absorption and excretion and other factors of practical importance, are not possible, but it does suggest that inherently more active sulfanilamide derivatives are not likely to be found.

Experimental

Materials.—All inorganic and common organic chemicals were of "Analytical Reagent" grade. Aniline was freshly distilled from zinc dust (water white, b. p. 94–95° (25–30 mm.)). Hydrogen gas (electrolytic, from pressure tanks) was further purified by passing it through an alkaline pyrogallol solution, dilute potassium permanganate and concentrated sulfuric acid. Chloranil, m. p. 298–300°; *m*-nitroaniline, m. p. 112–113°; *p*-nitroaniline, m. p. 146–147°; tetrachlorohydroquinone, m. p. 234–236°; *p*-toluidine, m. p. 44–45°; and triethylamine, b. p. 88–90°, were all obtained from Eastman Kodak Co., and further purified when necessary. The compounds listed in Table I were prepared in these Laboratories or obtained from the Calco Chemical Division, American Cyanamid Co.

Apparatus.—Electromotive force (e. m. f.) measurements were made with a Leeds and Northrup no. 7660 vacuum-tube meter. Acid constants in 50% ethyl alcohol were measured with a Beckman (Model G) *p*H meter, employing a glass electrode and a saturated potassium chloride-calomel electrode. Hydrogen and calomel electrodes were of standard type. Measurements in acetic acid were made using a chloranil electrode[25] and a calomel reference electrode. The two electrodes were connected by a salt bridge, fitted with ground glass joints, and containing acetic acid saturated with lithium chloride.[26] Two smooth platinum inert electrodes were used for the chloranil part of the cell. These electrodes were flamed before each immersion and all readings discarded in which the two electrodes failed to give the same e. m. f.

(24) Work is now in progress in these Laboratories to determine whether or not such an experiment can be carried out.

(25) Hall and Werner, THIS JOURNAL, **50**, 2367 (1928).

(26) Hall and Conant, *ibid.*, **49**, 3047 (1927).

The conductance bridge was made by using a Kohlrausch bridge, a Leeds and Northrup no. 4750 resistance box, and a Freas type conductance cell. This bridge was balanced by amplifying the signal with a General Radio no. 814-A amplifier and obtaining the null point from the minimum observed on a General Radio no. 726-A vacuum-tube voltmeter.

Acid Constant Determination.—The N^1-substituted sulfanilamide derivatives are amphoteric, since they contain a basic amino, as well as the acid sulfonamido, group. Formaldehyde titrations indicated that all the sulfanilamides used in this study, except the very acidic ones, were in the "non-zwitterion" form. Hence, the usual weak acid and weak base theories could be applied without considering the other group. The acid constants were determined from the pK_a values obtained from 0.05 N NaOH electrometric titration curves (hydrogen electrode). Experimentally, it was impossible to measure all the compounds by this method, since some were extremely insoluble in water, and, because of their high molecular weights, the pK_a values were not significant.

For the very insoluble sulfanilamides it was possible to use 50% ethanol as the solvent. It has been shown that in methanol–water and ethanol–water mixtures, acid constants, within each class of acids, exhibit roughly equal changes in any given solvent mixture.[27,28] It was found that compounds in the sulfanilamide series, which were measurable in water, when measured in 50% ethanol gave a smooth curve of $pK_{a(H_2O)}$ versus $pK_{a(50\%\ EtOH)}$ as shown in Fig. 5. From this curve, it was possible to determine the acid constants, for compounds in the same series, from $pK_{a(50\%\ EtOH)}$ measurements. The alcohol values in Table I have all been corrected, by means of Fig. 5, so that they may be compared directly with the values obtained in water.

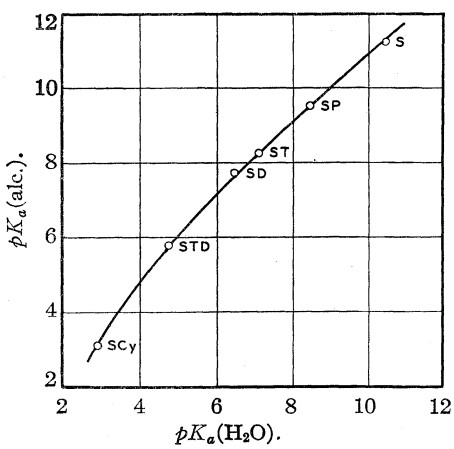

Fig. 5.—Standardization curve for 50% ethanol titrations (nos. from Table I): S, sulfanilamide (2); SP, sulfapyridine (15); ST, sulfathiazole (34); SD, sulfadiazine (23); STD, sulfathiadiazole (38); SCy, sulfanilylcyanamide (40).

Using these methods, it was possible to determine the acid constants for sulfanilamides more acid than approximately $K_a = 2 \times 10^{-11}$. Titration of acids weaker than this did not give curves sufficiently different from a blank titration to be reliable.

Base Constant Determination.—The basic groups of the sulfanilamides were all weak (pK_b = 11–13) and the results of 0.05 N HCl titrations were not significant unless the compounds were quite water soluble. Sulfanilamide, metanilamide and p-aminobenzoic acid were carefully studied by this method, using a hydrogen electrode. The base constants of sulfanilamide and p-aminobenzoic acid were also determined from conductance measurements on their hydrochlorides.[29] These results agreed very well with the water titration values. It was not possible to obtain the base constants of other sulfanilamides by this method, because of the low solubility of the free bases in water.

Using an acidic solvent such as 100% acetic acid, it was possible to increase the basic properties of these very weak bases and titrate them with a very strong acid. The chloranil electrode, which is reversible in 100% acetic acid,[26] was used to follow a titration of the base with 0.0835 N perchloric acid. Because of the low dielectric constant of the solvent, it was necessary to maintain a constant ionic strength. All the solvent had enough neutral triethylammonium perchlorate added to give an ionic strength of 0.2.[30] Employing the method of Hall[31] a standardization curve of $pK_{b(H_2O)}$ *versus* e. m. f. of chloranil electrode, at the $pK_{b(HAc)}$ point in the titration, was made as shown at Fig. 6.

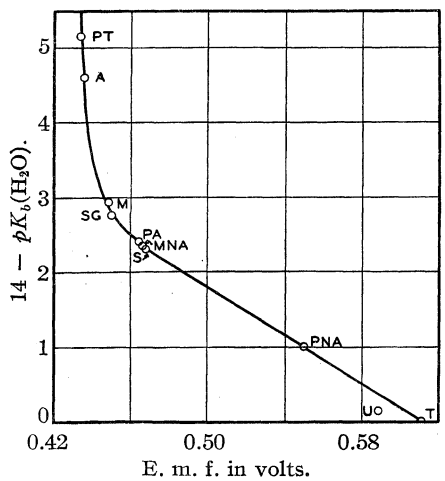

Fig. 6.—Standardization curve for acetic acid titrations (nos. from Table I): e. m. f. is that of a chloranil electrode *vs.* satd. calomel at pK_b (HAc) point of the titration: PT, p-toluidine; A, aniline; M, metanilamide; SG, sulfaguanidine (42); PA, p-aminobenzoic acid (1); MNA, m-nitroaniline; S, sulfanilamide (2); PNA-p-nitroaniline; U, urea; T, theory.

from the literature[32,33] except sulfanilamide, metanilamide and sulfaguanidine which were soluble enough to be measured in water, as outlined above. By means of the curve in Fig. 6, the K_b values in Tables I and II were obtained: the first K_b from the e. m. f. given when one-half equivalent of perchloric acid had been added and the second K_b when one and one-half equivalents had been added.

It should be pointed out that the second K_b obtained in this manner is not a measure of the group's basic character as it normally exists in a neutral solution, unless the stronger basic group is strong enough to be ionized at *p*H 7. The effect of ionic charge, depending on its sign, may either increase or decrease the apparent basic properties of the group being measured. A positive ion should decrease the negative character and the basic strength of the group, while a negative ion should have the reverse effect.

As pointed out above, the carboxyl group of *p*-aminobenzoic acid is better than 99% ionized at *p*H 7. The presence of the carboxyl ion may increase the basicity of the *p*-amino group somewhat over the value given in Table I, since this result was obtained in an acid medium where the carboxyl was not ionized. It is possible to show a relationship between the basic strength of substituted anilines and the acid constants of the N^1-sulfanilamides derived from them. From this relationship and the second K_a of N^1-*p*-carboxyphenylsulfanilamide (2nd pK_a = 8.24, for the sulfonamido group para to the completely ionized carboxyl) it may be possible to estimate the basic strength of the amino para to the carboxyl ion. Such indirect evidence suggests that the carboxyl ion of *p*-aminobenzoic acid increases the para amino basicity approximately threefold over the value obtained when the carboxyl group was un-ionized. If this is true, it is evident that the influence of a carboxyl ion on the base constant of *p*-aminobenzoic acid is relatively small.

The para amino groups of the sulfanilamide derivatives are the basic groups of primary interest. However, a number of the sulfanilamides contain two or more basic groups. The first K_b of Table I is only a true measure of the *p*-amino base constant when that group is the strongest in the molecule. When there was any question as to whether or not the paraamino was the strongest basic group in the polybasic compounds, it was checked by blocking the para amino group or removing it. In a large number of cases the benzenesulfonamido and N^4-acetyl derivatives (see Table II) were so much weaker bases than the corresponding *p*-amino compounds, that there was little doubt but that the para amino was the strongest basic group.

TABLE II

BASE CONSTANTS OF SULFONAMIDE COMPOUNDS

In each of these cases the *p*-amino was a weaker basic group than the *p*-amino of sulfanilamide. This is consistent with the corresponding acid constants, since any N^1-substituent which is more electronegative than hydrogen should be acid strengthening and base weakening. Because of these facts it did not seem likely that the first K_b of Table I was the base constant of the desired *p*-amino group for compounds nos. 13, 15, 16, 19, 20, 22, 26, 27, 42, 43 and 47 (nos. from Table I).

Acknowledgment.—We are greatly indebted to Dr. W. Harry Feinstone, Dr. Herbert Florestano and Mr. Roger D. Williams for the bacteriostatic results reported in this paper.

Summary

Based on the experimental observation that the acid dissociation constants of N^1-substituted sulfanilamide derivatives are related to their chemotherapeutic activity, a theory of the relation of structure to activity of these compounds is proposed.

The acid and base constants of a large number of sulfanilamide type compounds have been determined. A plot of acid constants *versus* bacteriostatic activity, gives a smooth curve which passes through a maximum as the acid strength

(32) Urea, *m*-nitroaniline, aniline, and *p*-toluidine: Landolt-Börnstein, "Tabellen," 5th ed., 1936.

increases. This correlation between acidic dissociation and activity is shown to be directly associated with the negative character of the SO_2 group. In brief, the theory may be stated as follows: the more negative the SO_2 group of an N^1-substituted sulfanilamide derivative, the greater is its bacteriostatic power.

The inductive constants of the various N^1-substituents have been evaluated. Based on this method, a quantitative treatment of the theory has been developed. The calculated value of the acid constant for optimum activity agreed very well with the experimental results. The relative activity of the ionic and molecular forms of the sulfonamides has also been predicted by this treatment.

Since acid constants are related to both the structure of the N^1-substituent and the activity of the derivative, an indirect correlation between structure and chemotherapeutic activity is established. Knowing something about the relative electron attracting power of the N^1-substituent, it is possible for the first time to predict the bacteriostatic power of any new sulfanilamide derivative of this type. A discussion of the relation of structure to activity, and a description of the proposed theory and its implications are given.

Mixed Heteropoly Acid Catalysts for the Vapor Phase Air Oxidation of Naphthalene[1]

BY HENRY TRUEHEART BROWN[2] AND J. C. W. FRAZER

Catalysts prepared from heteropoly acids were first used for the partial oxidation of naphthalene in the vapor phase by Marisic.[3] The chief products from this reaction were phthalic and maleic anhydrides together with traces of naphthoquinone and benzoic acid. The reader is referred to Marisic's paper for a discussion of other catalysts used in this reaction and of the reasons for investigating heteropoly acid catalysts.

The present investigation arose from a consideration of the catalyst prepared from ammonium phospho-vanado-tungstate,[3] which gave considerably higher conversions of naphthalene to phthalic anhydride than either vanadium pentoxide or tungsten oxide alone.

In view of the fact that (1) heteropoly acid ions have a cage-like structure[4] into which only groups of the right size can fit, *i. e.*, octahedrally coördinated molybdenum, tungsten, and vanadium oxide complexes, and that (2) mixed compounds of the phospho-vanado-tungstate type exist, it seemed desirable to attempt the preparation of mixed heteropoly acids which should vary in composition from 12-molybdosilicic acid to 12-tungstosilicic acid wherein the mixed anions should contain both tungsten and molybdenum. It was expected that a series of catalysts prepared from such acids should exhibit coactivation similar to that in ammonium phospho-vanado-tungstate.

Experimental

Preparation of the Catalysts.—The general method employed in preparing the "mixed heteropoly acids" was a stepwise acidification of a solution containing tungstate, molybdate and silicate ions in the desired proportions and then an ether extraction of the product. This method was adapted from North's[5] preparations of 12-molybdosilicic acid with careful attention to all of the precautions which he mentions.

Catalysts were prepared from carefully purified acid crystals of 8–14 mesh size. These crystals were slowly heated in a stream of air to 400° and maintained at that temperature for one hour.

Preparations of the Heteropoly Acids.—Because of the importance of this step in the work, detailed directions will be given for preparing a typical "mixed acid" while directions for the others, together with their analyses, are summarized in Table I.

6-Molybdo-6-tungsto-silicic acid was prepared by dissolving 12.5 g. sodium molybdate and 17.1 g. sodium tungstate in 100 ml. of water heated to 65°. Then 5 ml. of concentrated hydrochloric acid was added dropwise with mechanical stirring, followed by 2.8 g. of sodium silicate solution (d. 1.375) diluted with a little water. Seventeen ml. of concentrated hydrochloric acid was added dropwise with vigorous stirring and the hot solution was filtered through asbestos to remove a slight precipitate of silica. After cooling, 22 ml. of concentrated hydrochloric acid was added and the clear solution was extracted with ether and the ether layer was purified as directed by North.[5] The

$H_4SiW_{12}O_{40}$		30.0	2.5	60	100	32						

resulting crystals were dried in a vacuum desiccator before use.

Analysis of the Catalysts.—A dried sample of each catalyst was ignited below 400° in a porcelain boat and then heated to 270° in a stream of dry hydrogen chloride. This procedure removed molybdic oxide quantitatively[6] as an oxychloride and weighing gave molybdic oxide by difference. Similarly tungstic oxide was removed at about 500° leaving a white residue of silica. The results are given in Table I.

Apparatus and Experimental Procedure.—The apparatus employed was that described by Marisic[3] except that only one condenser loosely filled with glass wool was used to catch the condensable products, and the exit gases were analyzed. These gases were dried with phosphorus pentoxide, carbon dioxide was absorbed in soda lime, and "Hopcalite" catalyzed the oxidation of carbon monoxide which was then absorbed in soda lime. The two soda lime towers were weighed to 1 mg. before and after each run. Because of a better air regulator reproducible results were obtained with half-hour runs but otherwise the experimental procedure and analysis of the products were identical with Marisic's.

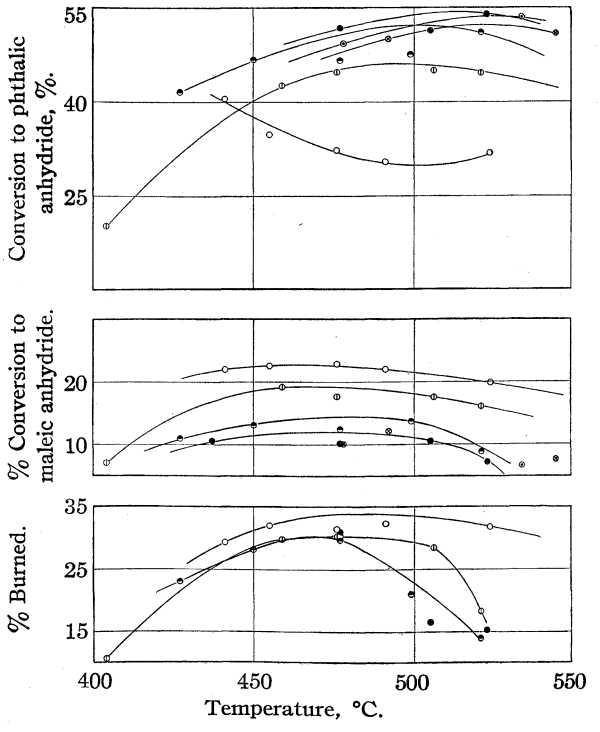

Fig. 1.—Catalyst from $H_4SiMo_{12}O_{40}$ at space velocity: ○, 6,850; ◐, 13,700; ◓, 24,000; ⊗, 26,200; ●, 29,200; ⊙, 32,000.

Experimental Data

Results for the air oxidation of naphthalene are given in Figs. 1–4.

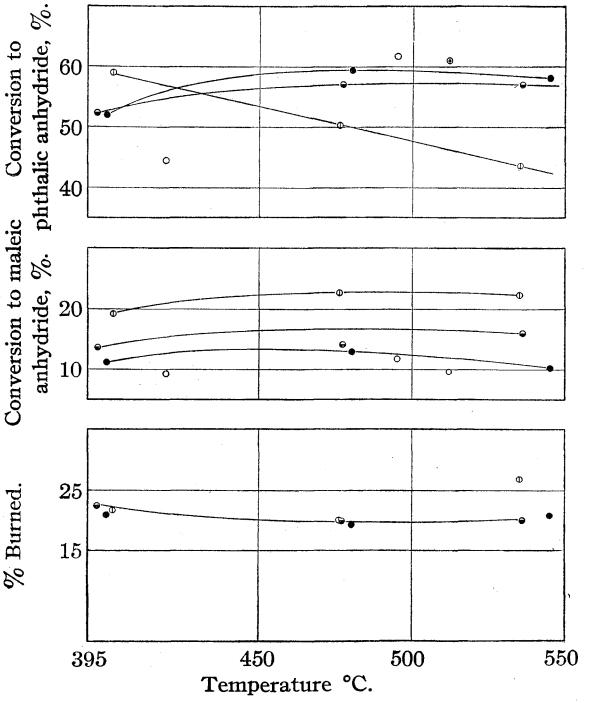

Fig. 2.—Catalyst from $H_4SiMo_9W_3O_{40}$ at space velocity: ◐, 13,700; ◓, 24,000; ●, 29,200; ○, 42,000; ⊙, 51,000.

Carbon Monoxide from the Catalytic Oxidation of Naphthalene.—It was observed in preliminary runs on the 12-molybdosilicic acid catalyst that carbon monoxide makes up a considerable proportion of the exit gases. In a series of runs at 476° the molar ratio of carbon dioxide to carbon monoxide was found to be a function of the space velocity and fell from 2.89 at s. v. 3420 to 1.87 at 8570, remaining constant at 1.87 up to a space velocity of 29,200.

This would seem to indicate that carbon monoxide is produced in large amounts at some stage

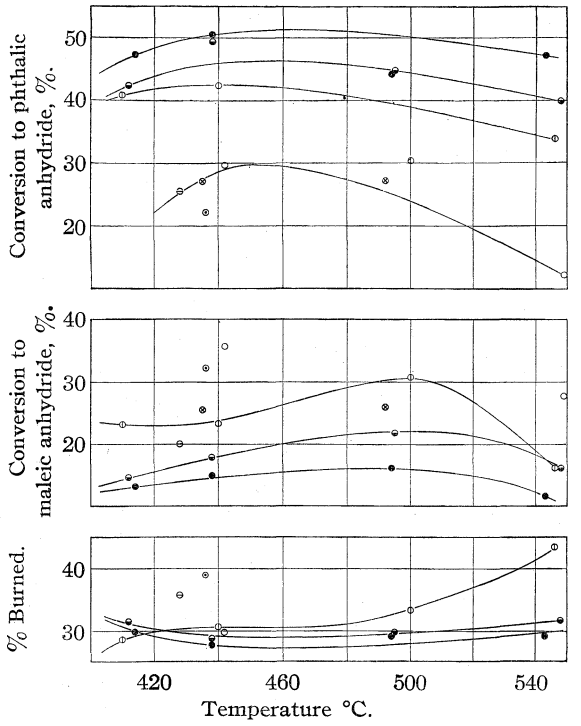

Fig. 3.—Catalyst from $H_4SiMo_6W_6O_{40}$ at space velocity: ○, 8,900; ⊙, 13,700; ⊕, 17,800; ⊗, 24,000; ◒, 31,100; ●, 37,800.

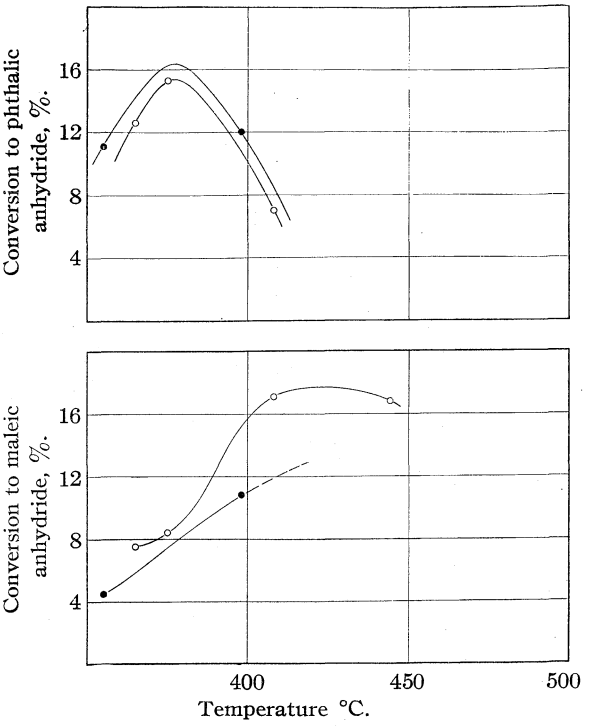

Fig. 4.—Catalyst from $H_4SiMo_3W_9O_{40}$ at space velocity: ○, 24,000; ●, 29,200.

of the oxidation and that part of the carbon dioxide detected comes from the oxidation of carbon monoxide. Later expts. showed that these catalysts are slightly active for the oxidation of carbon monoxide.

Effect of Carbon Dioxide.—It was found that the addition of carbon dioxide to the air-naphthalene mixture suppressed the formation of maleic anhydride and increased the amount of phthalic anhydride. Using the catalyst from 12-molybdo-silicic acid at 496°, space velocity 24,000 and an air/carbon dioxide ratio of 6/1, 53.8% of the naphthalene was converted to phthalic and 14.1% to maleic anhydride. This represents an increased phthalic yield of 13% over a run under the same conditions with pure air.

Oxidation of Phthalic Anhydride.—Weighed samples of phthalic anhydride were vaporized into the air stream and passed over the catalyst from 9-molybdo-3-tungsto-silicic acid under conditions comparable to those in the oxidation of naphthalene. The results of these experiments are presented in Table II (vol. of catalyst was 2 cc.).

TABLE II

Temp., °C.	Space velocity	Phthalic anhydride, g.	Phthalic anhydride: Not oxidized, %	Phthalic anhydride: Converted to maleic, %	Phthalic anhydride: Burned, %
485	24,000	0.2608	56	17.6	26.4
490	36,000	.2525	68	10.0	22.0
492	51,000	.3110	73	8.1	18.9

Oxidation of Naphthoquinone-1,4.—Because it was suspected that naphthoquinone-1,4 might be an intermediate product in the formation of phthalic anhydride, small weighed samples were vaporized and oxidized over the 9-molybdo-3-tungsto-silicic acid catalyst as above. The amount of complete combustion at 500° and s. v. 24,000 was three times as much as naphthalene gave under the same conditions and the yield of phthalic anhydride was much smaller. These experiments seem to indicate that naphthoquinone-1,4 is not an important intermediate between naphthalene and phthalic anhydride.

Discussion of Results

The experimental results from this work seem to throw little new light on the mechanism of the catalytic oxidation of naphthalene. It seems likely that only a small part of the naphthalene is oxidized to phthalic anhydride via naphthoquinone-1,4. Possibly the other naphthoquinones, 1,2 and 2,6, may be intermediates, but the first decomposes at the melting point and the second was not readily obtainable, so neither could be

TABLE III

Catalyst	Temp., °C.	Space velocity	% Conversion to Phthalic	Maleic	Complete combustion
12 Mo	523	29,000	54.0	7.2	15.2
9 Mo–3 W	495	42,000	61.6	11.7	....
6 Mo–6 W	438	37,800	50.5	14.9	27.7
3 Mo–9 W	375	24,000	15.3	8.4	Very high
12 W	410	Any or all	Practically complete combustion		

tested. It may also be concluded that perhaps all of the maleic anhydride results from the oxidation of phthalic anhydride and that with a given catalyst the amount of maleic is a function of the space velocity. If the oxidation data for $H_4SiMo_9W_3O_{40}$ at 495° are plotted against space velocity it can be seen that decreasing the time of contact increases the yield of phthalic at the expense of the maleic anhydride. At the same time the amount of complete combustion is essentially unchanged. This last fact together with the results from oxidizing phthalic anhydride seems to indicate that phthalic and maleic anhydrides are burned at approximately the same rate and that the reaction is not just a series of steps leading finally to complete oxidation.

The effect of catalyst composition is summarized in Table III, giving conditions for optimum yields.

It may be seen that the effect of increasing the ratio of tungsten to molybdenum in these catalysts is to lower the temperature for optimum yields of phthalic anhydride. The catalyst 9 Mo–3 W gives a maximum yield of 61.6% phthalic anhydride, which is considerably better than the 54% for 12 Mo, at a temperature which is 28° lower. These two effects can hardly be explained by assuming a mixture of crystals of 12 Mo and 12 W and constitute the strongest indication that the catalysts were prepared from mixed acid ions.[7]

Summary

1. A series of catalysts has been prepared from heteropoly acid crystals containing tungsten and molybdenum.

2. The activities of these catalysts have been studied for the partial oxidation of naphthalene.

3. The catalyst from $H_4SiMo_9W_3O_{40}$ gave considerably higher conversion to phthalic anhydride than either of the parent acids, $H_4SiMo_{12}O_{40}$ or $H_4SiW_{12}O_{40}$.

4. The addition of carbon dioxide to this air oxidation reaction improved the yield of phthalic and decreased the yield of maleic anhydride.

6. The catalyst from $H_4SiMo_9W_3O_{40}$ was employed in the oxidation of phthalic anhydride, naphthoquinone-1,4 and carbon monoxide.

(7) An unsuccessful attempt was made to obtain more direct evidence for the existence of mixed acid ions by means of their ultraviolet absorption spectra.

The Catalytic Interchange of Groups in Aliphatic Amines. I

BY KENZIE NOZAKI

A number of reactions are known in which the groups attached to a given kind of atom are exchanged between molecules under the influence of certain metal halide catalysts. Two thoroughly studied examples are the migration of alkyl groups in benzene derivatives,[1] and the redistribution of organo-metallic substances, recently investigated by Calingaert and co-workers.[2] The reactions so far observed have been confined almost exclusively to the exchange of groups attached to either carbon or metals. In this paper we wish to report a case where groups attached to nitrogen are exchanged.

It was found from preliminary experiments that when aliphatic amines are heated in the presence of metal halide catalysts, the alkyl groups and the hydrogen atoms attached to the nitrogen atom may be redistributed. In this redistribution process, all the possible combinations of the alkyl groups and the hydrogen atoms with the nitrogen atom occur. Calingaert and co-workers found similar results with the metal alkyls. Since the

interconversion of amines is of practical as well as of theoretical importance, it seemed worth while to study the reaction. In this paper some of the work which has so far been carried out is reported.

Experimental Results

Much of the work reported in this paper involves the use of di-*n*-butylamine, which was chosen for study because it is relatively inexpensive, has a moderately high boiling point, and can readily be separated from *n*-butylamine and tri-*n*-butylamine by fractional distillation.

Characteristics of the Reaction.—The reaction described in this paper is apparently free of side reactions below 200°. Above this temperature a slow reaction occurs which produces a high boiling product. However, in all runs reported in this paper, the amount of this reaction was negligible. This side reaction, which is being studied further, is believed to be an alkylation of the alkyl groups of the tertiary amine.

During redistribution, the alkyl groups do not undergo the structural rearrangements which are often observed in Friedel–Crafts reactions.[3] Thus, careful observation of boiling points and the preparation of picrate derivatives has indicated that whenever a *n*-butylamine was taken initially, the reaction products were *n*-butylamines and ammonia. The absence of rearrangement within the alkyl groups during the redistribution of organometallics has been reported.[4]

Experiments in Open Vessels.—Experiments were first carried out in which di-*n*-butylamine was heated with a catalyst at atmospheric pressure. Under these conditions the ammonia which was formed in the reaction escaped and was lost. Thus equilibrium was never reached. However, the amount of tri-*n*-butylamine found at the end of any period of heating gave an indication of the amount of redistribution which had occurred.

In Table I are listed the results obtained when di-*n*-butylamine was refluxed with four different substances. It is observed that sulfuric acid has no catalytic effect and that the order of the catalytic activity of the metal halides, $AlCl_3 > FeCl_3 > ZnCl_2$, is the same as has been found for the Friedel–Crafts and allied reactions. Since aluminum chloride was the best catalyst, it was used in all subsequent work. It should be mentioned that di-*n*-butylamine heated alone in a sealed tube at 300° for several hours showed no evidence of redistribution or decomposition.

TABLE I

THE ACTION OF DIFFERENT CATALYSTS ON DI-*n*-BUTYLAMINE

Catalyst	Moles of catalyst per mole of amine	Reflux time, min.	Composition of reaction products, mole per cent. $NH_2(C_4H_9)$	$NH(C_4H_9)_2$	$N(C_4H_9)_3$
$AlCl_3$	0.126	240	9.7	74.2	16.1
$FeCl_3$	.129	240	4.6	89.6	5.8
$ZnCl_2$	.124	240	2.1	95.7	2.2
H_2SO_4	.422	1500	0.0	100.0	0.0

In order to obtain some information concerning the nature of the reaction, experiments were carried out in which the dependence of the rate of redistribution on the catalyst concentration was determined. It was found that when the quantity of aluminum chloride added to a given amount of di-*n*-butylamine was doubled, the time necessary for a certain fraction to be converted into tri-*n*-butylamine was decreased to one fourth. For example, the periods of heating required at 164° to produce 0.0072 mole of tri-*n*-butylamine in mixtures in which 0.0075, 0.015 and 0.030 mole of aluminum chloride had been added initially to 0.119 mole of di-*n*-butylamine were one hundred and twenty, thirty and eight minutes, respectively. These results seem to indicate that the reaction is of second order with respect to aluminum chloride concentration.

Experiments were next conducted to determine the effect of time of heating upon the amount of redistribution. In Table II are summarized the results of several runs in which 0.252 mole of aluminum chloride was added per mole of di-*n*-butylamine and the mixture refluxed for the period given. It is observed that, although the rates of formation of *n*-butylamine and tri-*n*-butylamine were probably the same at the start of the reaction, the rate of formation of *n*-butylamine fell off much more rapidly with time than that of tri-*n*-butylamine, and eventually the concentration of *n*-butylamine started to decrease. Substitution of the data into integrated rate expressions indicated that the rate of tri-*n*-butylamine formation fell off much more rapidly with time than it should have if the reaction were of first order with respect to di-*n*-butylamine concentration. The results of run 7 indicate that a nearly complete conversion of di-*n*-butylamine to tri-*n*-butylamine may be obtained when the heating is continued for a considerable period.

TABLE II

THE ACTION OF ALUMINUM CHLORIDE ON DI-*n*-BUTYLAMINE AT THE BOILING POINT

0.252 mole of aluminum chloride added initially per mole of amine.

Run	Reflux period, min.	Composition of reaction products, mole per cent. $NH_2(C_4H_9)$	$NH(C_4H_9)_2$	$N(C_4H_9)_3$
1	8	4.7	89.4	5.9
2	30	8.5	79.7	11.8
3	60	10.8	73.3	15.9
4	120	16.4	61.1	22.5
5	255	15.8	49.3	34.9
6	360	12.2	45.7	42.1
7	1440	0.5	15.9	83.6

Although the temperature coefficient of the reaction was not determined, it was found that no redistribution occurred at room temperature. Only the starting materials could be isolated from mixtures of aluminum chloride and di-*n*-butylamine which had stood for ten days.

Experiments in Sealed Tubes.—In order to study the reaction further, experiments were conducted in sealed tubes. In this manner the presence of ammonia among the reaction products was shown. For example, upon heating a mixture containing 0.045 mole of aluminum chloride and 0.18 mole of di-*n*-butylamine at 250° for 1800 minutes, the products were found to consist of 20.4, 6.2, 26.8, and 46.6 mole per cent. of ammonia, *n*-butylamine, di-*n*-butylamine and tri-*n*-butylamine, respectively. It was also shown that the same four products could be obtained by heating a mixture of ammonia and tri-*n*-butylamine with aluminum chloride. Thus a mixture made up of 0.040 mole of aluminum chloride, 0.014 mole of ammonia and 0.16 mole of tri-*n*-butylamine was found to consist of 5.6, 1.4, 5.0 and 88.0 mole per cent. of ammonia, *n*-butylamine, di-*n*-butylamine and tri-*n*-butylamine, respectively, after being heated at 250° for 1800 minutes.

In order to obtain a comparison of the reactivity of the *n*-butylamines and the ethylamines, di-*n*-butylamine and diethylamine were mixed separately with aluminum chloride in a mole ratio of 4 to 1 and the mixtures were sealed in tubes. After being heated at 190° for 1440 minutes, the tube to which di-*n*-butylamine had been added was found to contain 29 mole per cent. of tri-*n*-butylamine, while the tube to which diethylamine had been added was found to contain only about 1 mole per cent. of triethylamine. Thus, there is a very large difference in reactivity between the two amines.

Discussion

The mechanism of the reaction reported in this paper probably involves the initial formation of complexes between the amine and the catalyst, in which the metallic atom of the catalyst shares the free pair of electrons of the nitrogen atom. The attachment of the catalyst undoubtedly weakens the other bonds of the nitrogen, giving polarized addition products of the type, $R^+—\overset{\cdot\cdot}{\underset{\cdot\cdot}{\overset{R}{N}}}:AlCl_3$. This view is strongly supported by the work of Meerwein and co-workers[5] on complexes between boron trifluoride and alcohols. These complexes of the structure, $R:\overset{H}{\underset{\cdot\cdot}{\overset{\cdot\cdot}{O}}}:BF_3$, were not only strong acids, but also good alkylating agents. It should be added that Dougherty[6] had suggested some time ago that polarized or ionized intermediates of the type, $\overset{+}{R}—\overset{-}{\underset{\cdot\cdot}{\overset{\cdot\cdot}{Cl}}}:AlCl_3$, were involved in the Friedel–Crafts reaction. It is not considered likely that actual ionization of an alkyl group as a cation occurs in our proposed complexes since there was no indication of rearrangement within a primary alkyl group such as *n*-butyl. According to the views of Whitmore,[7] a rearrangement to the secondary or tertiary form would be expected if an alkyl cation were formed.

Our work has indicated that the reaction is of second order with respect to aluminum chloride concentration. This suggests that two complexes, such as we have discussed above, are involved in the step during which exchange occurs. In this step a larger complex may be formed which is held together by the ability of each aluminum atom to attain a coördination number of five[8] by sharing a pair of electrons of a chlorine atom attached to the other aluminum atom. Evidence for the existence of large complexes made up of two molecules of aluminum halide and two organic molecules has been supplied by Kohler[9] and more recently by Norris and co-workers.[10] Assuming that such complexes are involved, the role of the catalyst is not only to polarize the amine molecules, but also to hold them close enough together so that exchange may occur.

Experimental

Materials.—The amines were all Eastman Kodak Co. products, and they were carefully fractionated before use. The aluminum chloride, ferric chloride, zinc chloride and sulfuric acid were anhydrous C. P. products and were used without further purification.

Experiments in Open Vessels.—The catalyst and amine were mixed, with considerable evolution of heat, and the resulting mixture was heated under reflux. In almost every case a two-phase system was obtained. In experiments for which a constant temperature was desired, a large electrically heated oil-bath was used and the solution was frequently shaken. At the end of a definite period the mixture was cooled in an ice-bath and a considerable excess of aqueous sodium hydroxide was added. The amine layer was separated, washed with water, dried over potassium carbonate and finally fractionated.

For large quantities a fractionating column, 40 cm. long, 13 mm. i. d., electrically heated, and packed with glass helices was used. However, many runs were made using only about 30 cc. of solution, and in such cases a Vigreux column, 25 cm. long, and of 8 mm. i. d., was used. The column was very efficient, and, in general, a reflux ratio of 30 to 1 was maintained.

Experiments in Sealed Vessels.—Pyrex bomb tubes were used in this work. Ammonia, if required, was added to mixtures by condensing the gas in the tubes, using a dry ice–alcohol bath. Sealed tubes containing the reactants were heated in an electric furnace. After heating, the tubes were cooled in a dry ice–alcohol bath and then opened. The contents of the tubes were poured into an excess of cold aqueous sodium hydroxide, and the amine layer was separated. The aqueous layer was extracted twice with ether, the ether extracts being added to the amine layer. The aqueous layer was then distilled into a standard hydrochloric acid solution and the ammonia concentration was determined from the amount neutralized. The amine–ether fraction was dried over potassium carbonate and fractionated, using one of the columns described above.

Preparation of Picrates.—Although the boiling points of the amine fractions indicated that no rearrangements within the alkyl groups had occurred during redistribution, a check was desirable. This was done by preparing the picrates of amine fractions obtained by redistribution. Mixed melting point determinations with picrates prepared from amines obtained from the Eastman Kodak Co. indicated that no changes had taken place within the alkyl groups. The picrates were prepared by mixing 1 g. each of picric acid and the amine and heating until a brown solution was obtained. Six cc. of ethanol was then added and the mixture cooled. The fine yellow crystals which formed were filtered, washed and finally recrystallized from ethanol. The picrates of *n*-butylamine, di-*n*-butylamine and tri-*n*-butylamine melted at 151, 59 and 105°, respectively.

Summary

It has been found that when aliphatic amines are heated with metal halide catalysts, the groups attached to the nitrogen are redistributed. This redistribution reaction has been studied with respect to the catalytic activity of several substances and the order of the reaction with respect to catalyst concentration. The mechanism of the reaction has been discussed.

[COMMUNICATION NO. 827 FROM THE KODAK RESEARCH LABORATORIES]

Some Effects of Solvents upon the Absorption Spectra of Dyes. I. Chiefly Polymethine Dyes

BY S. E. SHEPPARD, P. T. NEWSOME AND H. R. BRIGHAM

Introduction

To examine the effect of solvents upon the absorption spectrum of a substance, it is desirable that the spectrum should be measured originally for the substances present as a gas at low pressures and at temperatures comparable with those of the solutions. This is far from easy with dyes, which possess rather large and complicated polyatomic molecules. Low pressures and rather high temperatures are required to volatilize them. Also, they are very liable to decomposition (pyrolysis) with formation of colored (yellow to brown) reaction products.

Experimental

The dyes in which we are primarily interested are photographically active sensitizing and desensitizing dyes such as cyanines (polymethine dyes), and xanthene and phenazine derivatives. Most of these are salts, and, while it was found possible to volatilize (sublime) a number of them, there was generally too much decomposition for satisfactory spectral measurement. Certain non-saline *merocyanines* first prepared by Brooker[1] could be volatilized at low pressures without contamination. Because of the low pressures necessary, a quite long optical path was used, *viz.*, a 15-ft. tube, operated as an electrical resistance heater furnace by wrapping it with nichrome wire and asbestos (*cf.* Fig. 1).

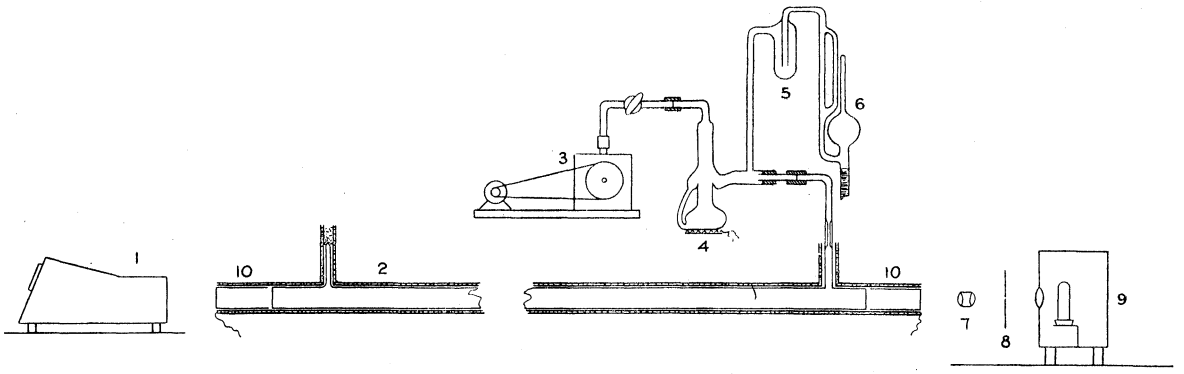

Fig. 1.—Diagram of vapor absorption apparatus: 1, spectrograph; 2, absorption tube with heating coils and insulation; 3, Hyvac pump; 4, condensation pump; 5, trap; 6, McLeod gage; 7, lens; 8, diaphragm; 9, light source; 10, end guards.

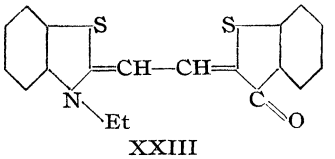
The total pressure was about 0.1 μ; the partial pressure of the dye was not measured. Consequently, we were unable to measure actual extinction coefficients, defined as

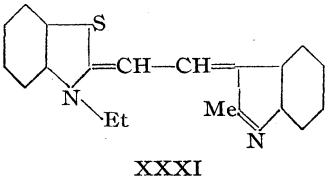
$$\epsilon_\lambda = \frac{1}{cd} \log \frac{I_0}{I}$$

where c = molar concentration, and d = thickness in cm.

However, the envelope of the band spectrum could be measured spectrophotometrically in terms of optical density; after analysis, the relative extinctions of the band maxima were obtained.

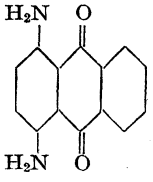


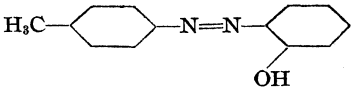
XXIII



XXXI

Beside the *merocyanines*, XXIII and XXXI (see above), measurements in the gas phase were made of *1,4-diaminoanthraquinone*, of *p-toluidine azo-β-naphthol*,





and of *indigo*. It is to be noticed further that, while absorption measurements were made at low pressures, the *temperatures* were much higher than those in the solutions. This is more or less inevitable, since rough calculation shows that to obtain an optical density of 1.0 at 25°, lengths of tube of the order of 10^7 to 10^{16} would be necessary.

Previous measurements on some vaporized dyes (indigo, alizarin, dianilidoanthraquinone) have been made by Koenigsberger and Küpferer.[2]

Representation and Analysis of Extinction Curves

A common graphic representation is a plot of $\epsilon_\lambda \sim D_\lambda$ against λ (wave length in mμ or Å.). Curves of this type are shown for gaseous *merocyanine* (dye XXIII) and *1,4-diaminoanthraquinone* at different temperatures (*cf.* Fig. 2). Similar curves for *merocyanine* (dye XXIII) dissolved in various solvents are shown in Fig. 3. However, for comparison and analysis of the effects of structural and environmental changes, there are many advantages in taking reciprocal values of the wave length as abscissas, as wave numbers $1/\lambda$ in cm.$^{-1}$. The use of log ϵ as ordinate is frequently useful, either to obtain compactness, or to enhance the apparent strength of minor bands[3]; ϵ_λ is a quantity having no dimensions, and representing the *probability* of the event occurring at the value λ.

The curves shown in Figs. 2 and 3 are only the envelopes of a definite group of related bands; in some cases, one or more of the subsidiary peaks are clearly defined; in others, they may be present only as a hump or shoulder, or merely as a strongly marked asymmetry of the extinction curve. Changes of environment may affect the relative sharpness and strength of the individual bands.

Such band complexes may be analyzed by semi-empirical methods, assuming that the ϵ ($\sim$ prob-

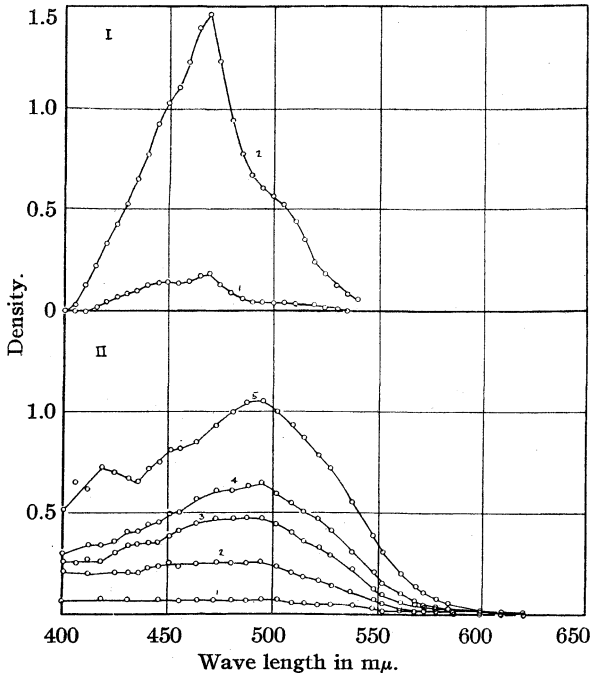

Fig. 2.—I, Merocyanine gas at 1, 228°; 2, 250°. II, 1,4-diaminoanthraquinone gas at 1, 135°; 2, 154°; 3, 168°; 4, 183°; 5, 195°.

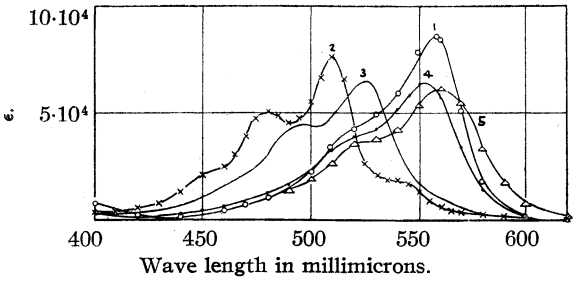

Fig. 3.—Merocyanine in 1, methyl alcohol; 2, *n*-hexane; 3, carbon tetrachloride; 4, quinoline; 5, methylene iodide.

ability of absorption) values are distributed about a maximum, usually according to a Gaussian function. We have used the method originally introduced by Henri,[4] and by Henri and Bielecki.[5] Their function

$$\epsilon_\nu = ke^{-[(\nu_0-\nu)^2]/2a^2} \text{ or } y = ke^{-x^2/2a^2}$$

where k is the ordinate, ϵ_{ν_0}, at the center of the distribution curve, *i. e.*, when $x = \nu_1 - \nu = 0$ and $2a$ is the breadth at a value 0.606 k, and ϵ_ν = the molar extinction coefficient.

It was observed that in the organic solvents employed, Beer's law is generally followed by these dyes.

In Figs. 4 and 5 are presented comparative extinction curves for the *merocyanine* dye—and *diaminoanthraquinone*—in which the analyzed components of the envelope are indicated.

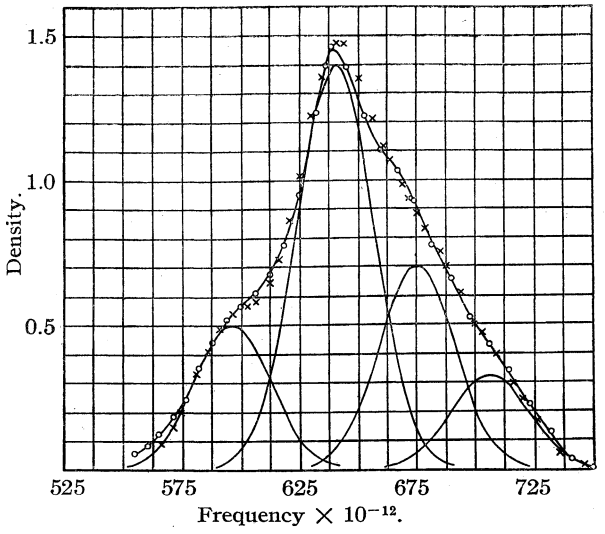

Fig. 4.—Analysis of merocyanine absorption.

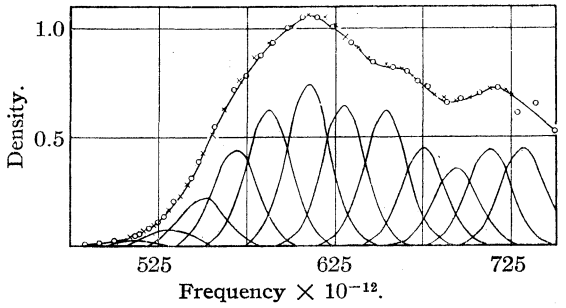

Fig. 5.—Analysis of 1,4-diaminoanthraquinone absorption (gaseous).

The data indicate that the band group persists as a whole in different media, and is displaced as a whole, not only with the merocyanine XXIII, a polymethine dye, but with diaminoanthraquinone, representing a quite different class. This conclusion is supported by graphic representation of the intensity ratios in the spectrum shown elsewhere.[6]

The persistence of this group of bands, adjacent to the band of maximum intensity, in the gaseous state, and in organic solutions, wherein Beer's law is followed, is of considerable importance. In aqueous solutions the ratio of intensities of the bands may change with the concentration. The auxiliary bands have been attributed to polymers of the single dye molecules.[7] But it is evident that this is incorrect, since these bands are

definitely present both in the gaseous state and in organic solutions following Beer's law. They correspond, therefore, to electronic transitions proper to the individual molecule, and all that can be said is that aggregation or polymerization may change the relative probabilities of these transitions.

The wave-number differences between successive bands in the polymethine dyes range from 900 cm.$^{-1}$ to 1700 cm.$^{-1}$; these are of the same order as such differences in the polyenes and linear benzenes.

Effect of Temperature on Solutions

A considerable range of temperature is open to study with solutions of dyes in organic solvents. A mixture of ethyl alcohol and ether is a good solvent for many cyanine (polymethine) dyes. The most evident effect is to sharpen the band components as the temperature is lowered, or conversely, increased diffusion as it is raised. This can be expressed to some extent quantitatively as the change of ϵ_{max} with temperature. Here it is most useful to plot log ϵ_{max} against $1/T$, where T is the absolute temperature, and characteristic curves are shown for several cyanine (polymethine) dyes (Fig. 6). The increased sharpening at lower temperature is due to reduction of rotational and vibrational energies, which cause the diffusion of the individual band. As very low temperatures are approached, this elimination becomes less, and the sharpening—shown by increase of ϵ_{max} and reduction of the half-width of the band—asymptotically approaches a limit, or a maximum. This latter phenomenon is very possibly due to separation of the dye from solution, but further study is required.

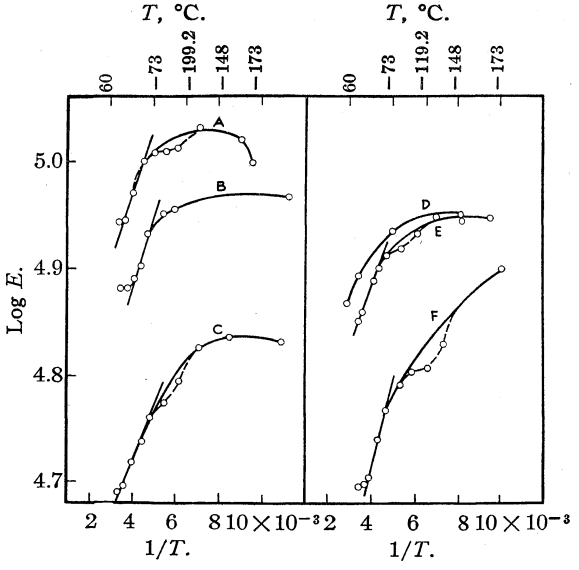

Fig. 6.—A = Dye XVIIIa; B = Dye XVIa; C = Dye XIXa; D = Dye Va; E = Dye XXa; F = Dye XVIIa.

There is liable to be a specific effect in aqueous solution, namely, a redistribution of intensities in the band complex. In consequence of this, the extinction coefficient ϵ_{max} of the long wave band tends to *increase* with rising temperature.

Comparison of Solvent Effects

There are at least two parameters for which solvent effects on absorption could be evaluated, *viz.*, in respect of band strength $\int \epsilon d\nu$ and band position—ν_{max} or λ_{max}. In regard to the former, Chako[8] made a comparison of expressions for band strength for a large variety of organic substances, but not including dyes, in various solvents. The principal expression, derived from classical theory, evaluates the influence of neighboring molecules due to the Lorentz–Lorenz force, *i. e.*, the force coming from the polarization of the surrounding molecules. According to this, if F_s is the transition probability in solution, and F_g, that in the gas state, then

$$F_s = F_g\left(\frac{9}{(n_0^2+2)^2}\right)$$

where n_0 is the refractive index of the solvent. Chako concluded from his review that "it is impossible to account for the influence of the solvent through the Lorentz–Lorenz force."

If the width of the absorption band in the different solvents is constant, we can substitute ϵ_{max} for $\int \epsilon d\nu$, and should have

$$\epsilon_{max}\frac{9}{(n_0^2+2)^2} = \epsilon_{gas} = \text{constant}$$

This has been computed for the merocyanine in various solvents having values of n_0 ranging from 1.327 to 1.576. The calculated values of ϵ_{gas} varied from 3×10^4 to 6×10^4. Some improvement occurs by evaluating the band strength F_s, but far from sufficient to account for 100% variation of ϵ_{gas}.

Displacement of Bands

In 1878 Kundt[9] concluded that with increasing (partial) dispersion of the solvent the absorption maximum of a dye is shifted toward longer wave lengths. Usually, the refractive index n_D is

considered instead of the dispersion. Numerous exceptions were observed, but chiefly for the ultraviolet absorption bands of substances other than dyes.

However, we found that if we definitely separate non-polar from polar solvents, Kundt's rule holds quite well, not only for dyes but for certain hydrocarbon prototypes, such as the polyenes, polyphenyls, and *lin*-benzenes. In many cases, the relation of γ_{max} to n_D is approximately linear —including the gaseous state with $n_D = 1.00$ (*cf.* Fig. 7). A relation between λ_{max} and the *dielectric constant* K was examined also for the merocyanines in non-polar media.

Simple electrostatic considerations[10] suggest that the change of energy required to displace an electron in a medium of dielectric constant K compared with that in a vacuum would be given by the relation

$$\Delta E = \frac{e}{2r^2}\left(1 - \frac{1}{K}\right)$$

Hence, for the displacement of an absorption band in a solvent of dielectric constant K, we should have $\Delta\nu = a(1 - (1/K))$, for constant r. Keeping to non-polar solvents, values are given in Table I for near ultraviolet bands for aromatic hydrocarbons, and a diphenyl polyene, and for visible bands of certain dyes.

It is thought that somewhat better agreement might be obtained if variation of a, the molecular radius parameter, could be allowed for. One or two calculations for benzene, using the volume change on mixing, indicate this.

Effect of Polar Moment

An over-all survey of our data for the merocyanine seemed to indicate that no direct and simple relation between the band displacement and the polar moment could be observed. However, on analyzing the results in terms of families of homologous compounds, in general, of increasing chemical complexity, certain regularities became apparent, as exhibited in Tables II, III, IV, and V. The displacement changes but slightly in this series and accords with the change of dielectric constant.

Pyridine	2.11	550	18182	3094

[a] Values for N_2 (nitrogen) by extrapolation.

A plot of the results so far is shown in the following graph (Fig. 8). This exhibits the following features: (i) progressive increase of the displacement Δ with K, (dielectric constant) for non-polar liquids ($\mu \cong 0$); (ii) progressive increase of Δ with μ for the aliphatic series Hydrocarbon → Ethers → Alkyl acetates → Ketones → Nitro·C_nH_{2n+1}. The alcohols form an outstanding exception. There is a distinct tendency for the sequence to give either two lines of different slope or perhaps to approach a "saturation" value. (iii) Starting with benzene ($\mu = 0$), the same types of compounds give, in part, a linear array of the same slope, but with a constant difference. Again, there is a well-marked trend or branch, of lower slope; the convergence of this with the "aliphatic" series, at the nitro-anisole "value" may be coincidental. It seems possible, however, that with the higher bond moments, *e. g.*, >C (—NO_2), this becomes of preponderant effect, and that a "saturation" limit is approached. (iv) The series of amines, N<$^{R_1}_{R_2}$ (including NH_3 and HN = C_5H_{10} (piperidine), gives a linear series; the line extrapolated back to $\mu = 0$ gives a

displacement corresponding approximately with that to be expected for liquid nitrogen (K = 1.47). While these results indicate definite regularities, it must be noticed that very definite exceptions occur. Thus, the *alcohols* give values quite out of proportion to their mean (molecular) moments: Aliphatic $\mu = \sim 1.70$ $\Delta = 3260$ cm.$^{-1}$, aromatic $\mu = \sim 1.70$ $\Delta = 3240$ cm.$^{-1}$. (Roughly as though the aliphatic alcohols had *three* times the monomeric moments, the aromatic, *twice* the measured moment.) Another group of related compounds which appears at first to defy reduction to order is that of the alkyl halides. The measurements so far obtained are given in Table IX.

TABLE IX

HALIDES OF METHANE AND ETHANE

	ΔCl	ΔBr	ΔI
CH_3X	..	992	2757
CH_2X_2	2757	3094	3419

CX_3CX_3	..	..	..

When these are plotted as functions of the average moments (best available values at 25°), it will be seen that something like a peculiar "shotgun pattern" is obtained. (The oblique line is the principal aliphatic line repeated from Fig. 9.) It would appear evident that very specific—even individual—combinations of the molecular forces are required to account for these results.

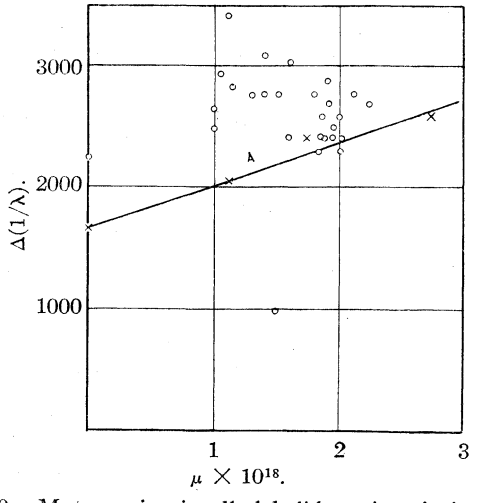

Fig. 9.—Merocyanine in alkyl halides: A, principal aliphatic curve.

Basicity and Acidity of Solvents

The avidity of a molecule for a proton (H^+ ion) is termed its basicity,[11] and, conversely, its facility in donating one to another molecule, its acidity. As is well known, quantitative measures of these values depend upon the solvent. For example, in water there is possible a pH range from 0 to 14; superacid solutions can be made in acetic acid plus acetic anhydride, but the relating of these to the water scale values is a matter of considerable uncertainty.

The relations of proton addition to the constitution and color of dyes is *per se* outside our subject.[12] However, two aspects of it affect the question of solvent influence, in particular with certain dyes which we have used.

Evidently a comparison of the basicities or acidities of our "solvents" obtained with these as "solutes" in a common, solvent medium, *e. g.*, water, or acetic acid will only give their relative order in the common medium. It will not give much, if any, information as to the absolute basicities or acidities of these solvent molecules in the presence only of their own congeners. It is none the less interesting to note that with two merocyanines (XXIII and XXXI) the displacement parameter varies in a very similar fashion with the (aquo) basicity figure.[13] The behavior of merocyanine XXIII with definitely acidic solutions and solvents may throw some light on the problem. First, in the series of media

$$\text{Water} \longrightarrow \text{Water:}\ \underset{\text{dilute}}{H_2SO_4} \longrightarrow \underset{\text{conc.}}{H_2SO_4} \longrightarrow \begin{cases} H_2SO_4 \\ SO_3 \end{cases}$$

the curves in Fig. 10 show a certain swing between two systems. Thus, in *water* the absorp-

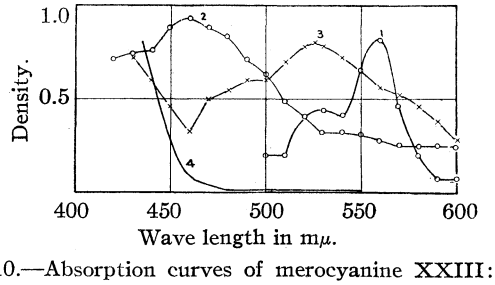

Fig. 10.—Absorption curves of merocyanine XXIII: 1, in water; 2, H_2O and H_2SO_4; 3, H_2SO_4; 4, H_2SO_4 and SO_3.

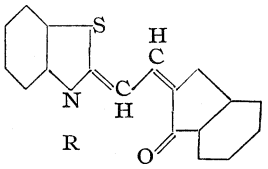
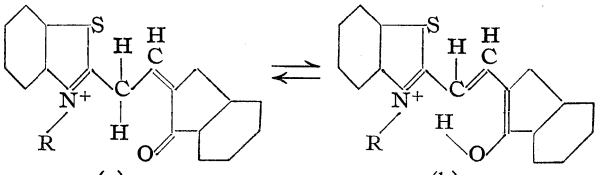
(12) G. Schwarzenbach, *Z. Elektrochem.*, **47**, 40–52 (1941).
(13) N. F. Hall, THIS JOURNAL, **52**, 5115 (1930).

tion curve is much the same as in alcohol or other hydroxylated solvent. And this is also the case *initially* in concentrated sulfuric acid, which is perhaps behaving as $O_2S(OH)_2$. However, on standing, the absorption system in the visible region disappears, to be replaced by a powerful system on the violet edge of the visible region and in the ultraviolet with its longest wave band at 4150 Å. By neutralization, the absorption in the visible region is restored, but to that in dilute sulfuric acid rather than to that in water alone. The absorption in *dilute* sulfuric acid is remarkable as giving a maximum at *ca.* 4600 Å. (see Fig. 10) which appears identical with that given by the dye in *formic acid*—but not in the other fatty acids.

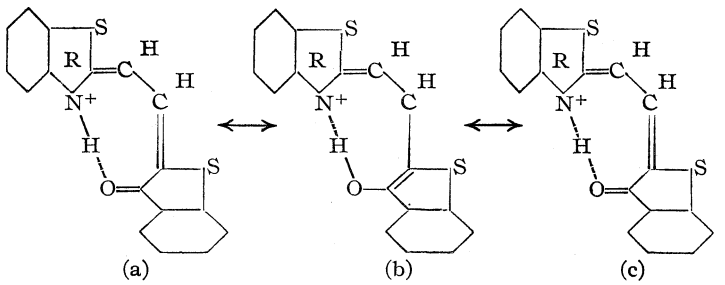
On considering the formula for merocyanine XXIII, it seems possible that the initial addition of a proton can give the alternative structures (a) and (b).





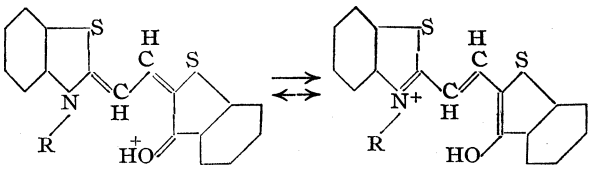
(a) (b)

And there might be actually resonance (mesomerism) between these structures, by which is developed the band at 4600 Å. in dilute sulfuric and in formic acid. M. L. Huggins has suggested the alternative possibility of the 8-ring shown below



(a) (b) (c)

with the same type of mesomerism over a wider circuit. This requires a slightly greater strain on the bond angles involved, to about 129°. Another configurational treatment is suggested in the following resonance scheme.



Owing to the instability of the $=OH^+$ grouping, the left-hand configuration would have considerably higher energy, and the passage from the merocyanine would involve "reversed halochromy"—hence the band at shorter wave length, 4600 Å. The behavior of the lower homologous fatty acids is interesting; the absorption curves are shown in Fig. 11. In order to remove traces of water, a small amount of acetic anhydride was added. It will be seen that the spectrum in formic acid is quite distinct from that in the higher homologs, while that in acetic acid shows a tendency to an intermediate type, with enhancement of a band at about 4800 Å. The position of the longest wave band, as shown in the table (Table X) is practically the same as that in the alcohols (588–555 mμ) so that these "associating" acids show the same tendency to behave as if having a much higher moment than that of the monomeric mole-

TABLE X

MEROCYANINE XXIII IN FATTY ACIDS

Acid	λ_m in mμ		$\Delta\nu$		μ
Formic	460	..	..	..	(1.2)
Acetic		480	557	3350	1.4
Propionic			555	3258	1.74
n-Butyric			555	3258	1.4
n-Valeric			560	3419	(0.9)

cule. Usually it appears that the moments of the polymers in associated liquids are reduced or entirely internally compensated. It is interesting that abnormal "displacements" of the same order are produced by *ethyl acetoacetate, acetylacetone,* and *acetonyl acetone*—all liquids in which the existence of similar configurations, potentially mesomeric, is highly probable. This general similarity is brought out in Table XI.

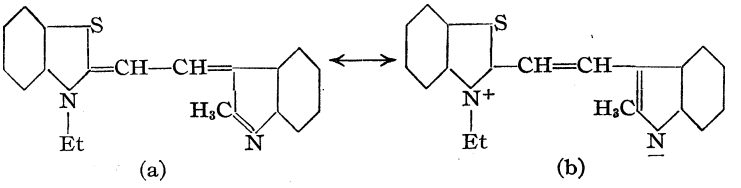
The "odd" behavior of formic acid is perhaps to be attributed to much higher "acidity" in the dimeric state, with ionization of the —CH and formation of dicarbeniate ions $H^+\left[C(=O\cdots H\cdots O)(O\cdots H\cdots O)C\right]^{=}H^+$ also, *ethyl acetoacetate,* if accounted as acetate ester, has a high moment—2.93 compared to 1.8.

TABLE XI

"HIGH" DISPLACEMENTS

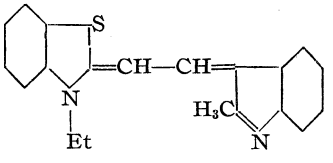
Substance	Tautomer or Polymer	Dipole moment μ	Δ Observed	Δ calcd. from μ
Water	 (or chain)	1.84	3419	2200
Alcohols	 (or chain)	1.70	3258	2300
Fatty acids		1.4 to 1.70	3258	2300
Ethyl acetoacetate		(2.93)	2757	2400
Acetylacetone		3.00	3193	2750
Acetonylacetone		2.8	2757	2680

Its "displacement" is about normal for its moment, but abnormal as an ester. Acetylacetone, so near in structure, has a slightly high moment as a ketone, but a "displacement" which is high both for the keto structure and for its moment.



Some Observations with Merocyanine Dye XXXI

We come now to some observations on a dye, representative of a class first prepared by Brooker, Sprague, Smyth and Lewis[14] which, while specifically a merocyanine, is especially interesting as being at the same time an ansolvo-base of an actual cyanine; Dye XXXI is



Brooker and his collaborators have shown that this base gives rise to "reversed halochromy," in that, on salt formation, by combination either with alkyl halide, or with acid (thus forming a cyanine), the main absorption shifts not to longer but to shorter wave lengths than for the base itself. To the base can be attributed two principal limit structures

Although having a very similar configuration to merocyanine XXIII, with the same length of conjugate chain between the key atoms in each case, the maximum absorption is very definitely dis-

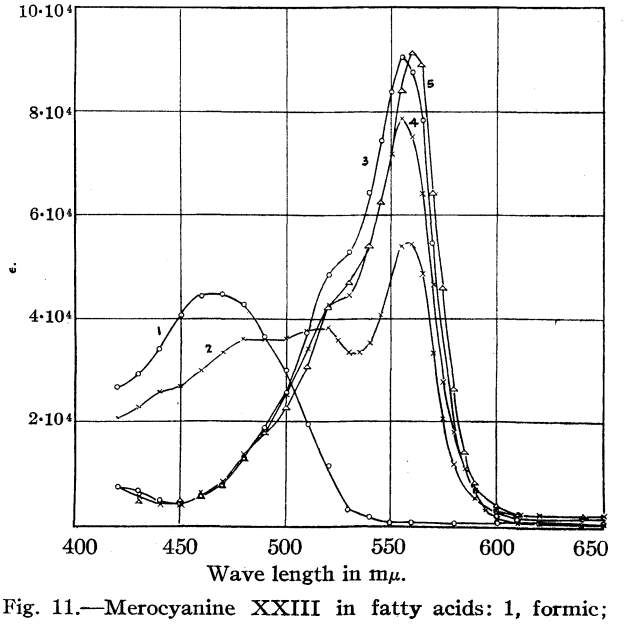


Fig. 11.—Merocyanine XXIII in fatty acids: 1, formic; 2, acetic; 3, propionic; 4, *n*-butyric; 5, *n*-valeric.

(14) L. G. S. Brooker, R. H. Sprague, C. P. Smyth and G. L. Lewis, THIS JOURNAL, **62**, 1116 (1940).

placed to higher frequencies than that for XXIII, a fact which may be attributed to the lower stability of the negatively charged N atom in (b) compared with the negatively charged O atom of XXIII. While XXXI can be volatilized at low pressures, so far we have not succeeded in obtaining a satisfactory value for the absorption curve *in vacuo* because of too considerable decomposition. At present actual "displacement" values cannot be given for the solvent influence, but instead the absolute values of $1/\lambda_m$ may be compared; and, owing to the complexity of the absorption spectrum, it is not always easy to be sure that the comparison *is* being made for the same member of the band complex.[15] The largest complicating factor is the "acidity" of the solvent, whether derived from extrinsic hydrogen ions (acid) or the intrinsic "acidity" of the liquid solvent molecules. It is a complicating factor because, by salt formation and development of one full charge, a true cyanine is developed, which, however, (reversed halochromy) has its absorption at higher frequencies than the base. The addition of another proton, giving two full charges, results in discharge of visible color, by blocking the resonance. Where possible, to assure the presence of the dye as free base, we may add a small amount, comparable with that of the dye, of a base such as diethylamine, following the procedure of Brooker, *et al.*, for methyl alcohol. The following table (XII) shows that in non-polar solvents the absorption band is displaced steadily toward the red with increase of dielectric constant (and refractive index) of the solvent.

The values with "+ d. e." indicate controls with the addition of diethylamine to ensure removal of the "acid" form. In order to control the origin of such values, some of the free base

(15) Compare the band system of merocyanine XXIII.

TABLE XII

DYE XXXI IN NON-POLAR SOLVENTS

Solvent	K	$\mu \times 10^{18}$	λ_m, α	λ_m, β
n-Hexane + d. e.	1.87	0	480	450
n-Decane + d. e.	1.95	0	482	455
Cyclohexane + d. e.	2.05	0	480	455
			480	455
Decalin	2.15	0		460
Carbon tetrachloride	2.20	0	490	465
Benzene + d. e.	2.38	0	495	470
			495	470
Carbon disulfide	2.65	0	510	478

was converted to the methiodide, as described by Brooker, Sprague, Smyth and Lewis. As they observed, the absorption of the "salt" is generally identical with that of the alkyl halide, but in certain solvents the methiodide gave a maximum at a somewhat longer wave length than the simple salt. It may be noted in advance that both the H-salt and the methiodide behaved like other full cyanine dyes in showing very little effect of polarity of solvent on the position of the absorption maximum.

In the following table (XIII) are summarized positions of the α-band maximum in a series of aliphatic solvents used with Dye XXXIII.

TABLE XIII

DYE XXXI IN ALIPHATIC SOLVENTS

Solvent	$\mu \times 10^{18}$	$\frac{1}{\lambda_m}$	Trace λ_m Base	Trace λ_m Acid
Hexane	0	20833		
Ethyl ether	1.12	20408	490	475
Alkyl Acetate	1.74 to 1.90	20202	495	
Alkyl ketone	2.7	20202	497	478
Propionitrile	3.4 to 3.66	20000	500	
Nitromethane	3.8	[20000]	?	

In the next table (XIV) a comparable series of aromatic solvents is presented.

TABLE XIV

DYE XXXI IN AROMATIC SOLVENTS

Solvent	$\mu \times 10^{18}$	$\frac{1}{\lambda_m}$	Trace λ_m Base	Trace λ_m Acid
Benzene	0	20202	495	
Diphenyl ether	1.05	19800 ←	505	
Phenyl acetate	1.50	19608		
Benzophenone	2.95	19724	507	495
Nitrobenzene	2.90	[20202]		

The "aliphatic" and "aromatic" series plotted in Fig. 12 show a general similarity with the corresponding series for merocyanine XXII; some deviations may be due to incomplete suppression of the salt form of XXXI. For example, in *nitromethane* the dye is definitely present for the most part in that condition. The addition of a drop of

diethylamine produces a quite transient deepening (reddening) of color. In *nitrobenzene* this deepening is more persistent and allows a value for XXXI (base) in this solvent. We have assembled also the results with Dye XXXI in associated and tautomeric solvents (Table XV).

TABLE XV

Solvent	$\mu \times 10^{18}$	$\frac{1}{\lambda_m}$	Trace λ_m Base	Trace λ_m Acid
Water	1.90	19800	505	
Alcohol	1.68	19800	505	482
Benzyl alcohol	1.69	19417	515	
Ethyl acetoacetate	2.93			
Acetyl acetone	3.00		490	

As in the case of merocyanine XXIII, the frequency is much lower than would correspond with the moment, except for *benzyl alcohol.*

It seems reasonable to regard the initial red displacement (bathochromy) as the same effect of the solvent as that upon merocyanine XXIII. This is supported by the fact that the slopes $\delta\nu/\delta\mu$ are the same in both cases, *viz.*, 350 cm.$^{-1}/1\mu$. But in the case of merocyanine XXXI, the solvents with the higher moments tend to stabilize the acid, or rather salt, form of the dye.

Ionized Cyanine Dyes

Dye XXII—the methiodide of XXXI—and the H-salt behave as cyanine dyes with a one full positive charge in respect of solvent action. Features of this behavior are low solubility in non-polar solvents (but increasing somewhat with increase of dielectric constant) and relative *independence* of the spectrum of the moment of polar solvents (see Tables XVI and XVII).

TABLE XVI

DYE XXXII IN SOLVENTS

Solvent	K	$\mu \times 10^{18}$	$1/\lambda_m$ (cm.$^{-1}$)
Carbon disulfide	2.65	0	20000
Benzene	2.38	0	20202
Ether	..	1.12	Insoluble
Alkyl acetate	..	1.74	20620
Ketone	..	2.74	20747
Propionitrile	..	3.50	20830
Nitromethane	..	3.80	20620

Comparing a symmetrical with an unsymmetrical dye, the independence of the band position in polar solvents was confirmed.

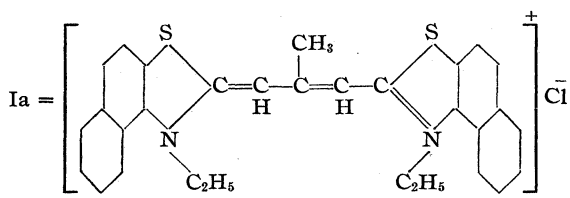
TABLE XVII

	Dye	$1/\lambda$ (Aliphatic)	$1/\lambda$ (Aromatic)
(Sym.)	Ia	17270 (±100) cm.$^{-1}$	16960 (±260) cm.$^{-1}$
(Unsym.)	XVb	20000 (± 90) cm.$^{-1}$	19600 (± 94) cm.$^{-1}$

The possibility that the solvent effect (of polar moment) might vary with the length of the conjugated chain between the nuclei was tested with three thiacyanine homologs. No difference was observed.

Alkyl Halides

In this group of solvents the behavior of the cyanine (ionized) dyes is more analogous to that of the merocyanines. The displacement is very variable, and seems to bear no direct relation to the dipole moment of the solvent nor to the dielectric constant. Using the (symmetrical) dye



Ia, there appears to be a rather significant advance in the magnitude of the "displacement" on passing from chloride → bromide → iodide, as shown in Table XVIII.

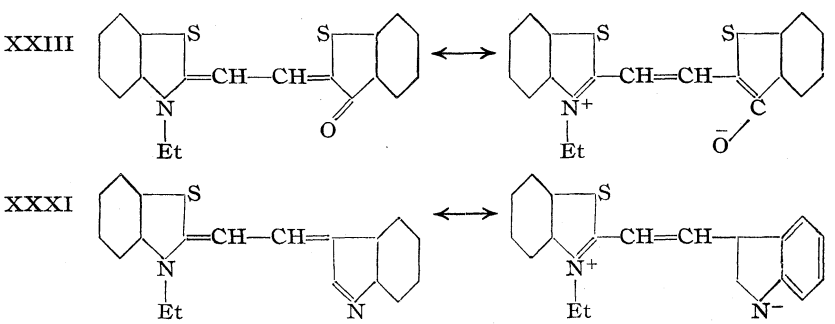
Discussion

The effect of solvents in displacing an absorption band may be attributed to van der Waals forces of three principal types: (i) dipole induction; (ii) orientation of permanent dipoles; (iii) mutual induction of electron clouds (dispersion forces). Of these, the first should be effective with dye molecules capable of a dipolar structure. The distance law is $F \propto 1/r^6$, and the electric forces operative between solute and solvent are not very powerful. The temperature coefficient is slight. The behavior of merocyanines in "non-polar" solvents may derive largely from this, but in part from "dispersion" forces, and to some extent from partial moments of the solvent molecule made effective by specific orientation.

The orientation of permanent dipoles permits more powerful intermolecular electric forces, the

distance law being $F \propto 1/r^3$. The temperature coefficient would be large; rise of temperature would disrupt orientation, and lower the "displacement" produced. This effect might be expected to diminish, the higher the polar moment of the solvent, and the nearer to saturation. How far "dispersion" forces can be expected to produce a displacement is uncertain. They have been invoked as favoring dimerization of dye cations, and thereby (in dimerization) coupling of vibrations with electronic transitions. The characteristic difference between aromatic and aliphatic solvents of the same chemical type certainly seems to indicate a specific "displacement" effect, which indeed persists with ionized cyanine dyes.

The merocyanines XXIII and XXXI are dyes of the type termed by Dilthey and Wizinger[16] "intramolecular ionoid," that is, they can be ascribed in ordinary valence symbols two structures; one a hybrid ion and the other neutral.



In general, in such molecules the two structures represent considerably different energy levels; depending upon the characters of the terminal nuclei A and B, one or the other may principally constitute the ground level, the other a relatively high excitation level, or the two configurations may be sufficiently near in energy for quantum mechanical resonance to occur.

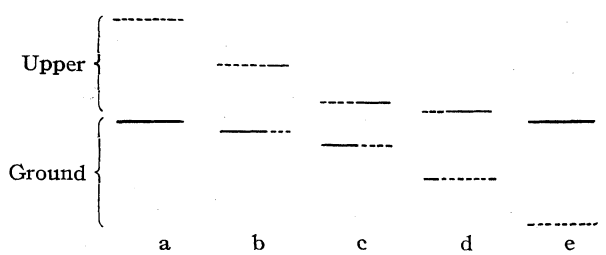


Fig. 13.—Energy levels of an intramolecular ionoid dye, with polar character increasing from *a* to *d*: – – – – proportion of polar; ——, proportion of non-polar contribution to the ground and excited states.

(16) R. Wizinger, "Organische Farbstoffe," F. Dummlers Verlag, Berlin. 1933, p. 44.

The various possibilities have been discussed by Th. Förster[17] (*cf.* Fig. 13). In the case represented by (a) the polar form has a much higher energy than the non-polar form, and represents an excited state which would only be produced by absorption of relatively short wave radiation or by an equivalent activation energy. As the energies of the two configurations are brought closer, the energy difference between the ground state and the lowest excited state is reduced, and absorption occurs at longer wave lengths. This is expressed in the diagram by a more equal "weighting" of the two limit structures in the ground and excited states, corresponding to increasing resonance. Such a progressive change could be brought about by change in the character of the auxochrome A and anti-auxochrome B (in the language of Dilthey and Wizinger), or more analytically, as pointed out by L. G. S. Brooker, *et al.*, [14] by change in the basicities of the terminal groups. Förster suggests that this progression might be carried over to an inverse state, in which the non-polar configuration became increasingly the *less* stable, or of higher energy than the dipolar form. This is indicated in the diagram for *d* and *e*, with reversion to shorter wave absorption. The tendency to reduction of the electrostatic energy of the dipole, with consequent relaxation to the non-polar form seems to make this little likely. Instead of the progression toward greater resonance $a \rightarrow b \rightarrow c$ being effected by internal change in the molecule, it could be brought about by change in the immediate environment, *e. g.*, of solvent.

Assuming that the action of induced and permanent solvent dipoles upon such "intramolecular ionoids" is to approach the energy states of the dipolar and non-polar configurations, the actual effect should be less, the nearer these two energies are in the isolated dye molecule. But a solvent effect still remains with dyes whose constitution guarantees equality of the energies of the limiting structures, and which, moreover, are not susceptible of dipole exaltation. Such for example are the ionized cyanine dyes.

With dyes carrying a full ionic charge, little or no effect of induced or permanent dipoles of the

(17) *Cf.* Th. Förster, *Z. Elektrochem.*, **45**, 548 (1939).

solvent molecules is to be expected, but, in terms of van der B. Houckgeest's theory,[18] there is a large effect upon solubility. However, there can be notable changes in the absorption with change of solvent for such dyes.[19] It seems unlikely to be due to dipole induction, and is at present most conveniently plotted as a function of refractivity (*cf.* Fig. 14). This effect—with ionized dyes—may be caused by the dispersion forces, as a resonance effect between the mobile electron cloud of the solvent and that of the dissolved dye. The increased "displacement" for a cyanine dye in alkyl halides in passing from the *chloride* to the *bromide* to the *iodide* is consistent with this view.

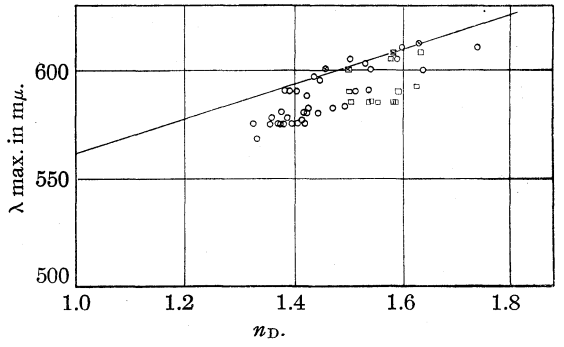

Fig. 14.—Dye Ia in polar O, aliphatic liquids; □, aromatic liquids. Line refers to non-polar liquids.

The "dispersion" contribution is also manifest in the difference between aliphatic and aromatic solvents of the same polar moment. Polar solvents of the same refractive index show, in general, a lower displacement than the non-polar ones. This is brought out in Fig. 14, which shows a reference line for non-polar solvents, and the generally lower group of polar ones. The effect of polar character is to reduce the displacement effect corresponding to a given refractive index, but is not expressible by a simple subtractive quantity. It appears indeed to be pronouncedly individual. Empirically, the nearest approximation is found in the expression

$$\lambda_s = \frac{kN^p}{\sqrt{1+\mu}}$$

where p is an integer. Since N^2 has some theoretical basis we illustrate the correlation in that case (Fig. 15).

Structure of Bands

The origin of the auxiliary bands of dye absorption in the optical region is not too clear at present. The principal band, *i. e.*, generally the long wave band of maximum extinction, is assigned to an electronic transition or charge transfer determined by the resonance structure of the dye.[20] A dye can be regarded as derived from an aromatic hydrocarbon or chain of conjugated ethylene bonds as a prototype (or a hybrid of these two types) by the introduction of auxochromes and anti-auxochromes.[16] The principal ultraviolet spectrum of anthracene—as a homolog of benzene—was first derived on quantum mechanical grounds by Sklar[19] and Förster,[16] with the important corollary of the displacement of the absorption to longer wave lengths with the number of linearly conjugated benzene nuclei. Similar considerations obtain for the polyenes. Development of the theory for the introduction of auxochromes has been carried out by Förster[17] with particular application to the triphenylmethane cation on substitution of $-NH_2$ groups. The conditions are not unlike the substitution of $-NH_2$ groups into anthraquinone

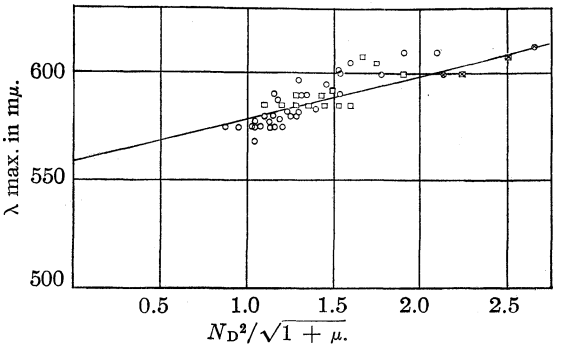

Fig. 15.—Dye Ia in polar O, aliphatic liquids; □, aromatic liquids.

(Anthracene) ⟶ Anthraquinone ⟶ {1-amino anthraquinone ⟶ {1,4-diamino-anthraquinone

In Fig. 16 are given very approximate term-diagrams for the evolution of the spectrum of anthraquinone with increase of auxochromic groups.

With the introduction of the auxochromes there appear not only new electronic transition bands, but increasing diffusion of the structure of the pre-existing shorter wave bands, owing to the increase in the number of vibrational levels and to the increased change of coupling of π-electrons (concerned in transitions) with others of antiparallel spin. The influence of solvents upon the *structure* of the absorption bands of dyes requires further investigation.

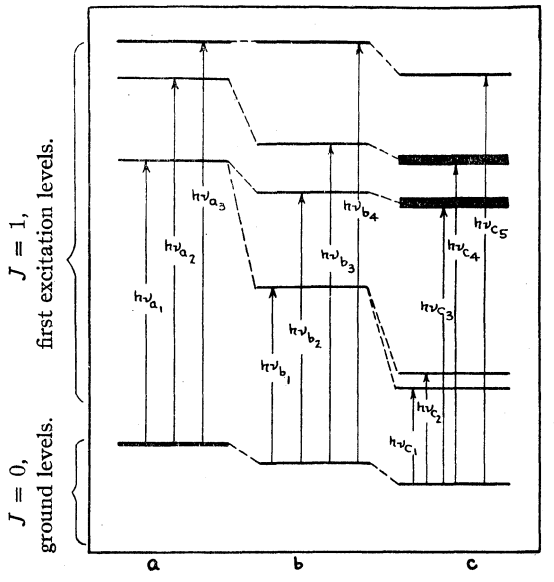

Fig. 16.—a, Anthraquinone; b, 1-aminoanthraquinone; c, 1,4-diaminoanthraquinone.

Associating Solvents

A systematic divergence in the effect of polar moment upon the merocyanine absorption spectrum was shown by "associating" solvents. This behavior is not shown by ionized cyanine dyes. It seems to be connected with the potential dipolar character of the merocyanines, and may indicate either an effectively higher dipole moment of these solvents in the liquid state, an effectively higher dielectric constant (than for individual molecules of the gas), or a marked effect of dispersion forces. Investigation of the temperature coefficient should help to decide.

Behavior of Alkyl Halides

A rather considerable degree of variation of the polar moment with temperature has been noted with these compounds, also a number of deviations from the theoretical values.[21] These derivations, however, are inadequate to explain the large variations of "red displacement" observed in these solvents. We believe that a rather definite approach to explanation of the facts is indicated in two articles by J. P. W. A. van B. Houckgeest[17] on the "Solvent and Dissociating Power of Chlorinated Hydrocarbons"—as exhibited in respect of quaternary ammonium salts. The "red displacement" with a merocyanine may be regarded as due to an "intramolecular ionization" or predissociation of a compound which is a potential or inner salt of a quaternary ammonium base. The arguments by which Houckgeest is able to place the alkyl halides in relative order as to their solvent powers are applicable to their displacement of the merocyanine spectrum, and we find that our results are concordant therewith. We have not space to detail the argument.[22] It deals in each case with orientation in the molecule of $\overset{+}{C}—\overset{-}{Cl}$ dipoles, of which the positive end is regarded as more active than the negative. The purely qualitative order was derived from stereochemical and energetic considerations alone. In the second paper the author derives a quantitative theory in terms of the thermodynamic potentials. This is perhaps less relevant to the displacement effect at one temperature, since then considerations as to change of number of molecular species are not involved. It may have definite application to the effects of temperature change upon the "displacement" in these solvents. In any case, the "solvation energies" calculated from the more complete theory fall in much the same order as our "displacements" of the merocyanine spectrum (*cf.* Table XIX). From the very specific behavior of the alkyl halides we suggest that with polar solvents and the merocyanine type of dye, there is formed an addition or molecular compound. This may be subject to a general "field" of the solvent molecules, but if there is only displacement, without radical transformation of the spectrum, it is probable that no quantum mechanical resonance occurs between the components.

TABLE XIX

SOLVENT POWER OF CHLORINATED ETHANES

Solvent	According to van B. Houckgeest[a] Cl	Br	I	$\Delta\nu$ obs. cm.$^{-1}$	$\mu \times 10^{18}$	K
CH_3CH_2Cl	100	92	82	2408	2.02	~11.0
CH_3CHCl_2	104	96	85	2584		10.8
CH_2ClCH_2Cl	122	114	102	2757	2.0 1.2	10.4

Richardson for certain absorption measurements in the ultraviolet region.

Summary

1. The absorption spectrum of a merocyanine dye has been determined for the gaseous state (*in vacuo*).

2. The displacement of the absorption band (or bands) in various solvents is referred to that *in vacuo*.

3. It is shown that, with certain families of compounds, there is a definite correlation of the displacement (to longer waves) with: (a) the refractive index and dielectric constant for non-polar solvents; (b) the polar moment for polar solvents.

4. With ionized (cyanine) dyes, it is shown that no displacement is effected by change of polar moment, but definite changes occur in non-polar solvents of increasing refraction and dielectric strength.

5. Theoretical considerations of the solvent effects are given in relation to the structures of the dyes. The exceptional behavior of the alkyl halides is discussed.

ROCHESTER, NEW YORK RECEIVED MARCH 25, 1942

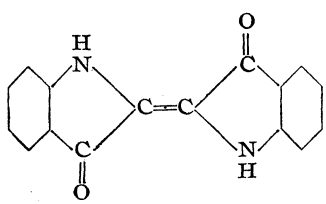
[COMMUNICATION NO. 869 FROM THE KODAK RESEARCH LABORATORIES]

The Effect of Solvents on the Absorption Spectra of Dyes. II. Some Dyes Other than Cyanines

BY S. E. SHEPPARD AND P. T. NEWSOME

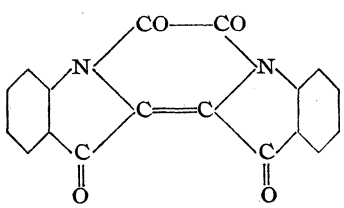
We have made some investigation of dyes other than the cyanines, and of which two can be vaporized and the absorption determined *in vacuo* (*i. e.*, as gas at low pressure) for comparison with solutions. These are *indigo* and *diaminoanthraquinone*, and they are of particular interest in comparison with the *merocyanines* since they are both non-ionic.

Indigo.—The formula usually assigned is

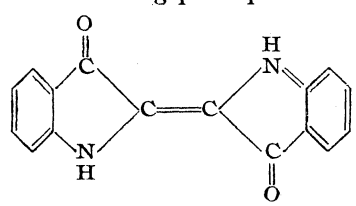


trans-form

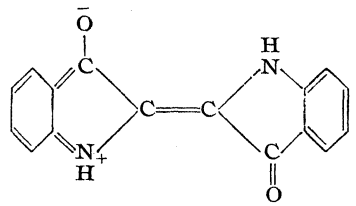
Evidence for a *cis*-form is mostly based on the production of cyclized derivatives of the *cis*-form, such as *oxalyl indigo*[1] and *N,N-styrolin-indigo*.[2]



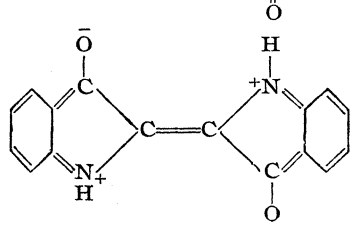
For the solid, crystalline form, the evidence favors the presence of the *trans*-form.[2] Apart from the steric variation, which in the case of the stilbenes[3] appears to affect the intensity of the absorption more than the location of the absorption bands, the nature of the "limit configurations" corresponding to the resonance and the color is not completely decided. For a review of the subject, papers by J. van Alphen[4] may be consulted. This author has suggested that indigo is a resonance hybrid having the following principal "limit structures"



(A)



(B)



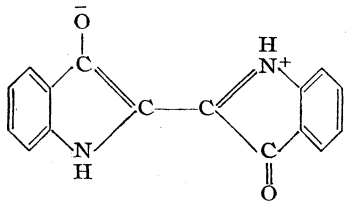
(C)

(1) *Cf.* R. Pummerer, H. Fiesselmann and O. Müller, *Ann.*, **544**, 206 (1940).

(2) A. Reis and W. Schneider, *Z. Krist.*, **68**, 543 (1928).

(3) A. Smakula and A. Wassermann, *Z. physik. Chem.*, **155A**, 353 (1931). There is some hypsochromic displacement in the *cis*-derivative relative to the *trans*-form.

(4) J. van Alphen, *Rec. trav. chim.*, **60**, 138–152 (1931).



(D)

A similar view was expressed by F. Arndt[5] and expanded by B. Eistert.[6] The latter considered the resonance A ⟷ D of principal importance, and form D, allowing "free" rotation about >C——C< according with the actual existence of only one form (*trans*) but with the possibility of *cis*-derivatives.

We have measured a number of absorption spectra of indigo in various solvents with the spectrophotometer; to conserve space the extinction curves are not given here but, as in Part I, only the absorption maxima and the corresponding "displacements." Compared with the merocyanines, the behavior of indigo in non-polar solvents is anomalous, in giving a smaller displacement in benzene and xylene than in carbon tetrachloride, although their dielectric constants are higher as are also the refractive indices. The solubility of indigo in this group of solvents is too low to permit extensive measurements.

TABLE IV

INDIGO IN HETEROCYCLIC SOLVENTS

Solvent	$\mu \times 10^{18}$	$1/\lambda_m$ in cm.$^{-1}$	$\Delta 1/\lambda$
Pyridine	2.11	16340	1975
Quinoline	2.16	16260	2055
Piperidine	1.17	16340	1975

On comparing these results with the data for the *merocyanines* XXIII and XXXI (Part I), the following conclusions were reached: (i) the behavior in non-polar solvents seems less simple, but owing to restricted solubilities the data are very scant; (ii) in the typical aliphatic and aromatic series of polar solvents, there appears to be no definite displacement of λ_m with change of polar moment as was found with the merocyanines (Part I); (iii) no regularity was apparent with amines of different polar moments, but both aliphatic and aromatic amines, as well as heterocyclic nitrogenous bases, show considerably greater displacements than other solvents of the same polar moment. Scheibe, Dörfling and Assmann[7] concluded that *aniline* is outstanding as a solvent for indigo and derivatives, in respect of "red displacement" of the spectrum. Our observations (*cf.* Tables I to IV) show others of equal potency, *formic acid* giving the greatest displacement. The behavior of indigo in the *associated* solvents, the alcohols and fatty acids, and in the tautomeric acetoacetate, is similar to that of merocyanine.

Scheibe and his co-workers concluded, particularly from the behavior of indigo in mixtures of non-polar and polar solvents, that no grounds exist for assuming specifically different structures in

(5) F. Arndt, *Ber.*, **72**, 860 (1939).

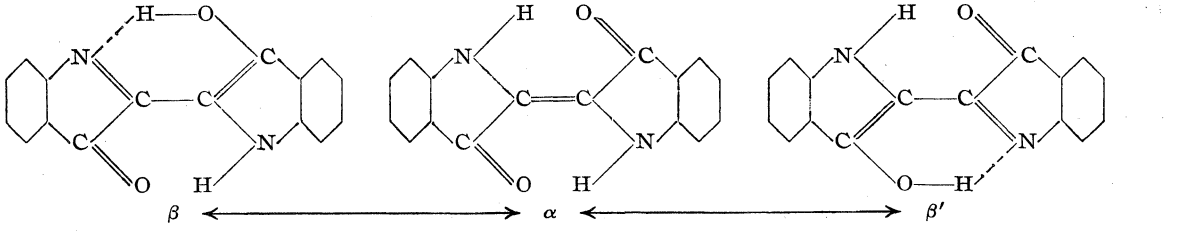
(6) B. Eistert, "Tautomerie und Mesomerie," F. Enke, Stuttgart, 1938, p. 189; also *Ber.*, **72**, 860 (1939).

(7) G. Scheibe, H. Dörfling and J. Assmann, *Ann.*, **544**, 240 (1940).

equilibrium as responsible for the color differences (tautomerism) nor for assuming molecular aggregation as a principal factor. As *positive* conclusions, they consider that the color changes are explainable "by displacement of the electron clouds within the molecules under the action of different solvents," and also that solvent molecules "whose dipoles are most strongly active outwardly (alcohols) displace the absorption most to the long waves."

The slight to inappreciable effect which a change of polar moment *per se* of a solvent has on the absorption spectrum indicates that the hybrid ion or bipolar (and quadrupolar) structures suggested by Eistert[6] and by van Alphen[4] are probably contributing little to the resonance system responsible for the first electronic transition band of indigo.

It seems possible that the resonance system in question is that indicated in the structural formulas



β and β' are similarly hydrogen-bonded structures which are suggested as the two identical most stable structures, *i. e.*, energetically lowest.

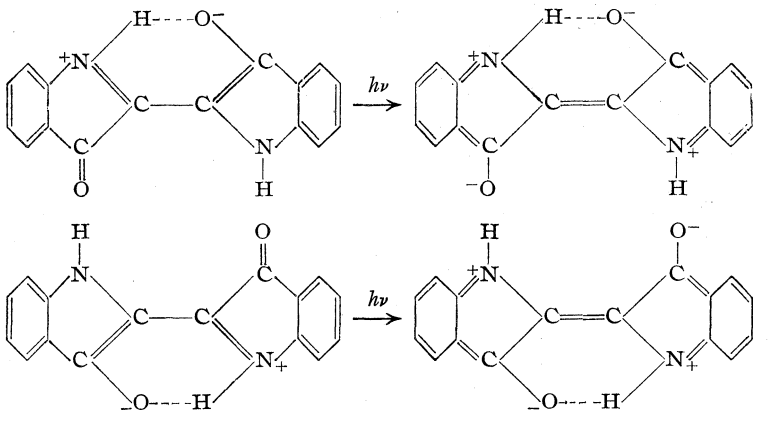
The normal structure α conventionally assigned to indigo would then represent an intermediate (mesomeric) state of higher energy.

It may be supposed that in associating solvents the structures β and β' would be less stable, producing a reduction in the energy difference from the splitting of levels, and hence displacement of the absorption band to longer waves.

The figures in Table V show the considerably lower sensitivity to solvent influence exhibited by indigo as compared with the merocyanine.

It may be pointed out here that any effect of solvent upon the absorption of light must involve a "solvation" preceding the act of light absorption, in accordance with the Franck–Condon principle that no movements of atomic nuclei can be concerned in it. On the resonance theory this is quite consistent with the solvent shifting, so to say, the center of gravity of the resonance system of the molecule.

In discussion with Dr. M. L. Huggins, he has suggested as alternatives or modifications of the formulations β and β' the structures γ and γ_1



thus indicating a certain ionic strength of the hydrogen bridge. The structures γ and γ_1 approach the structure D favored by Eistert (see above) but with diminished ionic strength (polarity) suggested; the structures indicated for excited states produced by absorption of light from γ and γ_1 similarly approach the structure C of van Alphen (as above).

TABLE V

	XXIII $\Delta 1/\lambda$, cm.$^{-1}$	Indigo $\Delta 1/\lambda$, cm.$^{-1}$

Alcohol	3300	1786
Formic acid	3258	2366

The hydrogen bonding possibilities of a solvent are undoubtedly very important for the spectrum of such molecules as indigo. The capability of such dye molecules to effect H-bridging *inter se* in condensed states might be expected therefore to be indicated in the spectrum of the *solid* state (*cf.* later, Fig. 7).

1,4-Diaminoanthraquinone.—Spectrophotometric absorption measurements were made in a

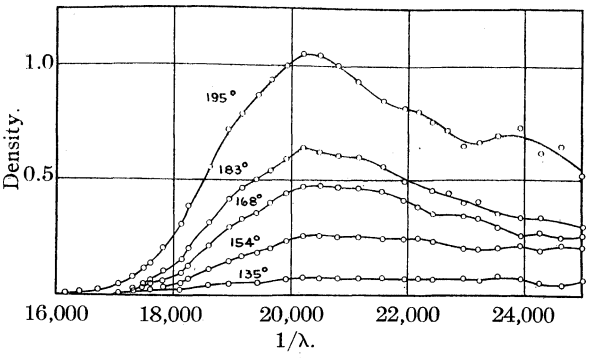

Fig. 1.—1,4-Diaminoanthraquinone vapor at various temperatures.

Water	1.90	582	1866	545	1972	505	1474

The values for the maxima in non-polar media have been plotted as a function of the refractive index (Fig. 3). While they fall on fairly smooth curves, they do not give a linear relation, as in the case of the merocyanine, though there is approach to this with increasing index.

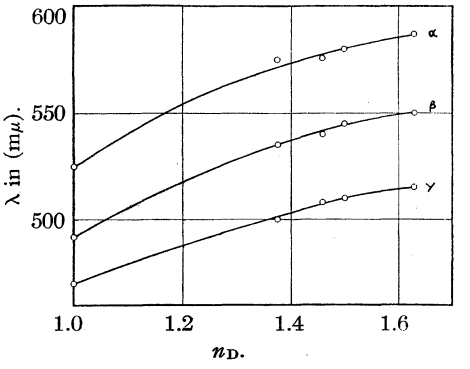

Fig. 3.—1,4-Diaminoanthraquinone in non-polar media.

In polar solvents, both aliphatic and aromatic, there is a very definite tendency for the displacement to increase with increase of polar moment of the solvent (*cf.* Figs. 4 and 5). The displacement,

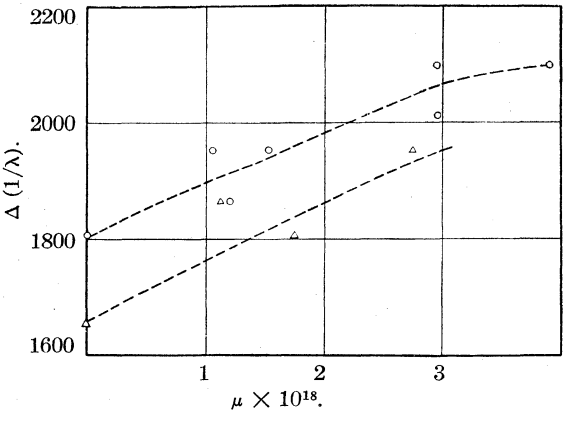

Fig. 4.—α-Band of 1,4-diaminoanthraquinone in polar media: Δ, aliphatic solvents; O, aromatic solvents.

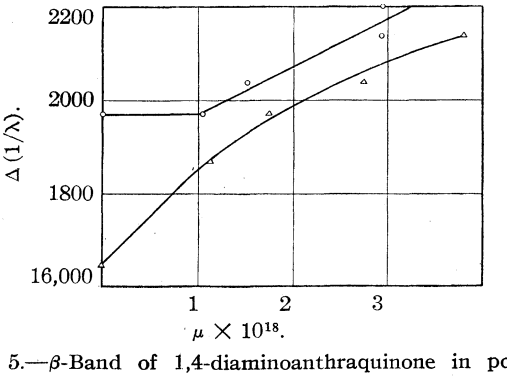

Fig. 5.—β-Band of 1,4-diaminoanthraquinone in polar media: Δ, aliphatic solvents; O, aromatic solvents.

in general, is greater in aromatic solvents than in aliphatic solvents of the same moment (*cf.* Table VIII and Figs. 4 and 5). The behavior is more like that of the merocyanines than is that of indigo.

TABLE VIII

1,4-DIAMINOANTHRAQUINONE IN AROMATIC SOLVENTS

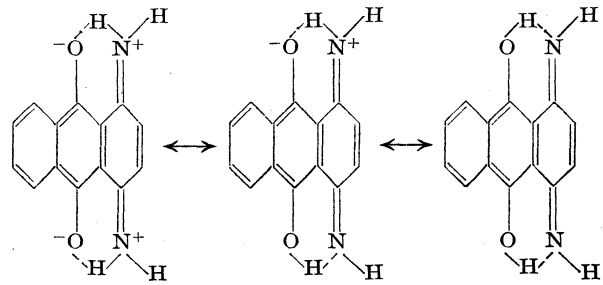
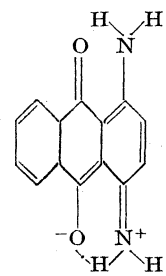
Quinoline	2.16	598	2326	560	2463	520	2045

The normal constitution assigned to *1,4-diaminoanthraquinone* readily admits hydrogen-bonded structures, such as were previously cited for the dioxyanthraquinone.[8] In recent papers on the constitution of certain (acid) anthraquinone dyes,[9] C. F. H. Allen, C. V. Wilson and G. F. Frame have given an interpretation of certain characteristics of their spectra based on hydrogen bonding in 1,4- and 1,5-diaminoanthraquinone derivatives. One feature in particular is thus explained "when there are in the 1- and 4-positions two groups which are able to furnish electrons by a mesomeric shift, the main band of absorption will have a double head. If but one group of this type is present, only a single head will be observed." This appears to be in agreement with the secondary characteristic of the evolution of the spectrum of 1,4-diaminoanthraquinone, *via* 1-aminoanthraquinone illustrated in Part I; the second amino group in the 4-position produces not only a considerable displacement of the longest wave band toward the red, but a splitting of the band. Actually, however, there are present in most absorption spectra of 1,4-diaminoanthraquinone three fairly well-marked sub-bands. The question as to whether these are independent electronic transitions or are due to superpositions of vibrational quanta on a main electronic transition is perhaps not yet clear.

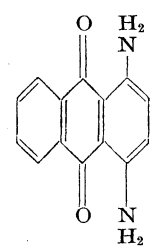
It is evident from the normal valence formula that a large number of structures could be written, not all of equal probability, but there are at present insufficient data to estimate more than roughly the energy differences implied. As in the case of indigo, we suppose hydrogen-bonded structures to be chiefly contributing to a lower state and normal and quadrupolar structures to higher levels. The structures of lower energy may be represented as follows



These represent three possible structures contributing to the resonance of the two parallel hydrogen bonds. As chiefly contributing to the first excited state, we may suggest such structures as



and the alternate: also, but chiefly contributing to a higher excited state, the structure shown.



We have again to thank Dr. Huggins for very helpful suggestions in regard to the formulation of the hydrogen-bonded structures. The interpretation proposed is quite tentative and purely qualitative. In Part I, in the discussion of the behavior of the merocyanines, there was reproduced a diagram from a paper of Th. Förster[10] indicating the participation of polar and non-polar structures of a dye in the principal lower and upper states corresponding to the main electronic transition, or absorption band. Förster indicated that *a priori* there would be a possibility of molecules in which (di)polar structures made the larger contribution to the ground state, these being more stable. We regarded this as improbable, in fact, because of the large coulombic energy in the separation of charges. However, it is possible that we were too hasty in this conclusion.

(8) L. Pauling, "Nature of the Chemical Bond," Cornell University Press, Ithaca, N. Y., 1940, p. 329.

(9) C. F. H. Allen, C. V. Wilson and G. F. Frame, *J. Org. Chem.*, **7**, 169 (1942).

(10) Th. Förster, *Z. Elektrochem.*, **45**, 548 (1939).

Hydrogen bonding can effect a relative stabilizing of (di)polar structures, which may lead to increased contribution of such structures to the ground state, though it may not allow the complete inversion suggested in Förster's discussion.

From the solvent data recorded in Part I for merocyanine (dye XXIII) and in this paper for *indigo* and 1,4-diaminoanthraquinone, as well as from the resonance systems indicated, we suggest the following approximate scheme for the polar, non-polar balance in the molecules of these dyes in the gas state (*in vacuo*). The diagram is based on that of Förster (Fig. 6) and expresses approximately the findings that the effects of increasing dielectric constant of non-polar liquids and of polar moment of polar liquids (normal or non-associated) are greatest with *merocyanine*, considerable with *diaminoanthraquinone*, and least (approaching zero) with *indigo*. From these considerations,

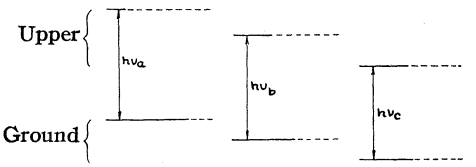


Fig. 6.—Polar non-polar characters of dyes in gaseous state:

	Merocyanine (XXIII) $h\nu_a = 2.63$ ev.	1,4-Diaminoanthraquinone Indigo $h\nu_b = 2.51$ ev.	$h\nu_c = 2.26$ ev.
λ_m in mμ	470	492	544
$1/\lambda$ in cm.$^{-1}$	21,276	20,320	18,315

it appears probable that the "associated" liquids (alcohols, aliphatic acids, acetoacetate, etc.) which give "high" displacements with merocyanine (dye XXIII) do so because, having "high" dielectric constants in the liquid state or because developing effective polar moments two to three times that of the gaseous molecule. The relatively lower effect of these solvent liquids with 1,4-diaminoanthraquinone and with indigo may be explained perhaps by the following considerations. (a) Their dipole moment will have some positive weight for the anthraquinone dye, practically none for the indigo. (b) Their tendency to form hydrogen bonds may reduce the stability of internal structures of this type in a dissolved dye molecule. This could lessen the energy difference between the upper and lower levels and, hence, displace the absorption to longer wave lengths. The relative tendencies to intermolecular combination in these three dyes are indicated to some extent by comparison of the vapor spectra of the dyes with the spectra of solid films sublimed on

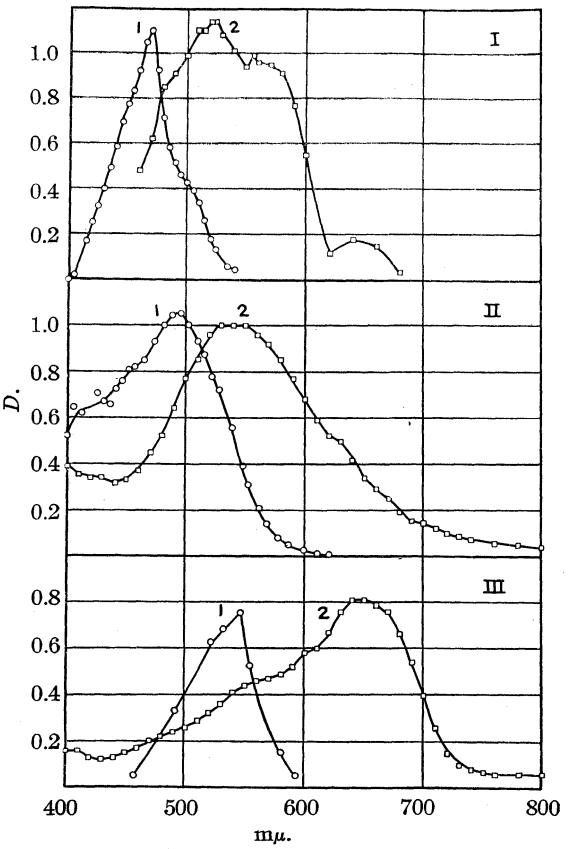

Fig. 7.—I, Merocyanine XXIII; II, 1,4-diaminoanthraquinone; III, indigo (1, vapor; 2, solid).

glass (*cf.* Fig. 7). The positions of the maxima in the solid films, also the wave number differences between λ_m (solid) and λ_m (gas) are given below:

TABLE IX

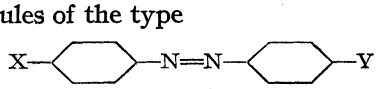
Merocyanine (XXIII)	1,4-Diaminoanthraquinone	Indigo
λ (solid) 520 mμ	540 mμ	650 mμ (670 mμ)[a]
$\Delta 1/\lambda$ 2036 cm.$^{-1}$	1820 cm.$^{-1}$	3015 cm.$^{-1}$

[a] From J. Königsberger and K. Küpferer (*Ann. Physik*, **37**, 601 (1912)).

There is a considerable change in each case, but largest for indigo. In view of the complications in the spectra of crystalline dyes[11] it appears premature to draw any very definite conclusions from these observations.

Azobenzene Derivatives

Molecules of the type



where X and Y are relatively basic and acidic (electropositive and electronegative) groups (Dilthey and Wizinger's auxochrome and antauxo-

(11) *Cf.* E. E. Jelley, *Ind. Eng. Chem.* (*Anal. Ed.*), **13**, 196 (1941).

chrome) give well-marked absorption bands in the near ultraviolet or the visible spectrum; the position varies with the potential drop between X and Y, being displaced farther to the long waves the greater the drop.

We have examined the influence of solvent (and of *p*H) on the following: (a) benzeneazodiphenylamine; (b) *p*-dimethylaminoazobenzene; (c) *p*-hydroxy-*p'*-nitroazobenzene; (d) *p*-amino-*p'*-nitroazobenzene; (e) *p*-dimethylamino-*p'*-nitroazobenzene.

The general character of the absorption spectra remains much the same with change of auxochrome groups. The long wave band is broad and considerably diffused, and this makes the assignment of values of $\lambda_{max.}$ (or $\nu_{max.}$) rather uncertain. Moreover, the addition of a proton (H^+) makes a large change in the resonance system, and consequently a large displacement of the absorption band. Since both bases and cations are "colored," overlap when conversion is incomplete can complicate the picture further. We shall give data only for *p-dimethylamino-p'-nitroazobenzene,* which are fairly representative of the group behavior.

The character of the absorption band and the shift with proton addition can be seen in Fig. 8. There can be discerned two major overlapping bands, α at longer, β at shorter wave lengths.

In Table X are given for λ_α and λ_β, the corresponding wave numbers for non-polar solvents, normal aliphatic and aromatic solvents of increasing polar moment.

	Acetophenone + drop of diethylamine		19300	20400
	Diethylamine	0.9	20900	22000

The base, *p*-dimethylamino-*p'*-nitroazobenzene obeys Beer's law, *e. g.*, in benzene and in acetone, but in accord with the breadth and diffuseness of the absorption, the extinction coefficients are relatively low: benzene $E_{max} = 2.40 \times 10^4$; acetone $E_{max} = 2.56 \times 10^4$. The base in normal aliphatic and aromatic solvents shows "red displacement" with increasing polar moment of the solvent (Figs. 9 and 10), but the magnitude of the displacement is not large, and, as in the case of

merocyanine XXII (Part I), the behavior is complicated by the incidence of halochromy.

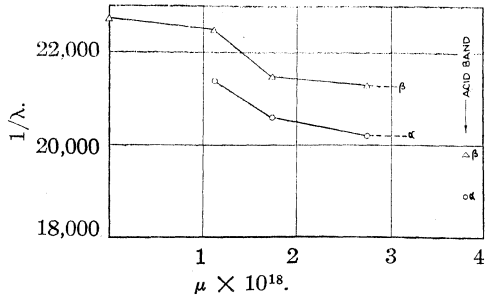

Fig. 9.—*p*-Dimethylamino-*p'*-nitroazobenzene (base) in aliphatic solvents.

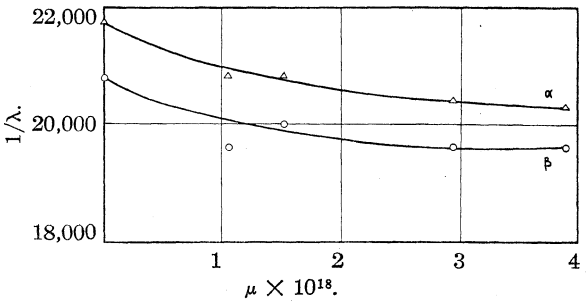

Fig. 10.—*p*-Dimethylamino-*p'*-nitroazobenzene (base) in aromatic solvents.

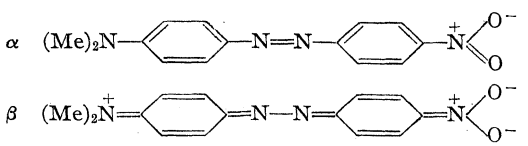
Addition of Proton

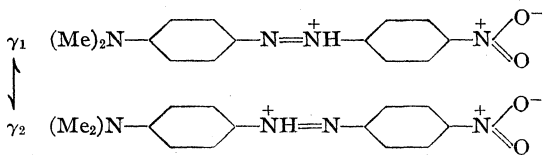
The weak acids, acetic, propionic and *n*-butyric, do not show the effect observed with merocyanine, with indigo, and 1,4-diaminoanthraquinone, of associating hydroxylated solvents. In fact, they behave as normal aliphatic solvents for the base. Formic acid, however, as found previously, behaves as a "strong" acid able to add a proton to the base.

The effect of this addition is quite strongly bathochromic, as may be seen from Fig. 8 and from the tables.

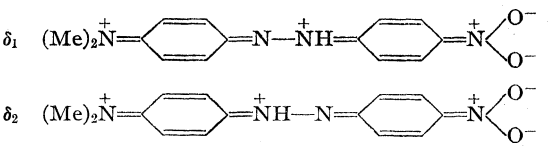
The two structures principally concerned in the resonance system of the base are very feasibly[12]



The upper structure α would be stabilized by the Kekulé resonance forms in the benzene rings, and perhaps, slightly by resonance in the $-N^{+}(O^{-})=O$ group. Perhaps the transition which arises from the splitting of the energy of these structures might give rise to an absorption of somewhat longer wave length than that of benzene, or rather of nitrobenzene itself, but it seems doubtful if we can assign even the shorter wave region of the main band of the base to this alone. The lower structure β is one of considerably lower stability, or of higher energy, than α, and as in the case of the merocyanines, may be considered as principally contributing to the first excited state. The effect of polarity of solvent on the "red displacement" is in accord with this interpretation. On adding a proton to the base we have two very similar but not identical alternates



γ_1 and γ_2 are tautomeric, and each structure is stabilized, as in α, by the Kekulé resonance, etc. To these there similarly correspond structures of higher energy



All these will have a single net positive charge, and consequently, as observed with the ionic cyanines, little effect of polar moment of the solvent is to be expected. The addition of still another proton would block the resonance, and this possibly accounts for the decolorization produced in concentrated sulfuric acid (*cf.* Fig. 8).

Hydrocarbons

The dye molecules may be considered as derived from certain hydrocarbon protomorphs, which are, however, already resonance systems, by substitutions of reactive atoms and/or groups (*cf.* Part I). It has appeared well, therefore, to include for comparison some data: (a) on the behavior of a visible colored polyene—*diphenyl-octatetraene*—which has a constitution with some affinity to that of the polymethine dyes. It is usually formulated as  . (b) On the behavior of the aromatic hydrocarbons, benzene, naphthalene and anthracene.

Diphenyl-octatetraene

The absorption data are compiled from the

(12) *Cf.* G. N. Lewis and M. Calvin, *Chem. Revs.*, **25**, 305 (1939), for the similar system of *p*-nitro-aniline.

paper of Hausser, Kuhn and Kuhn,[13] (*cf.* Tables XII and XIII).

Pyridine	2.11	24510	3423
Nitrobenzene	3.9	24332	3601

In non-polar solvents, the displacement increases continuously with increasing dielectric constant and refractive index (Fig. 11).

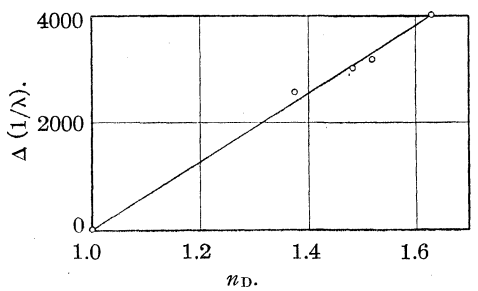

Fig. 11.—Diphenyl-octatetraene in non-polar media.

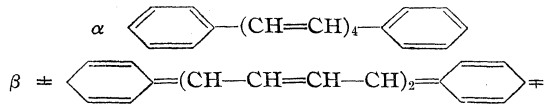
Data for the behavior in aliphatic and aromatic solvents of increasing polar moment are rather scant, and hardly permit definite conclusions. Certainly, it may be said that the displacement is greater in aromatic than in aliphatic solvents of comparable polar moment, but, while there are some indications of an influence of polar moment (*cf.* Fig. 12), they are not conclusive. Chloroform gives an apparently unduly large, methyl alcohol an unduly small displacement. The sensitivity to polar moment appears in any case to be small. The resonance system for the diphenyl polyene is probably somewhat similar to that of the azobenzenes



The upper structure α is stabilized by the Kekulé resonance of the terminal phenyl groups, and would contribute mostly to the ground level. The lower structures β are dipoles of considerably higher energy and would be expected to contribute mostly to the (first) excited level. Such effect as there is of polar moment would be in accord with this.

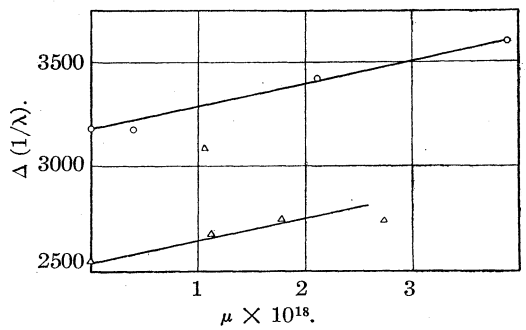


Fig. 12.—Diphenyl-octatetraene in polar media (Band I): Δ, aliphatic solvents; O, aromatic solvents.

Data on the solutions of *benzene* in different solvents are given by Lauer and Oda[14] for the absorption bands in the near ultraviolet. The first and second bands (the first band being of longest wave length and so on) show small *negative* displacements (*i. e.*, to shorter wave lengths) in solutions as compared with the vapor. These displacements—of the order of 300 cm.$^{-1}$—are much the same for the solvents tested, with the exception of water, in which it is smaller. The higher frequency bands show small *positive* displacements of the same order of magnitude, and again practically independent of the solvent, except that the shift in water is again smaller. The behavior of liquid benzene indicates an effect of the congener molecules little, if at all, different from that of the other solvents.

The insensitivity to solvents is in accord with the resonance system attributed to benzene,[15] and to the quantum mechanical theory developed by Sklar[16] and Förster.[10]

Similar in some respect to the aromatic fused-ring hydrocarbons are the phthalocyanine dyes

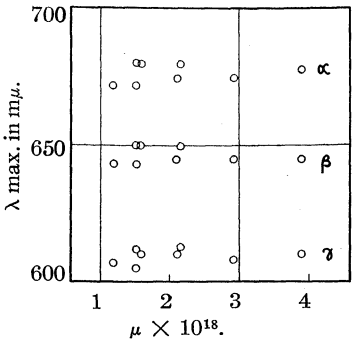

Fig. 13.—Zinc phthalocyanine in polar media.

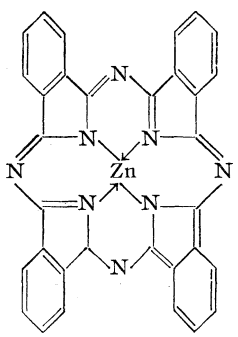
(and thereby the porphine macrocyclic compounds in general).

Our spectrophotometric measurements on the phthalocyanines, exemplified by *zinc phthalocyanine* show no definite effect of polar moment of solvent on the absorption (Fig. 13). This indifference may be taken to mean that no ionized (dipolar) structures are represented in the first excited state; the resonance system is presumably by way of the two alternately covalently and coördinately linked pairs of the four interior N-atoms,[17] through the central atom, making the system resemble benzene with its basic Kekulé resonance. A notable difference from benzene, however, is the great intensity (extinction) of the longest wave absorption band.



(17) The conjugation extends, of course, through the external —N= links.

Acknowledgment.—We desire to express our thanks for helpful suggestions and criticisms to Dr. M. L. Huggins, and to Mr. H. R. Brigham for the preparation and spectrophotometry of sublimed solid films of certain dyes.

Conclusion

The results presented in this paper extend the tentative conclusions expressed in Part I. So far as these orienting investigations go, they indicate that the sensitivity of the absorption spectra of dyes to solvent influence is rather closely related to the resonance system of the dye, and may throw some light upon this. Correlatively, it appears possible that, with increased investigation, the effect of given solvents on the absorption spectrum of selected dyes may improve our understanding of the molecular structure of liquids. The rather notable behavior of halogenated alkyls suggests a promising field for further investigation as also the observations on hydroxylated solvents.

The Solubility of Calcium Oxalate Monohydrate in Pure Water and Various Neutral Salt Solutions at 25°

BY WILBUR H. MCCOMAS, JR.,[1] AND WM. RIEMAN III

Because of the importance of calcium oxalate in analytical work, accurate data on its solubility are very desirable. A survey of the literature reveals, however, very discordant figures for the solubility in pure water and very few reliable data on the effect of neutral salts.[2] Table I summarizes the previous work on the solubility in pure water. Since the equilibrium between calcium oxalate and its saturated solution is established rather quickly, the major source of error in the solubility determinations probably lies in the failure to obtain pure calcium oxalate.

(1) This paper is taken from part of a thesis submitted by Wilbur H. McComas, Jr., in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(2) Hammersten, *Compt. rend. trav. lab. Carlsberg*, **17**, 11 (1929), has studied the effect of several salts at 37°, mostly at ionic strengths below 0.2.

Solubility in Pure Water

Experimental.—Calcium oxalate monohydrate, product A, was prepared as follows:[2a] fifty mmol. of ammonium oxalate contained in 400 ml. was added slowly (twenty-five minutes) with vigorous stirring to 60 mmol. of calcium chloride contained in 1600 ml. at room temperature. Then 200 ml. of 0.1 *N* hydrochloric acid was added with vigorous stirring. The precipitate was digested for one day at 95–100°. After cooling, the precipitate was washed by centrifugation until a negative test for chloride ion was obtained in the wash water. It was stored under water until used.

(2a) Kolthoff and Sandell, *J. Phys. Chem.*, **37**, 459 (1933).

TABLE I

SOLUBILITY OF CALCIUM OXALATE IN PURE WATER AT 25°

Investigator	Solubility, molarity × 10^5
Richards, McCaffrey and Bisbee[3]	5.31
Herz and Muhs[4]	23.3
Kohlrausch[5]	4.84
Henderson and Taylor[6]	7.13
Scholder, Gadenne and Niemann[7]	5.23[a]
Hammarsten[2]	4.66[a]
Medes[8]	4.46[a]
Kolthoff and Sandell[9]	6.70
Pedersen[10]	4.84
Shehyn and Pall[11]	6.00[a]

[a] Solubility at 25° calculated from Kohlrausch's value of d log solubility/d(1/T).

Product B was prepared by an identical method except that the precipitation was performed in the presence of excess oxalate ions. Fifty mmol. of calcium chloride in 400 ml. were added to 60 mmol. of ammonium oxalate in 1600 ml., etc.

The solubility of each product was determined by agitating about a gram of precipitate with two liters of pure water for an hour at 25.0 ± 0.2°. Longer periods of saturation did not alter the result. The solution was separated from the precipitate by means of a porcelain micro filter stick. The first portions of the filtrate were rejected. Then 200-ml. portions were titrated with 0.02 N ceric sulfate by the method of Willard and Young.[12] Appropriate blank titrations were performed. The mean of six determinations for the solubility of product A was (4.46 ± 0.04) × 10^{-5} molar. The mean of seven determinations for product B was (4.63 ± 0.03) × 10^{-5} molar.

Discussion.—The close agreement between these two results is evidence for the purity of the products. The mean, 4.55 × 10^{-5} M, is in good agreement with the results of Kohlrausch, Hammarsten, Medes and Pedersen.

Solubility in Salt Solutions

Experimental.—About 1 g. of the pure calcium oxalate monohydrate in aqueous suspension was centrifuged and washed three times with portions of the standard salt solution. This precipitate was then added to about 2 liters of the standard salt solution, and the solubility was determined as in pure water.

Results.—The results are given in Table II. Each value in Column 4 is the mean of six determinations.

TABLE II

SOLUBILITY OF CALCIUM OXALATE IN SALT SOLUTIONS

Salt	Molarity of salt	Ionic strength	Solubility, molarity × 10^5	pS' Found	pS' Calculated
None	0.000	0.00018	4.55	8.684	8.670
NaCl	.100	.100	11.79	7.856	7.815
	.200	.20	15.47	7.621	7.623
	.300	.30	17.64	7.507	7.505
	.400	.40	19.50	7.420	7.415
	.500	.50	21.10	7.350	7.353
	.600	.60	22.58	7.292	7.300
	.700	.70	23.79	7.247	7.255
	.800	.80	24.82	7.210	7.216
	.900	.90	26.10	7.166	7.182
	1.000	1.00	27.08	7.135	7.151
KCl	0.64	0.64	22.99	7.277	7.281
$HCOONH_4$	.36	.36	22.34	7.302	7.450
Na_2SO_4	.213	.64	34.94	6.913	7.282

Since none of the solutions listed in Table II were sufficiently acid to change significant quantities of secondary oxalate ion to the primary anion, the classical solubility product, S', is simply the square of the molar solubility. Extrapolation of the experimental values of pS' to $\mu = 0$, gives 8.730 for the thermodynamic solubility exponent, pS. This figure was then used in conjunction with the equation of Gronwall, LaMer and Sandved[13] to calculate theoretical values of pS'. When a is 4.85 Å., the figures of Column 6 are obtained. These values are in good agreement with the experimental data for sodium and potassium chlorides to surprisingly high ionic strengths.

Summary

The solubility of pure calcium oxalate in water and in solutions of sodium chloride, potassium chloride, ammonium formate and sodium sulfate at 25° has been determined.

The Effect of *p*H on the Solubility of Calcium Oxalate

BY WILBUR H. MCCOMAS, JR.,[1] AND WM. RIEMAN III

The literature contains no accurate data on the effect of *p*H on the solubility of calcium oxalate. The purpose of our work was to supply such data and also to compare the observed effect of *p*H with theoretical predictions.

Theory

The solubility of calcium oxalate in any solution should follow the equation

$$[Ca^{++}]T = S' \frac{(H^+) + K_2'}{K_2'} \qquad (1)$$

where brackets denote the concentration of the enclosed species; parentheses denote activity; T is the total concentration of oxalate, *i. e.*, the sum of $[C_2O_4^=]$ and $[HC_2O_4^-]$; S' is the classical solubility product of calcium oxalate; and K_2' is the semiclassical second ionization constant of oxalic acid, defined by the equation

$$K_2' = \frac{(H^+)[C_2O_4^=]}{[HC_2O_4^-]} \qquad (2)$$

In the absence of excess calcium or oxalate

$$L = [Ca^{++}] = T \qquad (3)$$

where L is the solubility of calcium oxalate in moles per liter. Combination of these three equations yields

$$L = \sqrt{S' \frac{(H^+) + K_2'}{K_2'}} \qquad (4)$$

This equation can be used to predict the solubility of calcium oxalate in any given solution provided that values of S', (H^+), and K_2' are known. Data for S' are given in the previous paper. (H^+) may be calculated from *p*H measurements by the equation

$$p\mathrm{H} = -\log (H^+) \qquad (5)$$

The non-thermodynamic assumptions implied in this equation do not introduce serious errors for our purpose.

Second Ionization Constant of Oxalic Acid

Solutions of the composition listed in Table I were prepared. Sodium hydrogen oxalate was not added as such, but sodium oxalate and oxalic acid were mixed to yield the indicated concentrations. The *p*H values of these solutions were measured at 25° with a Beckman *p*H meter (previously standardized against 0.0500 molal potassium acid phthalate), and the pK_2' values were calculated with equation (2). No corrections were applied to the concentrations of primary or secondary oxalate ions for the progress of the reaction

$$HC_2O_4^- \longrightarrow H^+ + C_2O_4^=$$

because these corrections would be smaller than the limit of error in measuring the *p*H, ±0.03 unit.

TABLE I

By combining the data of Harned and Fallon[2] for the e. m. f. of the cell

$$H_2 \mid NaHC_2O_4(xm_1), Na_2C_2O_4(xm_2), NaCl(xm_3) \mid AgCl + Ag$$

with the data of MacInnes[3] for the single activity coefficient of the chloride ion, values of the semi-

(1) This paper is taken from part of a thesis submitted by Wilbur H. McComas, Jr., in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(2) Harned and Fallon, THIS JOURNAL, **61**, 3111 (1939).

(3) MacInnes, *ibid.*, **41**, 1086 (1919).

classical second ionization constant of oxalic acid can also be computed. These values agree with ours within ± 0.03 pK unit throughout the range of Harned and Fallon's measurements ($\mu = 0.03$ to 0.17).

From a large-scale graph of the foregoing pK_2' values against the square root of ionic strength, it can be seen that the effect of sodium and ammonium chlorides is the same, but that the graph for potassium chloride lies above the other, the divergence beginning at about $\sqrt{\mu} = 0.4$.

Solubility of Calcium Oxalate in Formate Buffers

Buffers of formic acid and ammonium formate were prepared. Each buffer was 0.36 M with ammonium formate, and therefore had an ionic strength of 0.36. The concentration of formic acid in the buffers was varied. The solubility of calcium oxalate monohydrate at 25° was determined in each of these buffers as described in the previous paper. The pH of each filtrate was also determined with the Beckman pH meter. The results are presented in Table II.

The values in the last column were calculated by equation (4) with $S' = 4.97 \times 10^{-8}$ and $K_2' = 1.97 \times 10^{-4}$. Good agreement is obtained between the observed and theoretical solubilities up to 0.5 M formic acid. Greater concentrations of formic acid not only increase the hydrogen-ion activity but also alter the solvent properties of the medium. Since equation (4) does not take the latter effect into account, it is not accurate in high concentrations of formic acid.

TABLE II

SOLUBILITY OF CALCIUM OXALATE IN FORMATE BUFFERS

Molarity of HCOOH	pH	Solubility of CaC_2O_4, molarity $\times 10^4$ Observed	Calculated
0.0000	5.96	2.23	(2.23)
.0246	4.75	2.26	2.32

1.38	2.93	4.84	5.88
2.46	2.60	5.89	8.30

Summary

The semiclassical second ionization constant of oxalic acid has been determined at ionic strengths from 0 to 1 in the presence of sodium, potassium, and ammonium chlorides. The solubility of calcium oxalate monohydrate in formate buffers of constant ionic strength has been studied. Good agreement between observed and theoretical solubilities has been found.

[CONTRIBUTION FROM THE WESTERN REGION BUREAU OF MINES, UNITED STATES DEPARTMENT OF THE INTERIOR]

The Specific Heats at Low Temperatures of Anhydrous Sulfates of Iron, Magnesium, Manganese, and Potassium.[1]

BY G. E. MOORE[2] AND K. K. KELLEY[3]

The Pacific Experiment Station of the Bureau of Mines for the past year has been engaged primarily in determining thermodynamic values of substances important in the metallurgy of strategic materials, particularly manganese and chromium. It is desirable to have these data not only for compounds of these metals themselves but also for the compounds of the metals associated with them in the ores and from which they must be separated. This paper deals with low-temperature specific heat measurements of anhydrous sulfates of iron, magnesium, manganese and potassium.

(1) Published by permission of the Director, Bureau of Mines, U. S. Department of the Interior. Not copyrighted.

(2) Associate Chemist, Western Region, Bureau of Mines.

(3) Senior Chemist, Western Region, Bureau of Mines.

Materials.—Reagent quality ferrous sulfate heptahydrate was heated slowly for several days to 125°, while evacuating with an oil-pump. It was then transferred to a high-vacuum line (mercury diffusion pump) and the heating continued. It was found necessary to heat to 235° to remove the last of the water, and some decomposition was unavoidable at this temperature. Analysis gave 37.30% Fe and 63.1% SO_4 compared with the theoretical figures 36.77 and 63.23%. Ferric iron corresponding to 1.6% Fe_2O_3 also was determined. Upon the basis of the iron analyses, which are the more significant, the purity of the sample is 98.4%. Higher purity would be desirable, but tests conducted at various stages in the dehydration process indicated that it is not possible to dry completely without decomposition. A 124.02-g. sample of this material was used in the measurements.

Reagent quality magnesium sulfate heptahydrate was dehydrated by heating in air in large nickel crucibles, the final temperature (400°) being maintained for two hours.

This procedure is essentially that recommended by Archibald.[4] Analysis gave 33.60% MgO; theoretical 33.49%. No calcium was found by the procedure given by Hillebrand and Lundell[5] for detecting small amounts of calcium in the presence of large amounts of magnesium. A small amount of magnesium oxide as such was found in the sample and directly determined by titration as 0.10 to 0.15%. The specific-heat measurements were made on a 142.95-g. sample.

Manganous sulfate tetrahydrate, reagent quality, was dehydrated by heating in air up to 400°, and this temperature was maintained overnight. After crushing and screening the heating was repeated, 400° being held for several hours.[6] The manganese content of the product was determined by precipitation as sulfide, washing and converting to anhydrous sulfate. This resulted in 36.33% (theoretical 36.38%). Sulfate analyses gave 63.77% (theoretical 63.62%). A 152.03-g. sample was used in the measurements.

Reagent quality anhydrous potassium sulfate was heated to 140° and used without further purification. Analysis for sulfate showed the material to be at least 99.7% pure. The sample used in the measurements contained 169.05 g.

Specific Heats.—The methods and apparatus used in the present work are the same as previously employed.[7] The results of the specific heat measurements, expressed in defined calories (1 calorie = 4.1833 int. joules), are given in Table I and shown graphically in Fig. 1. The formula masses employed and given in Table I are in accord with the 1941 International Atomic Weights.

104.7	19.34	205.3	26.61		

Figure 1 shows that all four substances exhibited normal behavior throughout the temperature range studied. Consequently, no discussion of the character of the specific heat curves appears necessary, and there are no previous data with which to compare. It should be mentioned that a small correction, ranging from 0.05 to 0.10%, depending on the temperature, has been applied to the magnesium sulfate results to compensate for the small quantity of oxide detected in the analysis.

No corrections for impurities were applied in the other instances.

It is desirable to record here that the heat capacity curve of the empty calorimeter was redetermined completely at the conclusion of the measurements reported in this paper. In the interim between these calibration measurements and the preceding set some 20 substances had been studied, a few minor repairs had been made, and a new White potentiometer had been installed. The new calibrations agree so well with the old that no error, in the specific heats of the substances studied in the interim, greater than 0.05% may be attributed to the combined sources of lack of constancy in the heat capacity of the empty calorimeter and difference in measuring instruments.

Entropies.—The entropies at 298.16°K. were obtained in the usual manner; the measured portions between 50.12° and 298.16°K. were computed graphically from C_p *vs.* log T curves, and the portions below 50.12°K. were extrapolated. For the latter purpose, the specific heat curves were fitted with the function sums listed below, and the temperature range represented is given in parentheses.

$FeSO_4$: $D\left(\frac{176}{T}\right) + 2E\left(\frac{329}{T}\right) + 2E\left(\frac{801}{T}\right)$, (51 to 200°K.)

$MgSO_4$: $D\left(\frac{242}{T}\right) + 2E\left(\frac{378}{T}\right) + 2E\left(\frac{866}{T}\right) + E\left(\frac{1683}{T}\right)$, (51 to 298°K.)

$MnSO_4$: $D\left(\frac{163}{T}\right) + 2E\left(\frac{304}{T}\right) + 2E\left(\frac{813}{T}\right)$, (51 to 220°K.)

K_2SO_4: $D\left(\frac{132}{T}\right) + 3E\left(\frac{198}{T}\right) + 2E\left(\frac{738}{T}\right)$, (51 to 225°K.)

The results are shown in Table II. Some correction of the ferrous and manganous sulfate values may be necessary to compensate for unextracted magnetic entropy when the pertinent data become available. The assigned errors apply only to the measurements and normal extrapolations made and do not allow for this contingency.

TABLE II

ENTROPIES AT 298.16°K. CAL./DEG. MOLE

	$FeSO_4$	$MgSO_4$	$MnSO_4$	K_2SO_4
50.12°K. (extrap.)	2.10	1.10	2.72	4.82
50.12–298.16°K. (graph.)	23.60	20.78	24.07	37.21
$S_{298.16}$	25.7 ± 0.3	21.9 ± 0.2	26.8 ± 0.3	42.0 ± 0.6

Previous entropy values have been reported for magnesium and potassium sulfates only[8]; 20 ± 2 and 44.8, respectively, have been estimated from decomposition data. The present values, of course, are preferable.

Related Thermal Data.—Free-energy-of-formation values from the elements, calculated from the third law of thermodynamics, are shown in column 4 of Table III. These values are based upon the present entropy results, the entropies of the elements,[8] and heat-of-formation data adopted by Bichowsky and Rossini,[9] except in the instance of manganous sulfate, for which the recent value of Southard and Shomate[10] is employed. Values computed from other considerations by Kelley,[11] in his survey of thermal properties of sulfur-containing compounds, are shown in column 5.

TABLE III

FREE ENERGIES OF FORMATION AT 298.16°K. CAL./MOLE

Substance	$\Delta H_{298.16}$	$\Delta S_{298.16}$	$\Delta F°_{298.16}$ (T.L.)	$\Delta F°_{298.16}$ (misc.)
$FeSO_4$	−221,300	−86.5	−195,500	...
$MgSO_4$	−304,950	−91.6	−277,640	−285,180
$MnSO_4$	−254,180	−86.5	−228,380	−228,020
K_2SO_4	−342,660	−94.1	−314,600	−314,580

Except for magnesium sulfate, the values are in good agreement. In this instance there exists a rather gross discrepancy between the third law and decomposition pressure results. At present the authors prefer the third-law value for this substance.

Summary

Specific heat measurements of anhydrous sulfates of iron, magnesium, manganese and potassium are reported in the temperature range 51 to 298°K.

The entropies at 298.16°K. were computed to be 25.7 ± 0.3 for $FeSO_4$, 21.9 ± 0.2 for $MgSO_4$, 26.8 ± 0.3 for $MnSO_4$, and 42.0 ± 0.6 for K_2SO_4.

Free-energy-of-formation values based upon the third law of thermodynamics are computed and compared with results from other data.

The Molecular Structure of Methyl Isocyanide

BY WALTER GORDY[1] AND LINUS PAULING

It is known from its Raman spectrum[1a] and an earlier electron diffraction investigation[2] that the structure $CH_3—N{\equiv}C$: makes a larger contribution to the normal state of the methyl isocyanide molecule than the structure $CH_3—\dot{N}{=}C$:. If the latter structure were of much importance the C—N—C bond angle might differ somewhat from 180°. The infrared spectrum of the substance has been studied by Badger and Bauer,[3] who pointed out that the absence of splitting of certain lines indicates that the molecule is linear. We have made an electron diffraction investigation of the substance with the improved technique now available, and have verified that the molecule is linear or very nearly linear.

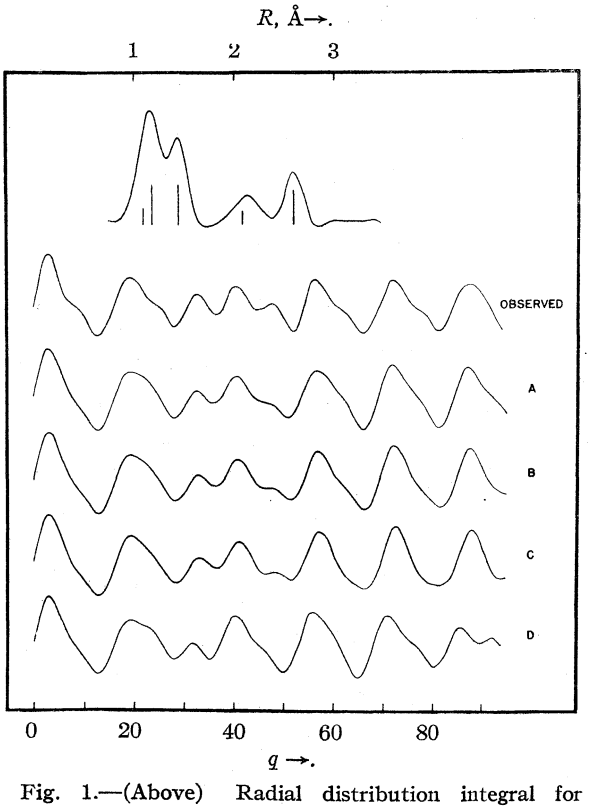

Fig. 1.—(Above) Radial distribution integral for methyl isocyanide, with lines indicating interatomic distances for the accepted structure. (Below) A curve representing the visual appearance of the photographs, and calculated simplified intensity curves for four models.

The samples used were prepared by Mr. David H. Brown from silver cyanide by the methods of Hartley and Gautier, and electron diffraction photographs were made and measured in the usual way. The photographs were much better than those obtained by Brockway, with seven measurable rings instead of three. The visual appearance of the photographs is represented by the sketched curve marked "Observed" in Fig. 1. The radial distribution integral calculated from this curve, also shown in Fig. 1, is seen to have principal peaks at 1.17, 1.43 and 2.59 Å. The first of these represents the shorter C—N bond distance with the C—H bond distance (1.09 Å.) unresolved. The effect of the latter on the position of the maximum should be small; we estimate it to be 0.01 Å., leading to 1.18 Å. for the shorter C—N bond distance. The peak at 1.43 Å. corresponds to the longer C—N bond distance and that at 2.59 Å. to the C—C distance.

The fact that the third distance is equal (to within 0.02 Å.) to the sum of the other two indicates that the C—N—C bond angle is close to 180°; for 160° the value 2.57 Å. would be expected, and for 150° the value 2.52 Å. Assuming that the probable errors of the radial distribution values are about 1%, we see that it is not likely that the angle is less than 160°.

Simplified intensity curves calculated for various models are shown in the figure[4]; the C—H distance was taken as 1.09 Å. and the methyl carbon bond angles as tetrahedral throughout. Temperature factors for the C—H terms were introduced as described by Stevenson, Burnham and Schomaker.[5] The other parameters of the models are the following

Model	$H_3C—N$, Å.	N—C, Å.	Angle C—N—C
A	1.44	1.18	180°
B	1.44	1.18	163°
C	1.44	1.18	156°
D	1.48	1.17	180°

(1a) A. Dadieu, *Ber.*, **64B**, 358 (1931).

(2) L. O. Brockway, THIS JOURNAL, **58**, 2516 (1936).

(3) R. M. Badger and S. H. Bauer, *ibid.*, **59**, 303 (1937).

(4) The curves were calculated by an equation differing somewhat from that which we have used heretofore; this equation and a brief discussion of the radial distribution integral are given by R. A. Spurr and V. Schomaker, THIS JOURNAL, **64**, 2693 (1942).

(5) D. P. Stevenson, H. D. Burnham and V. Schomaker, THIS JOURNAL, **61**, 2922 (1939).

Curves C and D (Brockway's model) are unsatisfactory; C does not show the shelves for the 5th and 6th rings, and D makes the 4th ring much less pronounced than observed. A and B are about equally satisfactory. We conclude from this, as from the radial distribution integral, that the deviation from linearity is not greater than about 20°.

The observed frequency of the normal mode of oscillation corresponding mainly to bending of the CNC chain is 290 cm.$^{-1}$, and the corresponding force constant[6] has the value 0.205×10^{-11} erg radian^{-2}. The zero-point energy $h\nu$ for this degenerate oscillation corresponds to a root-mean-square deviation of 9.6° of the C—N—C angle from 180°, and the equipartition energy 2 kT at room temperature corresponds to the somewhat larger value 11.4°. The model indicated by the spectroscopic data would hence give a calculated intensity curve lying between A and B, and somewhat closer to B than to A. The electron diffraction photographs are accordingly compatible with this model.

The quantitative comparison of model A with the measured ring diameters leads to the C—N interatomic distances H_3C—N = 1.44 and N—C = 1.18 Å., in essential agreement with the radial distribution values. From these the average C—C distance is calculated, with consideration of the bending oscillation, to be 2.59 Å.

TABLE I

Max.	Min.	$q_{obs.}$	q_A	$q_A/q_{obs.}$
	1	12.7	13.0	(1.02)
1		19.2	19.3	1.005
	2	28.1	28.1	1.000
2		32.5	32.6	1.003
	3	36.4	35.8	0.983
3		40.2	40.6	1.010
	4	44.4	..	..
4		47.5	..	..
	5	51.4	50.9	0.991
5		56.5	56.7	1.003
	6	65.6	65.9	1.004
6		71.8	71.9	1.002
	7	80.9	81.2	1.003
7		87.5	87.0	0.994
			Average	1.000

The H_3C—N value 1.44 Å. (which is 0.04 Å. smaller than that reported by Brockway) differs from the single-bond radius sum by only 0.03 Å., whereas the observed H_3C—C distance in methyl cyanide is 0.05 Å. smaller than the radius sum.[7] This indicates that hyperconjugation of the methyl group and the triple bond is smaller for the isocyanide than for the cyanide, which is reasonable in view of the fact that the corresponding structure $H^+CH_2{=}\overset{+}{N}{=}\ddot{C}{:}^-$ for the isocyanide has an unstable distribution of charge.

An explanation in terms of resonance can be given of the fact that the observed bending frequency of methyl isocyanide, 290 cm.$^{-1}$, is much smaller than that, 376 cm.$^{-1}$, for methyl cyanide, and that the bending force constants computed from the oscillational frequencies, 0.205×10^{-11} and 0.320×10^{-11} erg radian^{-2}, respectively, are similarly related. The force constant for the cyanide represents essentially the resistance to bending of a single bond and triple bond. In the case of the isocyanide the structure $H_3C\diagdown\underset{..}{N}{=}C{:}$, for which the bent configuration is the stable one, makes an increasing contribution to the normal electronic state as the molecule deviates by increasing amount from linearity, and the resultant increase in resonance energy lowers the wings of the electronic-energy curve, leading to a smaller force constant and oscillational frequency.

We thank Dr. V. Schomaker for his assistance and advice during this work.

Summary

The electron diffraction study of methyl isocyanide shows the molecule to be linear, with interatomic distances H_3C—N = 1.44 ± 0.02 Å. and N—C = 1.18 ± 0.02 Å.

Non-carbohydrate Substances in the Cereal Starches

BY THOMAS JOHN SCHOCH

In a preliminary communication,[1] the author has reported the removal of fatty acids from the cereal starches by extraction with certain hydrophilic fat solvents. Recently, Evans and Briggs[2] have investigated the solvent extraction of corn starch, particularly as regards the identity of the fatty acids so liberated, and their development during ripening of the corn kernel. The present paper offers further data to indicate that the lipids of the common cereal starches are merely adsorbed on the starch. This is in contrast with the earlier views of Taylor and his co-workers,[3] who maintained that the fatty acids of the cereal starches were esterified with the alpha-amylose, contributing to the insolubility of that fraction.

The extent of removal of fatty material from corn starch depends on the nature of the solvent. Hydrocarbons or chlorinated hydrocarbons have little effect, while hydroxylated fat solvents remove much of the lipid material. This is illustrated by a series of Soxhlet extractions of corn starch with various solvents (Table I). While anhydrous dioxane gives inferior extraction, it will be noted that the constant boiling mixture of 80% dioxane with 20% water is among the most effective solvents.

Soxhlet extraction technique is limited to small quantities of material and to the use of pure solvents or constant boiling mixtures. Hence, extractions were likewise run by suspending one part of corn starch in three parts of the specified solvent, refluxing for one hour on the steam-bath with mechanical stirring, then filtering and digesting twice further in similar fashion with fresh solvent (Table II). Both dioxane and methanol were found to function more effectively when diluted with a small amount of water.

TABLE I

SOXHLET EXTRACTION OF CORN STARCH

Solvent	Hours extracted	Total material removed[a]	Fat content of extracted starch[b]
Mixed petroleum and ethyl ethers	18	0.04%	
Carbon tetrachloride	18	.04	
Ethyl acetate	18	.07	0.84%
Dioxane (anhydrous)	18	.15	.78
Isopropyl alcohol	18	.40	.72
Isoamyl alcohol	18	.42	
Methanol	18	.90	.10
Dioxane (80%)	18	.95	.06
Dioxane (80%)	3	.91	.26
Methyl cellosolve	3	.99	.18

[a] Determined by drying the extract to constant weight. Coloring matter and a portion of the protein are extracted from the starch by some of these solvents, and are included with fatty material under this heading. [b] The original raw starch analyzed 0.80% fat. All analyses for fat in starch reported in this paper were run in duplicate by the acid hydrolysis procedure,[4] and are corrected to dry starch basis. The precision of results by this method of analysis is of the order of ±0.02%. However, values tend to run slightly high, due to carry-over of dextrins by the mixed ethers used for extraction.

TABLE II

EXTRACTION OF FATTY MATERIAL FROM CORN STARCH

Solvent	Fat content of extracted starch[a]
Dioxane (anhydrous)	0.70%
Dioxane (80%)	.12
Dioxane (60%)	.34
Methanol (anhydrous)	.30
Methanol (85%)	.18
Methanol (75%)	.38
Methanol (65%)	.38

[a] By acid hydrolysis method. Original raw corn starch analyzed 0.84% fat.

The fat content of corn starch can be reduced by cold percolation with solvents, though this procedure is much less effective than hot extraction methods. Leaching with a large volume of cold 85% methanol decreased the fat content from 0.84 to 0.41%, or to 0.44% using 80% dioxane. Coloring matter is removed readily by this method.

The lipids extracted from corn starch prove to be free fatty acids, various samples ranging in acid number from 134 to 153. Exhaustive extraction with hot 85% methanol decreased the phosphorus content only slightly, from 0.017 to 0.015%. Most of this phosphorus must be esterified with the carbohydrate, since prolonged electrodialysis of an autoclaved paste of defatted corn starch at 1300 volts direct current potential merely reduced

(3) Taylor and Nelson, THIS JOURNAL, **42**, 1726 (1920); Taylor and Iddles, *Ind. Eng. Chem.*, **18**, 713 (1926); Taylor and Werntz, THIS JOURNAL, **49**, 1584 (1927); Taylor and Walton, *ibid.*, **51**, 3431 (1929); Taylor and Sherman, *ibid.*, **55**, 258 (1933).

(4) *Assoc. Official Agr. Chem.*, Official and Tentative Methods of Analysis, 4th ed., p. 208, 1935.

the phosphorus content to 0.013%, indicating the absence of any considerable amount of inorganic phosphate.

As estimated by Kjeldahl determinations, only a portion of the total protein is extracted from corn starch by 80% dioxane or by 85% methanol (Table III). It is assumed that the remainder of the protein either is of a different type, or is heat-denatured during extraction.

TABLE III

EXTRACTION OF PROTEIN FROM CORN STARCH

Treatment	% Protein
A, Raw corn starch	0.34
B, After four digestions with 85% methanol	.24
C, Product B, after twenty-four hours of Soxhlet extraction with 80% dioxane	.21
D, Raw corn starch, after forty-eight hours Soxhlet extraction with 80% dioxane	.26

The fatty material of rice starch can be similarly removed, but as the soap rather than the free fatty acid. It is presumed that the sample here employed was manufactured under alkaline steeping conditions.

Fat content of raw rice starch	0.59%
After seven successive digestions with 85% methanol	.03%
After forty-eight hours of Soxhlet extraction with 80% dioxane	.07%

In the case of wheat starch, the phosphorus appears to be present as a phospholipid, since both phosphorus and fat are removed concurrently (Table IV). After purification by solution in carbon tetrachloride, the extracted lipid analyzes high in phosphorus.

TABLE IV

EXTRACTION OF FATTY MATERIAL AND PHOSPHORUS FROM WHEAT STARCH

Treatment	% Fat[a]	% P[b]
Raw wheat starch, Sample A	0.50	0.054
Sample A, Soxhlet extracted forty-eight hours with 80% dioxane	.08	.008
Sample A, after seven digestions with 85% methanol	.04	...
Raw wheat starch, Sample B	.64	.059
Sample B, Soxhlet extracted forty-eight hours with 80% dioxane	.16	.022
Sample B, after seven digestions with 85% methanol	.03	...
Extracted fatty material from Sample B	...	2.25

[a] By acid hydrolysis. [b] Phosphorus was determined alkalimetrically, on the various starch samples after the dry-ashing procedure of Howk and De Turk,[5] and on the fatty extract by the A. O. A. C. method.[6] All analyses in duplicate.

These results are of particular interest since Stamberg and Bailey[7] have characterized the amylopectin fraction of wheat starch on the basis of its phosphorus content. From the above results, it appears that the phosphorus is present merely as an adsorbed phospholipid, and hence cannot be considered as truly characterizing either fraction. In contrast, prolonged Soxhlet extraction of potato starch with 80% dioxane does not materially reduce its phosphorus content.

Raw potato starch	0.095% P
After forty-eight hours of extraction with 80% dioxane	.087% P
After one hundred and twenty hours extraction with 80% dioxane	.084% P

Just as lipids can be removed by certain hydrophilic solvents, so it is also possible to impregnate starch with fatty acid by use of those same solvents. While this added fat cannot be removed by hydrocarbon solvents, it is readily extracted by hydrophilic solvents. Under similar conditions, carbon tetrachloride is inferior as a medium for impregnating starch with fatty acid:

A, 50 g. raw corn starch was suspended in 100 ml. of methanol containing 25 g. of oleic acid and evaporated to dryness on the steam-bath. The pasty mass was washed with hot xylene, then Soxhlet-extracted for twenty-four hours with carbon tetrachloride, dried and analyzed. Initial fat content of raw corn starch = 0.84%; final fat content = 2.26%.

B, Similar procedure, using defatted corn starch. Initial fat content = 0.17%; final fat content = 1.27%.

C, Similar procedure, but impregnating defatted corn starch with a 25% solution of oleic acid in carbon tetrachloride, instead of methanol. Initial fat content = 0.17%; final fat content = 0.26%.

D, Same procedure as in A, but using potato starch. Initial fat content of potato starch = negligible; final fat content = 0.77%. A portion of this fatted potato starch was Soxhlet-extracted for an additional twenty-four hours with carbon tetrachloride, thereafter analyzing 0.81% fat. A second portion was similarly extracted, but with 80% dioxane, which reduced the fat content to 0.04%.

The concept of a carbohydrate fatty ester is considered untenable. The selective removal of lipids by certain solvents cannot be attributed to ester exchange, since the free fatty acid or the soap is isolated. Also, no such mechanism could be formulated for dioxane. To ascertain whether a simple sugar fatty ester might decompose under the conditions of starch extraction, glucose penta-

(5) Howk and De Turk, *Ind. Eng. Chem., Anal. Ed.*, **4**, 111 (1932).

palmitate was refluxed for forty-eight hours with methanol and with 80% dioxane. In each case, the sugar ester was recovered quantitatively and unchanged. To clarify further the specific action of hydrophilic solvents in removing fatty material, oven-dried samples of corn starch were confined in closed containers over various solvents until constant weight was attained. The increase in weight of the starch due to solvent–vapor adsorption is directly related to the hydrophilic nature of the solvent, and hence is interpreted as a measure of solvent adsorption into the granule (Table V).

TABLE V

ADSORPTION OF VARIOUS SOLVENT VAPORS BY DRIED CORN STARCH

Solvent	Gain in weight, %
Benzene	0.6
Xylene	0.9
Carbon tetrachloride	1.1
Ethyl acetate	1.6
Dioxane (anhydrous)	3.3
Acetone	6.4
Methanol	19.6
Methyl cellosolve	20.6
Water	25.8

The lipids of the cereal starches appear to be distributed through the granule, loosely bound to the carbohydrate by polar adsorption, as suggested by Lehrman.[8] These lipids can only be displaced by fat solvents which can penetrate into the granule and adsorb preferentially on the starch by virtue of their hydrophilic loading. With dioxane and methanol, the hydrophilic qualities are markedly enhanced by the addition of a small amount of water.

The defatted cereal starches give clearer pastes possessing more pronounced gelling qualities than the original raw starches. The alkali lability is not increased by removal of lipid material. With corn starch, the apparent alkali number[9] drops slightly (*e. g.*, from 12.1 to 10.7), due to removal of fatty acid and protein, which consume a small amount of alkali in this test. Extraction of fatty acid raises the *p*H of corn starch to 6.0, within the range of minimum hydrolysis at elevated temperatures.[9] While raw corn starch pastes undergo slight hydrolysis during autoclaving, due to the acidity imparted by the presence of free fatty acid, no such effect is noted with pastes of defatted corn starch. At concentrations of 1–3%, defatted corn starch pastes may be dispersed by autoclaving for two hours at 19 pounds pressure, without any rise in the alkali number. The presence of lipid material appears to promote retrogradation of the cereal starches, and for this reason may interfere with enzymatic conversions. To avoid these effects, and for purposes of purification, it is the general practice in this Laboratory to defat all cereal starches intended for fundamental investigations. Recommended procedure is as follows: one part of starch is suspended in three parts of 85% (by volume) methanol, refluxed for several hours on the steam-bath with adequate stirring, filtered hot, then resuspended in fresh 85% methanol and extracted four times further in similar fashion. Five such extractions are sufficient to reduce the fat content of corn, wheat and rice starches to the vanishing point.

(8) Lehrman, THIS JOURNAL, **61**, 212 (1939); Lehrman has recently shown [*ibid.*, **64**, 2144 (1942)] that the adsorption of palmitic acid from methanol solution by potato starch or defatted corn starch follows a Freundlich isotherm, and that this adsorbed fatty acid is not removed by extraction with carbon tetrachloride.

(9) Schoch and Jensen, *Ind. Eng. Chem., Anal. Ed.*, **12**, 531 (1940).

Summary

The fatty acids of corn starch are removed without hydrolytic degradation by extraction with suitable hydrophilic fat solvents. Similarly, the fatty material can be removed from rice starch as the soap and from wheat starch as a phospholipid, together with substantially all the phosphorus of the original raw wheat starch. Consequently, these lipids cannot characterize any amylose fraction, but must be considered as natural impurities adsorbed on the starch. By the use of such hydrophilic fat solvents, corn starch or potato starch can be impregnated with fatty acid, and this added fat can only be removed by the same type of solvent used to introduce it.

Prior to use for any fundamental studies, it is recommended that the common cereal starches be purified of such lipid material by successive extractions with hot 85% methanol.

Fractionation of Starch by Selective Precipitation with Butanol

BY THOMAS JOHN SCHOCH

Introduction

The existence of several component amyloses in the common cereal and tuber starches has long been presumed. However, the literature records little agreement on the methods for isolating these components, or on their individual chemical and physical characteristics and relative proportion in the native starch. Most of this confusion can be traced to four principal sources of error: 1, incomplete dispersion of the starch prior to separation studies, thus including swollen and partially fragmented granules in the insoluble fraction; 2, slow separation methods, as by prolonged leaching or electrophoresis, permitting the starch to "retrograde" to less soluble form; 3, hydrolytic changes suffered either preliminary to or during the fractionation, as the use of starch solubilized by ball-milling or by alcoholic acid treatment, or the application of doubtful enzymatic methods to effect a separation; 4, interference by non-carbohydrate impurities, especially by fatty acid in the case of corn starch.

Based on the selective precipitant action of normal butyl alcohol toward starch sols,[1] a new technique of fractionation has been developed which avoids the above difficulties and which yields products[2] of markedly different physical and chemical characteristics. It has not as yet been established whether this mode of separation isolates two specific amyloses existing in the starch, or whether it fractionates a graded series of starch components. However, it is hoped that the methods here presented will help to clarify the problem of starch structure, by affording two chemically different fractions which may be studied individually and by comparison with one another. The fractionation involves four separate steps: (1) dispersion of the starch without attendant hydrolysis by autoclaving within carefully controlled *p*H limits, (2) selective precipitation of one fraction under conditions which prevent retrogradation, presumably through complex formation with the precipitating agent, (3) separation of this product by supercentrifuging, and (4) a system of purification of this fraction by washing or by reprecipitation. The specific application of these methods to corn starch, potato starch and waxy maize will be considered in turn.

(1) Schoch, *Cereal Chem.*, **18**, 121 (1941).

(2) The author prefers not to identify these fractions as alpha and beta amyloses, nor as amylose and amylopectin, since these terms have been so confused by indiscriminate usage. Until a more exact nomenclature can be devised, based on the identification of specific configurational differences between these fractions, they will be designated merely as the "butanol precipitated fraction" and the "butanol non-precipitated fraction."

Corn Starch

Removal of Fatty Material.—In a previous publication,[3] the use of defatted corn starch has been advised for all investigations of a fundamental character, and a method of purification has been outlined, consisting of five successive extractions with hot 85% methanol. This defatted starch is preferred as starting material for fractionation studies, since its *p*H is stabilized at 5.9–6.0 permitting autoclaving without glucosidic hydrolysis. While raw starch can be used, the lower *p*H (5.0–5.3) prohibits autoclaving and the presence of fatty acid interferes with the fractionation.

Dispersion of the Starch.—Regardless of whether the several fractions of starch are uniformly distributed throughout the granule, or whether one fraction constitutes an outer envelope, it is imperative to effect optimum dispersion of the granule structure preliminary to any fractionation study. In the opinion of the author, autoclaving affords the nearest approach to ideal dispersion, provided that hydrolytic breakdown is prevented by rigid maintenance of the *p*H between 5.9–6.3.[4] If a raw corn starch paste is adjusted within these limits by means of sodium hydroxide, the *p*H will drift badly during autoclaving. If sufficient buffer salts are added to maintain a stable *p*H, the presence of this electrolyte interferes with subsequent flocculation of the butanol precipitated fraction. Fortunately, the *p*H of defatted corn starch stabilizes at 5.9–6.0 during the entire separation. Presence of butanol during the autoclaving aids the breakdown of granule structure, by markedly lowering the gelatinization temperature of the starch, possibly a surface tension effect. A mixture of 14 liters of water and 2 liters of butanol in a 5-gallon Pyrex stock bottle is heated to boiling on the steam-bath, and a suspension of 150–450 g. (preferably 300 g.) of defatted corn starch in 1 l. of water is slowly added with vigorous mechanical stirring (Flow Sheet). This amount of butanol is considerably in excess of the 8% required to saturate the aqueous phase, to provide for loss during autoclaving. Also, it is desirable to have a supernatant layer of excess butanol present during the entire separation, to prevent the formation of insoluble "skins" by surface evaporation. The 1–3% paste is then autoclaved for two to three hours at 18–20 lb. pressure. Tests have shown that the viscosity drops to a minimum (indicative of granule disinte-

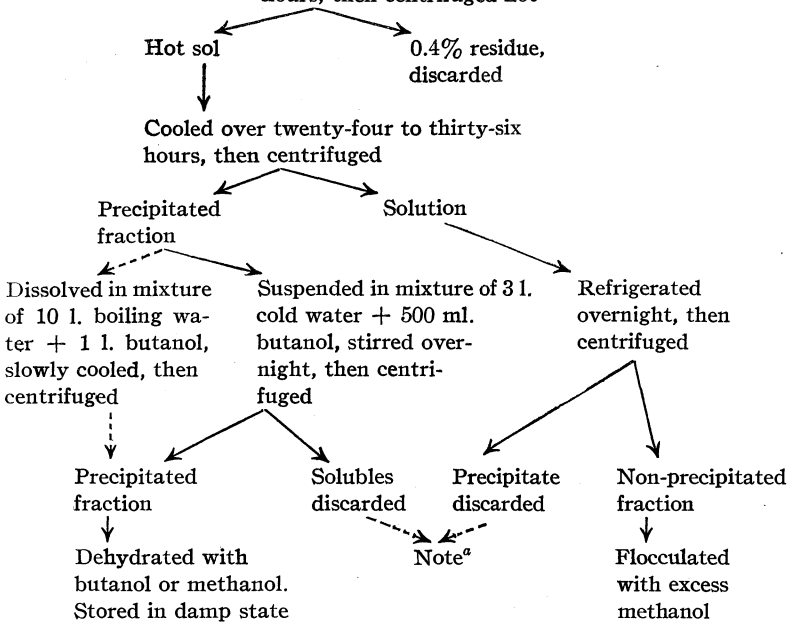
FLOW SHEET.—FRACTIONATION OF CORN STARCH: 150–450 g. of defatted corn starch pasted in a mixture of 15 l. of water + 2 l. of butanol, autoclaved two hours, then centrifuged hot



Dotted lines indicate alternative procedures.

[a] Soluble and precipitated residues are usually slight in amount and may be discarded. Where total recovery is desired, they may be combined at this point, dissolved by autoclaving, then reprecipitated and separated.

gration) in one to one and one-half hours under these conditions. If maximum purity of product is desired, the hot starch sol may be passed through the continuous supercentrifuge at this point, removing impurities and incompletely dispersed starch, totalling approximately 0.4% of the original starch. This insoluble residue is dark in color and may analyze as high as 10% ash. It appears to represent an irreducible minimum of undispersed material.

As an alternative but somewhat less effective method of dispersion, the butanol–water–starch paste may be boiled under reflux for five to six hours with vigorous mechanical agitation. This digestion time exceeds that required to reduce the viscosity to a minimum. The hot sol is then passed through the supercentrifuge, removing 1–3% of undispersed material. While this method is not recommended, it yields products similar in properties and amount to those obtained from autoclaved pastes, thus justifying use of the more efficient autoclave methods for dispersing the starch.

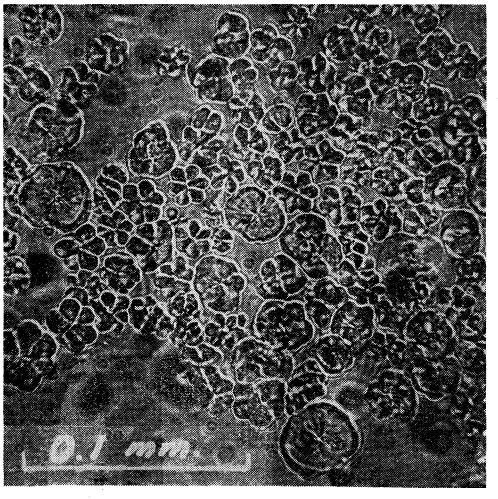


Fig. 1.—Butanol precipitate from corn starch.

Flocculation and Separation.—The hot starch sol, by whichever method prepared, is cooled slowly and without agitation to room temperature over a period of twenty-four to thirty-six hours. This can be accomplished by insulating the container with a thick wrapping of cloth. A "crystalline" floc forms in the neighborhood of 50°, usually as more or less perfect six-segmented spherulites, 15–50 microns in diameter (Fig. 1). Separation is preferably effected by means of a Sharples continuous supercentrifuge, fitted with a clarifier bowl, operating at 50,000 r. p. m., and capable of passing 20 l. of liquid per hour. The precipitated fraction is deposited in the rotor of the centrifuge as a stiff white cream. When operating satisfactorily, the centrifugate should be optically void under the polarizing microscope.

The Precipitated Fraction.—These spherocrystalline formations are birefringent under polarized light, giving an interference pattern somewhat similar to the familiar "Maltese Cross" of native starches. If lightly stained with a solution of iodine in butanol, they become dichroic under crossed nicols. The crystalline form is not disturbed by treatment with cold water saturated with butanol. However, if treated with cold water alone, the spherulites instantly fracture and swell. The product as removed from the bowl of the centrifuge may be dehydrated with methanol or butanol without altering its character, provided that the alcohol is not permitted to dry off. If the butanol precipitated fraction from corn starch is thoroughly dried, the spherulites lose all birefringence, though retaining their outward form. While this product swells in hot or cold water, it does not dissolve. The damp product as removed from the centrifuge, or after dehydration with methanol or butanol, is readily soluble in boiling water, either in the presence or absence of butanol. Relatively clear solutions can be prepared at concentrations as high as 10–15% solids. These are highly unstable, showing exaggerated retrogradation tendencies and forming insoluble skins with great facility. Even at dry solids concentrations as low as 1.5%, solutions of the precipitated fraction will set to hard irreversible gels on cooling to room temperature. At concentrations below 0.5%, solutions are reasonably stable at room temperature, though they eventually retrograde on standing. From its mode of prepara-

TABLE I

BUTANOL FRACTIONATION OF CORN STARCH

Batch	Method	% Yield of precipitated fraction	Alkali no. of fractions Precipitated	Alkali no. of fractions Non-precipitated
CA	Single precipitation from autoclaved 1.5% defatted corn starch paste	25		
CB	Similar	29		
CC	Similar	27

CY	Similar to Batch CV, but at 1% concentration	23.3		5.8

tion and solubility behavior, it is suggested that the spherulites may represent a crystalline addition compound between butanol and a specific starch fraction. This product is stable in the presence of excess butanol, but reverts to insoluble form on removal of the latter, whether by treatment with cold water or by drying.

The reason for the selective precipitating action of normal butyl and isoamyl alcohols is obscure, possibly depending on some undefined optimum of molecular volume or "hydrophil balance." No satisfactory separation could be effected with lower alcohols, while octyl alcohol or cyclohexanol precipitated all the starch substance indiscriminately.

After removal of the butanol precipitated fraction, the centrifugate gives no further precipitate, either on long standing, or on refrigeration, or after a second autoclaving. The non-precipitated fraction can be obtained readily by the usual practice of flocculating with excess methanol and triturating with fresh portions of methanol until dehydrated.

Purification.—Either of two methods may be used for purifying the butanol precipitated fraction. The product may be merely suspended in water previously saturated with butanol, thoroughly stirred, then centrifuged. In most cases, this simple washing procedure is adequate. For more thorough purification, the precipitated fraction may be "recrystallized." The moist product as removed from the centrifuge (representing 30–100 g. of dry substance) is slowly added with vigorous agitation to a boiling mixture of 10 l. of water and 1 l. of butanol. On slow cooling, the butanol precipitated fraction flocculates out in minute particles, possibly 1–2 microns in diameter. Efforts to increase the size of these crystals by various cooling procedures have not been successful. However, the product is readily centrifuged, and recovery is 90–95%. This reprecipitated product is dehydrated by suspending in butanol, then filtered on a Büchner and bottled as a damp product, containing 40–50% dry solids. The yields of butanol precipitated fraction from corn starch have averaged 22% (on dry starch basis), under various conditions of preparation, isolation and purification (Table I).

Properties of the Corn Starch Fractions.—After thorough drying, the non-precipitated fraction from corn starch is soluble in cold water to the extent of 4–5%, and in hot water to 10–12%. When hot 10% solutions are cooled down, they give pasty gels which are readily liquefied by heating. Solutions show no tendency to retrograde on long standing, even at refrigerator temperatures. This behavior suggests that the non-precipitated fraction constitutes the more stable and colloidally soluble portion of the starch. In contrast, the butanol precipitated fraction might be considered as responsible for the gelation and retrogradation tendencies of corn starch.

An outstanding chemical difference between the butanol separated fractions lies in their respective alkali labilities. Various samples of the precipitated fraction average an alkali number[4] of 25, much higher than the original defatted corn starch. The non-precipitated fraction is correspondingly lower, averaging 5.6. Calculating the composite alkali number of the original defatted starch from these average values and from the proportion of each fraction in the starch, an estimated value of 10.0 is obtained, in good agreement with the observed alkali number of 11.0. This is taken as evidence that fractions of high and low alkali lability exist as such in the original starch, and are not produced by some obscure hydrolytic change during the process of fractionation.

It is believed that the alkali number is an index of ter-

minal aldehyde content. However, in view of the possible presence of branched chain configurations in starch, no direct relationship can be deduced between alkali number and molecular weight. In this connection, Bear[5] has recently reported that the butanol precipitated fraction gives a V-type X-ray pattern, while that of the non-precipitated fraction is relatively diffuse and amorphous. On the basis of the degree of orientation during flow, Rundle and Baldwin[6] suggest that the precipitated fraction consists of the unbranched component of the starch, while the non-precipitated fraction is composed of branched material.

The Ostwald viscosity of the two fractions can be compared by dissolving the dried products in cold 0.4 *N* sodium hydroxide solution. In this medium, the non-precipitated fraction has been slightly but consistently more viscous than the butanol precipitated material.

Behavior toward butanol must be considered as a specific difference between the fractions. For example, after alkali number determinations on the individual fractions (involving extensive degradation in hot aqueous alkali), if butanol is added to the cooled and neutralized solutions, the butanol precipitated fraction gives an immediate crystalline floc. The non-precipitated fraction remains clear, even on refrigeration.

Pacsu and Mullen[7] have recently reported an exceedingly interesting method of starch fractionation by selective adsorption on cotton. The butanol precipitated fraction possesses a strong affinity for cellulose, while the non-precipitated fraction is not adsorbed. While not necessarily identical, the two methods of starch separation appear to be very similar, not only in the nature of the fractions produced, but likewise in the adsorption mechanisms involved. A comparative study of the two methods is now in progress.

Periodic acid does not distinguish between the butanol separated fractions, since both oxidize at the same rate and with the same total consumption of oxidizing agent.

Phosphorus does not appear to have any very significant function in characterizing the corn starch fractions. The non-precipitated portion can be separated into sub-fractions of high and low phosphorus content by electromigration of a 1.5% solution at 1300 volts direct current potential. These sub-fractions do not differ materially in solubility behavior or in alkali number (Table II).

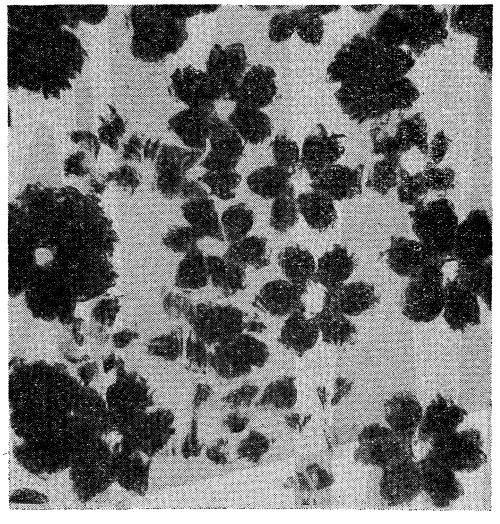

Fig. 2.—Butanol precipitate from potato starch, stained with iodine.

TABLE II

DISTRIBUTION OF PHOSPHORUS IN THE CORN STARCH FRACTIONS

Sample	Alkali no.	% Phosphorus[a]
Defatted corn starch	11.0	0.0153
Dried butanol precipitated fraction, extracted with hot water	23.2	.0088
Non-precipitated fraction	5.1	.0107
Migrated sub-fraction (77% recovery from non-precipitated fraction)	5.2	.0116
Non-migrating sub-fraction (20% recovery from non-precipitated fraction)	5.0	.0029

[a] Phosphorus determined by the method of Howk and De Turk, *Ind. Eng. Chem., Anal. Ed.*, **4**, 111 (1932).

Potato Starch

Fractionation of potato starch is accomplished in much the same manner as described for corn starch. Obviously, defatting is unnecessary. Samples of potato starch employed in this investigation tested 6.0 *p*H and no adjustment was required. The concentration of the autoclaved paste should not exceed 2%. Centrifugal clarification of the hot autoclaved sol may be omitted, since undispersed material runs less than 0.1%.

The yields of butanol precipitated fraction from potato starch averaged 22%, identical in amount with that from corn starch. However, several pronounced differences have been noted between the butanol precipitated fractions from corn starch and from potato starch. The latter separates either as large, well-formed, six-petalled rosets, 50–80 microns in diameter (Fig. 2), or as clumps of hair-like needles. After thorough drying, the precipitated fraction from potato starch remains relatively water-soluble, with little tendency to gel or retrograde. Its alkali number averages 11.

TABLE III

BUTANOL FRACTIONATION OF POTATO STARCH

Batch	Method	% Yield of precipitated fraction	Alkali no. of fractions Precipitated	Non-precipitated
PA	Slow precipitation from 1.5% boiled starch paste, washed with butanol–water	21.3	10.6	5.9
PB	Slow precipitation from 3% autoclaved paste, then washed with butanol–water	24.6	10.1	5.0
PC	Slow precipitation from 1.5% autoclaved paste, then dissolved and reprecipitated	21.0	11.5	6.6

The phosphorus content of potato starch is located principally in the non-precipitated fraction. Unlike corn starch, this fraction migrates completely in an electrophoretic cell, retaining substantially all its phosphorus.

TABLE IV

DISTRIBUTION OF PHOSPHORUS IN THE POTATO STARCH FRACTIONS

	Alkali no.	% Phosphorus
Original potato starch	7.5	0.072
Butanol precipitated fraction	11.5	.0103
Non-precipitated fraction	6.6	.079
Non-precipitated fraction, electromigrated (98.6% recovery)	6.4	.072

These results correct earlier observations by Taylor and Schoch.[8] In the latter investigation, no fractionation of potato starch could be obtained by electrophoresis, and it was assumed that the phosphorus was randomly distributed, without characterizing any specific fraction. With the more sensitive butanol precipitation technique, the presence of fractions is definitely established, and phosphorus is shown to be preferentially attached to the non-precipitated portion.

The butanol precipitated fraction from potato starch gives a pure blue coloration with iodine, while the non-precipitated portion tends toward the purple.

Waxy Maize Starch

Waxy maize starch has recently occasioned considerable interest, by reason of its red coloration with iodine and its reputed lack of retrogradation tendencies.[9] Since these qualities are suggestive of the non-precipitated fraction, an investigation of its behavior toward butanol was undertaken.

Waxy maize starch was defatted in the prescribed manner, reducing the total fat content from 0.11 to 0.04%. This defatted starch analyzed an alkali number of 4.1, much lower than any of the common cereal or tuber starches. Butanol treatment of autoclaved pastes gave no trace of crystalline flocculate. A small amount of slime and impurities (less than 3%) was separated by the supercentrifuge, but most of this material could be dispersed by further autoclaving and did not subsequently precipitate with butanol.

(8) Taylor and Schoch, THIS JOURNAL, **55**, 4248 (1933).

(9) Hixon and Sprague, *Ind. Eng. Chem.*, **34**, 959 (1942).

Summary

By means of selective precipitation with butanol, a method of starch fractionation has been developed which avoids retrogradation and hydrolytic degradation. The precipitated fraction (constituting 22% of either corn or potato starch) is isolated in unique spherocrystalline form, probably as an addition compound with the butanol. The butanol precipitated fractions from corn and potato starches are more alkali labile than the respective raw starches, while the non-precipitated fractions are correspondingly more alkali stable, indicative of definite chemical differences.

The butanol precipitated fraction from corn starch tends to revert to insoluble form and appears to be the component of the starch responsible for gelation and retrogradation. The non-precipitated fraction from corn starch constitutes the more soluble and stable component.

With potato starch, the physical differences between the fractions are less pronounced, since the butanol precipitated portion is more soluble and less subject to retrogradation than the corresponding fraction from corn starch. The phosphorus in potato starch is principally associated with the non-precipitated fraction.

Waxy maize starch is peculiar in possessing an unusually low alkali lability and in giving no precipitate with butanol.

Synthesis of Derivatives of Diphenylethane Related to Materials Occurring Naturally. IV. Stilbene-2-acetic Acid

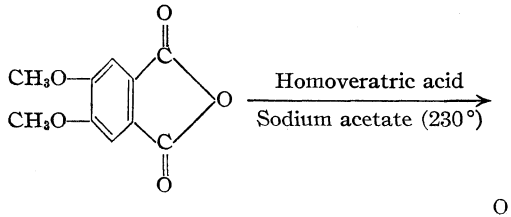
BY SAMUEL NATELSON AND SIDNEY P. GOTTFRIED[1]

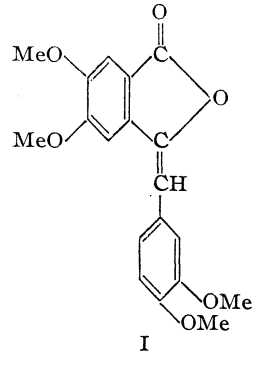
In an earlier communication[1a] the authors indicated the relationship between benzalphthalide and benzylisoquinoline. In order to continue the study of this series, it was necessary to convert the previously synthesized stilbene-2-aldehyde to stilbene-2-acetic acid ($C_6H_5CH{=}CHC_6H_5CH_2COOH$).

At first this was accomplished by the condensation of the aldehyde with hippuric acid, and the hydrolysis and oxidation of the resulting azlactone.

While studying the method for the hydrolysis of the azlactone, it was observed that the intermediate, *o*-styryl-α-benzamido cinnamic acid could be obtained in excellent yield with dilute barium hydroxide. This compound could be hydrolyzed and oxidized to stilbene-2-acetic acid by boiling with sodium hydroxide solution and then treating the resultant solution with hydrogen peroxide.

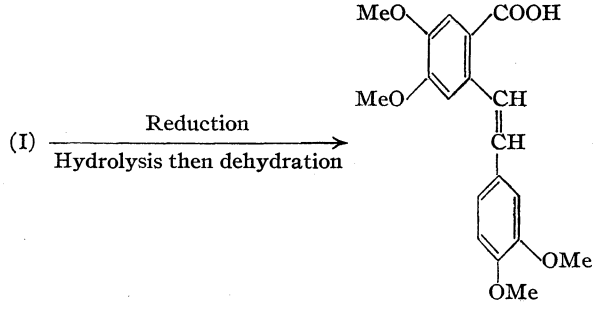
The yields of stilbene-2-acetic acid from the aldehyde through the azlactone were unsatisfactory. It was decided, therefore, to devise an alternate method of synthesis. The aldehyde was converted to the alcohol, then to the corresponding chloride and the latter to the cyanide. The cyanide yielded, on hydrolysis, stilbene-2-acetic acid and some stilbene-2-acetamide. Although this process is lengthier, the over-all yield is better. Stilbene-2-acetamide hydrolyzes to stilbene-2-acetic acid and the amount of this material obtained depends upon the length of time of the hydrolysis.





I

In anticipation of the application of this method to the preparation of papaverine, itself, *m*-hemipinic anhydride was condensed with homoveratric acid to yield tetramethoxybenzalphthalide (I). Reduction of (I), hydrolysis and dehydration yielded tetramethoxystilbene-2-carboxylic acid.



Preliminary attempts to convert stilbene-2-acetic acid to the lactone and then to the imide were unsuccessful. This imide, if obtained, could be converted to benzylisoquinoline by reduction and dehydration. Attempts in this direction are being maintained.

Experimental

Stilbene-2-aldehyde.—This compound is prepared, essentially by the procedure described previously[1a] with this improvement. 2-Stilbene-carboxylic hydrazide is prepared in about 60% yield by refluxing stilbene-2-carboxylic ester with 85% hydrazine hydrate (10% excess) with mechanical stirring for twenty hours. Any unreacted ester is recovered by extracting the reaction mixture with benzene. The residue is the hydrazide. On evaporating the benzene, the ester is recovered.

Before the 2-stilbene-carboxylic hydrazide is condensed with toluenesulfonyl chloride, it is made anhydrous by drying with benzene using a distillation trap of the type employed in determining moisture content of materials.

Stilbene-2-methyl Alcohol.—0.2 mole (41.6 g.) of stilbene-2-aldehyde is added to 1 liter of molar aluminum isopropylate in anhydrous isopropyl alcohol. The mixture is refluxed for one-half hour and slowly distilled until the distillate shows no test for acetone with 2,4-dinitrophenylhydrazine. The residue is poured into 1000 cc. of 10%

(1) Now in the armed forces of the U. S. A.

(1a) Natelson and Gottfried, THIS JOURNAL, **63**, 487 (1941).

sulfuric acid. The alcohol, which crystallizes in pearly plates, is filtered off, and recrystallized from dilute alcohol; yield 40 g.; m. p. 92–93°.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.71; H, 6.67. Found: C, 85.32; H, 6.72.

Stilbene-2-methyl Chloride.—Forty grams of stilbene-2-methyl alcohol is dissolved in 80 cc. of ether and 160 cc. of thionyl chloride (large excess) is added slowly with stirring and cooling. The mixture is refluxed for one-half hour; the ether and thionyl chloride are removed under vacuum. The residue is picked up in ether and washed well with water and dilute sodium bicarbonate. The mixture is dried over anhydrous sodium sulfate and vacuum distilled; yield 32 g., b. p. 170–185° (15 mm.).

Anal. Calcd. for $C_{15}H_{13}Cl$: Cl, 15.51. Found: Cl, 15.10, 15.30.

Stilbene-2-acetonitrile.—Seventeen grams of stilbene-2-methyl chloride, 4.5 g. of sodium cyanide dissolved in a minimum quantity of water, and 25 cc. of ethyl alcohol are refluxed for eight hours. The mixture is thrown into 200 cc. of water and extracted with ether. The ether is washed with water, dried over anhydrous sodium sulfate, and vacuum distilled, collecting from 200–210° (fifteen minutes). The distillate crystallizes; yield 10 g., m. p. 81–82°.

Anal. Calcd. for $C_{16}H_{13}N$: N, 6.39. Found: N, 6.38, 6.27.

Stilbene-2-acetic Acid. Method 1.—Ten grams of stilbene-2-acetonitrile is refluxed with 100 cc. of glacial acetic acid, containing 40 cc. of concentrated hydrochloric acid, for four hours. The mixture is poured into water and extracted with ether. The ether is extracted with sodium bicarbonate solution. The bicarbonate solution is then acidified. The precipitated acid is recrystallized from ligroin. White needles are obtained; yield 7 g., m. p. 105–106°.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.67; H, 5.93; neut. equiv., 238. Found: C, 80.24; H, 6.04; neut. equiv., 245.

Stilbene-2-acetamide.—The ether extract of the sodium bicarbonate solution was evaporated to dryness, and the residue treated with hot 10% sodium hydroxide to remove traces of the acid. The alkali insoluble portion was recrystallized from alcohol to yield white leaflets (2 g.), m. p. 152–153°. Hydrolysis of this product with glacial acetic acid and concentrated hydrochloric acid, as described for the nitrile, yielded stilbene-2-acetic acid.

Anal. Calcd. for $C_{16}H_{15}ON$: N, 5.90. Found: N, 5.83, 5.79.

Stilbene-2-acetic Acid. Method 2.—Twenty grams of sodium hydroxide in 200 cc. of water is added to 10 g. of stilbene-2-(benzamido)-acrylic acid. The solution is refluxed for eight hours, and treated at 0° with 10 cc. of 30% hydrogen peroxide (excess). The mixture is allowed to stand overnight in the refrigerator. It is then acidified and the mixture of stilbene-2-acetic acid and benzoic acid is recrystallized from dilute alcohol to remove the benzoic acid. The residue of stilbene-2-acetic acid is further recrystallized from benzene or ligroin; yield 2 g.; m. p. 105–106° (mixed m. p. with the product from method 1 showed no depression).

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.67; H, 5.93; neut. equiv., 238. Found: C, 80.48; H, 6.01; neut. equiv., 242.

***o*-Styryl-α-benzamidocinnamic Acid.**—2-Phenyl-4-*o*-styrylbenzylidene-5(4)-oxazolone (20 g.) from hippuric acid and stilbene-2-aldehyde (1), is mixed with 1000 cc. of water and 250 g. of hydrated barium hydroxide and heated at 85° with stirring for eight hours. The white barium salt is filtered off and washed several times with warm water. The free acid is obtained by boiling the barium salt with 100 cc. of alcohol and 20 cc. of concentrated hydrochloric acid mixture. The mixture is cooled, filtered, and the precipitate washed well with water. The acid is recrystallized from alcohol to yield a pale yellow crystalline powder; yield 13.6 g.; m. p. 199–202°.

Anal. Calcd. for $C_{24}H_{19}O_3N$: C, 78.03; H, 5.14; N, 3.79; neut. equiv., 369. Found: C, 78.41; H, 5.47; N, 3.90, 4.01; neut. equiv., 370, 376.

Tetramethoxybenzalphthalide.—Ten grams of *m*-hemipinic anhydride and 10 g. of homoveratric acid were mixed with 0.5 g. of anhydrous sodium acetate. The mixture was heated at 230° for two hours in an open flask. The mixture was cooled, broken up, dissolved in hot alcohol and filtered. The alcohol was allowed to cool, yield 10 g. of yellow crystals, m. p. 179–180°; soluble in glacial acetic, slightly soluble in hot alcohol, almost insoluble in cold alcohol.

Anal. Calcd. for $C_{19}H_{18}O_6$: C, 66.67; H, 5.26. Found: C, 67.01; H, 5.39.

Tetramethoxybenzylphthalide.—Ten grams of the tetramethoxybenzalphthalide was dissolved in 100 cc. of hot 20% sodium hydroxide and then diluted to a liter with water. The solution was cooled to room temperature, 2 g. of sodium, dissolved in 60 g. of mercury was added and the mixture was vigorously stirred for four hours. The solution was acidified and the separated tetramethoxybenzylphthalide was recrystallized from alcohol; yield 9.5 g., m. p. 146–148°.

Anal. Calcd. for $C_{19}H_{20}O_6$: C, 66.28; H, 5.81. Found: C, 66.01; H, 6.00.

Tetramethoxystilbene-2-carbonic Acid.—Ten grams of tetramethoxybenzylphthalide was dissolved in 200 cc. of ethyl alcohol containing 3 g. of potassium hydroxide. The mixture was slowly evaporated to dryness on a hot-plate. The temperature was raised to 180° and kept there for one hour. The residue was dissolved in water, filtered and acidified. The tetramethoxystilbenecarbonic acid obtained was recrystallized from alcohol, m. p. 209–211°; yield, 7 g.

Anal. Calcd. for $C_{19}H_{20}O_6$: C, 66.28; H, 5.81. Found: C, 66.47; H, 5.97.

Summary

Stilbene-2-acetic acid and tetramethoxystilbenecarbonic acid, proposed intermediates for the preparation of benzylisoquinoline and papaverine, respectively, have been prepared.

Grignard Reactions. XVI[1]

BY FRANK C. WHITMORE AND C. E. LEWIS[2]

The effect of an accumulation of substituents adjacent to the functional group of a carbonyl compound on its reaction with a Grignard reagent was first shown by Conant and Blatt.[3]

The present study is a continuation of the work started in this Laboratory on the enolization of aliphatic hindered carbonyl compounds by Grignard reagents.[1,4] Many of the compounds studied exhibit sufficient steric hindrance to prevent the addition reaction entirely. The results of the enolization studies are given in Table I.

The Grignard machine used in this work is essentially the same as the one originally designed by Kohler[5] and has been in use in this Laboratory.[1] The usual procedure was followed except for a few modifications. The reaction flask was always heated to ensure optimum reaction conditions. Aniline was used instead of water for decomposition of the excess Grignard reagent in order to eliminate the variation due to the vapor pressure of water. This allowed the elimination of a drying tower from the system. All calculations were based on the assumption that the amount of condensation of these carbonyl compounds is negligible.

TABLE I

Compound	Enolization, %	Addition, %
Et_3CCOCH_3	94	0
$Et_2MeCCOCH_3$	84	0
$EtMe_2CCOCH_3$	14	74

$Me_3CCH_2COCH_3$	0	100
$Et_3CCOCH_2CHMe_2$	85	0
$Et_3CCOCH{=}CH_2$	0	58
Et_3CCO_2Et	0	0
Et_3CCO_2Me	0	0
Et_2MeCCO_2Et	25[b]	45
Et_2MeCCO_2Bu	22[b]	60
$EtMe_2CCO_2Et$	0	100
$Et_3CCOCH_2CH_2OH$	58[c]	27
$(Et_3CCO)_2CH_2$	91/2	55/2
$(Et_3CCO)_2CHCH_3$	79/2	19/2

[a] Ref. 1. [b] The apparent enolization of these compounds is due to that of the ketones formed from the methylmagnesium bromide and the esters. [c] Corrected for the CH_4 liberated by the alcohol group.

The reactions in the series, methyl triethylcarbinyl ketone, methyl methyldiethylcarbinyl ketone, methyl dimethylethylcarbinyl ketone and pinacolone, illustrate the effect of an accumulation of substituents on the carbon adjacent to the carbonyl, the percentage enolization being 94, 84, 14 and 5, respectively. The difference in the amount of steric hindrance exerted by the methyl and ethyl groups is again clearly demonstrated. That substituents on the beta carbon have less effect on the carbonyl reaction than those on the adjacent carbon is shown by the fact that methyl neopentyl ketone gave 100% addition and no enolization while pinacolone gave 5% enolization. The effect of ethyl groups on the addition reaction is also shown in the action of the Grignard reagent with the esters of triethylacetic, methyldiethylacetic and dimethylethylacetic acids. These esters gave per cent. additions of 0, 45 and 100, respectively.

Vinyl triethylcarbinyl ketone gave only the addition reaction. This is to be expected since enolization would necessitate the formation of an allene system. The effect of introducing a substituent into the active methylene of beta-diketones is shown by the action of the Grignard reagent with bis-triethylacetylmethane and with 1,1-bis-triethylacetylethane. This introduction of a methyl group decreased both the enolization and addition reactions. The greater effect is shown on the addition reaction.

None of the monoketones investigated gave a positive test for the enol form by the usual ferric chloride and peroxide tests. Thus the "enolization reaction" between the carbonyl compound and the Grignard reagent starts with the carbonyl group. It is a competitive reaction, the extent of which is determined by the nature of the groups adjacent to the carbonyl.

We thank R. S. George of this Laboratory for his help.

Preparations

The Grignard reagents used in this work were prepared in the usual way. All fractionations were done with the

(5) Kohler, Stone and Fuson, *ibid.*, **49**, 3181 (1927).

usual type of column[6] having 12–18 theoretical plates. The procedure used in making the enolization measurements was the same as that described by Whitmore and Block.[1] Methylmagnesium bromide in dibutyl ether was used. For the monoketones the reaction mixture was heated for two to five minutes at reflux temperature. Comparable results were obtained for several different periods of heating. Methyl methyldiethylcarbinyl ketone gave the same results when heated at reflux temperature for two minutes as when it was heated at 90° for one hour. In no case did prolonged heating have a noticeable effect. The diketones required longer heating at the reflux temperature, maximum reaction being obtained in ten minutes. The esters were heated by immersing the reaction flask in a water-bath at 75–80° upon addition of the methylmagnesium bromide, heating to 95–100° in ten minutes and holding at that temperature for thirty minutes. In all cases refluxing provided the necessary agitation.

The preparations of triethylacetyl chloride, methyl triethylcarbinyl ketone, bis-triethylacetylmethane and 3-keto-4,4-diethylhexan-1-ol have been described.[7] The methyldiethylacetyl chloride was prepared by standard reactions as follows

$$\mathrm{MeCOEt} \xrightarrow{\mathrm{EtMgBr}} \mathrm{MeEt_2COH} \xrightarrow{\mathrm{HCl}} \mathrm{MeEt_2CCl} \xrightarrow{\mathrm{Mg}} \mathrm{MeEt_2CMgCl} \xrightarrow{\mathrm{CO_2}} \mathrm{MeEt_2CO_2H} \xrightarrow{\mathrm{SOCl_2}} \mathrm{MeEt_2COCl}.$$

The acid chloride had b. p. 157° at 734 mm.

Vinyl Triethylcarbinyl Ketone.—Dehydration of 3-keto-4,4-diethylhexan-1-ol[7] by refluxing over anhydrous cupric sulfate gave vinyl triethylcarbinyl ketone, b. p. 97° at 36 mm., n^{20}D 1.4495–8. The ketone polymerized to a transparent resin on standing.

Isobutyl Triethylcarbinyl Ketone.—To one mole of isobutylmagnesium bromide was added 49 g., 0.3 mole, of triethylacetyl chloride. Decomposition and fractionation gave 16 g., 0.12 mole, or 40% of 2,2-diethylbutan-1-ol, b. p. 96–100° at 40 mm., n^{20}D 1.4392–1.4412, α-naphthylurethan m. p. 131–132° and 24.4 g., 0.13 mole, or 43% of isobutyl triethylcarbinyl ketone, b. p. 86–87° at 12 mm., n^{20}D 1.4381–2. No derivative of the ketone could be made.

Methyl Methyldiethylcarbinyl Ketone.—To an excess of methylmagnesium bromide was added 37.1 g., 0.25 mole, of methyldiethylacetyl chloride. Decomposition and fractionation as usual gave 15.3 g., 0.12 mole, or 48% of methyl methyldiethylcarbinyl ketone, b. p. 77–79° at 20 mm., n^{20}D 1.4489–98, 2,4-dinitrophenylhydrazone, m. p. 73–74°.

Methyl Dimethylethylcarbinyl Ketone.—Methyl-*t*-amylcarbinol was prepared by the action of *t*-amylmagnesium chloride with acetaldehyde. A solution of 33 g. of chromic oxide in 60 cc. of 65% aqueous acetic acid was added slowly to 56 g. of the carbinol in 25 cc. of glacial acetic acid. The reaction mixture was kept below 30°. About 150 cc. of water was then added, the oil layer was steam distilled and dried. Fractionation gave about 20 g. of methyl dimethylethylcarbinyl ketone, b. p. 130° at 733 mm., n^{20}D 1.4100, 2,4-dinitrophenylhydrazone m. p. and mixed m. p. 112°.

(6) Whitmore and Lux, THIS JOURNAL, **54**, 3451 (1932).

(7) Whitmore and Lewis, *ibid.*, **64**, 1618 (1942).

Preparation of the Ethyl Esters.—The ethyl esters were all prepared according to the same procedure. The addition of triethylacetyl chloride to sodium ethylate illustrates the procedure used.

To 50 cc. of absolute ethanol was added 6 g. of metallic sodium. After the reaction was completed, 24 g., 0.15 mole, of triethylacetyl chloride was added slowly. The excess sodium ethylate was decomposed by pouring on ice. The oil layer was separated, dried and fractionated.

Ester	B. p. °C.	Mm.	n^{20}D	Yield, %
Ethyl triethylacetate	85–7	30	1.4218–9	57
Ethyl methyldiethylacetate	73	35	1.4129–32	64
Ethyl dimethylethylacetate	140–141	744	1.4025	63

Methyl Triethylacetate.—The procedure described above was used except that absolute methanol was substituted for ethanol, and the oil layer was distilled from a Claisen flask. The ester had b. p. 164–5° at 734 mm., n^{20}D 1.4240–1.

***n*-Butyl Methyldiethylacetate.**—To 250 cc. of *n*-butyl alcohol was added 12 g. of metallic sodium. When the reaction was completed, 26 g., 0.17 mole of ethyl methyldiethylacetate was added. The reaction mixture was heated for twelve hours at 125° under a reflux condenser held at 100°. The ethyl alcohol was thus removed as it was formed. The solution was acidified with 20% hydrochloric acid with cooling in an ice-bath. The alcoholic solution of ester was separated and dried. Fractionation gave 14.6 g., 0.08 mole, or 46% of *n*-butyl methyldiethylacetate, b. p. 104–5° at 38 mm., n^{20}D 1.4212–8.

Alkylation of Bis-triethylacetylmethane.—Metallic sodium, 1.5 g., and 25 cc. of anhydrous ether were added to 17.2 g., 0.064 mole, of bis-triethylacetylmethane.[7] The reaction mixture was refluxed on a steam-bath for forty-eight hours. The ether was removed by evaporation, and 25 cc. of dioxane and 21 g., 0.15 mole, of methyl iodide were added. This reaction mixture was heated on a steam-bath for twenty-four hours. The dioxane and the excess methyl iodide were distilled off. The residue was cooled, and just enough water to dissolve the sodium iodide was added. The oil layer was separated and dried. Fractionation gave 7.4 g., 0.026 mole, or 41% of 1,1-bis-triethylacetylethane, b. p. 164° at 6 mm., n^{20}D 1.4718–22. The beta-diketone did not give a positive test with ferric chloride or a derivative with ammoniacal cupric acetate.

Methyl Neopentyl Ketone.—This ketone was prepared by the dichromate oxidation of diisobutylene. It had b. p. 125.5° at 727 mm., n^{20}D 1.4038.

Summary

1. The study of sterically hindered aliphatic carbonyl compounds, especially in relation to their enolization, has been continued.

2. Fifteen such compounds have been analyzed in the Grignard machine with methylmagnesium bromide.

3. The degree of enolization of the carbonyl compounds was shown to be dependent upon the character of the substituents on the carbon ad-

jacent to the carbonyl. Substitution on the beta carbon had no noticeable effect on the reactions of the carbonyl.

4. Vinyl triethylcarbinyl ketone gave only the addition reaction.

5. Substitution in the active methylene of a beta-diketone decreased the extent of both enolization and addition.

Grignard Reactions. XVII.[1] The Reactions of Esters and Acid Chlorides with Grignard Reagents

BY FRANK C. WHITMORE AND W. S. FORSTER[2]

In the course of the preparation of large amounts of diethyl-*t*-butylcarbinol, it was found that while ethylmagnesium bromide reacted with trimethylacetyl chloride to give 26% of this tertiary alcohol and 60% of the secondary alcohol, ethyl-*t*-butylcarbinol, the same reagent reacted with methyl trimethylacetate to give 78.5% of the tertiary alcohol and only 8.6% of the secondary alcohol.

TABLE I

TRIMETHYLACETYL CHLORIDE–METHYL TRIMETHYLACETATE

Grignard reagent	Products[a]	Acid chloride	Ester
Ethyl	Ethyl-*t*-butylcarbinol	60	8.6
	Diethyl-*t*-butylcarbinol	26.1	76.5
n-Propyl	Neopentyl alcohol	20[3]	0[4]
	n-Propyl-*t*-butylcarbinol	76[3]	48[4]
	Di-*n*-propyl-*t*-butylcarbinol	0[3]	40[4]
Isopropyl	Neopentyl alcohol	23[3]	0
	Isopropyl-*t*-butylcarbinol	53[3]	44.8
n-Butyl	Neopentyl alcohol	28[3]	0
	n-Butyl-*t*-butylcarbinol	71[3]	40[4]
	Di-*n*-butyl-*t*-butylcarbinol	0[3]	50[5]
Isobutyl	Neopentyl alcohol	61[3]	0
	Isobutyl-*t*-butylcarbinol	26[3]	25.7
	Isobutyl-*t*-butyl ketone	0	29.4
	t-BUTYLACETYL CHLORIDE–METHYL *t*-BUTYLACETATE		
Ethyl	Diethylneopentylcarbinol	57.6[5]	68.5
	Ethyl neopentyl ketone	0[5]	5

	Di-*n*-butylneopentylcarbinol	9.9	71.4
	n-Butyl neopentyl ketone		trace
Isobutyl	Isobutylneopentylcarbinol	48.9	9.2
	Diisobutylneopentylcarbinol	13.8	34.2
	Isobutyl neopentyl ketone	20.1	32

[a] The percentage yields of products given by the acid chloride and the ester are listed under the respective headings.

These results made desirable a comparison of the reactions of Grignard reagents with esters and with the chlorides of the corresponding acids. The results in Table I include those of this investigation as well as some from other work which completes the comparison.

Although use of the ester in place of the acid chloride decreased the amount of reduction product, it will be seen that structure is also a factor. When a normal Grignard reagent was used, the yield of tertiary alcohol from the ester was greater than from the acid chloride. However, methyl Grignard reagent with the methyl ester of methyl-*t*-butylneopentylacetic acid, beta-Butlerow's acid,[6] gave no reaction at 34° in diethyl ether or at 142° in di-*n*-butyl ether. This is in contrast to the reaction of the corresponding acid chloride which has been shown by Whitmore and Randall[7] to give a 90% yield of methyl methyl-*t*-butylneopentylcarbinyl ketone when treated with the methyl Grignard reagent. With trimethylacetyl chloride only methyl and ethyl Grignard reagents gave tertiary alcohols. With *t*-butylacetyl chloride only the primary reagents gave tertiary alcohols. Reduction to the primary alcohol fails with the primary *t*-butylacetyl chloride as compared with the tertiary trimethylacetyl chloride. It is significant that in no case was any primary alcohol found from the reaction of an ester with a Grignard reagent. This would indicate that aldehydes are not intermediates in the formation of secondary alcohols from esters.[8] This is in sharp contrast to the fact that trimethylacetyl chloride is reduced to neopentyl alcohol even by primary Grignard reagents in yields as high as 60%.[3] *t*-Butylacetyl chloride, however, gave no primary alcohol with the Grignard reagent.[5]

Dimethylethylacetyl chloride reacts with isopropylmagnesium bromide to give products corresponding in structure and yields to those given by trimethylacetyl chloride.[3] This lack of effect of a single ethyl group corresponds to the observations on the related methyl ketones.[1]

We thank Dr. W. A. Mosher of the Hercules Powder Company and R. S. George of this Laboratory for their help.

Experimental

All Grignard reagents were prepared from the corresponding alkyl bromides in the usual manner.[9] The addition of the ester or acid chloride, unless specified, was carried out at room temperature; the rate of addition was about 1 mole per hour. The products were worked up by shaking with cracked ice, separating the ether and steam distilling the residues. The steam distillates were combined with the respective ether extracts. This method minimized any dehydration of the tertiary alcohols. After stripping off the ether, the products were fractionated through columns of 12–15 theoretical plates.

Preparation of Materials.—Trimethylacetic acid was obtained from the oxidation of triisobutylene with sodium dichromate and sulfuric acid.[10] The crude acids from the oxidation were dried and fractionated through a 12-plate column to give material of b. p. 93° (45 mm.). The pure acid was converted to the chloride by treatment with thionyl chloride at steam-bath temperature. The excess thionyl chloride was distilled off, and the crude chloride was fractionated through a 14-plate column to give an 80% yield of material with b. p. 57.6° (150 mm.) and $n^{20}D$ 1.4121–2. The methyl ester was prepared from the acid chloride, either crude or fractionated, by the addition of methanol and subsequent distillation to give the ester, b. p. 99.5° (731 mm.), $n^{20}D$ 1.3891–1.3900; the yield of ester was about 50% from the acid.

t-Butylacetyl chloride, b. p. 79.5° (165 mm.), $n^{20}D$ 1.4210–6, was prepared from the acid in 84% yield by treatment with thionyl chloride. The crude acid chloride was refluxed with methanol; the product was washed with water and sodium bicarbonate solution and fractionated to give a 94% yield of ester, b. p. 128° (735 mm.), $n^{20}D$ 1.3995–9.

Dimethylethylacetic acid was prepared by carbonating *t*-amyl Grignard reagent. The *acid chloride*, b. p. 129.8° (727 mm.), $n^{20}D$ 1.4242–8, was obtained in 50% yield by refluxing with thionyl chloride.

Reaction of Methyl Trimethylacetate with Ethylmagnesium Bromide.—The reaction of 1.87 moles of methyl trimethylacetate with 4.5 moles of ethylmagnesium bromide gave 18.4 g. or 8.6% of ethyl-*t*-butylcarbinol,[3] b. p. 67° (55 mm.), $n^{20}D$ 1.4223–32, and 196.2 g. or 76.5% of diethyl-*t*-butylcarbinol, b. p. 84° (40 mm.), $n^{20}D$ 1.4410–26. No neopentyl alcohol was found.

Reaction of Methyl Trimethylacetate with Isopropylmagnesium Bromide.—The reaction of 1.5 moles of ester with 4.5 moles of the Grignard reagent gave 34.2% of unreacted ester and 87.4 g. or 44.8% of isopropyl-*t*-butylcarbinol; b. p. 75.5° (53 mm.); $n^{20}D$ 1.4268–92; phenylurethan m. p. and mixed m. p. 88–90°. No neopentyl alcohol could be detected.

Reaction of Methyl Trimethylacetate with Isobutylmagnesium Bromide.—The reaction of 0.5 mole of ester with 1.7 moles of the Grignard reagent gave 27.2% of unchanged ketone, 29.4% of isobutyl-*t*-butyl ketone, b. p. 70° (38 mm.), $n^{20}D$ 1.4128–72, 2,4-dinitrophenylhydrazone m. p. and mixed m. p. 94–95°, and 25.7% of isobutyl-*t*-butylcarbinol, b. p. 74° (23 mm.), phenylurethan m. p. and mixed m. p. 114–115.5°. Isobutyl-*t*-butylcarbinol was oxidized to the corresponding ketone, 2,4-dinitrophenylhydrazone m. p. and mixed m. p. 94–95°, by treatment with sodium dichromate and sulfuric acid. No neopentyl alcohol was found.

Reaction of Methyl *t*-Butylacetate with Ethylmagnesium Bromide.—Addition of 1 mole of ester to 4 moles of the Grignard reagent gave 108.4 g. or 68.5% of diethylneopentylcarbinol, b. p. 54° (5 mm.), $n^{20}D$ 1.4394–1.4403, d_{20} 0.845, mol. ref. calcd. 49.6, found, 49.4; and 7.6 g. or 5% of ethyl neopentyl ketone, b. p. 75–80° (63 mm.), $n^{20}D$ 1.4158–63, 2,4-dinitrophenylhydrazone m. p. and mixed m. p. 135–7°.

Reaction of Methyl *t*-Butylacetate with *n*-Propylmagnesium Bromide.—The reaction of 1 mole of ester with 4 moles of the Grignard reagent gave 10.6 g. or 7% of *n*-propyl neopentyl ketone, b. p. 42° (5 mm.), $n^{20}D$ 1.4161–70, semicarbazone m. p. and mixed m. p. 93–5°, 29.3 g. or 20.4% of *n*-propylneopentylcarbinol, b. p. 47.5° (5 mm.), $n^{20}D$ 1.4261–78, phenylurethan m. p. and mixed m. p. 81.5–82°, and 115 g. or 61.8% of di-*n*-propylneopentylcarbinol, b. p. 67° (3 mm.), $n^{20}D$ 1.4423–8, d_{20} 0.8386, mol. ref. calcd., 58.8; found, 58.9. There was no evidence of neopentylcarbinol.

Reaction of Methyl *t*-Butylacetate with Isopropylmagnesium Bromide.—The ester, 1 mole, was added to 4 moles of the Grignard reagent to give 78.6 g. or 55.3% of isopropyl neopentyl ketone, b. p. 107.2° (180 mm.), $n^{20}D$ 1.4114–29, 2,4-dinitrophenylhydrazone m. p. 128–129°, semicarbazone m. p. and mixed m. p. 168–169° and 23.3 g. or 16.1% of isopropylneopentylcarbinol, b. p. 74.8° (25 mm.), $n^{20}D$ 1.4286–95, d_{20} 0.825, mol. ref. calcd., 45.0; found, 45.2, *α-naphthylurethan* m. p. 88–90°.

Anal. Calcd. for $C_{20}H_{27}O_2N$: N, 4.47. Found: N, 4.49.

Reaction of Methyl *t*-Butylacetate with *n*-Butylmagnesium Bromide.—The addition of 0.9 mole of ester to 3.6 moles of Grignard reagent gave 137.4 g. or 71.4% of di-*n*-butylneopentylcarbinol, b. p. 83° (3 mm.), $n^{20}D$ 1.4462–9, d_{20} 0.8403, mol. ref., calcd., 67.96; found, 67.8; a small amount of material believed to be *n*-butyl neopentyl ketone was obtained, semicarbazone m. p. 79–80°, but identification was not conclusive. No *n*-butylneopentylcarbinol was found.

Reaction of Dimethylethylacetyl Chloride and Isopropylmagnesium Bromide.—To 4.16 moles of Grignard reagent was added 1 mole of the acid chloride. The products were *t*-amylcarbinol, 30 g., 29.4%, b. p. 34.5° (7 mm.), $n^{20}D$ 1.4208–12, phenylurethan m. p. and mixed m. p. 65–68°; isopropyl-*t*-amylcarbinol, 76 g., 49.3%, b. p. 52–3° (6.5 mm.), $n^{20}D$ 1.4395–1.4400, d_{20} 0.8489, mol. ref. calcd.,

(10) Unpublished work by C. S. Miner, Jr., in this Laboratory.

44.9; found, 45.0, phenylurethan m. p. 58–59°, *α-naphthylurethan* m. p. 76.5–77.5°.

Anal. Calcd. for $C_{20}H_{27}O_2N$: N, 4.47. Found: N, 4.52.

Reaction of Trimethylacetyl Chloride with Ethylmagnesium Bromide.—The reaction of 2.54 moles of acid chloride with 6.1 moles of the Grignard reagent gave 26.1% of diethyl-*t*-butylcarbinol,[3] b. p. 59.2° (35 mm.), $n^{20}D$ 1.4230 and 60% of ethyl-*t*-butylcarbinol,[3] b. p. 73° (24 mm.), $n^{20}D$ 1.4424–6. No neopentyl alcohol was found.

Reaction of *t*-Butylacetyl Chloride with Isopropylmagnesium Bromide.—The reaction of 1 mole of acid chloride with 4 moles of Grignard reagent gave 32.7% of isopropyl neopentyl ketone, b. p. 61° (26 mm.), $n^{20}D$ 1.4120–9, 2,4-dinitrophenylhydrazone m. p. 128–129°, semicarbazone m. p. and mixed m. p. 168–9° and 26.7% of isopropylneopentylcarbinol, b. p. 76.7° (32 mm.), $n^{20}D$ 1.4283–1.4302, d_{20} 0.825, mol. ref. calcd., 45.0; found, 45.2; *α-naphthylurethan* m. p. 88–90°.

Anal. Calcd. for $C_{20}H_{27}O_2N$: N, 4.47. Found: N, 4.49.

Attempted Reaction of the Methyl Ester of Methyl-*t*-butylneopentylacetic Acid with Methylmagnesium Bromide.—The ester was made from methanol and the acid chloride[6] in 88% yield; b. p. 97–8° (13 mm.), $n^{20}D$ 1.4450–2. The treatment of the ester with the Grignard reagent was carried out in diethyl ether at 34° and in di-*n*-butyl ether at 142°. The lower temperature gave almost quantitative recovery of unreacted ester. At 142° there were obtained a 70.3% recovery of unchanged ester and a 13% yield of methyl-*t*-butylneopentylacetic acid formed by the splitting of the ester.

Reaction of *t*-Butylacetyl Chloride with Isobutylmagnesium Bromide.—The reaction of 0.5 mole of the acid chloride with 1.45 moles of the Grignard reagent gave isobutyl neopentyl ketone, 15.7 g., 0.102 mole, 20.1%, b. p. 65.5° (15 mm.), $n^{20}D$ 1.4127–91; isobutylneopentylcarbinol, 38.6 g., 0.244 mole, 48.9%, b. p. 75° (15 mm.), $n^{20}D$ 1.4237–79, α-naphthylurethan m. p. and mixed m. p. 100–100.5°; diisobutylneopentylcarbinol, 14.7 g., 0.069 mole, 13.8%, b. p. 68.5° (3 mm.), $n^{20}D$ 1.4395–1.4410, d_{20} 0.8317, mol. ref. calcd., 67.96; found, 68.0.

Reaction of Methyl *t*-Butylacetate with Isobutylmagnesium Bromide.—To isobutylmagnesium bromide prepared from 1.7 gram atoms of magnesium and 1.83 moles of isobutyl bromide was added 65 g., 0.5 mole, of the ester. Fractionation gave isobutyl neopentyl ketone, 32.1 g., 0.16 mole, 32%, b. p. 66.4° (15 mm.), $n^{20}D$ 1.4120–98; isobutylneopentylcarbinol, 15.2 g., 0.046 mole, 9.2%, b. p. 43–44° (3 mm.), $n^{20}D$ 1.4232–82, *α-naphthylurethan* m. p. and mixed m. p. 99–101°; diisobutylneopentylcarbinol, 27.0 g., 0.17 mole, 34.2%, b. p. 69.5° (2 mm.), $n^{20}D$ 1.4375–1.4411, d_{20} 0.8313, mol. ref. calcd., 67.96; found, 68.0.

Anal. Calcd. for $C_{21}H_{29}O_2N$: N, 4.26. Found: N, 4.25.

Summary

1. A comparison of the reactions of trimethylacetyl chloride and methyl trimethylacetate and of *t*-butylacetyl chloride and methyl *t*-butylacetate with ethyl, *n*-propyl, isopropyl, *n*-butyl and isobutyl Grignard reagents has been made. The esters were found to give distinctly less reduction products than the corresponding acid chlorides.

2. The fact that no primary alcohol was found in the reaction of the esters with Grignard reagents indicates that aldehydes are not intermediates in this reaction.

3. The methyl ester of methyl-*t*-butylneopentylacetic acid did not react with methyl Grignard reagent at 34° or at 142°.

4. Isopropylneopentylcarbinol and isopropyl-*t*-amylcarbinol have been prepared.

Grignard Reactions. XVIII.[1] Reactions of Benzylmagnesium Chloride

BY FRANK C. WHITMORE AND T. K. SLOAT[2]

The type of rearrangement given by the benzyl Grignard reagent is well known. The first case reported was the reaction of formaldehyde with benzylmagnesium chloride to give *o*-tolylcarbinol instead of the expected benzylcarbinol.[3] The action of a variety of substances with benzylmagnesium chloride has been reported. Not all reactants give rearranged products with this Grignard reagent. The products of rearrangement are usually *o*-tolyl derivatives. In some cases the *p*-tolyl derivative has been reported.[4] Excellent investigations and reviews of the reactions of benzylmagnesium chloride have been made by Gilman and Kirby[5] and by Austin and Johnson.[6] More recently Coleman and Forrester[7] have investigated the action of benzylmagnesium chloride with monochloramine. No rearranged products were found in this case.

The present study was undertaken with the hope that repetition of some of the reactions of benzylmagnesium chloride, on a larger scale and with the fractionating equipment now available, might give some rearranged products with reactants which previously had shown no rearrangement. *The results of previous investigators were confirmed without exception.* Our experiments with benzylmagnesium chloride gave only the normal products with acetonitrile, acetamide, acetaldehyde, carbon dioxide, oxygen, ethyl acetate, benzyl chloride and water. The reaction of the benzyl Grignard reagent with acetyl chloride gave the rearranged product, methyl *o*-tolyl ketone. Temperature was shown to have little effect on the yield of ketone, this being 18% at 0° and 16.5% at 25°.

In our experiments the benzylmagnesium chloride was added to an excess of the reactant unless otherwise specified. The order of addition of the Grignard reagent had a decided effect on the yield of rearranged product. In the reaction of acetyl chloride with benzylmagnesium chloride, the yield of methyl *o*-tolyl ketone was 18% when the Grignard reagent was added to the acid chloride while addition of the acetyl chloride to the Grignard reagent gave only 3% of this ketone. This is in agreement with the work of Schmidlin and Garcia-Banùs[8] who reported similar results with aromatic aldehydes.

Several mechanisms have been proposed for the *o*-tolyl rearrangement.[5,6,9] In an attempt to investigate further the mechanism of this rearrangement, acetyl chloride, toluene and anhydrous magnesium chloride were mixed in diethyl ether and refluxed for several hours. No reaction took place. This type of process is similar to that investigated by Tzukervanik and Sidorova.[10] Furthermore, dry toluene was added to ethylmagnesium chloride and then a large excess of acetyl chloride was added. As in the first of these test reactions, no methyl benzyl ketone or methyl *o*-tolyl ketone could be found.

We thank R. S. George of this Laboratory for his help.

Experimental

The benzylmagnesium chloride used in this work was prepared in the usual manner.[11] Titration showed the yields to be over 90%. All fractionations were done with the usual type of column[12] having 12–18 theoretical plates. The reactions of benzylmagnesium chloride with the compounds investigated were all run according to conventional procedures. In many cases only the fractions in the boiling point ranges of the possible rearranged products were thoroughly investigated. The reaction of acetamide with the benzyl Grignard reagent illustrates the procedure used.

To 59 g., 1 mole, of acetamide was added 3 moles of benzylmagnesium chloride. The reaction products were worked up in the usual way. Fractionation gave 55.3 g. or 41.3% of ketone fraction; b. p. 122–125° (50 mm.). The ketone was characterized by its 2,4-dinitrophenylhydrazone; m. p. 152–153°; a mixed m. p. with derivative of authentic methyl benzyl ketone gave no depression.

The experimental part of the study can best be summarized in table form.

TABLE I

Compound	% Normal primary[a] addition	% Primary[a] rearranged product	Order of addition.[b] Direct—reagent added to soln. of benzylmagnesium chloride
Acetamide	41.3	None	Reverse, excess Grignard reagent
Acetaldehyde	65.6	None	Reverse, excess acetaldehyde
Acetonitrile	15.8[c]	None	Reverse
Carbon dioxide	62.7	None	Direct
Oxygen	69.4	None	Direct
Water	95.3	None	Direct
Benzyl chloride	67.6	None	Reverse
Ethyl acetate	2.7[d]	None	Reverse
Acetyl chloride	Trace	18	Reverse, excess acid chloride
	Trace	16.5	Reverse, ditto[e]
	...	3	Direct, excess acid chloride

[a] These figures represent only the products given by the first step of the Grignard reaction. The high boiling tertiary alcohol fractions were not investigated. [b] Unless specified the Grignard reagent and the reactant were present in equal molecular proportions, and the reaction was run at 0°. [c] About 70% of toluene was also obtained. [d] Yield of high boiling alcohol was about 90%. [e] The reaction temperature was 25°.

Acetyl Chloride, Toluene and Magnesium Chloride.—A mixture of 0.75 mole of toluene and 0.75 mole of magnesium chloride in anhydrous ether was stirred for sixteen hours. To this was added 1.5 moles of acetyl chloride, and the mixture was then refluxed for four days. Fractionation gave no methyl *o*-tolyl ketone or methyl benzyl ketone.

Ethylmagnesium Chloride, Toluene and Acetyl Chloride.—To 1 mole of ethylmagnesium chloride in ether and 1 mole of toluene was added 3 moles of acetyl chloride, and the mixture was refluxed for two days. Fractionation gave no methyl *o*-tolyl ketone or methyl benzyl ketone.

Summary

1. Acetaldehyde, acetonitrile, acetamide and water have been shown to give only normal products with benzylmagnesium chloride.

2. Repetition of the reactions of carbon di-

The Dehydration of Alcohols. XIX.[1-4] *t*-Amyl Alcohol and the Related Dimethylneopentylcarbinol

BY FRANK C. WHITMORE, C. S. ROWLAND,[5] S. N. WRENN AND G. W. KILMER

Despite the amount of work done on the dehydration of alcohols since the discovery of ethylene by the four Dutch chemists in 1795, practically no generalizations of any value have been presented. This is largely because few, if any, cases have been studied with proper control of the variables involved. Moreover, the dehydration mixtures obtained from any but the simplest alcohols are likely to be so complex as to be unmanageable with ordinary equipment and techniques.[1] Even with a simple alcohol like *t*-amyl alcohol (I) the results in the literature are highly conflicting.[6] In all this work the only consistent fact is that trimethylethylene (IV) is the chief product. The different proportions of olefins obtained by different investigators indicated that equilibrium conditions had not been obtained for the olefin mixture. The unasked question as to whether the olefin mixture obtained by dehydration of an alcohol is identical with the equilibrium mixture of the olefins has long existed. For strongly acid catalysts this question was answered in the affirmative in this Laboratory when essentially identical mixtures of olefins were obtained by passing the following over phosphoric acid on silica gel: (a) methyl-*t*-butylcarbinol, (b) *t*-butylethylene, (c) 1,1-methylisopropylethylene and (d) tetramethylethylene.[7] Recently Cramer and Glasebrook[8] published their results with a less acidic catalyst, namely, activated alumina, in which they obtained high yields of *t*-butylethylene from methyl-*t*-butylcarbinol instead of the 3–5% of that olefin characteristic of the equilibrium mixture.[7b] These results have been repeatedly checked in this Laboratory.[9] The method of Cramer and Glasebrook[8] is now recommended for the preparation of large quantities of *t*-butylethylene as more convenient than the pyrolysis of pinacolyl acetate.[10]

It may be mentioned in passing that making the catalyst even slightly alkaline prevents dehydration at anything below cracking temperatures.[11]

Since 1930 there have been repeated indications in this Laboratory that the two alcohols *t*-amyl alcohol (I) and dimethylneopentylcarbinol (II) behave differently on dehydration. This is in spite of remarkable similarities in structure. Both are tertiary alcohols containing two methyl groups and a methylene group and both are dehydrated readily without rearrangement. In each, the proton for dehydration must come from one of the two methyl groups or from the methylene group. The only difference is that in one the methylene group is attached to methyl while in the other it is attached to *t*-butyl. Evidently this difference has a profound effect on the otherwise identical methylene groups.

$$(CH_3)_3C-CH_2-\underset{CH_3}{\overset{OH}{C}}-CH_3 \longrightarrow$$

(II)

$$(CH_3)_3C-CH_2-\underset{CH_3}{C}=CH_2 + (CH_3)_3C-CH=\underset{CH_3}{C}-CH_3$$

(V) (VI)

This pair of alcohols was chosen for study because of the facts given above. Moreover, they are both dehydrated by refluxing with an excess of 15% sulfuric acid. This allows dehydration under almost identical conditions and avoids the vigorous treatment required to dehydrate primary or secondary alcohols. The olefins III and IV are readily separable in a 60-plate column.[12] This Laboratory had long been familiar with olefins V and VI, the well-known diisobutylenes.[13]

Repeated dehydrations of the alcohols, I and II, with 15% sulfuric acid and careful study of the resulting olefin mixtures indicate that *t*-amyl alcohol (I) gives 1,1-methylethylethylene (III) and trimethylethylene (IV) in the ratio 1:7 while dimethylneopentylcarbinol (II) gives 1,1-methylneopentylethylene (V) and 1,1-dimethyl-2-*t*-butylethylene (VI) in the ratio 4.5:1. Thus, a methylene group attached to methyl loses a proton about 30 times as readily as a methylene attached to *t*-butyl. In other words, an ethyl group loses a proton much more readily than does a neopentyl group. This greater activity of the ethyl group has been observed repeatedly in this Laboratory.[3b] The sluggishness of the neopentyl group in this respect is well illustrated by the dehydration of diethylneopentylcarbinol, which takes place 90% from the ethyl group to yield 2,2-dimethyl-4-ethyl-4-hexene.[3c] The dehydration of 3,5,5-trimethyl-3-heptanol indicates an even more sluggish behavior for the neohexyl group (*t*-amylcarbinyl).[4]

A good example of the difficulty of drawing generalizations regarding the dehydration of alcohols is given by a comparison of dimethylneopentylcarbinol and methylneopentylcarbinol.[3a] As stated above, the former gives dehydration from the two methyl groups and the one neopentyl group in the ratio of 4.5:1. It might thus be argued that *one* methyl group would give up a proton about twice as readily as one neopentyl group. This is contrary to the fact[3a] that methylneopentylcarbinol undergoes dehydration from the one methyl group and the one neopentyl group in the ratio of about 1:4:5. The fallacy here lies in comparing a tertiary alcohol with a secondary alcohol, the one being dehydrated with excess 15% sulfuric acid at about 100° and the other with a small amount of 100% sulfuric acid at perhaps 135°.

In connection with the present work it should be noted that the ratio 4.5:1 for the olefins V and VI checks with the equilibrium present in the diisobutylenes.[13] The equilibrium between III and IV is being studied. It has been found that 15% sulfuric acid does not isomerize either III or IV.

The dehydration of alcohols and the study of equilibrium relations of the resulting olefin mixtures is being continued.

We thank Dr. W. A. Mosher of the Hercules Powder Co. for help in the preparation of this paper.

Experimental

Materials.—Commercial *t*-amyl alcohol, Sharples, was fractionated through a 15-plate column to give material of b. p. 101° (742 mm.), $n^{20}D$ 1.4049. Dimethylneopentylcarbinol was prepared by the action of methylmagnesium bromide on methyl neopentyl ketone, $n^{20}D$ 1.4038. The product, after decomposition in the usual manner, was fractionated through a 10-plate column to give material of b. p. 70.5° (43 mm.), $n^{20}D$ 1.4286.

Dehydration of *t*-Amyl Alcohol.—*t*-Amyl alcohol, 319 g., was dissolved in 395 ml. of 15% sulfuric acid and refluxed under a column of 60 theoretical plates while the olefins formed distilled out. The yield of olefin was 97.8% allowing for 16.7 g. of recovered alcohol. The olefin mixture, 227 g., was dried over potassium carbonate and fractionated through a 60-plate column with 0.5 g. of potassium carbonate in the still pot to prevent isomerization. Ice-water was circulated through the condenser and receiver system while dry-ice traps protected all outlets. The loss on distillation was 2%.

Two olefins were found on fractionation: 2-methyl-1-butene, 27 g., 33–35° (740 mm.), 1.3788, 11.9%; and 2-methyl-2-butene, 195 g., 39.5° (740 mm.), 1.3870, 85.9%. The structures were confirmed by ozonolysis.

Dehydration of Dimethylneopentylcarbinol.—The alcohol, 150 g., was dehydrated by refluxing with an equal weight of 15% sulfuric acid under a 10-plate column and distilling off the olefins as formed. Taking 33 g. of recovered carbinol into account, the yield of olefin was 96%. Distillation of the olefin through a 60-plate column gave 2,4,4-trimethyl-1-pentene, 77.2 g., 78%, 103° (742 mm.), 1.4086–8; and 2,4,4-trimethyl-2-pentene, 17.7 g., 17%, 106.5 (740 mm.), 1.4152–5. The identity of these olefins has been repeatedly checked by ozonolysis in this Laboratory.

Summary

1. The difficulty in drawing generalizations on the dehydration of alcohols is emphasized.

(12) Rose, *Ind. Eng. Chem.*, **33**, 594 (1941); Fenske, Tongberg, Quiggle and Cryder, *ibid.*, **28**, 644–5 (1936).

(13) Whitmore and co-workers, THIS JOURNAL, **53**, 3136 (1931), **54**, 3706, 3710 (1932).

2. The relation of acidity of the dehydrating catalyst to the equilibrium in the resulting olefin mixture is considered.

3. Two closely related tertiary alcohols have been dehydrated under mild but definitely acidic conditions. In *t*-amyl alcohol and dimethylneopentylcarbinol, under similar conditions, the ethyl group yields a proton in dehydration about thirty times as readily as does the neopentyl group.

Factors Determining the Course and Mechanism of Grignard Reactions. V. The Effect of Metallic Halides on the Reaction of Grignard Reagents with Benzalacetophenone and with Benzophenone

BY M. S. KHARASCH AND D. C. SAYLES

It has been shown that small amounts of some metallic halides exert a profound effect on the reactions of Grignard reagents with many compounds.[1] The present paper describes the results obtained when methyl- and ethylmagnesium bromides react with benzalacetophenone (chalcone) and benzophenone in the presence of ferric chloride, cuprous chloride, manganous chloride or cobaltous chloride.

The structures of the products formed by the addition of Grignard reagents to some α,β-unsaturated aldehydes and ketones have been determined by Kohler and his co-workers.[2] They report that, with chalcone, phenyl- and ethylmagnesium bromides give, respectively, 94 and 99% of the 1,4-addition product.[2c] The reaction between methylmagnesium bromide and chalcone has not been investigated, but Kohler reports that methylmagnesium bromide reacts with benzalethyl methyl ketone to give 70% of the 1,4-addition product. Smith and Hanson,[3] on the other hand, record only the 1,2-addition product of benzalpropiophenone and methylmagnesium iodide.

It is desirable to elucidate the conditions under which an optimum yield of β-phenylbutyrophenone (the 1,4-addition product) is obtained by condensation of methylmagnesium bromide with chalcone. Kohler and Peterson[2d] state explicitly that an excess of Grignard reagent is necessary to prevent the formation of "secondary" products, but they do not mention the exact proportion of the reagents employed. In the experiments here reported in detail, a 40% excess of Grignard reagents was used, and (Table I) large quantities of 1,3,5-triphenyl-4-benzoylhexadiene-1,3 (m. p. 176°) (III) were produced, probably according to the equation

$$\underset{\text{I}}{C_6H_5CH(CH_3)CH_2COC_6H_5} + \underset{\text{II}}{C_6H_5CH{=}CHCOC_6H_5} \xrightarrow{CH_3MgBr} C_6H_5CH(CH_3)C(COC_6H_5){=}C(C_6H_5'){-}CH{=}CHC_6H_5$$

III

The structure of III was confirmed by independent syntheses from I and II where pyridine, trimethylamine or sodium ethylate was used as condensing agent. Other experiments showed that in order to avoid completely the formation of III, a very large excess of the Grignard reagent (200%) was required.

Although (Table I) no one of the metallic halides (2 to 5 mole per cent.) has any effect on the ratio of the 1,2 and 1,4 addition of methylmagnesium bromide to chalcone, yet they profoundly influence the nature of the products formed in the reaction. This effect is most marked with cobaltous chloride. In the presence of this metallic halide the Grignard reagent does not add to the chalcone, but acts as a reducing agent leading to the formation of two products which melt at 197 and 276°, respectively.

$$C_6N_5CH{=}CHC_6H_5 + 2CH_3MgBr \xrightarrow{CoCl_2} [(C_6H_5COCH_2\underset{|}{C}HC_6H_5)]_2$$

(IV, m. p. 197° and V, m. p. 276°)

These two substances (IV and V) were shown by analyses, molecular weight determinations and the melting points of mixtures to be identical

Stereoisomer of (II), m. p. 276° (V)	..	4	..	..	18

[a] A 40% excess of Grignard reagent was used in all experiments. [b] Total yield of products was between 93 and 95% of the amount calculated on the basis of chalcone used. [c] One mole per cent. was added at the beginning of the reaction, and another mole per cent. midway in the addition of the chalcone.

with products previously obtained by reducing chalcone with zinc dust and glacial acetic acid,[4] or with vanadous sulfate.[5] Substance IV is considered to be 1,4-dibenzoyl-2,3-diphenylbutane because it readily undergoes intramolecular condensation to form a cyclopentene derivative.[4] Substance V is regarded as a stereoisomer of IV, since distillation partly converts it into that substance.

Compounds IV and V have not hitherto been observed as products in the reaction of any Grignard reagent on chalcone. They are, however, formed whenever chalcone is treated with a powerful reducing agent or with methylmagnesium chloride in the presence of small amounts of cobaltous chloride. The latter reaction is readily explained by the chain mechanism proposed by Kharasch and Fields[1d] to account for the catalytic effects of cobaltous, nickelous and ferrous chlorides on certain Grignard reactions.

$$CH_3MgBr + CoCl_2 \longrightarrow CH_3CoCl + MgBrCl$$
$$CH_3CoCl \longrightarrow CH_3 + (CoCl)$$
$$(ClCl) + C_6H_5CH{=}CHCOC_6H_5 \xrightarrow{MgBrCl} C_6H_5CHCH{=}CC_6H_5 + CoCl_2$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OMgBr$$
$$2C_6H_5CHCH{=}CC_6H_5 \xrightarrow[\text{and hydrolysis}]{\text{dimerization}} C_6H_5COCH_2CHC_6H_5CHC_5H_5CH_2COC_6H_5$$
$$\qquad\qquad\qquad\quad OMgBr \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \text{IV and V}$$

In all such catalytic reactions the rate of the reaction and the stability of the compound RCoCl at the temperature used are highly important. Their influence is illustrated in the reaction of ethylmagnesium bromide and benzophenone. At ordinary temperatures (20–25°) ethylmagnesium bromide adds to benzophenone either in the presence or in the absence of cobaltous chloride to give diphenylethylcarbinol; no reduction to benzopinacol or benzohydrol occurs.[6] However, at −12°, a 50% yield of benzopinacol is readily obtained even though only 2 mole per cent. of cobaltous chloride is used. This large temperature effect is explained by the fact that at higher temperatures C_2H_5CoCl decomposes almost instantaneously with the liberation of metallic cobalt. Thus no chain reaction of the kind indicated is initiated.

Phenylmagnesium bromide, when added to chalcone, yields by 1,4 addition a saturated ketone, the product isolated by Kohler. The presence of small amounts of metallic halides has little effect on the course of this reaction; it is, however, significant that in the presence of ferric or cobaltous chloride (2–5 mole per cent.) even this Grignard reagent yields 2–5% of V.

The results here reported for the addition of ethylmagnesium bromide to chalcone differ considerably from the 94% of 1,4 addition reported by Kohler. In a number of experiments a 60% yield of the saturated ketone (β-phenylvalerophenone VI) was obtained. The remaining 40% was an oil which could not be crystallized. This oil readily absorbed bromine and decolorized potassium permanganate solution; it gave no ketonic reactions, and could not be acetylated by acetic anhydride in pyridine. It decomposed when distilled *in vacuo*. The only feasible method for purifying this oil was first to free it of ketonic materials by shaking it with a water solution of acethydrazide pyridinium chloride,[7] and then to decolorize an ethyl alcohol solution of the water insoluble residue with norite. Evaporation of the alcohol again yielded an oil. Analysis of this oil indicated that it is probably styrylphenylethylcarbinol (VII). The additions of ethyl- and methylmagnesium bromide to chalcone thus differ significantly in the proportion of 1,2- and 1,4-addition products formed.

The discrepancy between the results here reported and those obtained by Kohler is not to be explained by the order in which the reagents are

$$C_6H_5CH{=}CHCOC_6H_5 + C_2H_5MgBr \begin{cases} \xrightarrow{1,4\ \text{Addition}} C_6H_5CH(C_2H_5)CH_2COC_6H_5\ \text{(VI)},\ 60\% \\ \xrightarrow{1,2\ \text{Addition}} C_6H_5CH{=}CHC(OH)(C_2H_5)C_6H_5\ \text{(VII)},\ 40\% \end{cases}$$

added to the reaction mixture. For the present no explanation can be offered.

The effect of temperature on the direction of addition of ethylmagnesium bromide to chalcone is slight. The amount of 1,2 addition is about 20–30% less at low temperatures (−25°) than at 25°.

Experimental Part

The organic compounds used were first purified by distillation or crystallization. Methyl bromide was obtained from the Dow Chemical Company. Benzalacetophenone was prepared according to "Organic Syntheses."[8] The cuprous chloride was the commercial anhydrous reagent; anhydrous manganous chloride was prepared by heating the hydrated chloride in an oven for eight hours at 120°; anhydrous ferric chloride was prepared from analytical grade iron wire and chlorine; anhydrous cobalt chloride was prepared by heating the hydrated dihalide at 150° in a stream of hydrogen chloride.

Preparation of Grignard Reagent.—Each Grignard reagent (prepared from sublimed magnesium) was siphoned from the reaction vessel through a glass tube filled with a glass wool plug into a dark storage bottle. Two milliliter aliquots were removed for standardization by the acid titration method.

General Procedure.—Aliquot parts of the Grignard reagent were transferred to three-necked flasks, each fitted with reflux condenser, mercury seal stirrer, dropping funnel and calcium chloride tubes. One flask was used as a control. Weighed quantities of anhydrous metal halides were added to the other flasks. The Grignard solution upon the addition of the metal salts changed color. Cobalt chloride produced a black solution; cuprous chloride, a blue-green solution; manganous chloride, a yellow solution.

Reaction of Methylmagnesium Bromide and Chalcone.—Benzalacetophenone (0.19 mole) dissolved in anhydrous ether was added drop by drop to an excess of Grignard reagent (0.26 mole). During the addition, the temperature of the reaction mixture was maintained at 0–5°. After addition was complete, the reaction mixture was stirred for an additional thirty minutes; then the temperature was allowed to rise; finally, the mixture was refluxed for one hour and allowed to stand.

The reaction mixture was decomposed by pouring it onto 200 g. of cracked ice mixed with excess glacial acetic acid (25 cc.). The solution was filtered. The ethereal layer was separated, and the aqueous layer was extracted with ether. The combined ethereal layers after being washed with aqueous bicarbonate and water, were dried over anhydrous sodium sulfate. The ether was finally evaporated. The ethyl alcoholic extract of the residue (when methylmagnesium bromide was used) yielded a substance melting at 72°. The material insoluble in alcohol after crystallization from an ethanol–dioxane mixture yielded a compound melting at 176°.

Anal. Calcd. for $C_{31}H_{26}O$: C, 89.83; H, 6.28; mol. wt., 414. Found: C, 89.20; H, 6.90; mol. wt., 400.

The structure of this latter compound was proved by its synthesis. To an anhydrous ether solution of 0.5 g. of chalcone and 0.5 g. of β-phenylbutyrophenone was added a condensing agent (either pyridine or methylmagnesium bromide), the whole mixture was refluxed for one hour. The solvent was evaporated, and the residue crystallized from a mixture of ethanol and dioxane. A quantitative yield of a solid melting at 176° was obtained. This melting point was not lowered by addition of the compound (m. p. 176°) obtained from the reaction of methylmagnesium bromide with chalcone.

Dibenzyldiacetophenone.—In the experiments in which ferric, cuprous or cobalt chloride was used as a catalyst, a solid separated at the ether–water interface, when the reaction mixture was decomposed. This solid, when crystallized from an ethanol–dioxane mixture, melted at 197–198°. The material insoluble in the ethanol–dioxane, after crystallization from pyridine, melted at 276°.

Determination of β-Phenylvalerophenone (VI).—In the reactions between ethylmagnesium bromide and chalcone, the dried ethereal solution obtained as described above was transferred to a 100-cc. volumetric flask and made up to volume. A 5-cc. aliquot was removed to a weighed 50-cc. Erlenmeyer flask, the solvent evaporated and the flask reweighed. The total weight of product was thus obtained.

The ketonic material in this oil was determined by precipitation with 2,4-dinitrophenylhydrazine.[9] The validity of this method of analysis was checked by control precipitations on chalcone and β-phenylvalerophenone.

Separation of the β-Phenylvalerophenone from Styrylphenylethylcarbinol (VII).—An aliquot of the ethereal solution was taken, and the solvent evaporated. The residue was dissolved in absolute alcohol containing 10% acetic acid and acethydrazide pyridinium chloride.[8] The reaction mixture was then refluxed for an hour, and finally decomposed by being poured into ice-water containing sodium carbonate. The aqueous solution was extracted several times with ether, and the combined ethereal extracts were washed with water. When the solvent was evaporated, the unsaturated alcohol, styrylphenylethylcarbinol, was obtained.

Anal. Calcd. for $C_{17}H_{18}O$: C, 85.71; H, 7.56, mol. wt., 238. Found: C, 84.68; H, 7.84; mol. wt., 269.

Estimation of Styrylphenylethylcarbinol (VII) by Oxidation.—The solvent was evaporated from an aliquot of the ethereal solution, and the residue was dissolved in purified acetone. Finely powdered potassium permanganate was added to the solution, and the whole was vigorously stirred. The temperature was kept below 20°. The unused potas-

(8) "Org. Syn." Coll. Vol. I, p. 71.

(9) Cooper, Ph.D. Thesis, University of Chicago.

sium permanganate was finally titrated. The accuracy of this oxidation method was checked by oxidation of chalcone.[2]

An unusual compound was isolated in one determination where manganous chloride was used as a catalyst. The ethereal solution was evaporated, and the residue crystallized from alcohol. A solid which melted at 136° was obtained.

Anal. Calcd. for $C_{32}H_{32}O_2$: C, 85.71; H, 7.14; mol. wt., 448. Found: C, 85.82; H, 7.14; mol. wt., 470.

This compound could possibly be formed by the condensation of β-phenylvalerophenone and chalcone in a manner similar to the substance obtained from β-phenylbutyrophenone and chalcone. This compound yielded a 2,4-dinitrophenylhydrazone.

Anal. Calcd. for $C_{38}H_{36}O_8N_4$: N, 8.92. Found: N, 9.11.

The compound could not be synthesized by condensing β-phenylvalerophenone with chalcone when either pyridine or ethylmagnesium bromide was used as a condensing agent.

Addition of Benzophenone to Ethylmagnesium Bromide.—Benzophenone (0.5 mole) in 40 cc. of anhydrous benzene was added slowly to a 100% excess of ethylmagnesium bromide containing 6 mole per cent. of cobaltous chloride. The temperature of the reaction was kept below 20°. A mixture of diphenylethylcarbinol and diphenylpropylene was obtained. The reaction product was dehydrated to diphenylpropylene by distillation with a trace of iodine. The yield was quantitative.

Benzophenone, 0.05 mole, in 40 cc. of anhydrous benzene containing 6 mole per cent. of cobaltous chloride was slowly added to 100% excess of ethylmagnesium bromide; the reaction temperature was kept at −12°. The reaction mixture was then stirred for two hours at −12°, and allowed to stand overnight at room temperature. By the usual methods of isolation, benzopinacol (45%) and diphenylethylcarbinol (55%) were obtained from this mixture.

Summary

1. The effect of some metallic chlorides on the reaction of Grignard reagents with benzalacetophenone has been studied.

2. It has been shown that manganous chloride has little catalytic effect on the reaction between methylmagnesium bromide or iodide and chalcone. Cobalt chloride is a powerful catalyst for the formation of reduction dimers. Cuprous and ferric chlorides are intermediate in their catalytic effect.

3. Metallic halides do not markedly affect the reaction between ethylmagnesium bromide and chalcone; they slightly favor 1,2 addition. Variations in temperature and in the order of addition of the reagents also produce only a slight effect.

4. Benzophenone at 25° reacts with ethylmagnesium bromide containing cobalt chloride to give only the addition product. Benzophenone at −12° reacts with ethylmagnesium bromide containing cobalt chloride to give both benzopinacol and diphenylethylcarbinol.

Carboxylation. IV. Direct Introduction of the Chloroformyl (—COCl) Group into Alicyclic and Aliphatic Acid Chlorides

BY M. S. KHARASCH, KENNETH EBERLY AND MORTON KLEIMAN

In the course of work on the introduction of the chloroformyl (—COCl) group[1] into cyclohexane by the use of trichloromethyl chloroformate, there was obtained under optimum conditions (six hours of heating at 225°) a 3% yield of a disubstitution product, identified as 1,1-dichloroformylcyclohexane by hydrolysis to cyclohexane-1,1-dicarboxylic acid. Despite careful search, no hexahydrobenzoyl chloride could be detected.

This rather striking result suggested that diphosgene reacts more readily with hexahydrobenzoyl chloride than with cyclohexane. Upon further investigation, it was found that ten hours of heating of hexahydrobenzoyl chloride with diphosgene in a sealed tube at 225°, subsequent hydrolysis of the reaction product, and crystallization of the hydrolyzate from an ether–ligroin mixture, gave an 81% yield of cyclohexane-1,1-dicarboxylic acid.

In a like manner, diphosgene reacts with isobutyryl chloride to give a 70% yield of dimethylmalonyl chloride; with α-ethylbutyryl chloride to give a 90% yield of diethylmalonyl chloride; and with α-ethylhexoyl chloride to give a 30% (or possibly higher) yield of ethylbutylmalonyl chloride. In many experiments with propionyl chloride and diphosgene, however, the maximum yield of methylmalonic acid was only 15%. No

(1) For previous references, see Kharasch, Kane and Brown, THIS JOURNAL, **64**, 1621 (1942).

malonic acid was obtained from acetyl chloride. With phenylacetyl chloride, the best yield of phenylmalonic acid so far obtained is only 2%.

From these findings, it appears that a chloroformyl group derived from diphosgene readily replaces a tertiary hydrogen atom on the α carbon atom of an acid chloride. The same reagent replaces secondary hydrogen atoms with considerable difficulty (if low yield be regarded as a criterion). Replacement of a primary hydrogen atom by this method seems to be impossible.

Experimental

Reaction of Cyclohexane with Diphosgene.—A mixture of 7 g. of cyclohexane and 8.3 g. of diphosgene was sealed in a bomb-tube and heated for ten hours at 225°. The tube was then allowed to come to room temperature, cooled by immersion in liquid nitrogen, and opened. After allowing the volatile products to boil away, the content of the tube was poured into water, allowed to stand for a few hours at room temperature, and finally evaporated to dryness on a steam-bath. A solid material (0.2 g.) which melted at 172° (dec.) was thus obtained. This substance, after crystallization from a mixture of ether and ligroin, melted at 178° (dec.) and did not depress the melting point of a known sample of cyclohexane-1,1-dicarboxylic acid.[2]

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.78; H, 7.03. Found: C, 55.59; H, 6.96.

The cyclohexane-1,1-dicarboxylic acid was further identified by decarboxylation (at 200°) to the hexahydrobenzoic acid and conversion of the latter substance (with the aid of thionyl chloride and ammonia) to the known hexahydrobenzamide (m. p. 186°).

Anal. Calcd. for $C_7H_{13}ON$: N, 11.02. Found: N, 11.01.

The volatile components were distilled from the mixture obtained by the interaction of cyclohexane and diphosgene. In order to prepare the diamide of cyclohexane-1,1-dicarboxylic acid, the residue was poured into a large excess of aqueous ammonia. The dark sludge which separated was taken up in hot dilute alcohol, treated with bone black, and filtered. The filtrate was reduced to a small volume and allowed to stand. Small, colorless crystals melting at 261° were obtained. The melting point of this material was not altered by further crystallization from dilute alcohol. *Anal.* Calcd. for $C_8H_{14}O_2N_2$: N, 16.47. Found: N, 16.21. The melting point of this diamide recorded by Dox and Yoder[2] is 237°. The reason for this discrepancy is unknown.

Preparation of Cyclohexane-1,1-dicarboxylic Acid from Hexahydrobenzoyl Chloride.—A mixture of 4 g. of hexahydrobenzoyl chloride and 5.4 g. of diphosgene was heated for ten hours in a sealed tube at 225°. The bomb-tube, after being cooled in the usual manner, was opened, and the volatile products were allowed to boil away. The residue was then hydrolyzed with water. When the water solution was evaporated to dryness, 3.8 g. of crude cyclohexane-1,1-dicarboxylic acid (m. p. 170°) was obtained. This yield is 81% of that calculated on the basis of the amount of hexahydrobenzoyl chloride used. Recrystallization (with bone black) of the crude product from an ether–ligroin mixture gave colorless crystals of the acid melting at 176° (dec.).

Synthesis of Dimethylmalonyl Chloride by Interaction of Isobutyryl Chloride with Diphosgene.—A mixture of 3 g. of isobutyryl chloride and 2 g. of diphosgene was sealed *in vacuo* in a heavy glass bomb-tube and heated for ten hours at 225°. The bomb-tube was cooled to −80° before opening. The combined products of eleven such bomb reactions, when fractionated, yielded unreacted isobutyryl chloride (5.2 g.) and dimethylmalonyl chloride (31 g.), b. p. 153–159° (749 mm.). The dimethylmalonyl chloride was further identified by hydrolyzing it to the corresponding dimethylmalonic acid, m. p. 187°. The yield of dimethylmalonyl chloride, based upon the amount of isobutyryl chloride consumed in the reaction, was 70%.

Synthesis of Diethylmalonyl Chloride by the Interaction of α-Ethylbutyryl Chloride with Diphosgene.—A mixture of 4 g. each of α-ethylbutyryl chloride and diphosgene was sealed *in vacuo* in a heavy glass bomb-tube and heated at 225° for ten hours. The combined products of ten such bomb-tube reactions, when fractionated, yielded 9 g. of unreacted ethylbutyryl chloride and 39.4 g. of diethylmalonyl chloride (b. p. 190–194°). This yield is 90% of that calculated from the amount of ethylbutyryl chloride consumed in the reaction. The diethylmalonyl chloride was further identified by preparing the known diamide, m. p. 224–226° (cor.).

Synthesis of Ethylbutylmalonyl Chloride by the Interaction of α-Ethylhexoyl Chloride with Diphosgene.—Many attempts were made to carry out this reaction in glass bomb-tubes; however, except when extremely small amounts of reactants were used, the bomb-tubes exploded. A steel bomb proved more satisfactory. But, unfortunately, despite all efforts to make this bomb gas-tight, it leaked slightly at the high pressure produced during the reaction. In this steel bomb, a mixture of 25 g. of ethylhexoyl chloride and 35 g. of diphosgene was heated ten hours at 225°. The reaction mixture when fractionated yielded 3.5 g. of unreacted ethylhexoyl chloride, and 9 g. of crude ethylbutylmalonyl chloride, b. p. 190–220°; the latter was identified by hydrolyzing it to the known ethylbutylmalonic acid, m. p. 116–117°. Since the yield of ethylbutylmalonyl chloride (based upon the amount of the ethylhexoyl chloride consumed in the reaction) was 30%, it seems likely that, with satisfactory apparatus, a higher yield of this acid chloride may be obtained.

Reaction of Propionyl Chloride with Diphosgene.—A mixture of 3.5 g. of propionyl chloride and 7.5 g. of diphosgene was heated in a bomb-tube for ten hours at 225°. After cooling and opening the tube in the usual manner, the content was hydrolyzed with water and the solution evaporated to dryness on a water-bath. A 15% yield (0.65 g.) of crude methylmalonic acid was thus obtained. Crystallization (with bone black) of this product from an ether–ligroin mixture gave colorless crystals of methylmalonic acid [m. p. 132–133° (dec.)].

Reaction of Phenylacetyl Chloride with Diphosgene.—A mixture of 4 g. of phenylacetyl chloride with 5.1 g. of

(2) Dox and Yoder, THIS JOURNAL, **43**, 1366 (1921); Vogel, *J. Chem. Soc.*, **123**, 1487 (1929), report a melting point of 179.5° (dec.).

diphosgene was heated in a bomb-tube for ten hours at 150–175°. After cooling and opening the tube in the usual manner, the reaction mixture was hydrolyzed with water (over a period of twelve hours at room temperature), and evaporated to dryness on a water-bath. Since phenylmalonic acid is readily decarboxylated, the last traces of water were removed by drying the product over phosphorus pentoxide *in vacuo*. The mixture of phenylacetic acid and phenylmalonic acid thus obtained (3.8 g.) was decarboxylated at 220°. The carbon dioxide evolved was collected quantitatively. From the amount of carbon dioxide formed, it is estimated that the phenylmalonic acid present in the reaction mixture amounted to a 1.4% yield.

Summary

1. It has been demonstrated that the chloroformyl (—COCl) group can be directly introduced (at the α carbon atom) into aliphatic and aryl-substituted-aliphatic acid chlorides by the use of trichloromethylchloroformate (diphosgene) as the "carboxylating" agent.

2. The experimental conditions requisite for carrying out this type of carboxylation have been determined.

3. The syntheses with good yields of several di-substituted malonyl chlorides have been described.

4. The chloroformyl group (derived from diphosgene) replaces hydrogen atoms attached to the α carbon atoms of acid chlorides most easily when these α carbon atoms are tertiary and least easily when they are primary.

Alkylation of Amines. I[1]

BY JOHN H. BILLMAN, A. RADIKE AND B. W. MUNDY

The esters of sulfuric,[2] sulfurous,[3] and *p*-toluenesulfonic acids[4] have been used frequently for the alkylation of amines. Now that the methyl, ethyl and *n*-butyl esters of orthophosphoric acid have become readily available within recent years,[5] it was of interest to investigate the possibility of using these esters as alkylating agents for amines since Noller[6] has shown that they may be used to alkylate phenols.

All of the esters investigated appeared to be non-toxic under normal conditions and were quite stable toward hydrolysis. Three-quarters of an hour was required to saponify triethyl phosphate completely when boiled with the calculated amount of sodium hydroxide.

It was found that all three groups in the ester could be utilized in the alkylation. The reaction may be represented by the equation

$$3ArNH_2 + 2(RO)_3PO \longrightarrow 3Ar\text{—}\overset{R}{N}\text{—}R + 2H_3PO_4$$

Several attempts to alkylate *p*-nitroaniline by this method resulted in failure. The conditions necessary to effect alkylation resulted in decomposition.

When branched chain alkyl orthophosphates such as isopropyl phosphate were used, practically pure isopropylaniline was obtained.

The authors wish to thank the Commercial Solvents Corporation for some of the phosphate esters used in this work.

Experimental

Preparation of Orthophosphate Esters.—The *n*-propyl and the isopropyl esters of orthophosphoric acid were prepared from phosphorus oxychloride and the proper alcohol similar to the method described in "Organic Syntheses."[7] The yield of *n*-propyl phosphate was 54%, while that of the isopropyl phosphate was 65%.

Procedure for Alkylation of Amines.—A mixture of 0.3 mole of the amine and 0.2 mole of trialkyl phosphate in a 500-cc. flask provided with a condenser and boiling chips was refluxed at a moderate rate for two hours. In most cases, during the early stages of heating, the reaction became vigorous and the temperature rose sharply. As soon as rapid boiling ceased the stream of water in the condenser jacket was replaced by one of air. The mixture was then cooled to 50°, 25 g. of sodium hydroxide in 100 ml. of water added and the whole refluxed one hour, and then poured into a 400-cc. beaker where it was allowed to cool to room temperature. The oily layer of amine, which formed on top, was poured off from the solid sodium phosphate. The latter was extracted with ether and the combined extracts and oil dried over anhydrous sodium sulfate. The ether was then removed, the residue treated with an equal volume of acetic anhydride and allowed to stand overnight.

Ester	Primary amine	Tertiary amine	Yield, %
Methyl phosphate	Aniline	Dimethylaniline	67.9
Methyl phosphate	β-Naphthylamine	Dimethyl-β-naphthylamine	64.4
Ethyl phosphate	Aniline	Diethylaniline	99.0
Ethyl phosphate	α-Naphthylamine	Diethyl-α-naphthylamine	60.0
n-Propyl phosphate	Aniline	Di-*n*-propylaniline	78.1
Butyl phosphate	Aniline	Di-*n*-butylaniline	78.5

The mixture was treated with 20 ml. of concd. hydrochloric acid dissolved in 30 ml. of water and shaken until the base dissolved. The solution was extracted with two 30-ml. portions of ether and the water layer treated with a 25% sodium hydroxide solution to free the base. The oil which formed was collected by extracting the mixture with ether. The ether was dried over anhydrous sodium sulfate and distilled to recover the tertiary amine.

The yield of isopropylaniline from isopropyl phosphate and aniline was 80.5%.

The boiling points of the amines and the melting points of their solid derivatives corresponded to those found in the literature.

Summary

A method has been developed for the preparation of tertiary amines by treating an aromatic amine with alkyl esters of orthophosphoric acid. Six tertiary amines have been prepared in 60 to 99% yield by this procedure.

Physical Properties of Terpenes. I. The System α- and β-Pinene[1a]

BY ROBERT E. FUGUITT, W. DAVID STALLCUP[1b] AND J. ERSKINE HAWKINS

A knowledge of the physical properties of binary mixtures of α- and β-pinene is necessary for some phases of study of American gum turpentine which is composed largely of these two substances.[1c]

Data in the literature show a wide variation in the values for the physical constants for α- and β-pinene. Since it was desired to make a study of binary mixtures of these compounds, it was necessary first to establish constants for the pure substances.

With efficient fractionating columns it is possible to obtain α- and β-pinenes which, the authors believe, are of a higher degree of purity than has been reported heretofore. In a previous publication[2] the authors have shown that the spiral screen type of column developed by Lecky and Ewell[3] is well suited for the purification of α- and β-pinene.

Preparation of α-Pinene and β-Pinene

α-Pinene was prepared by the careful fractionation of four liters of commercial α-pinene,[4] from gum turpentine, through a spiral screen column[2] at 20-mm. pressure and a reflux ratio of 40 to 1. This column exerted 75 plates upon a mixture of *n*-heptane–methylcyclohexane at total reflux and atmospheric pressure. Fractions were collected at 75-cc. intervals. All fractions with a refractive index in the range 1.4631–1.4633 at 25.0° were combined and refractionated through the same column. Fractions were then collected at 50-cc. intervals and their refractive indices and optical rotations were measured at 25.0°. The fractions which had constant values of refractive index and optical rotation were combined and were considered to be pure α-pinene. In verification, a 100-cc. portion of the latter was fractionated through a column which had 60 plates determined as above. No change in these two physical constants was noted at any point during collection of the distillate.

For comparison, α-pinene from wood turpentine was desired. The preparation of this pure component from wood turpentine involved its separation from a small amount of camphene which boils about 3° higher. The intermediate fractions having constant refractive indices and optical rotations at 25.0° were then combined and refractionated. The material thus obtained had constant physical properties and was of the same purity as the α-pinene from gum turpentine.

The β-pinene used was prepared in an analogous manner from commercial β-pinene[4] obtained from gum turpentine.

These purified pinenes had the following constants

	B. p., °C. (20.0 mm.)	$n^{25.0}_D$	$d^{25.0}_4$	$[\alpha]^{25.0}_D$
α-(gum)	52.2	1.4631	0.8542	− 3.83
α-(wood)	52.2	1.4631	.8542	+34.07
β-(gum)	59.7	1.4768	.8666	−21.49

These constants are in close agreement with unpublished

data of J. P. Bain,[5] with much of the data of S. Palkin and co-workers,[1,6] with data of Waterman, Van't Spijker and Van Westen[7] and some of the data of Dupont.[8]

Experimental

Density Measurements.—These were made with a 25-ml. density bottle. In all cases values were obtained at least in duplicate which checked to the fourth decimal place. The thermostat was controlled by means of an Aminco Metastatic Thermoregulator connected to a vacuum tube relay circuit developed by Hershberg and Huntress.[9] The thermoregulator controlled the temperature within a limit of ±0.02°.

Mixtures of α- and β-pinene were made up to known concentrations by weight. Measurements of the variation of density with concentration were made using α-pinene from both gum and wood turpentine. The densities of the mixtures were independent of the source of the α-pinene used. The average deviation of the density determinations was 0.00004. These data may be expressed at 25.0° by the equation

$$d^{25}_4 = 0.8542 + 0.0129X - 0.0005X^2 \quad (1)$$

in which X is the mole fraction of β-pinene.

Refractive Index Measurements.—These were obtained with the pure substances and their mixtures by means of an Abbé refractometer calibrated against a known glass. Constant temperature was maintained by circulating water through the refractometer from the thermostat described above. The average deviation of the determinations was 0.00006.

Refractive index measurements of the two pure substances for the temperature range 15–35° show that both α- and β-pinene have a coefficient of 0.00045 unit per degree. Observations were made every two degrees, but since the relation is linear only the limiting points are given: α-pinene, $n^{15.0}_D$ 1.4676, $n^{35.0}_D$ 1.4586; β-pinene, $n^{15.0}_D$ 1.4813, $n^{35.0}_D$ 1.4723.

The variation of the refractive index with concentration for mixtures of β-pinene and either gum or wood α-pinene at 25.0° may be expressed by the equation

$$n^{25.0}_D = 1.4631 + 0.0144X - 0.0007X^2 \quad (2)$$

where X is the mole fraction of β-pinene.

The molar refractions of the pure components were calculated using the standard atomic refraction values of Auwers and Eisenlohr and also a value of 0.48 for the cyclobutane ring. In this manner the value of 43.99 was obtained for both α- and β-pinene. From the observed data the values of 43.93 and 44.40 were calculated for α- and β-pinene, respectively, by use of the Lorenz–Lorentz equation. The exaltation of 0.41 for β-pinene is probably due to the presence of the exocyclic double bond. Auwers[10] has proposed that values of from 0.32 to 0.52 be added to correct for the exocyclic double bond.

Polarimetric Measurements.—Since α-pinene has a rotation that varies with its source, sample, and time of year collected from the tree, the value of this constant has no diagnostic significance.[11] It has been pointed out by Darmois[12] that β-pinene has a constant specific rotation regardless of its source, and that this value is −22.44° for the j-line of mercury. Dupont[8] reported a value of −22.48°.

All rotations were observed at 25.0° in a jacketed two-decimeter tube. A Duboscq polarimeter, reading by vernier to 0.01° of arc and equipped with suitable filters, depending on the wave length of light, was used. Readings on the same tube could be made with an average deviation of 0.02° using the sodium light and 0.03° using a less intense mercury arc.

Listed in Table I are rotations of α- and β-pinene and their mixtures for the Na_D (589 μμ), Hg_j (578 μμ) and Hg_v (546 μμ) lines. Also given are the observed rotatory dispersions. Biot's law for the linearity of specific rotations of mixtures does not hold exactly. The maximum deviation is about 0.3° at a mole fraction of 0.5. The data could be expressed by a second degree equation. However, this relation would change with the variation in the value of the rotation of the pure α-pinene used.

Also, listed in column 3, Table I, are the mole fractions of β-pinene calculated by Biot's law from the observed data using the Na_D line. The deviations for the Hg_j and Hg_v lines are about the same.

Biot's law may be applied, to express rotatory dispersion for a given mixture, in the form

$$\frac{[\alpha]_v}{[\alpha]_D} = \frac{n_{\beta\text{-}}[\alpha_{\beta\text{-}}]_v + (1 - n_{\beta\text{-}})[\alpha_{\alpha\text{-}}]_v}{n_{\beta\text{-}}[\alpha_{\beta\text{-}}]_D + (1 - n_{\beta\text{-}})[\alpha_{\alpha\text{-}}]_D}$$

in which $n_{\beta\text{-}}$ is the mole fraction of β-pinene in the mixture, $[\alpha_{\beta\text{-}}]_v$ and $[\alpha_{\beta\text{-}}]_D$ are the specific rotations of β-pinene with the v-line and D-line, respectively, and $[\alpha_{\alpha\text{-}}]_v$ and $[\alpha_{\alpha\text{-}}]_D$ are the specific rotations of α-pinene with the v-line and D-line, respectively. When the values of dispersion are calculated on this basis only slight variations from the observed dispersions are noted. This deviation is illustrated for the $[\alpha]_v/[\alpha]_D$ dispersion by the data in column 7, Table I.

Dupont[12] observed that for high α-pinene con-

tent (approximately 70 mole per cent. or greater) the dispersion is a good indication of the α-pinene content. Ordinarily the $[\alpha]_V/[\alpha]_j$ ratio is used, probably because the two lines are obtained from the same source. However, the data show that $[\alpha]_V/[\alpha]_D$ gives a wider dispersion range and therefore should be a more satisfactory indication of α-pinene content.

Vapor Pressure Measurements.—These were determined in the pressure range from 15 to 80 mm. by use of a distillation column in which the vapors were allowed to come to equilibrium with the liquid. The column temperature was adjusted to within 1.5° of the temperature recorded by the condensing vapors in the head. The temperatures of the vapors were measured by the use of a calibrated mercury thermometer that could be read to ±0.05°. The bulb of the thermometer was wrapped with a single layer of cotton gauze.

The pressure was regulated by a manostat of the Hershberg–Huntress type.[9] The action of the vacuum pump on the manostat was partially checked by placing a stopcock between the pump and the manostat. The pressure fluctuations were minimized by including a five-gallon bottle in the system between the manostat and the column.

The manometer was connected to the head of the column so that the pressure of the condensing vapors would be recorded. The vapor pressures were measured with a Germann barometer,[13] using a cathetometer which could be read to 0.01 mm. The observed pressure readings were corrected to 0° for the difference in the expansion of the mercury and the brass scale at different temperatures[14] and were corrected to 45° latitude and sea level.[15] At each recorded temperature about 2 cc. of liquid was collected at a reflux ratio of 20 to 1.

Equations were obtained by applying the method of averages to the corrected data. It was found that the equation

$$\log p = 8.1020 - 2213/T \qquad (3)$$

represents the data for α-pinene for the stated pressure range. The experimentally determined values agree with the values calculated by the empirical equation with an average deviation of 0.08 mm. and a maximum deviation of 0.2 mm. Similarly, the equation

$$\log p = 8.1504 - 2280/T \qquad (4)$$

represents the data of β-pinene for the same pressure range. The experimentally determined values agree with the values calculated by the empirical equation with an average deviation of 0.11 mm. and a maximum deviation of 0.4 mm. From the slopes of the plots the latent heat of vaporization for the stated pressure range may be shown to be 10,130 cal./mole or 74.35 cal./g. for α-pinene and 10,430 cal./mole or 76.60 cal./g. for β-pinene.

The isobaric vapor–liquid compositions at 20.0 mm. were determined using a modified Sameshima apparatus.[16] About 100 cc. of mixture was placed in the flask and then brought to equilibrium, which was generally attained within two hours but four hours were allowed before a final measurement was made. Samples were then withdrawn from the flask and from the vapor receiver. The rate of flow, which averaged 1.5 cc./min., was regulated by the voltage applied to the internal heater. The thermostat temperature was kept about 2–4° above the estimated boiling temperature of the liquid. Cold brine solution was circulated through the two condensers, each of which contained a condensing coil made from a four-foot length of glass tubing. Experiments showed that there was no detectable vapor loss four hours after reaching equilibrium between liquid and vapor. The pressure control system was the same one described for the measurements of vapor pressures of the pure compounds. Samples were withdrawn by means of capillary

1.4647	.890	1.4644	.910
1.4641	.930	1.4639	.945
1.4637	.955	1.4636	.965

pipets. Data were observed by starting with mixtures rich in α-pinene and going to mixtures rich in β-pinene and also by starting with mixtures rich in β-pinene and going to mixtures rich in α-pinene. The compositions were determined by means of refractive index measurements and application of equation (2). The data obtained by this method are recorded in Table II.

In order to compare the observed values with those of an ideal system, pressures, $p_{\alpha\text{-}}$ and $p_{\beta\text{-}}$, of the pure components were calculated by equations (3) and (4) for the temperatures listed in Table III. Then for each temperature was calculated a liquid mixture composition at 20.0 mm. by applying Raoult's law in the form

$$20.0 = x_{\alpha\text{-}}p_{\alpha\text{-}} + (1 - x_{\alpha\text{-}})p_{\beta\text{-}}$$

where $x_{\alpha\text{-}}$ is the mole fraction of α-pinene in the liquid phase. The corresponding vapor composition was calculated from the relation

$$y_{\alpha\text{-}} = \frac{x_{\alpha\text{-}}p_{\alpha\text{-}}}{20.0}$$

where $y_{\alpha\text{-}}$ is the mole fraction of α-pinene in the vapor phase. The observed mole fraction of α-pinene in the vapor, corresponding to liquid composition $x_{\alpha\text{-}}$, in column 4, Table III, was obtained from a plot of the vapor–liquid relations at 20.0 mm., using the data in Table II. The difference between the observed and calculated vapor composition is a measure of the deviation from ideality of the mixtures. These deviations are listed in the last column of Table III.

From the plot of the data in Table II it can be seen that a minimum of 24 theoretical plates at total reflux are required to go from a mixture of 95 mole per cent. to 5 mole per cent. α-pinene. The same diagram shows a minimum of 50 plates between pure α- and pure β-pinene under total reflux conditions.

Summary

The densities, refractive indices and optical rotations for α- and β-pinene and their mixtures have been determined.

The vapor pressure–temperature relations of α- and β-pinene were measured in the range of 15 to 80 mm.

The vapor–liquid equilibrium composition data for mixtures of α- and β-pinene at 20 mm. pressure have been determined.

[A COMMUNICATION FROM THE CENTRAL RESEARCH DEPARTMENT, MONSANTO CHEMICAL CO.]

An Improved Method of Preparation of *bis*-Arylphosphonic Acids

BY GENNADY M. KOSOLAPOFF

The usual method of preparation of phosphonic acids, $RPO(OH)_2$ and R_2POH, involves the preparation of the corresponding halophosphines by the Friedel–Crafts reaction of the corresponding hydrocarbon with phosphorus trichloride, followed by oxidation and hydrolysis. Generally, the preparation of the halophosphines is quite unsatisfactory because of meager yields. At the same time, the odor and the vapor toxicity of the halophosphines frequently make them rather inconvenient to handle. Particularly unsatisfactory are the methods of preparation of the *bis*-arylphosphonic acids. The necessary halophosphines form only as by-products in the usual Friedel–Crafts reaction of the hydrocarbons with phosphorus trichloride, with the consequently very low yields. Some improvement in this respect was introduced by Pletz[1] who obtained fair yields of R_2PCl by the thermal decomposition of *tris*-arylphosphine dichlorides. However, this method of preparation of the phosphonic acids involves at least four steps, with the consequently lowered over-all yields and necessitates operations with the objectionable halophosphines.

It is felt that a direct, preferably one-step, method of preparation of *bis*-arylphosphonic acids was needed as a stimulus for investigations of this relatively little studied class of organic compounds of phosphorus. The elimination of the actual operations with the halophosphines was also highly desirable.

The most convenient method of attack appeared to be the Grignard reaction, which has been used with success in the preparation in good yields of tertiary phosphine oxides by the addition of phosphorus oxychloride into an excess of the desired Grignard reagent.[2] The reaction probably occurs in three stages, *i. e.*

$$POCl_3 + RMgX \longrightarrow RPOCl_2 + MgXCl$$
$$RPOCl_2 + RMgX \longrightarrow R_2POCl + MgXCl$$
$$R_2POCl + RMgX \longrightarrow R_3PO + MgXCl$$

the high order of reactivity of the intermediate halophosphines making the over-all reaction very rapid.

It was felt that it should be possible to separate the component reactions and to obtain the intermediate products by the proper choice of conditions. In the usual procedure for the preparation of R_3PO, the reaction is run with the phosphorus oxychloride always in position to react with an excess of the Grignard reagent. By reversing the addition order, it was thought to be possible to arrest the reaction at the desired stage of having the Grignard reagent always in position to react with an excess of the phosphorus oxychloride. The utilization of as dilute a solution as practicable and the employment of low temperatures were the remaining factors.

In preliminary experiments, solutions of Grignard reagents were added slowly to ether solutions of phosphorus oxychloride with vigorous stirring, with or without cooling. The drops of the Grignard reagent produced an immediate turbidity of the solution and as the reaction proceeded there was a gradual deposition of a white, or pale-yellow, solid on the flask walls. On working up the ether solutions they were found to be essentially free of magnesium compounds and to contain only the normal amounts of R–R and R–X, with very small amounts of the tertiary phosphine oxides. The solid precipitate, on hydrolysis, gave satisfactory yields (usually over 50%) of *bis*-arylphosphonic acids. No appreciable amounts of the mono-arylphosphonic acids were detected in the temperature range studied: 0° to the reflux temperature of the ether solution. A slight improvement of the yield of the phosphonic acid was found at the higher temperature, while dilution of the reagents also had a beneficial effect for dilutions up to approximately one liter total volume for 0.2-mole runs, which was regarded as a practical limit for dilution. The maximum molar ratio of phosphorus oxychloride to RMgX used was 1:1.

The above results indicate that the halophosphines, as formed, combine with MgXCl forming an ether-insoluble addition complex, probably of the type $R_2POCl \cdot MgXCl$. Generally, this is a crystalline solid, although in some cases gummy solids are formed.

The procedure probably can be extended to the aliphatic series.

Experimental

Diphenylphosphonic Acid.—Phenylmagnesium bromide (from 31.4 g. of bromobenzene and 4.86 g. of magnesium in 200 cc. of absolute ether) solution was diluted to 500 cc. by absolute ether, filtered with exclusion of air and added slowly (three and one-half hours) to a gently refluxing stirred solution of 30.6 g. of phosphorus oxychloride in 500 cc. of absolute ether; after standing overnight the ether solution was decanted from the solid precipitate and the latter treated with 200–300 g. of ice-water. The white solid which was insoluble in water was washed with water and triturated with 1 l. of warm dilute sodium hydroxide solution, filtered and filtrate acidified with dilute hydrochloric acid. The precipitated diphenylphosphonic acid was filtered, dried and recrystallized from dilute alcohol; m. p. 190–192°; yield 12 g., 55%. The sodium hydroxide-insoluble solid on repeated recrystallization yielded 4 g. of triphenylphosphine oxide, m. p. 152–153° (from dilute alcohol).

***bis-p*-Chlorophenylphosphonic Acid.**—The Grignard reagent from 39 g. of *p*-chlorobromobenzene was diluted to 400 cc. with absolute ether and added in the course of one and one-half hours to a gently refluxing stirred solution of 30.6 g. of phosphorus oxychloride in 500 cc. of absolute ether. After standing overnight, the reaction mixture was worked up as above, yielding 15 g. (51%) of *bis-p*-chlorophenylphosphonic acid, m. p. 133–135° (from dilute alcohol) and 4.5 g. of *tris-p*-chlorophenylphosphine oxide, m. p. 171–2.5° (from dil. alcohol).

Anal. Calcd. for $C_{12}H_9O_2PCl_2$: eq. wt., 287; Cl, 24.7. Found: eq. wt., 283; Cl, 24.58.

Summary

An improved method for the preparation of *bis*-arylphosphonic acids has been devised in which phosphorus oxychloride is treated with Grignard reagents in dilute solution.

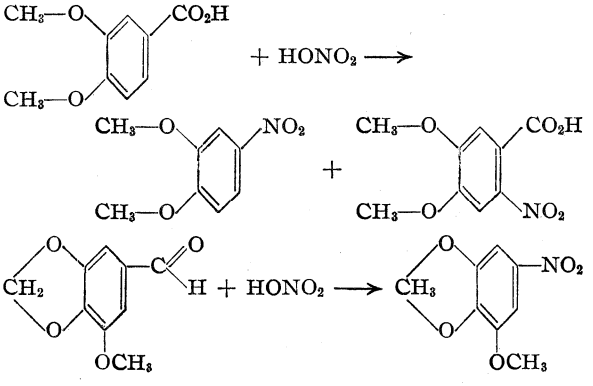
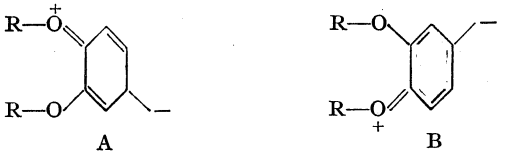
Studies in the Veratrole and Methylenedioxybenzene Series

BY RICHARD T. ARNOLD AND FREDERICK BORDWELL[1]

Interest in the veratrole (*o*-dimethoxybenzene) and methylenedioxybenzene (1,3-benzodioxole) compounds has been aroused largely for two reasons. First, these nuclei frequently make up important component parts of well known naturally occurring substances (opium alkaloids, apioles, etc.); and, second, the parent substances have exceedingly reactive benzenoid rings which orient incoming substituents in a unique and (according to the classical orientation rules) unpredictable manner. Two typical examples may be cited to illustrate the latter point.[2,3]



The remarkable susceptibility of these aromatic rings to attack by electrophilic reagents at the positions para to the oxygen atoms can be accounted for by resonance contributing structures of the type A and B.



A B

In spite of the easily recognizable similarities, it is well established that the benzenoid ring of methylenedioxybenzene is more reactive than that of veratrole.[4]

To enable us to make a comparative study of the aromatic bond types in these two series we have prepared a number of substituted phenols (I–IX below) and have measured their *pK* values under identical circumstances. These values were determined by measuring the *p*H of half-

	pK		*pK*
I, X = —CHO	9.12	V, X = —CHO	8.90
II, X = —CN	8.69	VI, X = —CN	8.41
III, X = —NO_2	8.33	VII, X = —NO_2	8.17
IV, X = —CO_2H	4.60	VIII, X = —CO_2H	4.58

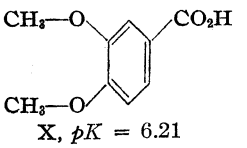
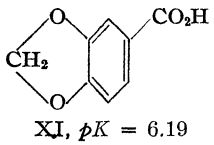
IX, pK = 8.68
(8.28 calcd. for 50% ethanol)



X, pK = 6.21



XI, pK = 6.19

neutralized solutions of the phenols in ethanol solutions (50% by volume). The value for compound IX was measured in 67% ethanol because of its relative insolubility.

It will be noticed that the pairs of related compounds X and XI, as well as IV and VIII, have the same acidity. The high acidity of *o*-hydroxy acids has been adequately explained by Branch and Yabroff.[5]

A comparison of I, II and III with V, VI and VII reveals that the methylenedioxy derivatives are more acidic than those of the veratrole series by 0.2–0.3 pK units. Such slight differences may be due to a combination of factors: a slight increased double bond character in the methylenedioxybenzene ring between the carbon atoms attached to groups OH and X,[6] dipolar effects and resonance effects.[7]

Nevertheless, the above discussed differences are so small that one must conclude that the benzenoid rings in the two series under consideration are very much alike. As Sutton and Pauling[8] have pointed out, however, "a small influence exerted on the benzene ring can produce important changes in reaction velocity."

Failures to prepare a number of the compounds described here have been reported.[9,16] In several other cases worthwhile modifications of reported syntheses are described.

Experimental

Methyl Veratrate.—Veratraldehyde was oxidized by a procedure similar to that used for the oxidation of piperonal[10]; the yield of veratric acid was 88%. This material was dissolved in ten times its weight of methanol and saturated with hydrogen chloride. After standing overnight the solution was distilled and yielded 73% of the ester; b. p. 165° (15 mm.); m. p. 58–59°.

Methyl 5-Nitroveratrate.—Since the method of Zincke and Francke[11] gave poor results in our hands, the following procedure was employed. Twenty-one grams of methyl veratrate was dissolved in 50 cc. of glacial acetic acid and while this solution was being stirred and cooled in an ice-bath, 100 cc. of nitric acid (d. 1.59) dissolved in 50 cc. of acetic acid was added during the course of one hour. Stirring was continued for two hours and the solution was then poured into ice water. The nitro ester was recrystallized from 600 cc. of methanol; yield 23.2 g.; m. p. 144–145°.

Methyl 5-Aminoveratrate.—The corresponding nitro compound dissolved in five times its weight of methanol was reduced at 110° with Raney nickel and hydrogen at 1000 pounds pressure; yield 80%; m. p. 128–129°. Zincke and Francke,[11] using stannous chloride, report a melting point of 133°.

Methyl 5-Hydroxyveratrate.—This substance has been obtained by direct esterification of the hydroxy acid[12] and from the amino ester.[11] Zincke and Francke[11] claimed poor yields and did not describe their procedure.

The amino ester (11.9 g.) was powdered and added to a warm solution of 13 cc. of sulfuric acid in 60 cc. of water. Cooling gave a thick paste of the amine salt which was diazotized with 4.0 g. of sodium nitrite in 15 cc. of water. The hydroxy ester was obtained pure by adding the diazonium solution dropwise to boiling copper sulfate solution. The yield of ester which steam distilled was 8.7 g.; m. p. 95–96° after one recrystallization from methanol.

5-Hydroxyveratric Acid.—The acid was obtained from the ester by refluxing the latter with sodium hydroxide (5%) until solution was effected. Acidification gave a white solid; m. p. 204–205° (dec.). Clark[13] reports 201–202°.

5-Hydroxyveratraldehyde.—Six grams of aminoveratraldehyde[14] was added to 400 cc. of water and treated with 6.0 g. of sulfuric acid in 100 cc. of water to form a suspension. Two grams of sodium nitrite in a saturated solution was added to the cold, well-stirred suspension. After one and one-half hours the solution was filtered and decomposed in boiling copper sulfate solution. The steam distillate was extracted with ether and there was obtained 2.8 g. of hydroxyaldehyde. Recrystallization from ethanol gave a product melting at 106–107°. Robertson[15] reports 107°.

Methyl 6-Aminopiperonylate.—The method described below is a modification of Bogert and Elder's[9] procedure which gave a much more pure product.

The amino ester (9.3 g.) was suspended in a mixture of 10 cc. of sulfuric acid and 50 cc. of water. Diazotization was accomplished with 3.4 g. of sodium nitrite dissolved in 20 cc. of water. The diazonium solution was diluted with four times its volume of water and added dropwise to a boiling solution of copper sulfate (50%). The steam distilled ester was perfectly white and weighed 6.9 g. after recrystallization from aqueous methanol solutions; 100–101°. The over-all yield to this point is 36% as compared to 18% reported earlier.[9]

6-Hydroxypiperonal.—The diazotization of aminopiperonal proved difficult and the use of dilute solutions was found to be distinctly advantageous.

The aminoaldehyde (10.6 g.) was powdered and suspended in 300 cc. of water. To this mechanically stirred suspension was added 10 cc. of sulfuric acid in 80 cc. of water. To the cool well-stirred suspension 4.5 g. of sodium nitrite in 50 cc. of water was added dropwise. After standing for thirty minutes the solution was filtered and slowly decomposed with copper sulfate solution as described above. Six to eight liters of distillate was collected; yield 5.2 g.; m. p. 125–126°.

Anal. Calcd. for $C_8H_6O_4$: C, 57.82; H, 3.64. Found: C, 57.68; H, 3.69.

6-Hydroxypiperonal Oxime.—The oxime was obtained quantitatively by treating 1.0 g. of the aldehyde in 7 cc. of ethanol with 0.8 g. of hydroxylamine hydrochloride and 0.6 g. of sodium carbonate in a few cubic centimeters of water. The mixture was warmed on a steam-bath for thirty minutes and then poured into water. After recrystallization from benzene the compound melted at 142.5–143.5°.

Anal. Calcd. for $C_8H_7O_4N$: C, 53.02; H, 3.90. Found: C, 53.17; H, 3.86.

6-Hydroxypiperononitrile.—6-Hydroxypiperonal oxime (3.1 g.) was refluxed for twenty minutes with 15 cc. of acetic anhydride and the solution was poured into 50 cc. of cold water. In one hour the solution was filtered and the solid product was gently refluxed with 15 cc. of sodium hydroxide (10%). About 15 cc. of water was added to keep the sodium salt in solution. After ten minutes the solution was neutralized with hydrochloric acid. The precipitate tenaciously held water and was dried overnight in a vacuum desiccator. Several recrystallizations from alcohol and a final one from benzene gave a substance (2.0 g.) melting at 220–225° (dec.).

Anal. Calcd. for $C_8H_5O_3N$: C, 58.87; H, 3.09. Found: C, 59.02; H, 3.00.

5-Hydroxyveratraldehyde Oxime.—This oxime was prepared as described above for the corresponding piperonal derivative; yield 90%; m. p. 146–147°.

Anal. Calcd. for $C_8H_5O_3N$: C, 54.82; H, 5.58. Found: C, 55.01; H, 5.79.

5-Hydroxyveratronitrile.—This compound was obtained in a 90% yield as described above for 6-hydroxypiperononitrile. The nitrile sinters at 120° and melts with decomposition at 142–145°.

Anal. Calcd. for $C_9H_9O_3N$: C, 60.33; H, 5.02. Found: C, 60.18; H, 4.99.

6-Acetoxypiperonal.—Following the directions given by Robertson and Head[15] in their preparation of 5-acetoxyveratraldehyde, 1.0 g. of hydroxypiperonal was dissolved in 4 cc. of pyridine and the solution was cooled until the whole solidified. To this was added 12 cc. of acetic anhydride and the mixture was kept at 35–40° for twenty hours before pouring into 125 cc. of water. The precipitate was recrystallized from aqueous alcohol and appeared as beautiful needles; yield 4.4 g.; m. p. 126–127°. A mixed melting point determination with the original aldehyde gave a value of 100° with considerable range.

Anal. Calcd. for $C_{10}H_8O_5$: C, 57.69; H, 3.85. Found: C, 57.36; H, 3.92.

6-Acetoxypiperonylic Acid.—While the phenolic hydroxyl group of the hydroxy acid could be acetylated readily in the presence of sulfuric acid and acetic anhydride, a pure product could be obtained only after numerous recrystallizations. The difficulties encountered by Bogert and Elder[9] are readily understandable. The oxidation of the corresponding aldehyde proved most satisfactory.

One gram of the acetoxyaldehyde was dissolved in 25 cc. of acetone and to this was added 1.3 g. of potassium permanganate in 30 cc. of water. After warming on a water-bath for fifteen minutes the mixture was treated with sulfur dioxide. The acetone was evaporated and the acetoxy acid was filtered immediately. The product was thoroughly dried in a vacuum desiccator and recrystallized from benzene; yield 0.67 g.; m. p. 149–150° (dec.).

Anal. Calcd. for $C_{10}H_8O_6$: C, 53.55; H, 3.60. Found: C, 53.78; H, 3.78.

5-Hydroxy-6-nitro-1,3-benzodioxole.—One gram of the nitroamine was added to a mixture of 25 cc. of water and 5 cc. of concentrated sulfuric acid. The cold solution was diazotized with a slight excess of sodium nitrite and the resulting diazonium salt was decomposed by boiling copper sulfate solution. The yellow nitrophenol steam distilled as it was formed; yield 0.4 g.; m. p. 82.5–84°.

Balaban[16] has reported an unsuccessful attempt to prepare this substance.

Anal. Calcd. for $C_7H_5O_5N$: C, 45.90; H, 2.73. Found: C, 46.24; H, 2.65.

4-Hydroxy-5-nitroveratrole.—This phenol is best prepared from 4-acetamido-5-nitroveratrole.[17]

The acetanilide (2.6 g.) was refluxed with 10 cc. of sulfuric acid in 24 cc. of water for fifteen minutes. The deep red solution was cooled and diazotized with 0.8 g. of sodium nitrite dissolved in a few cubic centimeters of water. Decomposition by the copper sulfate method followed by steam distillation gave 1.4 g. of the nitrophenol; m. p. 142–143°.

Anal. Calcd. for $C_8H_9O_5N$: C, 48.24; H, 4.55. Found: C, 48.58; H, 4.68.

5-Acetamido-2,2-dimethyl-1,3-benzodioxole.—From 5-nitro-2,2-dimethyl-1,3-benzodioxole[18] dissolved in two volumes of ethanol there was obtained an 85% yield of amine by reduction with hydrogen and Raney nickel. Acetylation in the usual way with acetic anhydride and a trace of sodium acetate gave a 95% yield of the acetanilide derivative; m. p. 108.5–109.5°.

Anal. Calcd. for $C_{11}H_{13}O_3N$: C, 63.77; H, 6.47. Found: C, 63.68; H, 6.40.

5-Hydroxy-6-nitro-2,2-dimethyl-1,3-benzodioxole.—Four grams of the above described nitroacetanilide was hydrolyzed by warming for twenty minutes with 35 cc. of methanol containing 2.0 g. of potassium hydroxide. The nitroamine weighed 3.0 g.; m. p. 127–128°. Sloof[18] reports 127°.

Diazotization of the amine was exceedingly slow. Approximately 0.8 g. of amine was suspended in a mixture containing 6 cc. of sulfuric acid (d. 1.84) and 50 cc. of water. The cooled suspension was diazotized with 0.33 g. of sodium nitrite in a few cubic centimeters of water, and after standing for one hour the solution was decomposed

with boiling copper sulfate; yield 0.1 g.; m. p. 148–149°. All attempts to raise this yield by a variation of conditions failed.

Anal. Calcd. for $C_9H_9O_5N$: C, 51.18; H, 4.26. Found: C, 51.24; H, 4.00.

Summary

1. Nine negatively substituted phenols in the veratrole and methylenedioxybenzene series have been prepared.

2. A measure of the relative acidities of these compounds strongly indicates that the benzenoid rings in the two series are very comparable in structure.

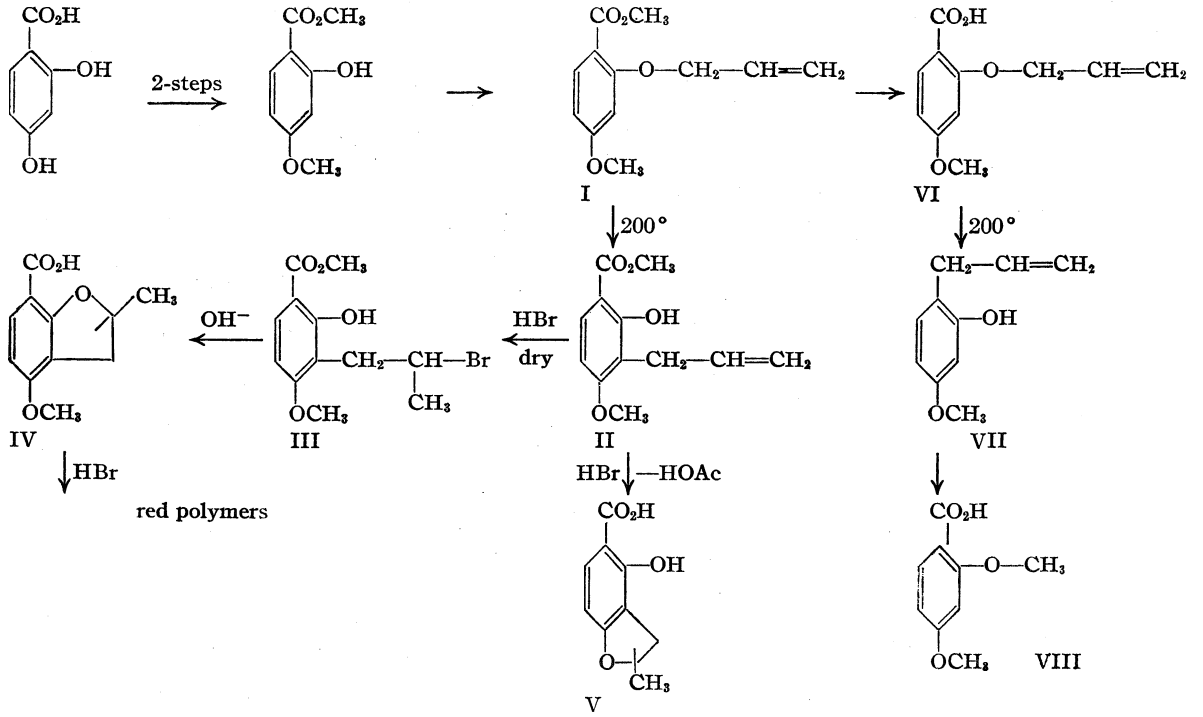
Studies in the Coumaran Series

BY RICHARD T. ARNOLD AND JOHN MORAN

In an attempt to ascertain whether or not the coumaran heterocyclic ring is partially cleaved to an opened chain intermediate in the presence of reagents which split ordinary ethers, we have prepared 2-methyl-4-methoxy-7-carboxycoumaran IV and subjected this molecule to treatment with concentrated solutions of hydrobromic acid.

Unfortunately no successful conditions were found for effecting this transformation directly. All experiments dealing with the cleavage of IV gave unidentifiable red polymers.[1,2] We wish to describe, however, a number of syntheses carried out during the course of this investigation. These can be summarized as follows



If during the cleavage of the methoxyl group the cyclic ether does form an opened chain derivative, it is to be expected that recyclization would involve the hydroxyl group para to the carboxyl group rather than that in the ortho position since the latter is rather firmly held in a chelate ring structure.

Substitution studies have repeatedly shown that the resorcinol nucleus is preferentially attacked at that position ortho to one hydroxyl group and para to the other. The thermal rearrangement of monoallylresorcinol[3] leads to the 1,2,4 configura-

(1) Schales, *Ber.*, **70**, 116 (1937).

tion. In this respect it is of interest that compound VI rearranges completely with decarboxylation to give 2-hydroxy-4-methoxyallylbenzene.[4] It may well be that decarboxylation precedes the rearrangement. The fact must not be overlooked, however, that below 160° the acid VI appears to be perfectly stable and above this temperature the carboxyl group may be eliminated through substitution by the allyl fragment.

When treated with hydrobromic acid, compound II did not cyclize easily but first underwent an ether cleavage followed then by ring closure to give a coumaran *o*-hydroxy acid (V). The relative position of the hydroxyl and carboxyl groups in V was established by the fact that the phenolic hydroxyl group was not attacked by diazomethane in twenty-four hours.[5,6,7]

Compound II reacted readily with anhydrous hydrogen bromide in the presence of catalytic amounts of ferric chloride to give a solid addition product (III) which in turn was converted to a methoxycoumaran acid IV when treated with alkali.[8]

Experimental

Methyl 2-Hydroxy-4-methoxybenzoate.—Seventy grams of 2-hydroxy-4-methoxybenzoic acid was dissolved in 140 cc. of methanol and to this was added a cooled solution of 16 cc. of sulfuric acid in 16 cc. of methanol. The mixture was refluxed for forty-eight hours. Crystals of ester separated when the solution was cooled but were not filtered. An excess of cold water was added and the whole was extracted with ether. Bicarbonate extraction of the ether layer yielded 2 g. of the starting acid. Removal of the ether and crystallization from ether–petroleum ether gave 62 g. of the ester; m. p. 49–51°.[9]

Methyl 2-Allyloxy-4-methoxybenzoate (I).—Sixty grams of methyl 2-hydroxy-4-methoxybenzoate was dissolved in 500 cc. of anhydrous acetone and treated with 46 g. of potassium carbonate, 50.5 g. of allyl chloride, and 25 g. of sodium iodide. The solution was refluxed while being efficiently stirred for fifty-two hours. The cooled solution was filtered and the bulk of the acetone was separated from the filtrate by distillation on a steam cone. The residue was taken up in ether and successively extracted with water, sodium hydroxide solution (5%), and a solution of sodium thiosulfate. The resulting ether layer was dried with sodium sulfate and warmed on a water-bath to remove the ether. Recrystallization of the residue from petroleum ether gave 49 g. of the expected product which gave no color reaction with ferric chloride; m. p. 49–50°.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35. Found: C, 64.90; H, 6.20.

(8) Stoermer, *Ber.*, **34**, 1810 (1901).
(9) Hersig and Wenzel, *Monatsh.*, **24**, 887 (1903).

Methyl 2-Hydroxy-3-allyl-4-methoxybenzoate (II).—Fifty grams of I was dissolved in 130 cc. of redistilled N,N-dimethylaniline and placed in a 200-cc. flask to which an air condenser was attached. The solution was refluxed in a nitrogen atmosphere for six hours. During this time the solution darkened but little. The dimethylaniline was largely removed by vacuum distillation. The residue was dissolved in ether and extracted with dilute hydrochloric acid. The dried ether solution was evaporated on a steam cone, and when cooled in a salt-ice bath the residue crystallized. Recrystallization from methanol solutions gave 34 g. of product melting at 57–59°. This substance gave a red-violet color with alcoholic ferric chloride.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35. Found: C, 64.70; H, 6.59.

Hydrobromic Acid Treatment of Compound II.—Ten and one-half grams of methyl 2-hydroxy-3-allyl-4-methoxybenzoate was dissolved in 40 cc. of glacial acetic acid and treated with 13 cc. of hydrobromic acid (40%). The mixture was warmed on a steam-bath for twelve hours then poured into cold water. The residue was completely saponified by refluxing with 50 cc. of sodium hydroxide solution (10%). The hot solution was partially decolorized with charcoal, filtered, cooled, and acidified. A crude mixture of acids melting at 150–190° was obtained and separated by fractional crystallization into two pure components m. p. 155–156° and m. p. 203–205°. The lower melting compound was assigned formula V. It gave a positive (red) color test with ferric chloride. In the presence of a four-fold excess of diazomethane a methyl ester was obtained which liberated the hydroxy acid on basic hydrolysis.

Anal. Calcd. for $C_{10}H_{10}O_4$: C, 61.83; H, 5.19. Found: C, 61.63; H, 5.06.

The high melting compound (203–205°) was assigned formula IV and was obtained in a more pure condition as described below.

Methyl 2-Hydroxy-3-(β-bromo-*n*-propyl)-4-methoxybenzoate.—Eight grams of compound II was dissolved in 20 cc. of anhydrous chloroform, cooled to 0° and treated with a few milligrams of black anhydrous ferric chloride. Dry hydrogen bromide was passed through the solution for thirty minutes and the solution was allowed to stand at room temperature for twenty-seven hours. The solvent was removed under diminished pressure and the residue immediately crystallized. When treated with ether, one gram of the residue remained undissolved and was filtered. After recrystallization from benzene–ethanol, it melted at 207–208° and proved to be a pure sample of the compound (IV) reported above as melting at 203–204°.

Anal. Calcd. for $C_{11}H_{12}O_4$: C, 63.40; H, 5.81. Found: C, 63.13; H, 5.96.

The ether solution was evaporated and 5 g. of a bromo derivative (III) was obtained after recrystallization from petroleum ether; m. p. 73–74°.

Anal. Calcd. for $C_{12}H_{15}O_4Br$: C, 47.54; H, 4.99. Found: C, 47.82; H, 5.50.

2-Methyl-4-methoxy-7-carboxycoumaran.—Five grams of the bromo compound (III) was shaken with 20 cc. of sodium hydroxide for fifteen minutes and was refluxed for an additional fifteen minute interval. The resultant solu-

tion was cooled, filtered, and carefully acidified. The precipitate was recrystallized from benzene–ethanol and melted at 207–208°. Mixed melting point determinations showed this substance to be identical with samples obtained in earlier experiments as described above.

2-Hydroxy-4-methoxyallylbenzene.—One and three-tenths grams of 2-allyloxy-4-methoxybenzoic acid dissolved in 12 cc. of N,N-dimethylaniline was refluxed for six hours, cooled, and poured into ether. The amine was removed from the ether layer by extraction with hydrochloric acid. Evaporation of the ether gave an oil which was soluble in sodium hydroxide and completely insoluble in sodium bicarbonate. A positive ferric chloride test was obtained. The structure of this oil was established by methylation, isomerization with alkali, and oxidation to 2,4-dimethoxybenzoic acid; m. p. and mixed m. p. 108°.

Summary

A number of reactions leading to the formation of substituted coumarans have been described.

Solvent Polarization Error and its Elimination in Calculating Dipole Moments

BY I. F. HALVERSTADT[1,2] AND W. D. KUMLER

An old idea in dipole moment literature is that P_{12}–N_2 (or p_{12}–ω_2) curves would be straight lines in the absence of intermolecular action[3] or molecular association. This idea is implicit in the usual methods of calculating the degree of molecular association from polarization concentration curves, and in the calculation of dipole moments by a linear extrapolation of P_2–N_2 curves, a method still used by a number of authors.

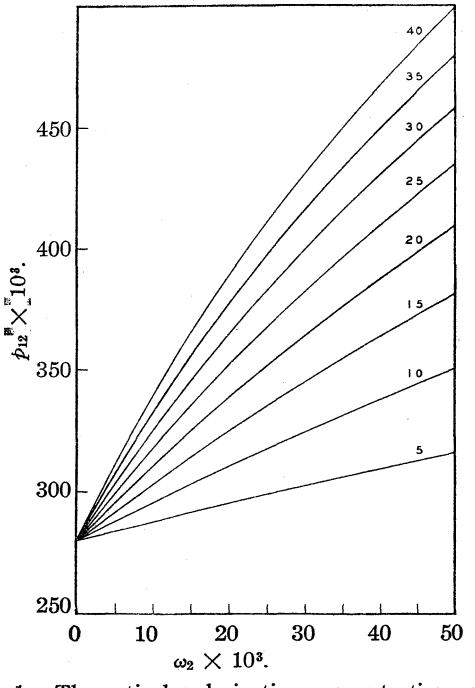

Fig. 1.—Theoretical polarization–concentration curves calculated by use of the Debye–Clausius–Mosotti equation for solutions in which ϵ_{12} is taken as linear with ω_2 (absence of association). β is taken in all cases as -0.2 and α has been varied from 5 to 40.

Considerable evidence has accumulated which indicates that the dielectric constant ϵ_{12} is a linear function of the weight fraction of solute ω_2[4,5,6,7] in dilute solutions.

We have examined over fifty compounds of widely different nature and have found ϵ_{12} to be linear with ω_2 in every case as long as ω_2 is less than 0.01. Now it can be shown from the nature of the relation

$$p_{12} = \frac{\epsilon_{12} - 1}{\epsilon_{12} + 2} \frac{1}{d_{12}}$$

that if ϵ_{12} is linear with respect to ω_2, p_{12} is not linear with ω_2. The extent of this deviation is shown in Fig. 1. The corresponding p_2–ω_2 curves are given in Fig. 2 and it is to be observed that the latter curves are neither horizontal nor straight. It is thus obvious that a linear extrapolation of p_2–ω_2 or P_2–N_2 curves introduces an error which is small in case of compounds with a low dipole moment and comparatively larger with compounds of high dipole moment.

This error is eliminated by the method of extrapolation proposed by Hedestrand.[8] However, serious errors may result even with the use of Hedestrand's method if it is not realized that the dielectric constant of the solvent in the solution sometimes differs considerably from the measured dielectric constant of the pure solvent.

Solvent Polarization Error

Two considerations are involved here. First, with the usual methods of handling, the solutions are exposed longer to air than is the pure solvent and consequently the solutions may absorb more water vapor than the solvent. Second, even if rigid methods are used to exclude moisture each $\Delta\epsilon$ value for the different solutions depends on a single solvent measurement of ϵ_1 and consequently the latter is much more heavily weighted than any single solution measurement of ϵ_{12}. Now since the ϵ_{12}–ω_2 curves are straight lines both of the factors giving rise to solvent polarization error can be essentially eliminated if the dielectric constant of the pure solvent is obtained by extrapolating the ϵ_{12}–ω_2 curves for the solution to $\omega_2 = 0$. By comparing the extrapolated value of ϵ_1 with the measured value one can also tell if there has been appreciable contamination of the solvent in handling the solutions. The method used to calculate p_{2_0} making use of the extrapolated value of ϵ_1 is as follows:

A Method of Calculating p_{2_0}[9]

In calculating p_{2_0} we use the equation

$$p_{20} = \frac{3\alpha v_1}{(\epsilon_1 + 2)^2} + (v_1 + \beta)\frac{(\epsilon_1 - 1)}{(\epsilon_1 + 2)} \qquad (1)$$

which is derived from the expressions

$$p_{12} = \frac{(\epsilon_{12} - 1)}{(\epsilon_{12} + 2)} v_1 \qquad (2)$$

$$\epsilon_{12} = \epsilon_1 + \alpha\omega_2 \qquad (3)$$

$$v_{12} = v_1 + \beta\omega_2 \qquad (4)$$

The corresponding equation in N_2 is

$$P_{20} = \frac{3\alpha' v_1}{(\epsilon_1 + 2)^2} M_1 + (M_2 v_1 + M_1\beta')\frac{(\epsilon_1 - 1)}{(\epsilon_1 + 2)} \qquad (5)$$

This is essentially the same as the equation proposed by Hedestrand.[8]

The ϵ_{12}–ω_2 and v_{12}–ω_2 curves are plotted. If one point is considerably off the curve and all other points on, it suggests an experimental error and that point is rechecked. If the plots show curvature, they suggest some abnormal behavior and this method is not used, or the method is applied to the points in dilute solutions where they are linear. A straight line equation is fitted to the data by the method of least squares using the points for the solutions and omitting those for the pure solvent.[10] The constants of these equations give the values of ϵ_1, v_1, α and β which are substituted in equation (1).

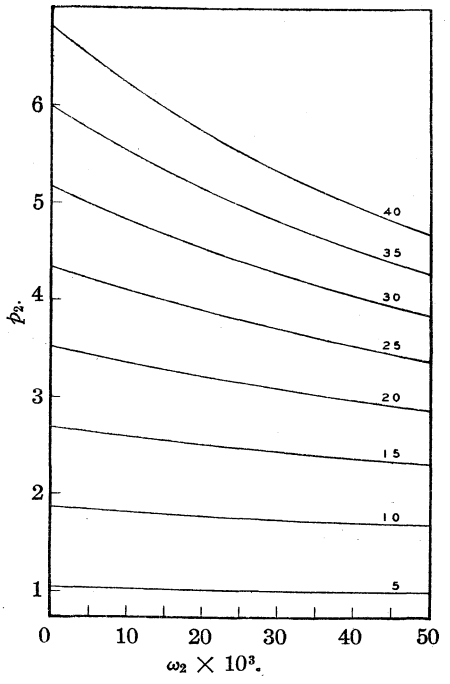

Fig. 2.—The theoretical p_2–ω_2 curves corresponding to the p_{12}–ω_2 curves in Fig. 1.

This calculation can be done graphically by plotting the ϵ_{12}–ω_2 and v_{12}–ω_2 curves. These are straight lines and can easily be extrapolated to $\omega_2 = 0$. The intercept of the ϵ_{12}–ω_2 line gives ϵ_1 and its slope is α. The intercept of the v_{12}–ω_2 line gives v_1 and its slope is β.

The advantages of this method of calculation are: first, it eliminates errors due to a difference in the dielectric constant of the solvent in the solution and the measured dielectric constant of the pure solvent. Second, it is objective and does

(9) The symbols used are: subscripts 1, 2, and 12 refer to solvent, solute and solution, respectively; ϵ, dielectric constant; d, density; v, specific volume, $1/d$; V, molecular volume; M, molecular weight; p, specific polarization; p_{2_0}, specific solute polarization at infinite dilution; P, molar polarization; P_{2_0}, solute molar polarization at infinite dilution; P_{E_2}, solute molar electronic polarization; ω, weight fraction; W, weight; m, moles; N, mole fraction; $\alpha = d\epsilon_{12}/d\omega_2$; $\beta = dv_{12}/d\omega_2$; $\alpha' = d\epsilon_{12}/dN_2$; $\beta' = dv_{12}/dN_2$; μ, dipole moment in Debye units; T, absolute temperature.

(10) The usual statistical method of least squares was used; for example, to fit the straight line $\epsilon_{12} = \epsilon_1 + \alpha\omega_2$ to the dielectric constant data, the equations

$$\Sigma\epsilon_{12} = N\epsilon_1 + \alpha\Sigma\omega_2$$

$$\Sigma(\omega_2\epsilon_{12}) = \epsilon_1\Sigma\omega_2 + \alpha\Sigma(\omega_2)^2$$

in which N represents the number of observations, were set up and solved for ϵ_1 and α. In this method if the data are accurate to five places, the summations need to be carried only to five places, but all numbers derived from these during the solutions of the equations should be taken to eight or nine places if anomalous solutions are to be avoided. This is necessary because ϵ_1 and α are obtained as the ratios of small differences between relatively large numbers and if these large numbers are given only to five places the differences will very often be given only to three places, which, of course, will lead to incorrect results. The calculation of the dipole moment of a compound by this method requires less than an hour if an electric calculating machine is used.

not involve the judgment of the calculator. Third, all extrapolations are carried out with straight line functions. Fourth, if the solutions are absorbing water this is easily detected because the extrapolated and measured dielectric constants for the solvent will be different.

If a contaminant such as water gets into the solutions it will cause the p_2 values to be too high and the magnitude of the error thus introduced will be greater the higher the dilution.

An examination of the literature reveals a number of cases of an abnormal rise in p_2 or P_2 values at high dilution. The effect is usually either ignored, attributed to experimental error, or to that convenient explanation of anomalous behavior—molecular association. Application of our method of calculation to some of these cases reveals a solvent polarization error and the abnormality in the moment disappears when our method is applied. For example, a case of a very marked upward trend at high dilution is found in the paper of Svirbely, Ablard and Warner.[11] They obtain the following values: *d*-pinene 2.67, *d*-limonene 1.56, methyl benzoate 2.52, ethyl benzoate 2.43. The first two values are much too high (1 to 2 units) for hydrocarbons with one and two double bonds. The last two values are about half a unit high for esters. We have recalculated their data using our method and obtained the following values which are consistent with those obtained by other authors[12] for the same compounds. The recalculated values are as follows: *d*-pinene 0.80, *d*-limonene 0.61, methyl benzoate 1.86, ethyl benzoate 1.94. No correction has been made for atomic polarization which will have an appreciable effect on the moments of the first two compounds. These are still probably high by about 0.2 of a unit.

The high values obtained by the above authors in very dilute solutions we believe are without significance and result most probably from solvent polarization errors.

Lewis, Oesper and Smyth[13] have measured trimethyl- and triethyllead chloride at high dilutions and obtain a higher value, 4.47, for the trimethyl compound than for the triethyl compound, 4.39. This is contrary to expectation because the ethyl groups are more polarizable than methyl groups and the large lead–chlorine moment should have a large polarizing effect. The trimethyl compound was measured in solutions about ten-fold more dilute than the triethyl compound so the effect of a small solvent polarization error on P_2 would be much greater for the trimethyl compound. A recalculation by our method gives values of the expected order, 3.81 for trimethyllead chloride and 4.27 for triethyllead chloride.

That solvent polarization errors can have an enormous effect on the observed moment of a compound as determined in very dilute solution is illustrated in the cases of urea and thiourea. The moments of these compounds as given in the literature were 8.6 and 7.6, respectively.[14] A redetermination of these moments under conditions in which solvent contamination was reduced and solvent polarization errors essentially eliminated by using our method of calculation gave values of 4.56 for urea and 4.89 for thiourea.[15]

Theoretically the dielectric constant of the solvent should be increased slightly[16] by the presence of a polar solute and the possibility exists that this effect is responsible for the abnormal increase of P_2 at high dilutions. There are, however, some serious objections to such an interpretation. First, the effect of the solute in increasing the dielectric constant of the solvent would be greater the higher the concentration of the solute. The observed effect is just the reverse, the P_2 values become more abnormal as the solutions become more dilute. Second, many investigators including ourselves do not always obtain the same measured value for the dielectric constant of the pure solvent and these variations are most noticeable with the very hygroscopic solvent dioxane and least noticeable with hexane. Third, where special precautions are taken to eliminate water[17] this sharp rise in P_2 curves at high dilutions is not present. The evidence thus points very strongly to absorption of water as the cause of the abnormally high P_2 values in dilute solutions.

A Test of Our Method of Calculation

A wide variation of dipole moment values in the literature is difficult to reconcile with the accuracy of the dielectric constant and density

measurements. Differences of 0.1–0.2 which represent errors of several per cent. are quite common. Most dielectric constant and density measurements are accurate to at least 0.5% when the total polarization is several times the electronic polarization, and measurements are made in solutions that are not too dilute. This discrepancy is evidently due to an error in the solvent polarization plus errors in extrapolation. If this is the case an application of our method to the data should reveal and correct such errors.

Nitrobenzene was chosen to test this point because it has been measured a number of times in benzene. Four sets of data were found in the literature in which the solutions were sufficiently dilute so that the dielectric constant values were linear with concentration. As seen in Table I the dipole moment values vary by 0.15 from 3.93 to 4.08. A recalculation by our method reduces the variation to 0.03. Part of this difference may be due to the decrease in the dielectric constant of the solvent with increase of temperature.

Data from: Kumler, THIS JOURNAL, **62**, 3292 (1940); Kumler and Halverstadt, *ibid.*, **63**, 2182 (1941); Kumler and Halverstadt, *ibid.*, **64**, 1941 (1942).

Rau and Narayanaswamy[18] found experimentally that the apparent moment of nitrobenzene in benzene increases about 0.01 for an increase of 5°. Since the temperatures of the measurements we used range from 20 to 25° this would reduce the variation to 0.02 which is about the magnitude expected. Taking an average of the values corrected to 25° the dipole moment of nitrobenzene in benzene appears to be 4.00 ± 0.01, no correction being made for the atomic polarization.

In Table II the dipole moment values from two previous papers have been recalculated by the new method. There appear to have been no serious solvent polarization errors with the exception of aniline where the old moment value is high by 0.17. In thirteen of the seventeen cases the old values are lower by 0.02–0.19 than the new values. This we attribute to the linear extrapolation of the P_2-concentration curves which we have previously shown are concave upward, and to solvent polarization errors. The conclusions that were originally drawn from the old data hold for the new more accurate values.

To show further how the new method of calculation avoids exaggeration of experimental error we have included in Table II two measurements on sulfanilamide carried out by different operators using different samples of solute and solvent. The moment values calculated by the old method are 6.63 and 6.52, a difference of 0.11, while the new method gives 6.65 and 6.64, a difference of 0.01.

Summary

The available data indicate that the dielectric constant–weight fraction, ϵ_{12}–ω_2 curves for polar solutes in non-polar solvents are straight lines in dilute solutions. If this is the case it follows that the polarization p_{12} as defined by the Debye–Clausius–Mosotti (D-C-M) equation cannot be a linear function of the concentration. The p_2-ω_2 curves are neither horizontal nor straight and their curvature increases as ω_2 decreases. As a result, dipole moments calculated by a linear extrapolation of p_2 or P_2 to zero concentration are in error although the error is small for compounds with small moments. Per cent. association calculated by the assumption that p_{12}–ω_2 or p_2–ω_2 curves are linear in the absence of association is likewise in error.

A new method of calculating polarizations at infinite dilutions has been devised which, first, eliminates solvent polarization error, second, is objective and does not involve the judgment of the calculator, third, all extrapolations are made either statistically or graphically with straight line functions.

Evidence is presented to show that solvent polarization errors are responsible for some erroneous dipole moment values in the literature.

Our method of calculation has been applied to some of the anomalous cases and values are obtained which are more consistent with other determinations on the compounds or with the moment expected theoretically.

A test of this method of calculation has been applied to four sets of accurate data in the literature on nitrobenzene in benzene. The dipole moment values given by the authors have a variation of 0.15; our method gives a variation of 0.02. Another test was made on sulfanilamide measured by two operators and calculated by both methods. The linear P_2 extrapolation gave a variation of 0.11; our method, a variation of 0.01.

SAN FRANCISCO, CALIFORNIA RECEIVED JANUARY 5, 1942

(18) Rau and Narayanaswamy, *Proc. Indian Acad. Sci.*, **1A**, 489 (1935). These authors obtained a value of 3.99 for the moment of nitrobenzene at 30° using Hedestrand's method of calculation. We did not recalculate their data because they measured only three solutions and one of these was at too high a concentration.

The Dipole Moment of *ms*-Tetraphenylporphine

BY W. D. KUMLER

The configuration of the porphine ring system is of much interest because of its presence in chlorophyll and hemoglobin. A dipole moment study of a compound such as *ms*-tetraphenylporphine appeared to offer a way to tell whether the compound and, hence, the ring system was symmetrical or unsymmetrical.

The *ms*-tetraphenylporphine used in these studies was the more abundant isomer with a hydrochloric acid number of 13.5.[1] The compound is highly colored and absorbs appreciably in the yellow, hence, the usual method of determining the electronic polarization by measuring the refractive index with the D sodium line could not be used. However, it appeared if light were used of a wave length that was not absorbed by the compound the refractive index might be measured despite the fact that the compound is highly colored. The orange 6143 line in a neon tube was found to be a suitable source. Abnormalities in the refractive index, which might have been expected had the wave length of light used been too near an absorption band, were not observed.

Results

The results are given in Table I.

TABLE I

MEASUREMENTS IN BENZENE AT 25°

ω_2	ϵ_{12}	v_{12}
0.002010	2.2777	1.1454
.004458	2.2807	1.1447
.005595	2.2816	1.1442
.006762	2.2834	1.1436
.007916	2.2851	1.1435

ϵ_1	v_1	α	$-\beta$	P_{2_0}	$P_{E_{2_0}}$
2.2742	1.1460	1.355	0.311	310	293

The P_{2_0} value was calculated by using the equations

$$p_{2_0} = \frac{3\alpha v_1}{(\epsilon_1 + 2)^2} + (v_1 + \beta)\frac{(\epsilon_1 - 1)}{(\epsilon_1 + 2)}$$

$$P_{2_0} = p_{2_0} M_2$$

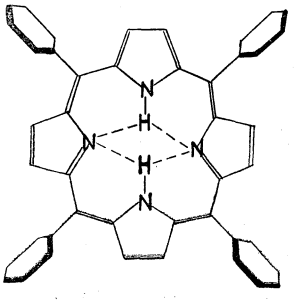
where the symbols have the same significance as in the previous paper.[2]

The values of α, β, v_1, and ϵ_1 were determined graphically. A combination of three factors, namely, the large size of the molecule, its low solubility, and the fact that its moment is small or zero, result in a very small difference in the dielectric constant of the various solutions. As a result the experimental error in both P_{2_0} and $P_{E_{2_0}}$ is probably about 7 cc.

The value of 310 for P_{2_0} and 293 for $P_{E_{2_0}}$ indicates that the compound has a small or zero moment. The experimental error is of such magnitude that a moment of a few tenths cannot be distinguished from a moment of zero. It is probable that this large highly resonating molecule has a comparatively large atomic polarization of the order of the difference between P_{2_0} and $P_{E_{2_0}}$.

The polarization of the compound was also determined at 5° intervals between 25° and 45° but no decrease in polarization with increasing temperature was observed which likewise indicates the compound has zero moment.

With zero moment the molecule must be arranged in some symmetrical fashion. A symmetrical structure might exist with the giant ring either puckered or flat. The giant ring is, however, a highly resonating system and the atoms must get into such a position that the alternate single and double bonds can shift their position without involving an appreciable movement of the atoms. This demands a flat structure with the giant ring, the pyrrole rings and the 1 and 4 carbon atoms of each benzene ring all in one plane. The two hydrogen atoms in the center can conceivably be arranged symmetrically in a number of ways. First, on opposite nitrogen atoms with one hydrogen above and one below the plane of the main ring. Second, as above but forming hydrogen bonds to one of the adjacent nitrogen atoms. Third, in the plane of the main ring and forming a bifurcated hydrogen bond with both adjacent nitrogen atoms (as in the figure). Fourth, the same as in the second case except the covalence to each hydrogen shifts (resonates), being attached first to one and then to the other nitrogen atom. Fifth, the same as in the third case except the covalence to



ms-Tetraphenylporphine.

(1) Rothemund and Menotti, THIS JOURNAL, **63**, 267 (1941).
(2) Halverstadt and Kumler, *ibid.*, **64**, 2988 (1942).

each hydrogen shifts among three nitrogen atoms. Case one is unlikely because it appears highly probable that hydrogen bonds are present.[3,4,5] If the actual situation is that of case four or five, which does not appear at all unlikely, there would be no isomerism due to the position of the hydrogen atoms.

It appears from a study of the Fisher models that a flat giant ring of this type can be constructed without undue strain. However, there is much interference between the pyrrole rings and the benzene rings if an attempt is made to place the latter in the same plane as the rest of the molecule. This suggests that the benzene rings do not have free rotation and are probably oscillating about a position perpendicular to the plane of the main ring. The general shape of the molecule would then be that of a flat disc with the four benzene rings cutting it at about right angles. If the benzene rings do not have free rotation then derivatives of *ms*-tetraphenylporphine having ortho or meta substituents should exist in a number of stereoisometric forms depending on whether the substituents are above or below the plane of the giant ring.

Experimental

The dielectric constant measurements were carried out with the same apparatus and in the same manner as described previously.[6] The refractive indices were measured with a Pulfrich refractometer using a neon Geissler tube as a light source.

The *ms*-tetraphenylporphine was recrystallized twice from benzene.

Acknowledgment.—We are indebted to Dr. O. L. Inman and Dr. Paul Rothemund of the C. F. Kettering Foundation at Antioch College for the sample of *ms*-tetraphenylporphine.

Summary

The more abundant isomer of *ms*-tetraphenylporphine was found to have a polarization of 310 and an electronic polarization of 297. Measurement of polarizations at different temperatures gave no evidence of a decrease of polarizations with increasing temperatures. Both methods indicate the compound has zero moment although the data do not enable one to distinguish between a moment of a few tenths and a zero moment.

The electronic polarization of the compound was obtained by measuring the refractive index of the solutions although they were highly colored. This was accomplished by using the orange line of a neon tube. This light had a wave length that was not absorbed by the solution.

The zero moment indicates the compound is symmetrical. The resonance demands that the giant ring and the pyrrole rings be in one plane. A study of the Fisher models suggests the benzene rings do not have free rotation and are perpendicular to this plane. With ortho or meta substituents on the benzene rings this hindered rotation will give rise to a number of stereoisomers.

The Serological Properties of Simple Substances. I. Precipitation Reactions between Antibodies and Substances Containing Two or More Haptenic Groups

BY LINUS PAULING, DAVID PRESSMAN, DAN H. CAMPBELL, CAROL IKEDA, AND MIYOSHI IKAWA

The study of serological precipitation reactions is complicated by the fact that ordinarily these reactions involve two proteins, the antigen and the antibody. The understanding of these reactions was greatly advanced by the introduction into their study of precise microanalytical methods and a further simplification involving the use of a nitrogen-free multivalent hapten of pneumococcus polysaccharide.[1] A few years ago it was reported by Landsteiner and van der Scheer[2a] that the precipitin reaction and anaphylaxis could be produced by simple substances formed by coupling two haptenic groups with resorcinol or tyrosine, in place of the azoprotein (containing the same haptenic group) which has been used as the antibody-producing antigen. Landsteiner[2b] suggested that "the ready precipitability of these

dyes is dependent upon peculiarities in constitution which, like those of fatty groups, diminish solubility in water and favor the formation of colloidal solutions." However, it seemed probable to us, on the basis of a theory of the structure of antibodies and the nature of the precipitin reaction,[3] that simple substances containing two or more haptenic groups would react with antibodies in essentially the same way as the homologous protein antigens containing the same haptenic groups; we accordingly prepared a half-dozen simple substances of this sort, each with two or more phenylarsonic acid groups per molecule, and observed each to precipitate antisera homologous to phenylarsonic acid azoprotein,[4] thus obtaining evidence for the generality of the phenomenon discovered by Landsteiner and van der Scheer.

The problem of obtaining from precipitation experiments evidence about the structure of antibodies and the nature of serological reactions is obviously greatly simplified by the replacement of protein antigens by simple substances of known structure. For this reason we began and are carrying on an extensive program of investigation of the reactions of simple substances with antisera. In this paper we report the quantitative study of the precipitin reaction for twenty simple substances containing two or more haptenic groups, and the results of tests of seven substances containing one group. It is found that the observations support the framework theory of serological precipitates.[5]

Discussion of Experimental Methods

Simple Antigens.—The simple antigens and haptens used in the investigation are listed in Table I; methods of preparations of these substances and the intermediates used are described in the following section.

Protein Antigens.—The immunizing antigens used for inoculations were made from diazotized arsanilic acid and sheep serum by the method described by Landsteiner and van der Scheer.[6] The ratio of arsenic to protein in these antigens ranged from 2 to 3%.

Test antigens were similarly made from purified ovalbumin by treatment with diazotized arsanilic acid, diazotized *p*-(*p*-aminophenylazo)-phenylarsonic acid, or diazotized *p*-aminobenzanilide-*p'*-arsonic acid. The azo-ovalbumins contained, respectively, 0.16, 4.0, and 2.0% arsenic.

Arsanilic acid was diazotized in hydrochloric acid solution by the addition of sodium nitrite solution at 0° to the starch–iodide end-point. The diazotizations of *p*-(*p*-aminophenylazo)-phenylarsonic acid and of *p*-aminobenzanilide-*p'*-arsonic acid were similarly carried out at 10° with end-point the disappearance of the slightly soluble amine hydrochlorides.

Preparation of Antisera.—Twenty-five rabbits were injected intraperitoneally or intravenously with 1- or 2-ml. portions of the atoxylazo-sheep-serum antigen described above, containing 0.5% protein. Several weekly courses of 3 to 5 injections were given, with intervening rest periods of a week or more. The rabbits were bled from the ear on the eighth, ninth, and tenth days after the last injection, 40 ml. of blood being taken from each rabbit each day. The blood was permitted to clot, and the antisera were pooled according to titer. The courses of injections and subsequent bleedings were repeated to obtain more pools of serum.

A measure of the total amount of antibody homologous to the atoxyl hapten (the phenylarsonic acid group) was made by determining the maximum amounts of antibody precipitated by the azo-ovalbumin test antigens. The most effective test antigen, that made from *p*-(*p*-aminophenylazo)-phenylarsonic acid, precipitated 2 mg. of antibody per ml. of antiserum A, 4 mg. per ml. of B, 1.5 mg. per ml. of C, and 4 mg. per ml. of D.

The Reaction of Antigen and Antiserum.—The precipitation tests were carried out by mixing portions of undiluted antiserum, usually 2 ml., with equal volumes of saline solution containing dye; usually four to six dye concentrations were tested, differing by powers of 2. The tubes were allowed to stand for one hour at room temperature and then overnight in the refrigerator. The precipitates were then centrifuged down, washed with three or four 10-ml. portions of normal saline, and analyzed for nitrogen. In some experiments colorimetric determinations were made of the amount of dye in the redissolved precipitates. In the tests with serum A the customary visual estimates of cloudiness were made one-half hour after the solutions were mixed.

Methods of Analysis.—Analyses for nitrogen were made by the semimicro Kjeldahl method, using the apparatus described by Redemann.[7] Sulfuric acid, copper sulfate, and potassium sulfate were used in the digestion mixture; hydrogen peroxide was found not to be needed.

The arsenic determinations were carried out by the method of Haurowitz and Breinl.[8] Carbon and hydrogen analyses were made with the usual semimicro technique. Colorimetric determinations of dye and azoprotein were made with a Klett photoelectric colorimeter after dissolving the precipitates in a few drops of 2 *N* sodium carbonate solution.

The reported values of antibody in precipitates are the values of antibody nitrogen multiplied by the factor 6.25, the antibody nitrogen being the difference between total nitrogen in the precipitate and antigen nitrogen calculated

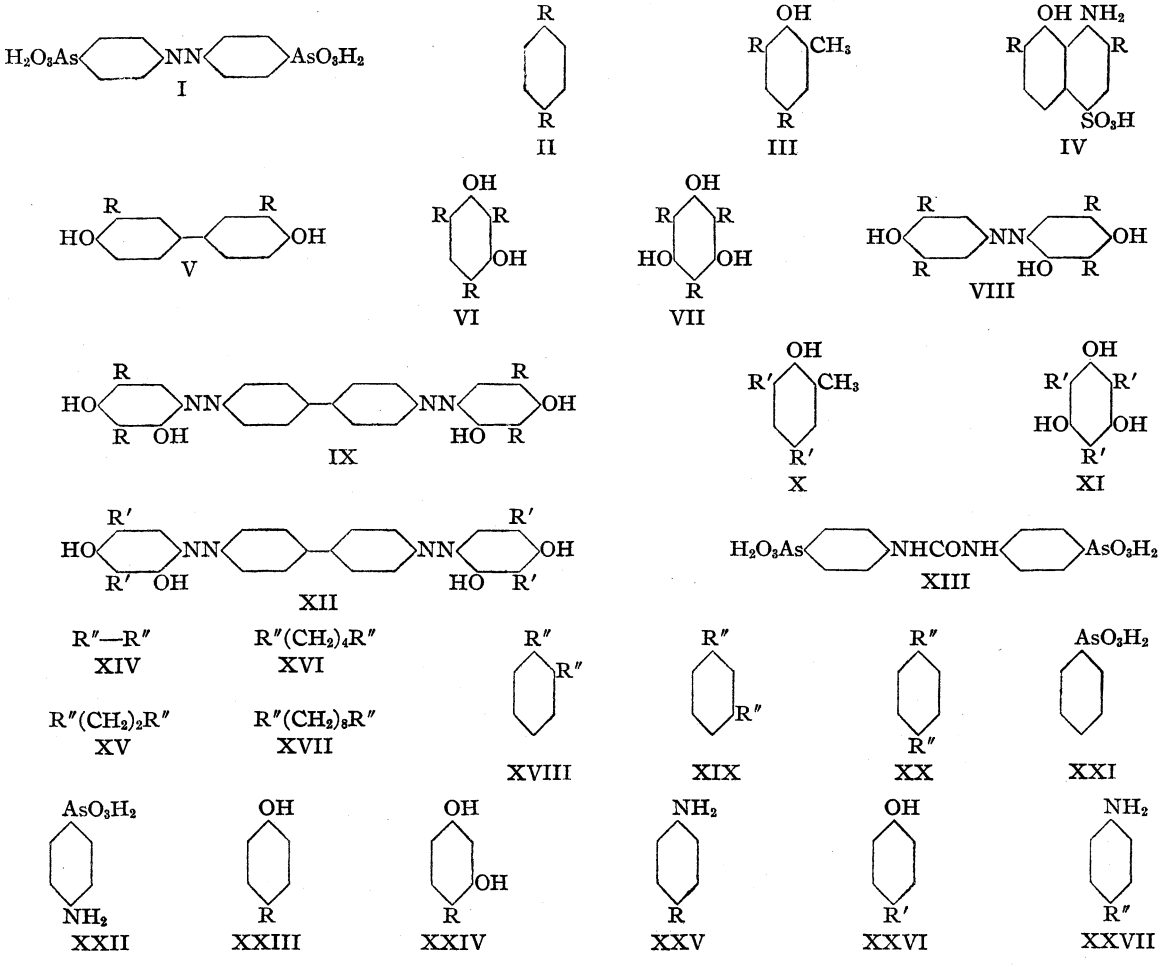
TABLE I

SUBSTANCES USED IN PRECIPITATION TESTS

R = *p*-azophenylarsonic acid, —NN⟨⟩AsO_3H_2

R′ = *p*-(*p*-azophenylazo)-phenylarsonic acid, —NN⟨⟩NN⟨⟩AsO_3H_2

R″ = phenylcarbamyl-*p*-arsonic acid, —CONH⟨⟩AsO_3H_2



from the amount of antigen as determined colorimetrically (for simple antigens this correction is very small).

The Preparation of Compounds

XXI, Phenylarsonic acid was prepared by Mr. David Brown by the Bart reaction.[9]

XXII, Arsanilic acid was prepared by the method of Bechamp.[10]

XXV, *p*-(*p*-Aminophenylazo)-phenylarsonic acid was made (a) by the hydrolysis in 2 *N* sodium hydroxide of the acetyl derivative made by condensing *p*-nitrosophenylarsonic acid with *p*-aminoacetanilide (20% excess) in glacial acetic acid by refluxing for three hours, and (b) by the hydrolysis for twenty minutes in boiling 1 *N* sodium hydroxide of the ω-methylsulfonate formed by reaction in 0.3 *N* sodium carbonate of diazotized arsanilic acid and aniline-ω-methylsulfonate (20% excess).[11] The two products, purified as the sodium salts, appeared to be identical.

Anal. Calcd. for $C_{12}H_{11}O_3N_3AsNa$: C, 42.04; H, 3.12. Found: (a) C, 41.98; H, 3.23; (b) C, 42.12; H, 3.40.

Nitrosophenylarsonic acid was made by the method of Karrer[12] from arsanilic acid and Caro's acid.

I, Azobenzene-*p*,*p*′-diarsonic acid was prepared by the method of Karrer[12] from *p*-nitrosophenylarsonic acid and arsanilic acid and was purified by repeated precipitation with acid from alkaline solution.

[a] Excess of phenol (per cent.). [b] Sodium salt.

II, *p*-Di-(*p*-azophenylarsonic acid)-benzene was similarly made from *p*-nitrosophenylarsonic acid and *p*-phenylenediamine and similarly purified.

Anal. Calcd. for $C_{18}H_{16}O_6N_4As_2$: C, 40.46; H, 2.94. Found: C, 38.85, 38.81; H, 3.12, 3.19.

III, 2-Methyl-4,6-di-(*p*-azophenylarsonic acid)-phenol; IV, 1-Amino-2,7-di-(*p*-azophenylarsonic acid)-4-sulfo-8-naphthol; V, 3,3′-Di-(*p*-azophenylarsonic acid)-4,4′-dihydroxybiphenyl; VI, 1,3-Dihydroxy-2,4,6-tri-(*p*-azophenylarsonic acid)-benzene; VII, 1,3,5-Trihydroxy-2,4,6-tri-(*p*-azophenylarsonic acid)-benzene; VIII, 2,4,4′-Trihydroxy-3,5,3′,5′-tetra-(*p*-azophenylarsonic acid)-azobenzene; IX, 4,4′-Bis-(azo-2,4-dihydroxy)-3,5-di-(*p*-azophenylarsonic acid)-biphenyl; X, 2-Methyl-4,6-di(*p*-(*p*-azophenylazo)-phenylarsonic acid)-phenol; XI, 1,3,5-Trihydroxy-2,4,6-tri-(*p*-(*p*-azophenylazo)-phenylarsonic acid)-benzene; XII, 4,4′-Bis-(azo-2,4-dihydroxy)-3,5-di-(*p*-(*p*-azophenylazo)-phenylarsonic acid)-biphenyl; XXIII, *p*-(*p*-Azophenylarsonic acid)-phenol; XXIV, 1,3-Dihydroxy-4-(*p*-azophenylarsonic acid)-benzene; XXVI, *p*-(*p*-(*p*-azophenylazo)-phenylarsonic acid)-phenol.—Compounds III to XII, XXIII, XXIV, and XXVI were made by coupling diazotized arsanilic acid or diazotized *p*-(*p*-aminophenylazo)-phenylarsonic acid with the appropriate phenolic nucleus in dilute sodium carbonate solution or (for XXVI) in sodium acetate–acetic acid solution. For III, X, and XI pyridine was added[13] in amount about 10% of the volume of the reaction mixture. The reaction mixtures were allowed to stand for a few days (1 to 4) and the products were then precipitated with hydrochloric acid and purified by repeated solution in dilute sodium hydroxide and reprecipitation with acid. Compounds X, XI, and XII were in addition purified by dialysis through Visking sausage casing against dilute borax solution with *p*H 10; this membrane permits passage of molecules containing only one haptenic group R′ but not those containing two or more of these groups. The compounds were washed free of sodium chloride and dried *in vacuo*. Experimental details, analytical results, and colors of solutions in alkali and in concentrated sulfuric acid are given in Table II.

A chromatographic method of analysis of the purity of these compounds was developed and applied by Mr. A. Pardee. The column packing used was a mixture of 30% Celite and 70% Neutrol Filtrol. A dilute solution of the dye was poured into the packed column and the chromatogram was developed with phosphate buffer of *p*H varying from 8 to 12 in different cases. The rate of passage of the dyes was greater the higher the *p*H. Compounds VI, VII, X, XI, XXIII, XXIV, and XXVI appeared to be quite pure, having at most only a slight trace of a second band. On the other hand, compounds I, II, III, V, VIII, IX, and XII contain appreciable colored impurity, as shown by the appearance of more than one band on the column. Compounds V, VIII, IX, and XII might be expected to be impure from the large number of steps in their preparation. The impurity in compound II was identified as XXV from a mixed chromatogram.

2,4,4′-Trihydroxyazobenzene was prepared by coupling diazotized *p*-aminophenol with resorcinol (100% excess) in the presence of sodium hydroxide. The product was purified by dissolving it in sodium hydroxide and reprecipitating with acid and finally by two crystallizations from 70% alcohol.

Anal. Calcd. for $C_{12}H_{10}O_3N_2$; C, 62.60; H, 4.38. Found: C, 62.39; H, 4.46.

4,4′-Bis-(azo-2,4-dihydroxy)-biphenyl was prepared by adding bisdiazotized benzidine to resorcinol (100% excess) in a sodium acetate buffered solution. The mixture finally was made alkaline with sodium hydroxide. The product was purified by washing.

Anal. Calcd. for $C_{24}H_{18}O_4N_4$; C, 67.60; H, 4.25. Found: C, 66.37; H, 4.62.

XXVII, *p*-Aminobenzanilide-*p*′-arsonic acid was prepared by the method of King and Murch[14] by the hydrolysis of the carbethoxyamino compound obtained by coupling *p*-arsanilic acid with *p*-carbethoxyaminobenzoyl chloride.

XIII, Carbanilide-*p,p'*-diarsonic Acid; XIV, Oxanilide-*p,p'*-diarsonic Acid; XV, Succinanilide-*p,p'*-diarsonic Acid; XVI, Adipanilide-*p,p'*-diarsonic Acid; XVII, Sebacanilide-*p,p'*-diarsonic Acid; XVIII, Phthalanilide-*p,p'*-diarsonic Acid; XIX, Isophthalanilide-*p,p'*-diarsonic Acid; XX, Terephthalanilide-*p,p'*-diarsonic Acid.—These dianilide compounds were prepared by essentially the methods of King and Murch[14] and Morgan and Walton,[15] involving the reaction of arsanilic acid with the required acid chloride or anhydride in a basic or buffered aqueous solution. The compounds were purified by repeated solution in sodium hydroxide and precipitation with hydrochloric acid followed by a thorough washing with hot water. The reactants used and the results of analyses are given in Table III.

Results of the Precipitation Experiments

The Precipitation Reactions between Multivalent Compounds and Antisera.—Precipitation tests were carried out between the antisera A, B, C, and D homologous to atoxylazoprotein and the twenty compounds I to XX, each of which contains in its molecule two or more haptenic groups R, R′, or R″. *In every case precipitation occurred.* The amount of precipitate was found to vary with concentration of the antigen in the same way as for ordinary antigens. There is an optimum antigen concentration (or amount while the volume of antigen solution is held constant) at which the amount of precipitate reaches a maximum.

The amounts of precipitated antibody found by analysis are given in Tables IV, V, VI, VII, and VIII and are represented graphically in Figs. 1, 2, 3, 4, and 5.

Errors in the determination of the amounts of precipitated antibody may arise in the separation and washing of the precipitate or in the nitrogen analysis. Examination of the reported results of duplicate determinations indicates a probable error of about 5% for individual determinations.

TABLE IV

AMOUNTS OF ANTIBODY PRECIPITATED FROM ANTISERUM A BY ANTIGENS I TO XII

Amounts of solutions used: 2 ml. antiserum, 3 ml. saline-antigen. The *p*H of the supernatant solutions was between 8.3 and 8.5. In Tables IV to VIII, inclusive, the amount of antigen used, in micrograms per ml. of antiserum, is given at the top of each column. The numbers in the columns are the amounts of precipitated antibody, in micrograms per ml. of antiserum. The meaning of the other symbols is given in the text.

Amount of antigen	3.13	6.25	12.5	25	50

	120	435	735	500	175

Test of the Customary Visual Estimation Method.—For the series reported in Table IV we took advantage of the opportunity of testing the customary visual-estimation method of studying antigen-antibody precipitation reactions. The tubes were inspected one-half hour after the solutions were mixed, and a record made of their appearance; this is given by the symbols in the table, which have the following meanings: −, no apparent cloudiness; ±, slight cloudiness; +, ++, +++, increasingly pronounced cloudiness; ↓, formation of clumps of precipitate. Comparison of these with the amounts of antibody precipitated in twenty-four hours shows that the correlation is reasonably good, and suggests that visual estimates of the amount of precipitate may be trusted to within about ± 30%. In this case each symbol represented about 60% more precipitate than the preceding one, as follows: −, 75; ±, 100; +, 150; ++, 250; +++, 400; ↓, 500 μg/ml.

TABLE VIII

AMOUNTS OF ANTIBODY PRECIPITATED FROM ANTISERUM D BY ANTIGENS II AND XIII TO XX

Amounts of solutions used: 2 ml. antiserum, 3 ml. saline-antigen.

Amount of antigen	3.13	6.25	12.5	25	50	100
II	140	280	780	1160	1150	930

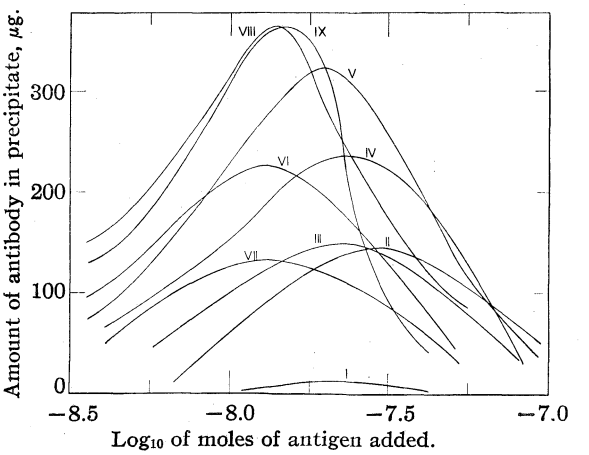

Fig. 1.—Amounts of antibody precipitated from antiserum A (per ml.) by antigens I to IX as functions of log of molal antigen concentration (Table IV). The curve for I represents an estimate. Smooth curves have been drawn through the experimental points, which are not shown.

Comparison Tests with Normal Serum.—Similar tubes were set up for each of the twenty antigens with normal rabbit serum in place of antiserum. In none did precipitation occur.

The Failure of Monohaptenic Compounds to Produce Precipitates with Antisera.—The seven

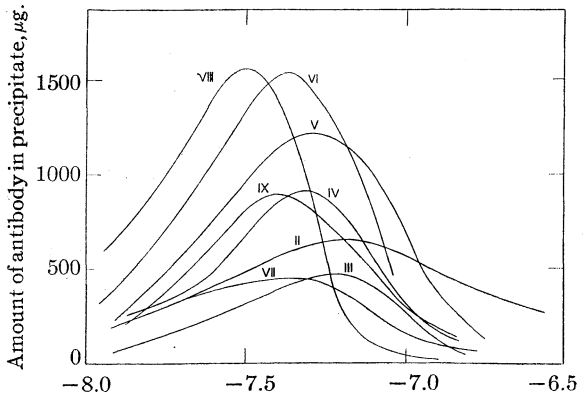

Fig. 2.—Amounts of antibody precipitated from antiserum B (per ml.) by antigens II to IX (Table V).

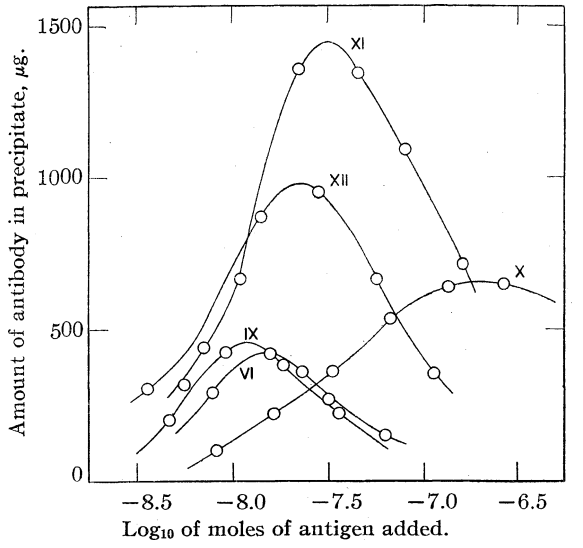

Fig. 3.—Amounts of antibody precipitated from antiserum C (per ml.) by antigens VI, IX, X, XI, and XII (Table VI).

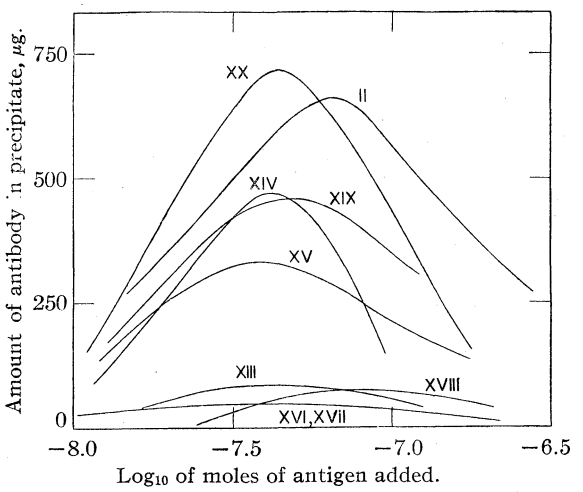

Fig. 4.—Amounts of antibody precipitated from antiserum B (per ml.) by antigens XIII to XX (Table VII) with antigen II for comparison (Table V).

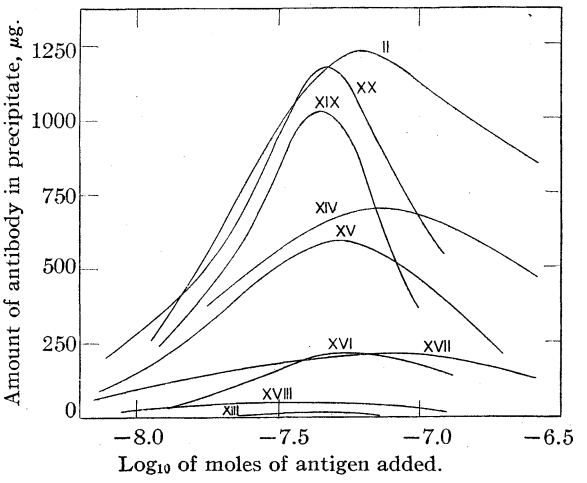

Fig. 5.—Amounts of antibody precipitated from antiserum D (per ml.) by antigens II and XIII to XX (Table VIII).

compounds XXI to XXVII, each of which contains one haptenic group per molecule, were tested with the antisera in the same way as the twenty compounds I to XX; no precipitate was formed by any of these "univalent" substances. This result is, of course, to be expected, in view of the failure of Landsteiner[16] to obtain precipitates between haptens and homologous antisera during his extensive experiments on the inhibition by homologous haptens of the azoprotein-antibody precipitation reaction.

Discussion

The fact that each of the twenty polyhaptenic substances precipitates hapten-homologous antibody, whereas substances containing only one haptenic group do not have this effect, provides strong support for the Marrack–Heidelberger framework theory (lattice theory) of the structure of serological precipitates, inasmuch as the framework theory gives a simple explanation of the phenomenon, and no other reasonable explanation has been proposed. Multivalent antibody molecules, whose existence is postulated in the framework theory, would be expected to combine with polyhaptenic molecules to form infinite aggregates, which would grow into visible precipitates, whereas with monohaptenic molecules they would form soluble small complexes containing one antibody molecule.

The general shape of all the curves of Figs. 1 to

(16) K. Landsteiner, "The Specificity of Serological Reactions," Charles C. Thomas, Baltimore, 1936, p. 118.

5, showing the dependence of amount of antibody precipitated on the amount of added antigen, is the same; the amount of precipitated antibody first increases, then reaches a maximum, and finally decreases, reaching zero for large amounts of antigen. This inhibition of precipitation by excess antigen, which occurs also for protein antigens, is explained as resulting from the formation of soluble complexes, such as A–B–A (A_2B) for a bivalent antibody (A = antigen, B = antibody). There may also be formed soluble complexes AB_2, A_2B_3, etc., which contain an excess of antibody, saturating the effective valences of the antigen molecules. The interpretation of the precipitation data in terms of the strength of the antigen-antibody bond is complicated not only by the necessity of considering these soluble complexes but also by the heterogeneity of antibody molecules.

The data for nine compounds I to IX which contain the group  used in the immunizing azoprotein are reproduced in Figs. 1 and 2. It is seen that there is agreement between the results obtained with the two antisera in most respects. From Fig. 1 we obtain the following sequence of precipitating ability of the haptens: VIII = IX > V > VI = IV > VII = III = II > I. Nearly the same sequence is given by Fig. 2. The principal difference is the interchange of VI and IX, and other data (as in Fig. 3) indicate that the order given by Fig. 1 is to be preferred. It is possible that some gross error was made in the work; on the other hand, the difference between Figs. 1 and 2 may well be real, resulting from difference between the two antisera.

The smallness of the amount of precipitate given by I  we attribute to two causes. First, the molecule contains only one azo group, so that in holding two antibody molecules the molecule cannot exert toward each the influence of the complete haptenic group  (present in the immunizing azoprotein); and second, two large antibody molecules clasping the two end halves of this very small antigen would be expected to interfere sterically with each other, and be prevented by this steric interference from forming as strong an antigen-antibody bond as would otherwise be possible.

Of the five dihaptenic compounds I to V the two most effective, IV and V, are those with the greatest hapten-hapten distance. We attribute their relative effectiveness to the resultant diminution in steric interaction of the attached antibodies.

Since in the immunizing azoprotein the azophenylarsonic acid groups are attached in part to tyrosine residues, a very effective haptenic group is expected to be  with one hydroxyl adjacent to the azo group. By considering this we explain the superiority of V  to IV  and of VI  to VII  .

It is interesting that the trihaptenic (VI and VII) and tetrahaptenic (VIII and IX) compounds are superior but not greatly superior to the dihaptenic compounds of similar size and structure. It was expected[3] that dihaptenic compounds would be inferior in precipitating ability because of the formation with bivalent antibody of soluble strings A–B–A–B–A–B– rather than insoluble frameworks. The observation that good precipitates are obtained with dihaptenic compounds indicates either that the long strings themselves precipitate easily or that enough trivalent antibody molecules are present to link the strings together.

The compounds X, XI, and XII, which contain the long haptenic group

are much more effective than the corresponding compounds III, VII, and IX; this increased effectiveness we attribute to decreased steric interference between the attached antibodies. The comparison of X  and XI  is especially interesting. The superiority of the latter is clearly to be attributed to its having three haptenic groups instead of two.

Why, then, does not XII  with

four, precipitate still more antibody? The answer may be that little gain is to be expected from increasing the number of haptenic groups from three to four, since three are enough to tie the strings together into a framework. In fact, XII is as effective as XI at low concentrations, and its later inferiority may be due to greater ability to form soluble complexes.

There is a striking relation between the number of haptenic groups per antigen molecule and the optimum antigen concentration for precipitation; a great change occurs from dihaptenic to trihaptenic antigens, and a much smaller change on addition of a fourth haptenic group. This is seen clearly in Fig. 3; the logarithm of the optimum molal concentration of X is −6.8, of XI −7.5, and of XII −7.65. Similarly the five dihaptenic antigens of Fig. 1 are grouped together at −7.6, and the others at −7.9.

The data represented in Figs. 4 and 5 show that the amide haptenic group  is essentially equivalent to the azo haptenic group  in its power to combine with antibodies homologous to the azo haptenic group. A straightforward comparison can be made between the amide compound XX  and the azo compound II  ; it is seen from the corresponding curves in Figs. 4 and 5 that these compounds are nearly equal in precipitating power.

The compound XIII  would be expected from steric considerations to be somewhat more effective than I  , because of the added CO group; this is borne out by experiment. The compound XIV  , containing two complete haptenic groups, should be still more effective. It is in fact surprisingly effective, with nearly the precipitating power of XX.

The compounds XVIII  , XIX  and XX  are increasingly effective in this order, with XVIII by far the weakest of the three. This is reasonably interpreted as due to steric interference of the attached antibody molecules.

This explanation cannot be extended, however, to the sequence XIV R″—R″, XV R″$(CH_2)_2$R″, XVI R″$(CH_2)_4$R″, XVII R″$(CH_2)_8$R″, since these compounds decrease in precipitating power in this order. A structural interpretation of this result in terms of the lack of rigidity of the polymethylene chain might be developed, but it is not very convincing.

The curves for compounds XIV and XV differ in shape from those for XIX and XX; no reasonable explanation of this has occurred to us.

It is important to note that the polyhaptenic simple antigens are not greatly inferior in precipitating power to azoproteins. Indeed, the best of the simple antigens, XI, was found to precipitate as much antibody as the test azoprotein.

Boyd[17] has recently reported failure to obtain precipitates between antisera and a number of simple substances containing two or more haptenic groups (including several substances also studied by us), and on the basis of this negative evidence he has drawn conclusions contrary to those which we have reached. In view of our observations, we consider it likely that his experiments were carried out under conditions unfavorable to precipitation—his antisera may have been weak, or his antigens may have contained monohaptenic impurities.

We are grateful to the Rockefeller Foundation for financial support of this work. We wish to thank Mr. Paul Faust and Mr. Shelton Steinle for their assistance in carrying out analyses, and Mr. David Brown for the preparation of phenylarsonic acid.

Summary

Twenty-seven simple substances containing the phenylarsonic acid group as haptenic group were prepared and used in precipitin tests with antisera made by injecting rabbits with azophenylarsonic acid sheep serum.

The twenty simple antigens containing two or more haptenic groups per molecule were found to give precipitates with the antisera, whereas

(17) W. C. Boyd, *J. Exptl. Med.*, **75**, 407 (1942); S. B. Hooker and W. C. Boyd, *J. Immunol.*, **42**, 419 (1941).

the seven monohaptenic substances failed to precipitate. It is pointed out that these results provide strong support of the framework theory of the precipitin reaction.

Data on the amounts of precipitate formed are discussed in relation to the structure of the simple antigens.

The Serological Properties of Simple Substances. II. The Effects of Changed Conditions and of Added Haptens on Precipitation Reactions of Polyhaptenic Simple Substances

BY LINUS PAULING, DAVID PRESSMAN, DAN H. CAMPBELL, AND CAROL IKEDA

During the course of the investigation of precipitation reactions of polyhaptenic simple substances reported in the preceding paper of this series[1] we found it desirable to carry out a study of the effects of changed conditions of precipitation and washing on the amount of residual precipitate. We also made some experiments on the inhibition of precipitation by added haptens, in order to see how great would be the effects of monohaptenic impurities possibly present in the substances studied. The results obtained are presented and discussed in this paper.

Experimental Methods.—The experiments were carried out in the way described in the preceding paper (I). In addition to antisera C and D mentioned in paper I, three antisera, E, F, and G, were used. E and G contained amounts 0.6 and 3.2 mg. per ml., respectively, of antibody precipitable by azo-ovalbumin test antigen; the strength of F was not determined.

The borate buffer solutions were made by adding suitable amounts of 0.16 *N* sodium hydroxide solution to 0.2 *M* boric acid solution containing 0.9% sodium chloride.

The Effect of Changed Conditions of Precipitation and Washing on the Amount of Precipitate.—It is seen from the data reported in Tables I, II, and III, obtained with two antigens (VI and X) and three antisera (C, E, and F), that the antigen-antibody precipitate is either dissolved slightly or carried away mechanically by the saline or borate buffer solutions with which it is washed. The loss in this way is, however, small, amounting to about 5 to 15% for eight or ten extra washings with 10-ml. portions of solution.

A few experiments were made (Tables II and III) to test the effects of changing the time and temperature of precipitation. It was found that increasing the precipitation time from one day to two days increases the amount of precipitate by about 10%. The amount of precipitate formed seems to increase with increase in temperature of

the tube during the first few hours of the precipitation period (Table III). However, the evidence is inconclusive as to whether the final amount of precipitate is increased or not by refrigeration during the later part of the precipitation period.

The data reported in Table IV show that the amount of precipitated antibody is decreased by the addition of buffer solution to the antigen-antibody mixture. The decrease is not proportional to the volume of buffer added, so that the phenomenon is not analogous to the solution of a

TABLE IV

THE EFFECT OF DILUTION WITH BUFFER SOLUTION ON AMOUNT OF PRECIPITATED ANTIBODY

2.5 ml. antigen VI, varying volume of borate buffer solution with *p*H 8.0, 2.5 ml. antiserum C.

10	470	655	450

well-defined compound. These observations provide further evidence of the heterogeneity of the antibodies in immune sera.

The Effect of Hydrogen-ion Concentration on Amount of Precipitate.—The results of experiments to test the effect of change in *p*H on the amount of precipitate are given in Table V. It is seen that for this antigen-antibody system the optimum *p*H is about 8.1, the amounts of precipitate in this region being greater than for either more acidic or more basic solutions. Evidence that the buffering substances do not have a large direct influence on the reaction is given by the agreement of the values at *p*H 8.1 for added saline solution and added borate buffer.

The optimum antigen concentration is seen to be changed only slightly by change in *p*H.

Less extensive experiments were also carried out with the amide antigen XIV (R″–R″) in place of the azo antigen; the results obtained, given in Table VI, are similar.

The Effect of Dilution with Normal Serum or Buffer Solution.—In order to determine the effect of change in the strength of a serum of fixed antibody composition on the position of the optimum zone, identical experiments were made with sera obtained by mixing antiserum G and normal serum. The results are given in Table VII. It is seen that for both antigens (III and VI) the maximum precipitation occurs at an amount of antigen about midway between 25 and 50 μg. (for 2 ml. of antiserum), and that on two-fold dilution of the antiserum, decreasing its antibody concentration by the divisor 2, the optimum amount of antigen is also decreased by about the divisor 2. The effect of diluting the antiserum is hence to cause the optimum zone to shift in such a way as to keep constant the ratio of antigen to antibody.

The same result is given by experiments on the effect of dilution with buffer solution, reported

in Table IV. In these experiments, in which the amount of antibody is kept constant, the position of the optimum zone does not change significantly.

These conclusions agree with those reached by many earlier investigators with protein antigens.

The Inhibition of Precipitation by Hapten.—It was discovered by Landsteiner[2] that a hapten such as arsanilic acid present in reasonable concentration in a mixture containing an azoprotein (made from this hapten) and the hapten-homologous antiserum decreases the amount or inhibits the formation of the antigen-antibody precipitate. It has also been found[3] that this phenomenon occurs with polyhaptenic simple substances replacing the azoprotein. Quantitative results were obtained by us with antigens VI, X, and XX, containing the groups R, R′, and R″, respectively, and haptens XXI, XXII, XXIII, and XXVII. These are given in Tables VIII to XI and Figs. 1 and 6. It is seen (Table VIII) that addition of hapten decreases the amount of precipitate without noticeable shift in the equivalence zone, and (Tables X, XI) that haptens differ in their inhibiting power.

The results obtained show that no significant error would be introduced in the experiments by the presence of haptens as impurities in the polyhaptenic antigens in amounts as great as 5%. It is improbable that any of the substances used contained this much monohaptenic impurity.

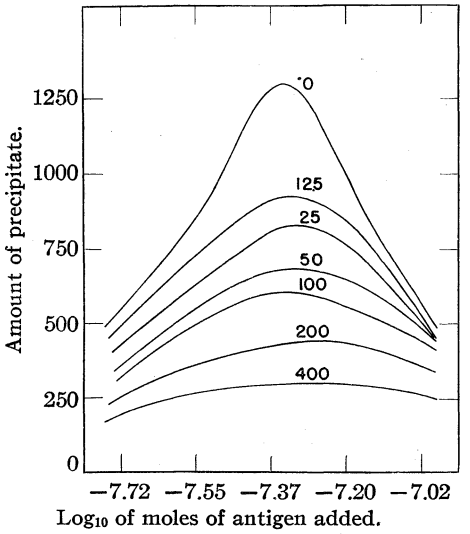

Fig. 1.—Effect of added hapten (in amounts given) on amount of antigen-antibody precipitate (Table VIII).

The data reported in Table XII indicate that the same final equilibrium is reached by the system antigen-antibody-hapten when the order of combining the reactants is changed.

TABLE XII

EFFECT OF ORDER OF COMBINATION OF REACTANTS

Reactants combined as indicated and allowed to stand indicated times at room temperature, then 24 hours in refrigerator: A, 3 ml. solution of antigen VI (37.5 μg.); H, 1 ml. solution of hapten XXI (100 μg.); S, 3 ml. antiserum E. *p*H of supernates 8.1.

[a] A precipitate formed before hapten was added.

Discussion

A reasonable interpretation of these results and those of the preceding paper can be given in terms of the multivalent-antibody theory. This interpretation is conveniently presented with the aid of a simplified model susceptible to easy mathematical treatment.[4]

Let us assume that our idealized antigen–antibody system consists of a solution containing antigen molecules A, antibody molecules B, soluble complex molecules A_2B, and molecules AB in equilibrium with a precipitate AB. We ignore other complexes A_3B_2, A_4B_3, AB_2, etc., and the known heterogeneity of antibody molecules in a serum.

For simplicity we assume that each of the two bonds in A–B–A is equal in strength to the bond in A–B, and that the equilibrium constants for the two reactions

$$A + B = AB$$

and

$$A + AB = A_2B$$

differ only by the entropy factor 4. We represent these by $4K$ and K, respectively, with K the equilibrium constant for combination of a single haptenic group of an antigen molecule and a single complementary region of an antibody molecule, and derive the equation

$$AB(\text{pp}) = A_{\text{total}} - s - \frac{1 + 2Ks}{2 + 2Ks}\{A_{\text{total}} - B_{\text{total}} + [s(1 + Ks)/K + (A_{\text{total}} - B_{\text{total}})^2]^{1/2}\} \quad (1)$$

(4) Somewhat similar quantitative theories of the precipitin reaction have been published by M. Heidelberger and F. E. Kendall, *J. Expil. Med.*, **61**, 563, **62**, 467, 697 (1935); **66**, 229 (1937); F. E. Kendall, *Annals N. Y. Acad. Sci.*, 153, 85 (1942); and A. D. Hershey, *J. Immunol.*, **42**, 455 (1941). These theories are designed to apply more broadly than ours, which is based on postulates suited to the special antigens and haptens which we are studying.

in which AB (pp) is the amount of precipitated compound, with solubility s, and A_{total} and B_{total} are the total amounts (per unit volume) of antigen and antibody in all molecular species, including the precipitate.

The curves of amount of precipitate for a given antiserum with varying amounts of antigen calculated with this equation have the general shape indicated by the experimental points.

Curves for the arbitrary values $s = 1$, $K = 1/2$ are plotted against A_{total} in Figure 2 for each of several values of B_{total}, corresponding to the strength of the serum. It is seen that in each case the maximum amount of precipitate is produced by an amount of antigen approximately equal to the amount of antibody. This is in agreement with the results obtained with diluted serum (Tables IV and VII).

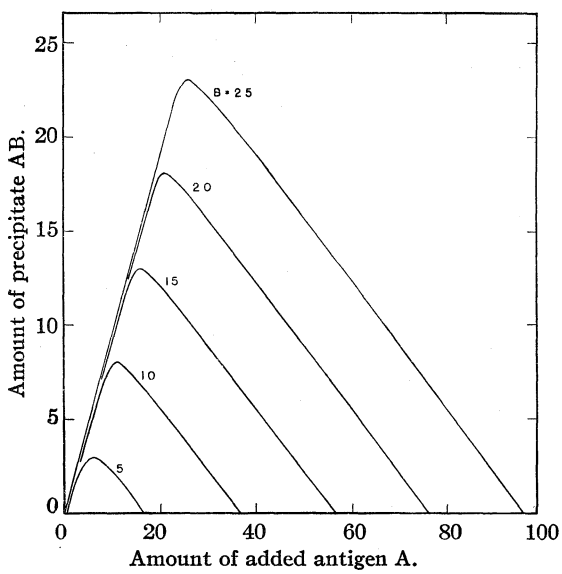

Fig. 2.—Theoretical curves showing amount of precipitate AB as function of amount of antigen A for antisera with varying antibody concentration $B = 5$ to 25. Values of constants used are $s = 1$, $K = 1/2$.

The observation, reported in the preceding paper, that different polyhaptenic antigens containing the same haptenic group have the same molal concentration for maximum precipitation with a given serum, although the amount of precipitable antibody in the serum varies with the antigen, requires explanation, since it might well be expected that the optimum antigen concentration would be proportional to the amount of precipitate. Let us assume that for antigens containing the same haptenic group the A–B bond constant K has the same value, but that the solubility s of the precipitate may vary. This might reasonably result from steric interference of the large antibody molecules in the chains –A–B–A–B–A–B- in the precipitate, which might cause a second bond formed by a bivalent antigen molecule to be much weaker than the first bond. The curves in Fig. 3, with K constant and s varying, represent this situation. We see that, as the result of the consecutive equilibria A + B = AB and AB + A = A_2B, the position of the maximum is constant when K is constant and the solubility s varies. It is found from the equation, in fact, that the maximum occurs at the point $A_{total} - B_{total} = 1/2K$, and is independent of s.

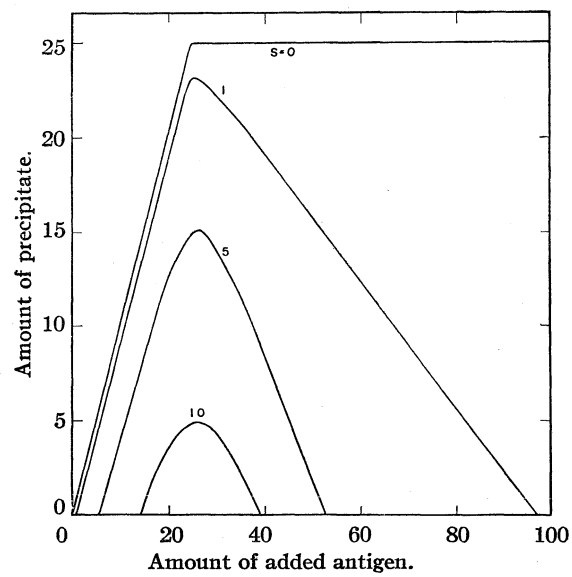

Fig. 3.—Calculated effect of variation of solubility of antigen-antibody precipitate on amount of precipitate; all curves for initial antibody concentration $B = 25$ and $K = 1/2$.

It is also found (Fig. 4) that variation in K produces little change in the optimum antigen concentration, except when the value of K becomes very small. It accordingly seems probable that the difference of the optimum concentration for antigens containing the haptenic group R and those containing the longer group R′, as shown in Fig. 3 of paper I, is evidence that the effective strength of the serum for groups R′ is greater than that for R, because of the presence of antibodies capable of combining with R′ and not with R.

The maximum amount of precipitate is independent of K; its value, as found from Equation 1, is $B_{total} - 2s$.

The fact that change in effective strength of a serum with change in pH is not accompanied by

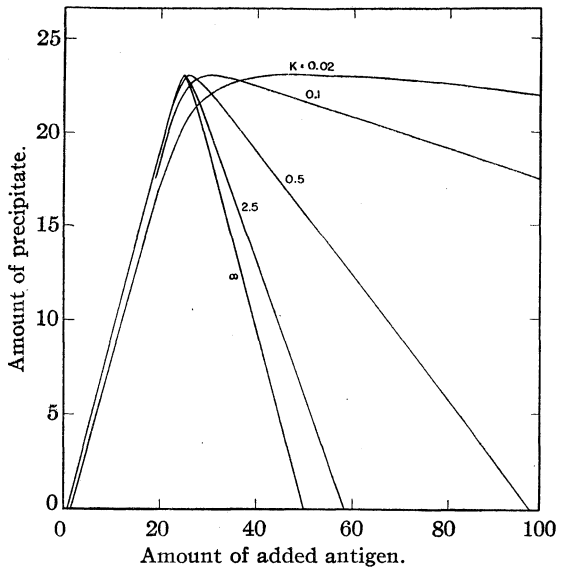

Fig. 4.—Calculated effect of variation of A–B bond-strength constant K on amount of precipitate; all curves for initial antibody concentration $B = 25$ and AB solubility $s = 1$.

shift of the optimum antigen concentration indicates that the effect is not due simply to change in the concentration of effective antibody molecules. Further experiments on the *p*H effect are under way.

The phenomenon of hapten inhibition has been explained by Landsteiner as resulting from combination of hapten and antibody to form a soluble complex, thus effectively neutralizing the antibody. The formation of soluble complex instead of a precipitate by antibody and hapten is explained by the framework theory as the result of the univalence of the hapten. It might be expected that as the maximum amount of precipitate which can be obtained from a serum is decreased by addition of hapten there would occur a corresponding decrease in the optimum antigen concentration, as was observed in the dilution experiments.

It is seen from Fig. 1, however, that the optimum antigen concentration is not shifted very much by addition of hapten. A small shift can be predicted by an extension of our simple theory. If we consider a system containing in solution the molecular species H, BH, BH_2, and ABH (H = hapten) as well as A, B, AB, and A_2B, and assume the B—H bond strength to be such that the equilibrium constants for the reactions

$$B + H = BH$$
$$BH + H = BH_2$$

and

$$AB + H = ABH$$

are $2K'$, $K'/2$, and K', respectively, we obtain the set of equations

$$AB(\text{pp}) = A_{\text{total}} - s - \alpha\{1 + 2K(s + z)\} \quad (2)$$

$$A_{\text{total}} - B_{\text{total}} = \alpha - \frac{s}{4K\alpha} + \alpha Ks - z - \frac{\alpha K z^2}{s} \quad (3)$$

$$z = -\frac{1}{2}\left(\frac{s}{2K\alpha} + s + \frac{1}{K'}\right) \pm \left\{\frac{1}{4}\left(\frac{s}{2K\alpha} + s + \frac{1}{K'}\right)^2 + \frac{sH_{\text{total}}}{2K\alpha}\right\}^{1/2} \quad (4)$$

in which H_{total} is the total hapten concentration. The auxiliary variables α (the concentration of the molecular species A in solution) and z (the concentration of the molecular species HB in solution) are related by Equation 4, by means of which z can be calculated for an assumed value of α. Then by use of Equation 2 the amount of precipitate can be found, and by Equation 3 the variable α can be replaced by A_{total} and B_{total}.

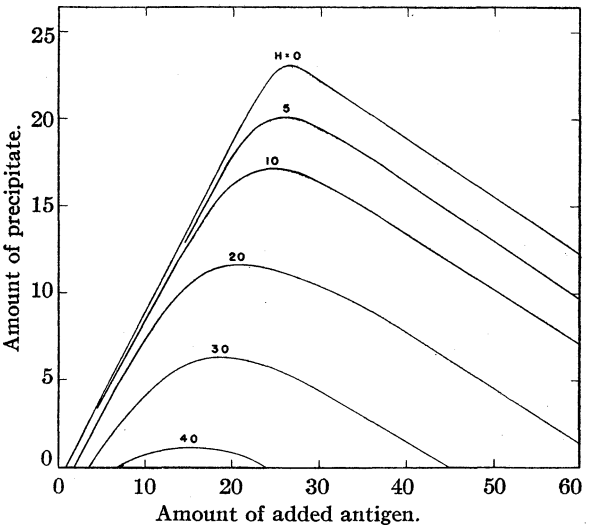

Fig. 5.—Calculated effect of addition of hapten on amount of antigen-antibody precipitate, for $B_{\text{total}} = 25$, $K = 1/2$, and $K' = s = 1$.

In Fig. 5 there are shown curves calculated in this way for $K = 1/2$, $K' = s = 1$, $B_{\text{total}} = 25$, and $H_{\text{total}} = 0$, 5, 10, 20, 30, and 40. It is seen that there is a small shift of the maxima toward lower antigen concentrations. In the region of the equivalence zone, where A_{total} equals B_{total}, the amount of precipitate formed is proportional to the hapten concentration, as is given by Equation 5, which is derived from Equations 2, 3, and 4.

$$\frac{dAB(\text{pp})}{dH_{\text{total}}} = -\frac{1/2 + Ks + (K^2s^2 + Ks)^{1/2}}{1 + Ks + \left(1 + \frac{1}{K's}\right)(K^2s^2 + Ks)^{1/2}} \quad (5)$$

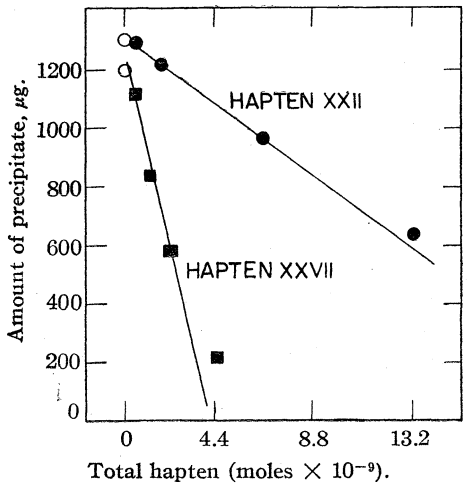

Fig. 6.—Observed effect of haptens XXII and XXVII on amount of precipitate between antigen XX and antiserum (Table XI).

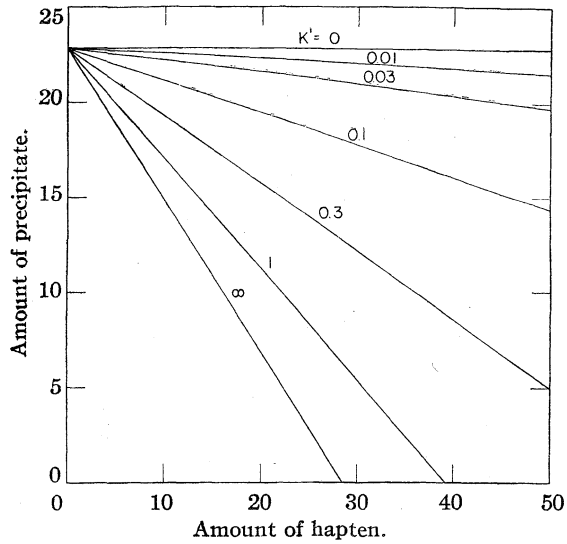

Fig. 7.—Calculated dependence of amount of antigen-antibody precipitate on hapten-antibody bond-strength constant K', for $A_{total} = B_{total} = 25$, $K = 1/2$, $s = 1$.

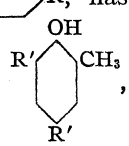
The experimental data at low hapten concentrations are in rough agreement with the straight-line relation, as shown in Fig. 6 for the data of Table XI.

In Fig. 7 there is shown the predicted effect of variation of the hapten-antibody bond-strength constant K'.

It might be expected from its similarity in structure with the antigen that hapten XXVII, NH_2⬡R'', would be much more effective than hapten XXII, arsanilic acid, in inhibiting precipitation by antigen XX, R''⬡R''; that this expectation is borne out can be seen from the slopes of the curves of Fig. 6. The data of Table X show that hapten XXIII, HO⬡R, has greater inhibiting effect for antigen X,



than has hapten XXII.

The data of Tables VIII and IX cannot be interpreted so reliably, since the antigen used (VI) is trihaptenic. The observation that hapten XXIII is very much more effective than hapten XXI, phenylarsonic acid, is however to be expected from the structures. We are planning to continue work on hapten inhibition, with the hope of obtaining quantitative information about the relative bond strengths of different haptenic groups with antibody.

We thank the Rockefeller Foundation for financial support of this work. We are indebted also to Dr. Verner Schomaker for helping with the theoretical treatment of antibody-antigen-hapten interactions, and to Mr. Shelton Steinle for carrying out analyses.

Summary

The results are reported of experimental studies of the effect of changed conditions, including time and temperature of precipitation, washing, addition of buffer solution and normal serum, hydrogen-ion concentration, and addition of hapten, on amount of precipitate formed by antisera and simple polyhaptenic antigens of known structure.

A simple theory of antibody-antigen-hapten interaction is formulated on the assumption of the bivalence of antibodies. It is found that this theory provides a reasonable interpretation of the experiments.

The Serological Properties of Simple Substances. III. The Composition of Precipitates of Antibodies and Polyhaptenic Simple Substances; the Valence of Antibodies

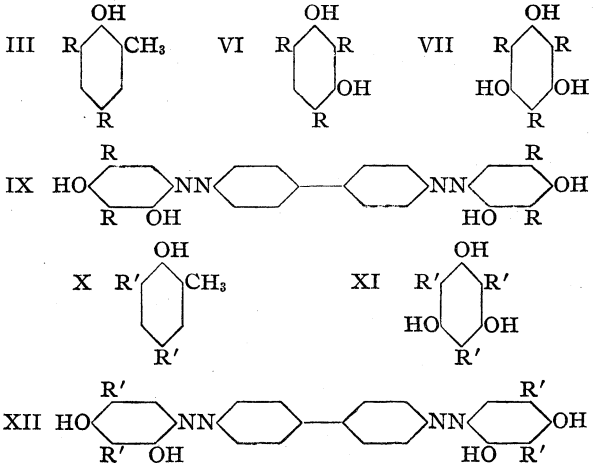
BY LINUS PAULING, DAVID PRESSMAN, AND CAROL IKEDA

The antibody–antigen mole ratio of precipitates formed by interaction of antigens and homologous antisera provides information about the relative combining powers or "valences" of antigen and antibody molecules. For protein antigens it has been found by Heidelberger and co-workers[1] and by other investigators[2] that the antibody–antigen mole ratio is greater than unity, and increases from the antigen-excess region (where the values approach unity) through the equivalence zone to the antibody-excess region, the values for the last region being nearly twice those for the equivalence zone. These results, which show that the effective valence of the protein antigen molecules is greater than that of the antibody molecules, have been accounted for in a reasonable way by the framework theory and the postulate that antibodies which act as precipitins are bivalent.[3] Since the mole ratio gives only the relative valences of antigen and antibody, and information about the valence of protein antigens is in general not at hand, these data do not directly provide information about the valence of the antibodies; but similar data for simple antigens of known structure should give this information. In this paper, the third in a series of studies of the serological properties of simple substances,[4] we present and discuss the results of about 400 analyses of precipitates formed by antibodies and polyhaptenic substances.

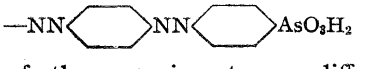
Experimental Methods.—The preparation of antigens and antisera and the techniques of precipitation and analysis have been described in the first paper of this series.

A series of tests was made to determine the extent to which the dyes used in the investigation might be non-specifically carried down with the specific precipitates. In each test 1 ml. of dye solution in borate buffer solution of *p*H 8 was added to 1 ml. of buffer solution containing 1 mg. ovalbumin; 1 ml. of antiovalbumin rabbit serum was then added, the tube was allowed to stand one hour at room temperature and overnight in the refrigerator, and the precipitate was then centrifuged down, washed three times with 10-ml. portions of saline solution, and analyzed for dye and protein. Six tests, with amount of dye increasing by threefold steps from 4 to 1000 μg., were made with each of the dyes III, VI, IX, X, XI, and XII. The amount of dye found in the precipitate was about 3 μg., exceeding this value only for the two largest amounts of added dye (1000 and 333 μg.). Since the amount of precipitated antibody in each test, about 6 mg., corresponds for specific precipitation to about 30 to 70 μg. of dye, a possible error of about 4 to 10% because of non-specific coprecipitation of dye is indicated.

Values of the Antibody-antigen Mole Ratio for Simple Antigens.—Many experiments were carried out in which equal volumes of antiserum were mixed with antigen solutions containing varying amounts of the dye. The following seven dyes were used



with R the short haptenic group —NN⟨⟩AsO_3H_2 and R′ the longer group



In most of the experiments no difference in

(4) L. Pauling, *et al.*, *ibid.*, **64**, 2994 and 3003 (1942).

composition was found to within the estimated reliability of the results (about ±10%) for precipitates obtained in the entire range from antigen excess to antibody excess. Data for three series of tests are represented in Fig. 1. It is seen that in these three series, two of which cover the range from antigen excess (at the right) to antibody excess, there is evidenced no significant trend of the mole ratio.

In Tables I to VI there are given the averaged values of the mole ratio for the forty-three series of tests carried out, with a description of the conditions for each series. The mean deviation of the ratios from the average for each series is also given. The average of all tests for each antigen and the mean deviation from the average are shown at the bottom of the corresponding table. The mean deviations give an indication of the probable reliability of the results.

In three series the hydrogen-ion concentration was varied from about *p*H 7.8 to *p*H 9.2 for the supernate; no significant correlation with the mole ratio was detected, and the values were averaged for inclusion in the tables.

The mole ratio values given in Tables IV, V, and VI show especially pronounced variation. We have not detected any reliable correlation with the changed test conditions, nor found any explanation of the variation.

In a few series, notably the two for antigen IX, a pronounced decrease of the mole ratio with decrease in the amount of added antigen was found. This behavior, which is the opposite to that shown by protein antigens, is hard to understand; and we plan to study it further, checking especially the possibility of some so far undetected source of error.

Discussion.—The most extensive and consistent set of analyses, that for the trihaptenic antigen VI (Table I), gave the average value 0.85 ± 0.11 for the antibody-antigen mole ratio. The same average, 0.85, is obtained by adding to the 186 analyses for this antigen the 53 analyses made for the other trihaptenic antigens XI and VII (Tables II and III).

The interpretation of this number requires an assumption as to the number of haptenic groups of the dye which are effective in forming bonds with antibody molecules. If all three of the haptenic groups were thus effective, the valence of the antibody would be given by the observed ratio as 3/0.85 = 3.5. But the observations indicate

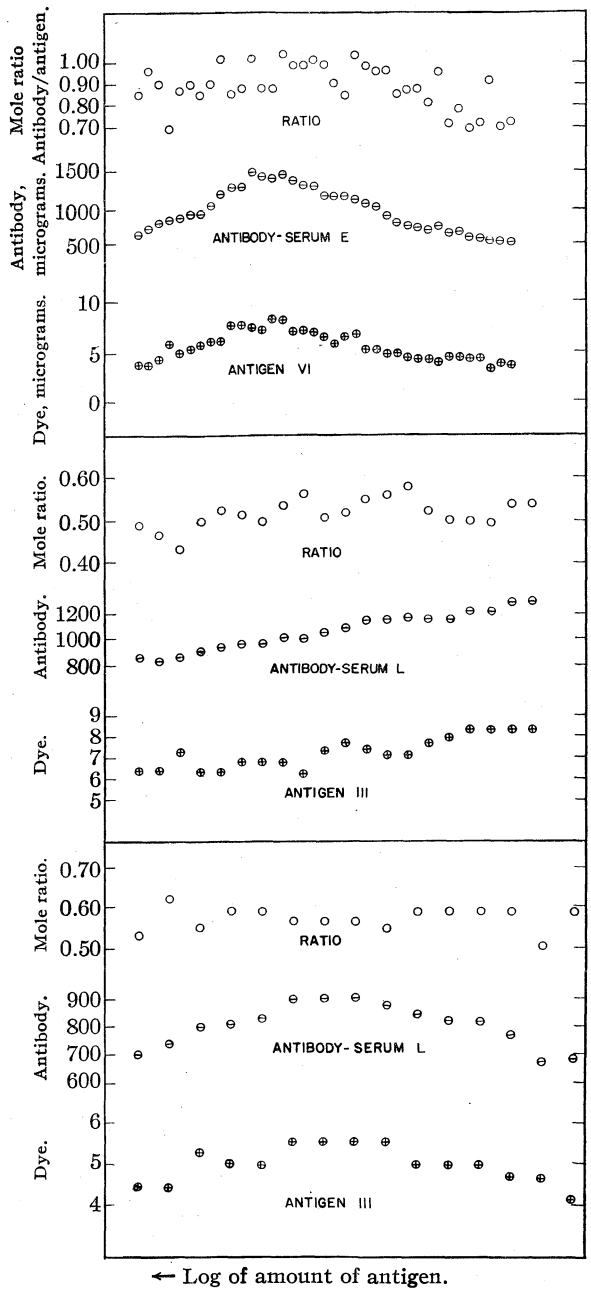

Fig. 1.—Values of (from bottom up) amount of antigen (micrograms) in precipitate, amount of antibody (micrograms) in precipitate, and antibody-antigen mole ratio. The three series of tests correspond to line 1 of Table I (top), line 6 of Table IV (middle), and line 7 of Table IV (bottom). The horizontal scale is the logarithm of the amount of antigen used, with the maximum at the left.

in several ways that the haptenic groups are not all effective. First, the average ratio from the 119 analyses for the dihaptenic dyes is 0.75, and that from the 44 analyses for the tetrahaptenic dyes is 0.83; and these numbers differ from the value for the trihaptenic dyes by much less than

the 33⅓% which could be expected if all of the haptenic groups were effective, the antibody valence remaining constant. Second, if all three haptenic groups of a trihaptenic dye were able to form bonds with different antibody molecules a pronounced change in composition of the precipitate with change of the total antibody-antigen ratio for the system would be expected, and this is not observed. For bivalent antibody and trivalent antigen the expected values of the antibody-antigen ratio are 1.0 for antigen excess, 1.5 for the equivalence zone, and 2.0 for antibody excess.[3] Such change in composition is observed for protein antigens; but it did not appear, to within the estimated probable error of the work, in any of our series (illustrated by that for antigen VI shown in Fig. 1).

It is, moreover, not unreasonable that the number of antibody molecules to which a small antigen molecule can be bonded should be limited. If, as has been postulated,[3] the bond between dye and antibody is formed by the insertion of the haptenic group into a complementary cavity in the antibody molecule (Fig. 2), then it might well occur that two antibody molecules attached to a dye molecule would by steric interference prevent others from attaching themselves to the other haptenic groups of the dye molecule. If this were to hold for every dye molecule the antibody-antigen ratio for bivalent antibodies would be 1.

Even with the minimum effective antigen valence, 2, compatible with the framework theory, the valence of the antibody molecules must be taken greater than 2 to account for the observed values less than unity for the mole ratio. The possibility that dye not specifically bonded to antibody is carried down with the precipitate was tested as described above, and it was found that about 3 μg. of dye per 6000 μg. of precipitated antibody was carried down by ovalbumin-antiovalbumin precipitates. If a corresponding 10% correction were made, the antibody-antigen ratios (for specifically precipitated dye) would become 0.83, 0.93 and 0.91, which are still less than unity. It is, of course, possible that the non-specific precipitation of dye is somewhat greater, but it seems more probable that the extra dye molecules are held by specific hapten-antibody bonds, as discussed below.

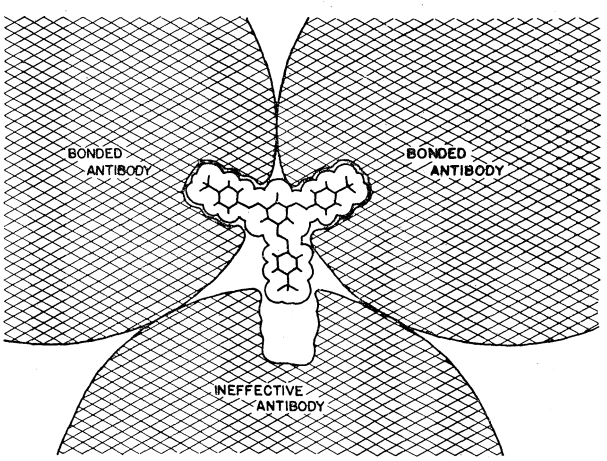

Fig. 2.—Scale drawing showing how steric interference of antibody molecules might prevent a trihaptenic dye from combining with more than two antibody molecules. The radius of curvature of the antibody molecules as drawn is 30 Å.

The calculation of the antibody valence on the basis of this assumption is not straightforward. If each dye molecule were to use two haptenic groups in bond formation the antibody valence given by the ratios would be 2/0.75 = 2.7 for

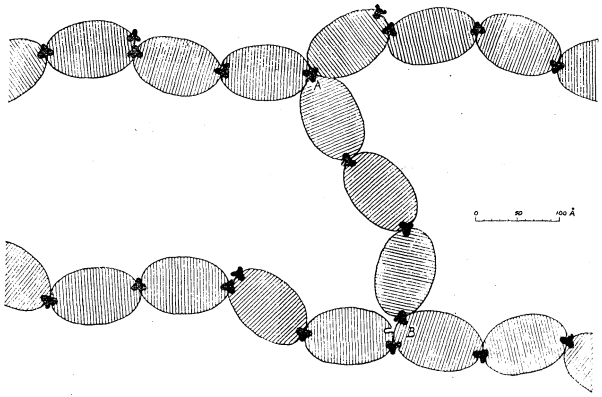

Fig. 3.—Scale drawing representing the structure of the precipitate formed by antibody and an antigen such as VI, $C_6H(OH)_2(NNC_6H_4AsO_3H_2)_3$, as indicated by the experimental results. Most of the antibody molecules are bivalent, and most of the antigen molecules use only two of their three haptenic groups for forming bonds with antibodies. Two long chains are shown, and a short connecting chain. This is attached at A to an antigen molecule bonded to three antibody molecules—a structural feature expected to be rare because of steric interference of the antibody molecules. The bond at B is to a trivalent antibody. There are four other trivalent antibodies, three with extra antigens attached, leading to the antibody-antigen ratio 0.85.

the precipitates with dihaptenic dyes, 2/0.85 = 2.3 for those with trihaptenic dyes, and 2/0.83 = 2.4 for those with tetrahaptenic dyes. If, on the other hand, extra dye molecules were held by a single bond to dye-antibody chains the increased antibody valence over 2 would need to be only one-half as great, and the antibody valence would be calculated to be 2.3, 2.2, and 2.2, respectively.

It seems not unlikely that some antibodies have more than two regions complementary to the haptenic group. Even if, as has been postulated,[3] only two parts of an antibody molecule assume configurations complementary to a portion of the surface of the immunizing antigen, this portion might include, in the case of an azoprotein, two or more haptenic groups, so that the resultant antibody molecule would be able to interact with three haptenic groups or more.

The picture of the antibody-dye precipitates indicated by our data is thus the following. Only two of the haptenic groups of a dye are ordinarily effective in reacting with antibody, others being presumably inhibited by steric interference of the attached antibody molecules. The effective valence of the antibody molecules is also usually 2, but some of these molecules, with three or more hapten-complementary regions, form bonds with additional dye molecules, causing the antibody-antigen mole ratio to fall below unity. Figure 3 illustrates various aspects of this picture.

We thank the Rockefeller Foundation for support of the work reported in this paper, and Mr. Shelton Steinle and Mrs. Elizabeth Swingle for carrying out analyses.

Summary

Many analyses of precipitates between dyes containing azophenylarsonic acid groups and hapten-homologous antisera have been made, leading to the average antibody-antigen mole ratios 0.75 for dihaptenic dyes, 0.85 for trihaptenic dyes, and 0.83 for tetrahaptenic dyes. The approximate equality of these values is interpreted as resulting from the limitation to 2 of the effective valence of polyhaptenic dyes by the steric interference of attached antibody molecules, and the approximation of the values to unity is taken to indicate bivalence of most of the antibody molecules.

The Serological Properties of Simple Substances. IV. Hapten Inhibition of Precipitation of Antibodies and Polyhaptenic Simple Substances

BY DAVID PRESSMAN, DAVID H. BROWN, AND LINUS PAULING

As part of a series of studies of the antigen-antibody reaction by use of polyhaptenic simple substances as antigens,[1,2,3] we have made a quantitative investigation of the ability of various substituted phenylarsonic acids to inhibit the precipitation of compounds containing two or more phenylarsonic acid groups with antiserum to sheep serum coupled with diazotized *p*-arsanilic acid.[4] The investigation included study of the effect of various concentrations of hapten XXIII  on the amount of precipitate obtained with antiserum and various concentrations of antigen VI  , where R is the *p*-azophenylarsonic acid group); the effect of changed conditions of precipitation for the same system; the effects of four haptens on the precipitation of each of five antigens and each of two pools of antiserum; and the effects of 24 different haptens on one precipitin reaction. The results are discussed in this paper.

Experimental Methods

Simple Antigens and Haptens.—The substances used are the polyhaptenic compounds

and XX  with R = , R′ =  , and R″ =  , and the haptens XXI  , XXIII , XXVIII , XXIX , and twenty others given in Table VI. The preparation of most of these substances has already been described[1] or will be discussed elsewhere.[5]

p-Benzoylaminophenylarsonic acid was prepared from *p*-arsanilic acid and benzoyl chloride by the Schotten–Baumann reaction. The product was precipitated with hydrochloric acid and purified by extraction with boiling ethanol.

p-Acetaminophenylarsonic acid was prepared from *p*-arsanilic acid and acetic anhydride in basic solution. The compound was purified by precipitation with hydrochloric acid and recrystallization from boiling water.

Antisera to sheep serum coupled with diazotized arsanilic acid were prepared as previously described, with use of the same rabbits.

Method of Analysis.—Each precipitate was centrifuged and washed thoroughly with three 10-ml. portions of 0.9% saline solution at room temperature. The amount of protein in the precipitate was determined with the Folin–Ciocalteu reagent[6] by a modification to be discussed elsewhere.

Buffer.—The borate buffer of *p*H 8.0 was prepared by adding 0.16 *N* sodium hydroxide solution to 0.2 *M* boric acid in 0.9% sodium chloride solution. The antigen and hapten solutions were all diluted with this buffer.

The Effect of Changed Conditions on Amount of Precipitate.—In order to observe the effect of standing on the amount of precipitate obtained in the presence of hapten, equal volumes of serum S, antigen VI (25 μg./ml.), and hapten XXIII (60 μg./ml.) were mixed and 5-ml. aliquots of the mixture were permitted to stand zero, three-quarters, or two hours or overnight at room temperature and were then placed in the refrigerator at 3° over zero, one, or two nights. The amount of precipitate obtained in each test was about 15% of that obtained in the absence of hapten. The results are given in Table I.

Only when the tubes stood overnight at room temperature without subsequent refrigeration was a significant decrease in the amount of precipitate observed. This effect was also observed with specific precipitates in the absence of hapten.[2] A slight decrease was observed when the tubes stood overnight at room temperature and then overnight in the refrigerator.

TABLE II

INHIBITION OF PRECIPITATION OF ANTISERUM S AND ANTIGEN VI BY HAPTEN XXIII

Antigen solution, hapten solution, and antiserum, 1 ml. each; 2 hours at room temperature, overnight in refrigerator. Blanks of antiserum and buffer: 0, 0, 0 μg. *p*H of all supernates 8.2.

[a] Values are averages of duplicate analyses, with mean deviation of ±5% from the averages, except for the values in parentheses, which represent single analyses.

The Effect of Various Amounts of Hapten XXIII on Amount of Precipitate Obtained with Various Amounts of Antigen VI.—The results of the study of inhibition by hapten XXIII of the precipitation of antigen VI are given in Table II. As previously observed with phenylarsonic acid as the hapten,[2] the optimum zone does not shift significantly with increasing amounts of hapten.

Experiments on the Relative Inhibiting Powers of Different Haptens.—Since the effect of hapten inhibition is most easily given theoretical interpretation in the antigen–antibody equivalence zone, experiments were carried out with antiserum pools S and T to determine the optimum zones (which may be taken as the equivalence zones) for antigens III, VI, XI, XV, and XX. The results are given in Table III. It is seen that antiserum S contained much more antibody than T. As previously observed,[1] antigen XI, with long haptenic groups, gave much larger amounts of precipitate than the others. It is interesting, as an example of the variability of antisera, that antigen XX gave more precipitate than antigens III, VI, and XV with antiserum T but less with antiserum S.

Hapten inhibition experiments were then carried out with haptens XXI, XXIII, XXVIII, and XXIX and these five antigens in the optimum zones for the individual antigens with each of the antisera S and T. The results are given in Tables IV and V.

Experiments were also carried out with antiserum S and antigen VI at the optimum concentration in the presence of each of twenty-four haptens at various concentrations, with the results shown in Table VI.

Discussion

The data on hapten inhibition given in the foregoing tables can be most effectively discussed by comparison with the simple theory developed in a preceding paper of this series.[2] It was shown that for the system postulated, with both antigen and antibody assumed to be bivalent, a plot of the amount of antibody precipitated, for the case

of equivalent amounts of antigen and antibody, against the amount of hapten present should be a straight line. Some examples of plots of this sort are given in Fig. 1, taken from the data of Table VI, which correspond to the optimum zones. It is seen that the curves approach the theoretical linear form only at low hapten concentrations; the deviation from linearity at higher concentration we attribute to the heterogeneity of the antiserum, which may contain antibodies with greatly varying combining powers.

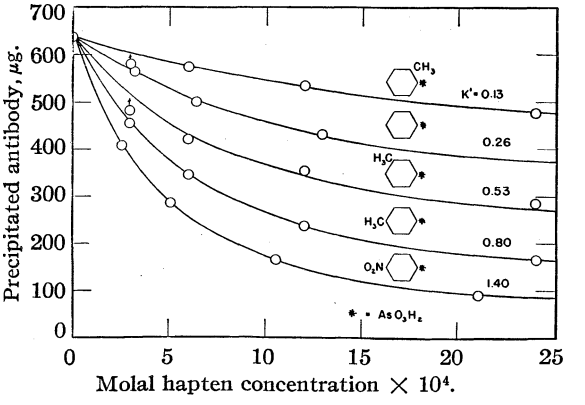

Fig. 1.—Effect of haptens in decreasing the amount of antibody precipitated by the trihaptenic antigen VI. Curves are shown for six of the twenty-four haptens for which data are given in Table VI.

Equation V of the earlier paper,[2] giving the value of the initial slope of the hapten-inhibition curve, may be rewritten in the form

$$-\frac{dH}{d\,AB(pp)} = \frac{C}{K'} + C' \qquad (1)$$

with

$$C = \frac{(Ks + K^2s^2)^{1/2}}{s\{1/2 + Ks + K^2s^2 + (Ks + K^2s^2)^{1/2}\}}$$

and

$$C' = \frac{1 + Ks + (Ks + K^2s^2)^{1/2}}{1/2 + Ks + (Ks + K^2s^2)^{1/2}}$$

Here H is the amount of hapten added, $AB(pp)$ is the amount of antibody precipitated, s is the solubility of the antigen-antibody complex, and K and K' are the bond-strength constants for the antigen-antibody bond and the hapten-antibody bond, respectively. Both C and C' for any antiserum depend only on the antigen and are independent of the hapten. The constant K' is characteristic of the hapten, indicating the strength of the bond between the hapten and the antibody. Thus for any given antiserum and antigen the reciprocal of the rate of decrease of amount of precipitate with increasing amount of hapten is a linear function of the reciprocal of the hapten constant K'.

From the form of Equation 1 we should expect the order of inhibitory activity of various haptens for a given antiserum to be the same for various antigens. This is the case for our experiments. With serum S the order of inhibition was XXIII > XXVIII > XXI > XXIX for each of the five antigens used (Table IV). The order observed for serum T was different; XXVIII > XXIII > XXI > XXIX; but this order was again observed for each of the five antigens (data for antigens VI, XI, and XX are given in Table V; less reliable results obtained for III and XV, not included in the table, also placed the haptens in the same order).

It is surprising that the amide compound  R″ was more effective in inhibition with serum T than was the azo compound HO  R, since the antibodies were produced by inoculation with an azoprotein and would accordingly be expected to combine preferentially with azo groups. Antiserum T was consistent in its greater reactivity with amide groups than with azo groups, insofar as it also gave a larger amount of precipitate with the amide antigen R″  R″ than with the somewhat similar azo antigens

(Table III). This is the reverse of the behavior observed for serum S and the antisera tested previously.[1]

Another example of the variability in properties of the antisera is that the amide antigen  gave more precipitate than the other amide antigen $R''(CH_2)_2R''$ with serum T but less with serum S.

In order to obtain from the data of Table VI numbers representing the inhibiting power of the twenty-four haptens, the following treatment was used. Plots were made of the amount of precipitated antibody for each hapten as a function of the number of moles of hapten added, as illustrated in Fig. 1. Smoothed curves were drawn through the points, and the initial slopes were read from the curves. Some consideration was given to the course of the curve throughout the range of concentration covered by the experiment in determining the value of the initial slope, with use of a family of curves deduced from the whole set of data. Plots against the log of hapten concentration were also used. The reciprocals of the negative slopes $-\mathrm{d}\,AB(\mathrm{pp})/\mathrm{d}\,H$ are given in Table VI, under the heading K'. These reciprocals would be proportional to K' if the value of C' in Equation 1 were negligible compared to the other term. In any case these numbers would be expected to represent qualitatively the combining power of the haptens with antibody. A constant factor was introduced such that the average value of K' for the two azo haptens became unity.

Many interesting correlations of the values of K' with the molecular structure of the haptens can be observed. The effects of a substituent on the bond-strength constants of the substituted phenylarsonic acid molecules are seen to be dependent both on the position of the substituent in the benzene ring and on the nature of the substituent. It would also be expected that, aside from direct structural effects, the constituents would be of influence through their effect on the second dissociation constant of the acids. The antibodies, produced presumably in about neutral solution in the animal, probably have combining groups for both singly ionized and doubly ionized arsonic acid molecules. The combining power of the latter is probably greater than that of the former because of the stronger forces resulting from the doubled electric charge,[7] as has been pointed out by Haurowitz.[8] Accordingly it would be expected that increase in the second dissociation constant of the acid, leading to increase in the number of doubly charged ions present, would lead to increase in bond-strength constants with the antibody. There are given in Table VI values of the second ionization constant for eighteen of the haptens.[5] It is seen that the correlation with K' is not very striking.

The ortho-substituted phenylarsonic acids are seen to be, with one exception (the *o*-nitro acid), the least effective of all in combining with antibody. An α-naphthyl residue is about equivalent to an ortho-substituted benzene ring. Meta-substituted compounds are somewhat more effective in general than phenylarsonic acid, and para-substituted compounds are still more effective. β-Naphthylarsonic acid is intermediate between the meta- and para-substituted phenylarsonic acids.

All of the para-substituted phenylarsonic acids are more effective in inhibition than phenylarsonic acid itself. This increased effectiveness on replacement of the para hydrogen atom by a larger atom or group is presumably the result of increased van der Waals interaction between the substituent and the antibody. The order of effectiveness of the para substituents in increasing the value of the constant K' is

$$NO_2 > CH_3CONH > \langle\bigcirc\rangle NN > \langle\bigcirc\rangle CONH > Cl, Br, I, CH_3 > OH > NH_2 > COOH > H$$

The same order holds also in the ortho and meta positions for the substituents NO_2, CH_3, and NH_2, data not having been obtained for others.

Whereas replacement of a hydrogen atom in the para position by a substituent group always leads to an increase in the value of K', this is not so for the ortho position. Both *o*-methylphenylarsonic acid and *o*-aminophenylarsonic acid, as well as the α-naphthyl compounds, are less effective in inhibition than phenylarsonic acid itself. This difference in behavior from the para-substituted compounds is attributed to steric effects. The immunizing antigen, a protein with attached *p*-azophenylarsonic acid groups, gives rise to

(7) This may be responsible for the fact that the maximum amount of precipitate with variation of *p*H is obtained at *p*H 8, instead of at about 7, which presumably prevails at the site of antibody formation.

(8) F. Haurowitz, *Z. physiol. Chem.*, **245**, 24 (1937).

antibodies which are molded to the *p*-azophenylarsonic acid group, and which in general do not allow sufficient space for a larger group than hydrogen in the ortho position. On the other hand, a para substituent may fit into the space provided for the azo nitrogen atoms, and so by increased van der Waals attraction for the antibody makes the hapten more effective than phenylarsonic acid itself.

The most striking and unexpected observation is that the nitro group in any position in the benzene ring causes a large increase in the bond-strength constant over the value for any other substituent in the same position. For the ortho compound this increase is so great as to overcome the steric effect and make the hapten more effective than phenylarsonic acid. The reason for this large effect of the nitro group is not obvious. The second acid dissociation cannot be advanced as the cause, since the value of K_{A_2} for *o*-nitrophenylarsonic acid is less than that of phenylarsonic acid, whereas its value of K' is greater. We suggest that this action of the nitro group is the result of the well-known effect of the group in aromatic compounds in causing increased van der Waals attraction for other molecules, which shows itself in the great ability of aromatic nitro compounds to form molecular compounds with other substances.

It is surprising that haptens containing the amide group —CONH— are nearly as effective as the corresponding haptens containing the azo group —NN—. As mentioned above, for antiserum T the amide group was found to be even more effective than the azo group. It will be interesting to see, by experiments with other pools of antisera, to what extent the order of combining power with antibodies of the haptens listed in Table VI varies with the antiserum used.

In the larger haptens the effect of substituents far removed from the phenylarsonic acid group is small. Thus substitution of an amino or nitro group in the para position in phenylcarbamidophenylarsonic acid leads to an increase of only 10% in the value of K', with the nitro group showing no greater effect than the amino group. Similarly *p*-hydroxyphenylazophenylarsonic acid and *p*-aminophenylazophenylarsonic acid show nearly the same value of K'.

There is now under way an investigation of the inhibition by various haptens of precipitation with simple antigens of antisera made with use of a protein with attached azophenylazophenylarsonic acid groups as the immunizing antigen.

This investigation was carried out with the aid of a grant from the Rockefeller Foundation. Mrs. Elizabeth Swingle, Mr. Frank Lanni, Mr. Stanley Swingle, and Mr. Shelton Steinle assisted with the analyses.

Summary

A study has been made of the inhibiting action of haptens (substituted phenylarsonic acids) on the precipitation of polyhaptenic simple substances containing two or more phenylarsonic acid groups by antiserum obtained by inoculating rabbits with sheep serum coupled with diazotized *p*-arsanilic acid.

It was found that the order of inhibitory activity of four haptens was the same for each of five test antigens with a given antiserum. The order depended on the antiserum used. The antiserum which showed stronger inhibition by amide haptens than by azo haptens also gave larger amounts of precipitate with amide antigens than with azo antigens.

The effect of each of twenty-four haptens on one antigen-antibody reaction was studied, and the data were interpreted to give relative values of the bond-strength constant of the haptens with the antibody. These values are shown to be correlated with the structure of the haptens.

The Electromotive Force of the Mercurous Bromide Electrode

BY WILLIAM R. CROWELL, RICHARD W. MERTES AND SIMPSON S. BURKE

The present paper deals with the effects of hydrogen, nitrogen, and air on the e. m. f. of the mercurous bromide electrode at 25° in 0.1002 *m* hydrobromic acid, and with measurements of the electrode e. m. f.'s in approximately 1, 2, and 3 normal hydrobromic acid solutions at 25° and 35°. The reference electrode consists of a hydrogen half cell using hydrobromic acid of the same concentration as that in the mercurous bromide compartment. Because of the differences in the values of the molal reduction e. m. f. of the mercurous bromide electrode reported by different investigators and because of the oxygen effect on the calomel electrode e. m. f. reported by Randall and Young[1] it was thought that there might also be a similar oxygen effect in the case of the mercurous bromide. While the mercurous bromide electrode is more sensitive to light than the calomel electrode, if properly prepared it is quite satisfactory in reproducibility and constancy. Although there is considerable formation of bromide complexes in solutions one normal or higher in hydrobromic acid, equilibria are easily obtained in solutions as high as three normal, and electrodes employing concentrations of acid from 0.1–3 *N* may be found to be convenient in certain cases where hydrobromic acid is used and when it is desired to eliminate unknown solution contact potentials.

Experimental

Reagents.—The hydrobromic acid was prepared from three times recrystallized potassium bromide dissolved in sulfuric acid solution. The hydrobromic acid was distilled from this solution, the portion going over between 110° and 127° again distilled and the constant boiling fraction retained.

The hydrogen was generated by electrolysis of a solution of sodium hydroxide. Tank nitrogen obtained from fractionation of liquid air was the source of the nitrogen. Both the hydrogen and the nitrogen were freed of oxygen by passage through chromous chloride solution. The mercury was passed through a dilute nitric acid tower and distilled *in vacuo*.

The mercurous bromide was prepared electrolytically by use of an apparatus which included a gas-stirred mercury anode and a platinum cathode with hydrobromic acid as the electrolyte. With this device the salt was prepared from and washed with acid which was of the same concentration as that used in the cell and which had been previously treated with the gas under investigation. The solution and mixture of mercury and mercurous bromide were then transferred to the mercurous bromide electrode chamber through which the gas being studied had been previously passed for twenty minutes to an hour. Finally the half cell was stoppered and rotated in a thermostat for several hours or until the solution was in equilibrium with the mercury and mercurous bromide. During these processes as well as during the cell measurements described later all light was excluded except that from a red light bulb which was used only when observations and experimental procedures made it necessary.

Cell Measurements.—A diagram of the complete cell is shown in Fig. 1. The mercurous bromide half cell was joined to the hydrogen electrode by means of a ground glass joint. The passages between the two half cells were flushed with hydrogen by use of the float which permitted the flow of gas before establishment of the liquid junction in the three-way stopcock. This junction was then established by sinking the float which was best accomplished by increasing somewhat the flow of hydrogen. Immediately before entering the hydrogen electrode chamber the hydrogen was bubbled through a solution of hydrobromic acid of the same concentration as that in the cell.

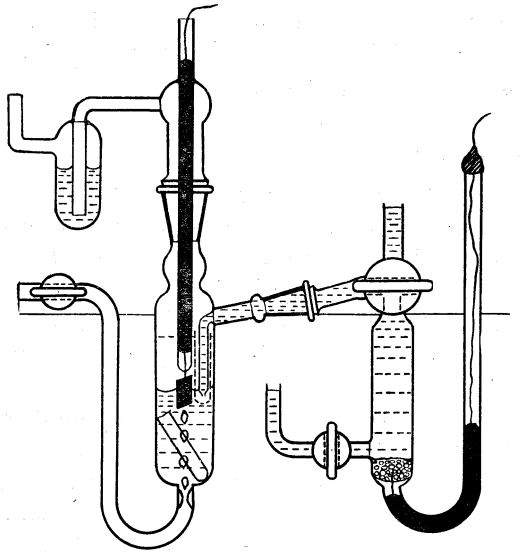

Fig. 1.—Schematic diagram of mercurous bromide–hydrogen cell.

Cell e. m. f.'s were measured by means of a Leeds and Northrup Type K potentiometer. The Weston cell used in adjusting the potentiometer current was checked against an Eppley cell which in turn had been standardized by the Bureau of Standards.

Results

Results are recorded in Tables I and II and are representative averages of several runs made over

(1) Randall and Young, THIS JOURNAL, **50**, 993 (1928).

TABLE I

EFFECT OF AIR ON THE ELECTROMOTIVE FORCE OF THE MERCUROUS BROMIDE ELECTRODE

	Cell e. m. f. at 25° in 0.1002 *m* hydrobromic acid and 1 atm. of hydrogen.			Molal reduction e. m. f. at 25°		
	Hydrogen	Nitrogen	Air	Hydrogen	Nitrogen	Air
Gerke and Geddes[4]	0.2685			−0.1392		
Ishikawa and Ueda[5]			0.26883			−0.1395
Larson[6]						− .1397
Authors	.2684$_1$	0.2684$_1$	.2688$_9$	− .1391	−0.1391	− .1396

a period of more than two years, using independently prepared reagents. Results in 0.1 *N* hydrobromic acid were reproducible within 0.05 millivolt and in the higher acid concentrations within 0.1 millivolt. The e. m. f. readings remained constant for periods ranging from twenty-four to sixty hours. Equilibrium was usually attained in less than three hours.

Table I shows results obtained from measurements made in approximately 0.1 *m* hydrobromic acid using mercurous bromide which had been prepared in an atmosphere of hydrogen, nitrogen, and air. Data of other investigators are shown for comparison with those of the authors. To put all results on the same basis they are corrected to 0.1002 *m* hydrobromic acid and one atmosphere of hydrogen. The molal reduction e. m. f., E^0, was calculated by use of the value of Harned, Keston and Donelson[2] for the mean ion activity coefficient of hydrobromic acid, namely, 0.805, employing the expression

$$E^0 = E - 0.1183 \log C\gamma^{\pm}$$

where E is the e. m. f. of the cell

$$H_2 \text{ (1 atm.)}, \text{ HBr (0.1002 } m\text{)}, Hg_2Br_2, Hg$$

C the concentration of the hydrobromic acid in moles per 1000 g. of water, and $\gamma^{\pm}$ the mean ion activity coefficient of the hydrobromic acid. In the term "molal reduction e. m. f." the sign convention and activity units were the same as those used by Latimer.[3]

A study of the procedures of the different workers indicates that Ishikawa and Ueda, and Larson probably did not insure the complete removal of all air from the solutions used in the preparation of the mercurous bromide, while Gerke and Geddes displaced all air with hydrogen. For this reason, the results of Ishikawa and Ueda and of Larson are placed in the column with the air values and the results of Gerke and Geddes are recorded in the column with the hydrogen values.

A comparison of the results in the table indicates that the electrode molal reduction e. m. f. has an accurately reproducible air free value of −0.1391 ± 0.0001 volt and an air value also accurately reproducible of −0.1396 ± 0.0001 volt. The 0.3 millivolt deviation of the results of Ishikawa and Ueda from those of Gerke and Geddes is probably due to this fact rather than because of greater experimental accuracy as claimed by the former.

Table II shows results of measurements of cell e. m. f.'s at 25 and 35° in approximately one, two, and three normal hydrobromic acid calculated on the basis of one atmosphere of hydrogen. In all these cases the mercurous bromide was prepared from and washed with hydrogen treated acid.

Since the main purpose of these measurements was to obtain data whereby the mercurous bromide electrode could be used as a reference electrode in cells requiring hydrobromic acid at these concentrations, the e. m. f. of the mercurous bromide half cell including a small solution contact e. m. f. was determined for each acid concentration. These e. m. f.'s at 25°, which are not to be confused with the molal reduction e. m. f.'s shown in Table I, are shown in Table II column 5 and were calculated by use of the cell data and hydrobromic acid mean ion activity coefficient values obtained from a curve plotted from data quoted by Harned,[7] employing the expression

$$E_{Hg,\ Hg_2Br_2\ (meas.)} = -E_{cell} - 0.05913 \log C\gamma^{\pm}$$

The values in column 6 which we term "calculated" are those for the half cell which one would obtain by use of the molal reduction e. m. f., E^0, and the activity of the hydrobromic acid, employing the expression

$$E_{Hg,\ Hg_2Br_2\ (calcd.)} = -0.1391 + 0.05913 \log C\gamma^{\pm}$$

TABLE II

E. M. F. OF MERCUROUS BROMIDE ELECTRODE AT HIGHER ACID CONCENTRATIONS

Concn. of HBr		Cell e. m. f. 1 atm. hydrogen		Electrode e. m. f. at 25°C.	
Molal	Normal	25°	35°	Measured	Calculated
1.029	1.000	0.14388	0.14310	−0.14130	−0.14168
2.117	2.002	.09058	.08867	− .11489	− .11480
3.246	2.987	.04845	.04524	− .09402	− .09353

(2) Harned, Keston and Donelson, THIS JOURNAL, **58**, 992 (1936).

(3) W. M. Latimer, "Oxidation Potentials," Prentice-Hall, Inc., New York, N. Y., 1938, pp. 2 and 3.

(4) Gerke and Geddes, *J. Phys. Chem.*, **31**, 886 (1927).

(5) Ishikawa and Ueda, *J. Chem. Soc. Japan*, **2**, 59–66 (1930).

(6) W. D. Larson, THIS JOURNAL, **62**, 765 (1940).

(7) Harned, THIS JOURNAL, **57**, 1867 (1935).

The activity coefficient values taken from the curve were 0.879 for 1.000 N acid, 1.217 for 2.002 N acid, and 1.816 for 2.987 N acid.

From the values in columns 3 and 4 the following expressions were derived for the cell e. m. f., E_t, at any temperature t from the vicinity of 25 to that of 35°

In 1.000 N hydrobromic acid E_t =
$$0.14388 - 0.000078(t - 25)$$
In 2.002 N hydrobromic acid E_t =
$$0.09058 - 0.000191(t - 25)$$
In 2.897 N hydrobromic acid E_t =
$$0.04845 - 0.000321(t - 25)$$

In these acid solutions as the concentration increases there is a tendency for the mercurous bromide electrode reduction e. m. f. to become increasingly less than the calculated value because of the decrease in activity of the bromide ions due to the formation of bromide complexes. This decrease in reduction e. m. f. is more or less compensated for by an opposing liquid junction potential at the zone of contact of the hydrobromic acid solutions of the two electrodes. Such behavior probably is responsible for the fairly close agreement between the experimental and theoretical values.

Summary

Determinations of the molal reduction e. m. f. of the mercurous bromide electrode at 25° in 0.1002 m hydrobromic acid solutions show that the values obtained in solutions free from air are about 0.5 millivolt higher than those in which air is not completely removed. Both values are accurately reproducible and are −0.1391 volt in air free solutions and −0.1396 volt in solutions containing air, using hydrogen as the reference electrode. Results of e. m. f. measurements made at 25 and 35° in approximately one, two, and three normal hydrobromic acid are also shown.

The Molar Dispersion and Refraction of Free and Bonded Ions[1]

BY NORMAN BAUER[1a] AND KASIMIR FAJANS

Introduction

This paper is a continuation of the series of "Refractometric Investigations,"[2] the main goal of which has been an understanding of the changes occurring in the electronic systems of ions, atoms and molecules when they combine with each other. Since the "valence" electrons are identical with those responsible for the optical behavior in the visible and near ultraviolet, it was justified to expect that optical properties would be especially suited to a study of this problem which is so closely connected with the nature of chemical forces. In fact, for substances having electronic systems of the noble gas type,[3] these refractometric investigations have revealed (see especially I, VII, XXX) the existence of two effects which prove to have great influence on the physical[4] and chemical behavior of substances:

(1) From a doctoral dissertation submitted by N. Bauer at the University of Michigan in June, 1941. The paper was presented in part at the 101st Meeting of the American Chemical Society, April 9, 1941.

(3) It has been shown (see, *e. g.*, K. Fajans, "Chemical Forces and Optical Properties of Substances," (Cornell Lectures), McGraw-Hill Book Co., Inc., New York, N. Y., 1931) on the basis of properties such as lattice distances, lattice energies, crystal structure, solubility, formation of complex compounds, color, etc., that deformation phenomena are more pronounced in substances formed from non-rare gas cations (Class II, *e. g.*, AgCl) than in substances derived solely from noble gas ions (Class I, *e. g.*, NaCl). However, the refractometric method has not yet given clear results for the former class of compounds (see XXX, p. 147–151); this seems to have the following reason. For most cases in Class I the refractometric effect caused by anion tightening is very much stronger than the opposite effect. In Class II, because of the deeper mutual interpenetration of the ions, and also because of the larger polarizability of non-rare gas cations, both effects are of the same order of magnitude and partly cancel each other.

(4) See, *e. g.*, K. Fajans, *Phys. Rev.*, **61**, 543 (1942).

namely, the tightening of electronic systems by neighboring positive charges and their loosening by negative charges.[5]

The existence of these two effects was first concluded on the basis of the large systematic deviations from additivity which the Lorentz–Lorenz molar refraction R shows. The analysis of these deviations was greatly aided by the derivation (I) of values of the molar refraction of individual gaseous ions, as distinguished from ions in solution or from those in molecules and crystals. Until now such a derivation has been carried out in this series of investigations only for the refraction R_D at a wave length corresponding to the sodium D line. Recent precision measurements of the refraction at various wave lengths in the visible for a number of electrolytes (XLVIII and IL), along with the accumulated data from previous work, now make it possible to obtain a set of provisional values for the molar dispersion of individual gaseous and aqueous ions.

A knowledge of the dispersion furnishes a means of extrapolating R_λ to $\lambda = \infty$. Since

$$R_\infty = \frac{4}{3}\pi N\alpha \qquad (1)$$

one can then arrive at a consistent set of values of the true electronic polarizability (α) of ions.[6] Seldom is R_D more than a few per cent. different from R_∞, and thus R_D has been a sufficiently accurate measure of α for a qualitative investigation of the role of polarizability in the physical and chemical behavior of substances. The R_∞ values should now help in developing the quantitative aspects of this problem.

However, the inclusion of the molar dispersion in this study is of importance in itself because, as this paper will show, it is a property which is even more sensitive to changes in the forces acting on the particles involved than is the molar refraction.

In the present paper we shall limit ourselves to establishing a set of values for the molar dispersion of ions and to showing by a few examples how its large deviations from additivity help in the study of electronic deformation.

1. Extrapolation to Infinite Wave Length on the Basis of Dispersion Theory.—It has been customary to define the dispersion of a substance as the difference ΔR[7] between molar refractions at two arbitrarily selected wave lengths in the visible (*e. g.*, $\Delta R = R_{H\beta} - R_{H\alpha}$).

For reasons apparent from the Introduction we have chosen the difference between the molar refraction for the sodium D line (R_D) and that for infinite wave length (R_∞) as the measure of the *molar dispersion* **D**. Extrapolations to $\lambda = \infty$ from measurements in the visible were made by the reciprocal plotting method of P. Wulff (XXV), based on the dispersion theory.

According to the dispersion theory,[8] the refraction R may be expressed as a function of the frequency $\nu = c/\lambda$ by an equation of the type

$$R_\lambda = \sum \frac{C_i}{(\nu_0)_i^2 - \nu^2} \qquad (2)$$

The summation includes one term for each of the characteristic frequencies $[(\nu_0)_i]$ of the system; the constants C_i are a measure of the probability of transition between the states which define the frequency $(\nu_0)_i$. If a single term is sufficient, then a plot of $1/R_\lambda$ *versus* ν^2 gives a straight line

$$\frac{1}{R_\lambda} = \frac{\nu_0^2}{C} - \frac{1}{C}\nu^2 \qquad (3)$$

The intercept on the $1/R_\lambda$ axis for $\nu^2 = 0$ gives the value of $1/R_\infty$. When more than one term is necessary, then, as Wulff has found, the $1/R_\lambda$ *versus* ν^2 curve is composed of straight lines and hyperbolas, the sum of which approaches a straight line for small values of ν^2.

Experience shows that when the maximum of the first principal electronic absorption band $[(\nu_0)_1]$ has a wave length less than about 250 mμ, and when infrared contributions are negligible, the plot becomes linear in the visible part of the spectrum.

In Fig. 1 several typical extrapolations are made from data of different degrees of accuracy for the molar refraction of crystals and the apparent molar refraction of aqueous electrolytes. For the case of solutions measured with the Pulfrich refractometer (see Fig. 1, part B), for which the accuracy is lower than that of the interferometric measurements in part A, the thin dashed lines show the extreme slopes of the possible straight lines which can be put through the experimental points. The errors in **D** (in Tables I, II and III) were estimated by taking half of the

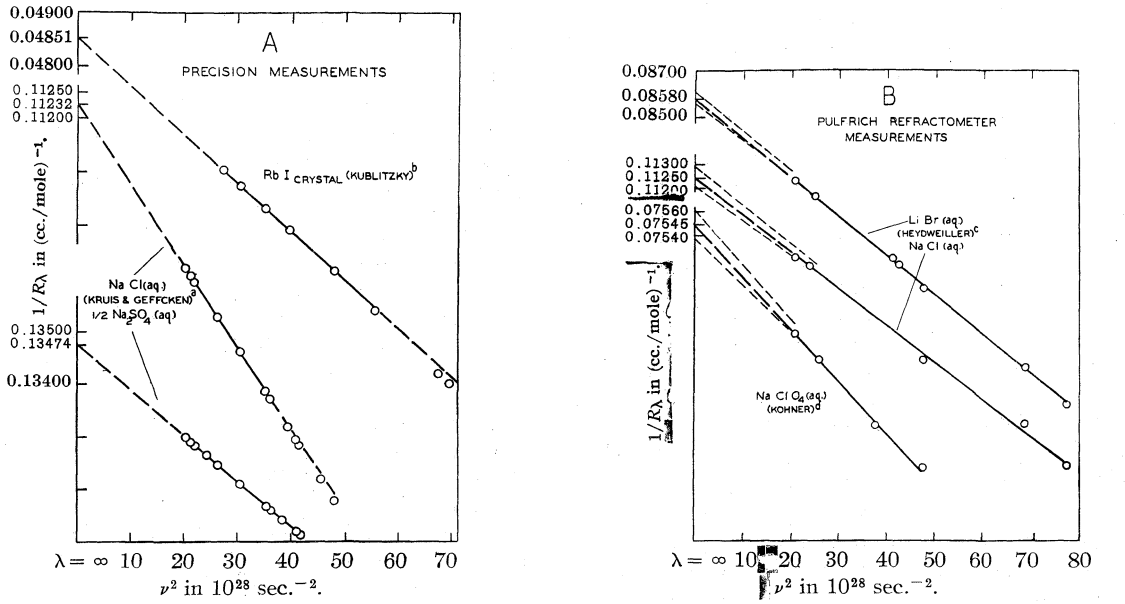

Fig. 1A and 1B.—Typical extrapolations to infinite wave length of the molar refraction of crystals and apparent molar refraction of aqueous electrolytes according to the reciprocal plotting method (P. Wulff, XXV): (a) see Table II; (b) see ref. (29); (c) see ref. (19); (d) see (IX).

difference between the values of $1/R_\infty$ given by the extension of the most probable line (*i. e.*, of the line drawn in full) and that given by the extreme possible line.

The curves in part A of Fig. 1, resulting from very accurate measurements on crystals and solutions, show departure from linearity in the direction of increasing negative slope for increasing values of ν^2. This downward curvature is to be expected on the basis of (2) for substances for which $(\nu_0)_2$ is not very much larger than $(\nu_0)_1$[9]. In general, and especially for the simple inorganic substances treated here, the experimental points fit a straight line the better, the nearer they come to the region over which extrapolation is made; thus the linear extrapolation appears to be well founded.

2. Selection of Data on the Dispersion of Simple Inorganic Substances.—The molar dispersions **D** given in Tables I, II and III were derived from the results of a large number of investigators who used various experimental techniques. Therefore, it is necessary to appraise the reliability of the various sets of data.

(a) Gases and Vapors (Table I).—The principal sources of data for gases were Cuthbertson and Cuthbertson,[10,11,13,16] Damkoehler (XL), Larsen,[12] Friberg[15] and Watson and Ramaswamy.[17]

We made the extrapolation to $\lambda = \infty$ for all gases except H_2Se by means of the dispersion formulas given in the original papers, which represented the experimental data (corrected to the ideal gas state) with great accuracy. The estimate of the error in dispersion was made from the relative uncertainty in the indices of refraction.

For H_2Se a plot of $1/R_\lambda$ *vs.* ν^2 was made in the usual way from the data of Frivold, Hassel and Skjulstad.[14]

(b) Aqueous Solutions of Electrolytes at Infinite Dilution (Table II).—Three principal series of measurements on aqueous electrolytes were used. The most accurate available data, which make the present partition into values of the molar dispersion of individual ions possible, are based on the precision measurements of Geffcken, Kruis and Beckmann (see Table II and XXIII) for five salts at 15 different wave lengths between 6678 and 4358 Å. The refractive indices and the densities of the dilute solutions

(9) An infrared contribution, corresponding to atomic polarization $[(\nu_0)_{i.r.} << (\nu_0)_1]$, would show up as a curvature of opposite sign at the red end of the spectrum when the dispersion for shorter wave lengths gives a linear $1/R_\lambda$ *vs.* ν^2 plot. Among substances included in this paper this was the case only for liquid water and was indicated by the precision measurements on aqueous Na_2SO_4 (see XXVII p. 59 and IL p. 65); the scale of Fig. 1A is too small to reproduce this indication. In such cases the linear part corresponding to the electronic contribution has to be used for the extrapolation. In general the contribution of infrared terms to the refraction in the visible is negligible. See, concerning a wide variety of crystals, *e. g.*, I p. 8, XXXVIII p. 181, and XXVII p. 59; concerning aqueous solutions of electrolytes, *e. g.*, IL p. 61.

4. Anions

	ΔD	Source
$F^- - Cl^-$	−0.289 ± 0.006	KF (XI)
$Br^- - Cl^-$	.28 ± .02	NaBr (XX), LiBr, CsBr[19,20,21]
$I^- - Cl^-$	1.0 ± .1	KI (XX), NaI[19]
$OH^- - Cl^-$	−0.141 ± .004	NaOH[18]
$ClO_4^- - Cl^-$	− .117 ± .007	$NaClO_4$ (IX)

[a] In part (1) of Table II the experimental values of $D_{aq.\ salt}$ are given, while in parts (2), (3) and (4) one has values of $\Delta D_{aq.\ salt}$ which represent the differences between $D_{aq.\ ion}$ and that of a reference ion (Na^+, NH_4^+, Cl^-). [b] All measurements were made at 25.0° except those at 18° by Heydweiller and Limann (see ref. 24). [c] The errors given for the differences ΔD were obtained by summing up all the estimated errors in the individual experimental values needed for the calculation of ΔD.

(18) Unpublished measurements of J. H. Faull, Jr., and P. Hoelemann.

(22) N. Bauer, "Dissertation," University of Michigan, 1941.

relative to that of water were determined at 25.0° with an accuracy of 0.073 (interferometric method) and 0.062 (differential buoyancy method), respectively. Usually about ten measurements were made on each salt between $2M$ and $0.01M$, so that uncertainties in the extrapolation to infinite dilution are very small.[23] Here the error in the apparent molar dispersion **D** is probably less than 1 per cent., as compared with up to 10 per cent. for measurements with the Pulfrich refractometer.

The values of **D** for some electrolytes were derived from earlier measurements in the "Refractometric Investigations" made with the Pulfrich refractometer, the use of which had been improved by Kohner and Geffcken (IX, X, XI). In this series, indices of refraction were measured for only three to five spectral lines, thereby making the extrapolation to $\lambda = \infty$ less certain.

A large number of salts was measured at 18°[24] by Heydweiller and his co-workers[19,20,21] with the Pulfrich refractometer and with the quartz spectrograph.[25] The number of spectral lines employed in the visible was two to five. For reasons discussed in XIV, the results were not always sufficiently accurate to establish the way in which the apparent molar refraction varied with concentration, thus bringing an uncertainty into the extrapolation to infinite dilution.[26]

The following values of **D** in cc./mole give examples of the best and poorest agreement between the various sets of measurements on salt solutions

NaCl	0.33 ± 0.03 (Heydweiller)	0.329 ± 0.002 (Kruis and Geffcken)
$NaClO_4$	.17 ± .02 (Heydweiller)	.212 ± .006 (Kohner)

The values of **D** for the various strong electrolytes at infinite dilution proved to be additive within the limits of experimental error; therefore it was possible to calculate values for the various ions with respect to reference ions (see footnote *a*, Table II).

(c) Alkali Halide Crystals (Table III).—The values of index of refraction given by Gyulai,[27] Spangenberg,[28] Kublitzky[29] and Wulff and Anderson (XLI) were used, some of which had already been extrapolated to $\lambda = \infty$ by

(23) The maximum which some refraction *vs.* concentration curves show (see LI and XLVIII p. 40) is not found in the corresponding dispersion curves. Therefore the extrapolation to $c = 0$ appears to be more certain for **D** than for *R*.

(24) The temperature coefficient of molar dispersion of aqueous electrolytes can be estimated from XX p. 351 to be less than 0.2 per cent. per degree, compared with about 0.05% per degree for refraction (XXI, p. 358). Therefore the difference between $D_{18°}$ and $D_{25°}$ is smaller than other uncertainties in Heydweiller's measurements. This result makes it also safe to use the values of $D_{cryst.}$ in Table III without a temperature correction because for refraction the values of $(dR/R)/dT$ are even smaller for crystals than for electrolytes (see XXI, p. 361).

(25) The values of R_∞ derived here from Heydweiller's data by the reciprocal plotting method differ up to 0.03 cc. from his own values, obtained by plotting R_λ against ν^2.

(26) The values of $D_{aq.}$ for rubidium and cesium salts contain an additional uncertainty because of the possible presence of impurities. Therefore even the rather large errors in Tables II and VII for these ions are only a lower limit. Thus it is uncertain whether the difference in the sequence of values shown in Fig. 3 for refraction (K, Cs, Rb) and for dispersion (K, Rb, Cs) is real.

Wulff and co-workers (XXXVIII, XXVII). When no measurements of the density were made on the samples used for the refractive index determination, the molar refraction was calculated using the best density values resulting either from direct measurements (see XXVII), or from X-ray determinations given in the "Strukturbericht." Some of the salts were measured above room temperature (up to 66°; see footnote (a), Table III). Concerning the negligible temperature dependence of $D_{cryst.}$ in this interval, see ref. 24.

From Table III it can be seen that the uncertainties in $D_{cryst.}$ vary from 2 to 10%.

TABLE III

MOLAR DISPERSION OF CRYSTALS IN CC.[a]

(a) Alkali Halides

LiF	0.031 ± 0.003	(27)		NaBr	0.42 ± 0.01	(27)

MgS	.38 ± .02	SrTe	2.13 ± .5
CaS	.71 ± .02	BaTe	3.41 ± .5

[a] The salts measured at other than room temperature are: KF (57°), RbCl (48°), NaBr (66°), KBr (48°), RbBr (35°), RbI (35°) and KI (60°). Concerning the negligible temperature dependence of $D_{cryst.}$ between 25 and 70°, see ref. 24.

(d) Compounds of Doubly Charged Cations and Anions of the Noble Gas Type (Table III).—Measurements of the index of refraction by Haase[30] were used. The number of wave lengths employed varied between 2 and 5. Since, except for BaTe and MgO, the density was not measured by Haase, we have taken densities used by him on the basis of V. M. Goldschmidt's X-ray determinations. The molar dispersion could be evaluated only to within about 10 per cent.

3. Deviations from Additivity for Molar Dispersion and Refraction Based on Direct Experimental Data.—Figure 2 contains experimental data for a selection of gaseous substances isoelectronic with the noble gases. The values of R_D and **D** are based on n^*, the index of refraction corrected to the ideal gas state. The values of the Lorentz–Lorenz refraction used in Fig. 2 are thus very nearly proportional to $(n^* - 1)/d$, which is a direct measure of the interaction between free particles and the electric field associated with the light waves: *i. e.*, these R_D and **D** values are practically independent of any alleged imperfections in the Lorentz–Lorenz expression possible in the case of condensed systems.[31] The substances in Fig. 2 corresponding to the sets of connected points (*e. g.*, H_2Se, HBr, Kr) have the same number of electrons (*e. g.*, 36) and differ only by the position of the protons, two of which in H_2Se and one in HBr are within the electronic shell, while in Kr all belong to the nucleus. One observes a large change (a decrease, excepting $\mathbf{D}_{NH_3} > \mathbf{D}_{CH_4}$) in both R_D and **D** corresponding to the process of successively transferring protons from an electronic shell into the nucleus; *e. g.*, the refraction drops from 11.57 cc. in H_2Se to 9.16 in HBr and finally to 6.40 in Kr, while for dispersion the corresponding values are 0.48, 0.27 and 0.129 cc., respectively.[31a] Thus there can be no doubt that the molar refraction and dispersion are properties which depend on the forces acting on a given electronic system, and indeed are very sensitive to changes in the forces.

Because the interionic forces in crystals and gases are different from those between ions and water molecules in solution, one can understand (*cf.* I, p. 7; XXX, p. 121) that, as Fig. 3 shows, the apparent molar refraction and dispersion of aqueous alkali and hydrogen halides differ from the corresponding values in the solid and gaseous states. Here it is of especial importance to note that also for electrolytes there is a close analogy between the kind of deviations from additivity exhibited by molar dispersion and by molar refraction (concerning Cs salts, see ref. 26). The magnitude of these deviations for both **D** and R increases systematically with increase in polari-

(30) M. Haase, *Z. Krist.*, **65**, 509 (1927); for MgS see M. Haase, *ibid.*, **68**, 82 (1928).

(31) See, *e. g.*, N. F. Mott and R. W. Gurney, "Electronic Processes in Ionic Crystals," Oxford University Press, New York, N. Y., 1940, p. 18. The Lorentz–Lorenz formula is supposed to account only for that part of the internal electric field acting on a given particle which is due to the dipoles induced in surrounding particles by the external electric field of the light waves; the formula does not attempt to include the effect of forces acting between the particles in the absence of the external field. In fact the results of the "Refractometric Investigations" demonstrate that the Lorentz–Lorenz expression fulfills its purpose excellently. The systematic deviations from additivity observed for a wide variety of gaseous, liquid and cubic-solid systems can be understood as a result of known forces acting between particles independently of the light wave. Only the minute deviations from additivity in mixtures of non-ionized liquids cannot yet be explained from this point of view (*cf.* XXX, p. 108).

(31a) *Note added on November 30, 1942.* The gradation of molar refraction and dispersion of isoelectronic molecules shown in Fig. 2 proves to be in line with a general principle: The tightness of a given electronic shell decreases (R and **D** increase) when the positive charges within the shell split or when their distribution becomes less symmetrical. The apparently exceptional gradation $\mathbf{D}_{H_3N} > \mathbf{D}_{H_4C}$ is due, as is also indicated by the peculiarities of the slopes of the lines leading to H_4Si, to the competition between two factors. In the transition from H_3N to H_4C the splitting of the core N^{5+} into C^{4+} and H^+ causes a loosening, the higher symmetry of H_4C a tightening of the electronic shell. See K. Fajans, *J. Chem. Phys.*, December, 1942.

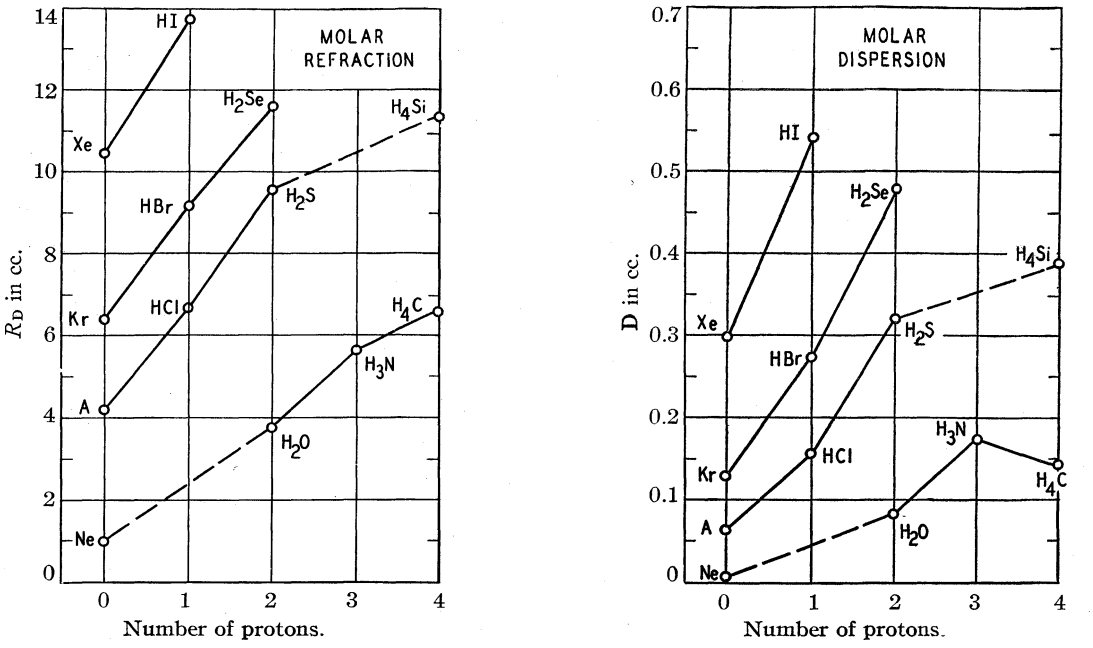

Fig. 2A and 2B.—Analogy between the changes of molar refraction and dispersion of gases due to a successive transfer of protons from the nucleus of the noble gases into the electronic shell.

zability and polarizing power of the particles involved, as has been discussed in former papers for the case of refraction, and as will be shown in Section 8 for dispersion.

4. Square Relation between Molar Refraction and Dispersion.—The similarities between the deviations from additivity of the molar refraction and dispersion noted in Section 3 lead one to expect a simple quantitative relation between these two phenomena. The dispersion theory leads to the following results.

If one assumes that a single term dispersion formula is adequate for representing the experimental data (which is the case, *e. g.*, for noble gases in the visible) one has $R_D = C/(\nu_0^2 - \nu_D^2)$, and $R_\infty = C/\nu_0^2$. From $\mathbf{D} = R_D - R_\infty$, $\mathbf{D} = (\nu_D^2/C)R_D R_\infty$. Since $R_D \approx R_\infty$ (in general within considerably less than 5%), one has

$$\mathbf{D} \approx \frac{\nu_D^2}{C} R_D^2 \qquad (4)$$

Considering the changes occurring in the molar refraction and dispersion of a given particle when it is subjected to an external influence (*e. g.*, when one ion combines with another), and assuming that in this case C remains practically constant,[32] one obtains the following square relation between R_D and $\mathbf{D}$

$$\mathbf{D} \approx \text{constant} \times R_D^2 \qquad (5)$$

therefore

$$\Delta\mathbf{D}/\mathbf{D} \approx 2\Delta R_D/R_D \qquad (6)$$

Thus one expects that a given change in the refraction will correspond to twice as great a relative change in the dispersion. It will be seen in this and following sections that in general, in simple cases, this expectation is fulfilled.[33]

Table IV, based on direct experimental data given in Table I, shows that the square relation applies to the noble gases, the hydrogen halides and H_2O, H_2S, and H_2Se with an accuracy sufficient for our present purpose. The squares of the ratios of the molar refraction for any two of these substances belonging to the same noble gas type agree within about 4% on the average with the corresponding ratios of the molar dispersion, which is surprisingly good in view of the approximations used in arriving at (5).

(32) The dispersion of noble gases and of Li, Na and K halides can be represented with sufficient accuracy in the visible by a single term (equation 2). For those salts of this group for which the cations can be expected to contribute only a few tenths of a per. cent to the total dispersion (*e. g.*, NaBr), one can compare the values of C and ν_0^2 for a noble gas with those of the corresponding halide ion in the crystal; whereas in such cases the ν_0^2 values differ by a factor of nearly two, the differences between $C_{N.G.}$ and C_{X^-} are less than 10%, on the average. Closely connected with this are the results of K. F. Herzfeld and K. L. Wolff, *Ann. Physik*, **78**, 50 (1925), who concluded from multiple term dispersion formulas that the total transition probability (number of electrons in classical theory) for argon was practically the same as that for Cl^- in NaCl and KCl.

(33) The ratio of $\Delta R/R$ to $\Delta D/D$ differs considerably from two in relation (12) for the hydration effect of Li^+, in Fig. 3 for the values for KI and RbI and in Table X. In all these cases, apparent quantities are involved.

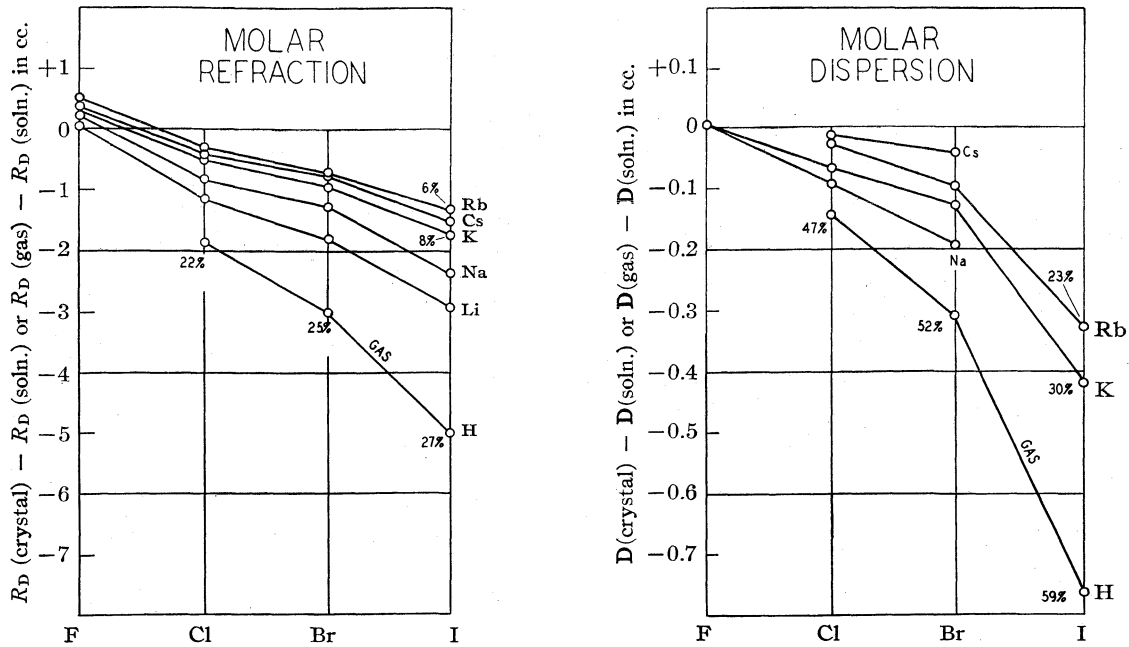

Fig. 3A.—Difference between the molar refraction of solid alkali halides and gaseous hydrogen halides and their apparent molar refraction in aqueous solution. Fig. 3B gives the corresponding differences for the molar dispersion **D**. The percentage deviations from additivity are given relative to the values of the aqueous electrolytes and are greater for dispersion than for refraction.

In (5) we have neglected the difference between R_D and R_∞, as well as the influence of a second frequency $(\nu_0)_2$. Such neglections will in general be the more justified, the smaller the values of R_D and $1/(\nu_0)_1$ are; therefore it is reasonable to apply the square relation (5) to ions having the same noble gas structure, providing their R_D and $1/(\nu_0)_1$ values are not larger than those of the substances used in verifying the relation (Table IV).[34]

TABLE IV

TEST OF THE SQUARE RELATION (5) BETWEEN MOLAR REFRACTION AND MOLAR DISPERSION

Ratios	For R_D	For R_D^2	For **D**
HCl/A	1.59	2.52	2.47
HBr/Kr	1.43	2.04	2.13
HI/Xe	1.315	1.73	1.78
H_2O/Ne	3.73	13.9	12.9
H_2S/A	2.28	5.20	5.00
H_2Se/Kr	1.875	3.52	3.69
H_2S/HCl	1.44	2.07	2.02
H_2Se/HBr	1.315	1.73	1.75

5. The Partition of the Molar Dispersion into Values for Individual Ions.—The above results, establishing an analogy between the behavior of the molar refraction and dispersion, justify the attempt to apply to the partition of dispersion the same principles which have been used in the case of refraction. For the latter, as mentioned in the introduction, it proved to be very helpful to introduce values for the refraction of free gaseous ions.

It is important to emphasize here that the molar refraction and dispersion of free gaseous ions are real physical quantities like those for a noble gas, and are connected by equation (1) with the electronic polarizability α of the free particles. In this respect the molar refraction and dispersion differ from the volume[35] or radii of free ions or atoms, which according to wave mechanics do not have an exact physical meaning.

For any property (X) of analogous ions, the value of which can be assumed to decrease monotonously with increasing forces between the nucleus and the electronic system, one can expect the following regularities to hold. They were in part stated in considering the relative size of noble gas ions,[36] and were extensively used for the derivation of ionic refractions (I and XXX).

(a) For ions possessing the same noble gas (N. G.) structure, the nuclear charge of which

(34) We assume that the agreement in Table IV is not due to an accidental cancelling of effects which might arise from the different symmetry of the particles involved.

(35) However, single ionic values of the apparent molar volume are defined quantities which for the case of infinitely dilute aqueous solutions have been approximately obtained. See, *e. g.*, K. Fajans and O. Johnson, THIS JOURNAL, **64**, 668 (1942).

(36) K. Fajans and K. F. Herzfeld, *Z. Physik*, **2**, 309 (1920).

increases in the following series from left to right, one has[37]

$$\cdots > X_{\text{ion}^{--}} > X_{\text{ion}^{-}} > X_{\text{N.G.}} > X_{\text{ion}^{+}} > X_{\text{ion}^{++}} > \cdots \quad (7)$$

(b) For a given noble gas type it should hold that

$$\cdots > \frac{X_{\text{ion}^{--}}}{X_{\text{ion}^{-}}} > \frac{X_{\text{ion}^{-}}}{X_{\text{N.G.}}} > \frac{X_{\text{N.G.}}}{X_{\text{ion}^{+}}} > \frac{X_{\text{ion}^{+}}}{X_{\text{ion}^{++}}} > \cdots \quad (8)$$

The inequalities (8) are based on the expectation that a given absolute difference in nuclear charge Z will cause the greater relative change in the property X, the smaller the magnitude of Z.

(c) For particles of a different noble gas type one can expect inequalities (9) to hold for the same reason given for (8); *e. g.*

$$\frac{X_{\text{F}^-}}{X_{\text{Ne}}} > \frac{X_{\text{Cl}^-}}{X_{\text{A}}} \quad \text{or} \quad \frac{X_{\text{Ne}}}{X_{\text{Na}^+}} > \frac{X_{\text{A}}}{X_{\text{K}^+}} \quad (9)$$

These regularities, in spite of being inequalities, were found (XXX) to provide a basis for the derivation of refraction values for free gaseous ions which is at least as reliable as other methods used for this purpose except for the case of helium type cations. The main difficulty in the derivation is caused by the fact that while the inequalities refer to free gaseous particles, the available experimental data extend only to noble gases and aqueous ions. However, for noble gas ions having strong electric fields it was possible to obtain an estimate of the differences $\Delta^{R}_{\text{hydr.}} = R_{\text{aq. ion}} - R_{\text{gas ion}}$ between the values of hydrated and gaseous ions (see Table VII, Sec. 6).

In order to obtain a set of values for the molar dispersion of individual ions, we proceeded in two ways which led to results agreeing within the limits of the uncertainties in both methods. One method is analogous to that applied previously (I) to the molar refraction. Besides the uncertainty connected with the hydration effect, the application of this method to the molar dispersion encounters an additional difficulty at present because of the low accuracy of the experimental values of **D** for the heavier alkali and halide ions.

The other method is based on an application of the square relation (5) between R_{D} and **D**. Assuming the values for the molar refraction of free gaseous ions to be known,[38] one can arrive directly at the values of molar dispersion of gaseous ions, using also the experimental values of R_{D} and **D** for the noble gases; comparing the results with the experimental information on aqueous ions one can further try to decide whether or not it is necessary to distinguish here between free gaseous and dissolved ions.

We shall present only the second method, which is based on a new principle and which has proved to be more straightforward than the first one. For reasons given in Section 4, it appears quite safe to use relation (5) in deriving molar dispersions for gaseous alkali and alkaline earth ions; very probably fluoride ion also obeys the square relation.[39] The results of the calculation are given in Table V, along with values for R_{D} and the ratios which correspond to the regularities expected from relations (8) and (9).

However, it is uncertain whether the application of the square relation to the larger halide ions can give exact enough results because their ν_0 values are considerably smaller than those of the noble gases, and they have large refractions. The results for these ions are therefore given in parentheses (see footnote *c*, Table V). For the doubly charged negative ions the same reservations apply, in addition to the restriction that here the values of both molar refraction and dispersion represent only extrapolated auxiliary quantities because these ions are not stable in the gaseous state.[40]

6. The Difference between the Molar Dispersion of Ions in the Free Gaseous State and in Aqueous Solution.—From the analogous behavior of refraction and dispersion, one would expect that the tightening of the electronic system of water molecules by cations would produce a negative hydration effect for molar dispersion, *i. e.*, $\Delta^{\mathbf{D}}_{\text{hydr.}} = (\mathbf{D}_{\text{aq. cation}} - \mathbf{D}_{\text{gas cation}}) < 0$ and that the absolute value of this effect should be greater, the greater the electric field of the cation (see XXX, p. 121). We can test this using the most accurately known values for $\mathbf{D}_{\text{g}}$ and $\mathbf{D}_{\text{aq. salt}}$: From $(\mathbf{D}_{\text{aq.}})_{\text{K}^+} - (\mathbf{D}_{\text{aq.}})_{\text{Na}^+} = 0.364 - 0.329 = 0.035 \pm .004$ (Table II, 1) and $(\mathbf{D}_{\text{g}})_{\text{K}^+} - (\mathbf{D}_{\text{g}})_{\text{Na}^+} = 0.0169$ (Table V) it follows that

$$(\Delta^{\mathbf{D}}_{\text{hydr.}})_{\text{Na}^+} = (\Delta^{\mathbf{D}}_{\text{hydr.}})_{\text{K}^+} - 0.018 \text{ cc./mole} \quad (10)$$

(37) Relation (7) was first applied to refraction by J. A. Wasastjerna [*Oeversikt av. Finska Soc. Foerdhandl.*, **LXIII A4**, 1 (1920–21); *Z. physik. Chem.*, **101**, 193 (1922)], to ionic radii by A. Landé, *Z. Physik*, **1**, 191 (1920).

(38) For reasons mentioned in XXX, p. 125 and in ref. (35) under 6c, the refractions given in XXX for gaseous ions can be expected to require some corrections. However, the results of the present paper give additional support to the belief that these refraction values cannot be far from the true ones, and that in any case they represent a consistent set.

(39) Although free fluoride ion can be expected to have an absorption band around 300 mμ (electron affinity ≈ 4 volts), which is closer to the visible than that of any of the substances used in verifying (5), the small value of its refraction ($R_{\text{F}^-} = 2.5$ cc. compared with $R_{\text{HI}} = 13.7$) makes it improbable that the second absorption band $(\nu_0)_2$ is important in the visible (see Sec. 4).

R_D	40.9	*2.13*	19.21	*1.84*	10.435	*1.60*	6.535	*1.38*	4.73

[a] The values of **D** were derived by using the square relation (5) between R_D and **D**, the above values of R_D and the experimental values of R_D and **D** for the noble gases. [b] The values of R_D are taken from XXX, Table (3), except for small changes in Xe and Kr, as given by Damkoehler (XL). [c] For reasons given in Section 6, we prefer to use (*e. g.* in Table VIII) the values of $D_{aq.} = 0.346$, 0.63 and 1.3 cc./mole (Table VI) for Cl^{-}, Br^{-} and I^{-}, respectively, as the provisional estimate of D_g. for these ions.

One can see that (10) agrees with the above expectation.

Since there is not sufficient information for evaluating the smaller hydration effect of K^{+}, we shall neglect it as a first approximation, as was done in the case of refraction[41]; *i. e.*, we put

$$(D_{aq.})_{K^+} = (D_{g.})_{K^+} = 0.0184 \text{ cc./mole} \qquad (11)$$

The numerical value in (11) comes from Table V. Using the experimental sums and differences given in Table II for aqueous electrolytes, the values of $D_{aq.}$ for all aqueous ions follow at once from relation (11). They are given in Table VI. By subtracting from the $D_{aq.}$ values for aqueous ions the values of $D_{g.}$ for those corresponding gaseous ions which in Table V are considered to be certain, one obtains the magnitude of the hydration effect $\Delta^{D}_{hydr.}$ The values of $\Delta_{hydr.}$, given in Table VII, allow one to test whether or not the derivation in Section 5 leads to a consistent system.

TABLE VI

APPARENT EQUIVALENT DISPERSION OF IONS IN AQUEOUS SOLUTION AT 25° IN CC.[a]

Li^{+}	−0.038	$\frac{1}{2}Be^{++}$	−0.047	F^{-}	0.057
Na^{+}	−0.0166	$\frac{1}{2}Sr^{++}$	− .010	Cl^{-}	.346
K^{+}	**.0184**	$\frac{1}{2}Ba^{++}$	.005	Br^{-}	.63
Rb^{+}	.04	$\frac{1}{2}Zn^{++}$	.002	I^{-}	1.3
Cs^{+}	.07	$\frac{1}{2}Hg^{++}$	.14	OH^{-}	0.205
NH_4^{+}	.046	$\frac{1}{2}Pb^{++}$	.24	NO_3^{-}	.50
Ag^{+}	.141	$\frac{1}{3}Al^{+++}$	− .041	ClO_4^{-}	.229
Tl^{+}	.53	H^{+}	(− .05)	$\frac{1}{2}SO_4^{=}$	.1416

[a] Based on the experimental values of **D** for electrolytes at infinite dilution (Table II) and relation (11).

Assumption (11) leads to the conclusion that for alkali ions larger that K^{+}, the hydration effect should also be negligible, while for the hydrogen ion,[42] lithium ion and small cations of double or triple charge, the value of $\Delta^{D}_{hydr.}$ should have a negative sign and its absolute value should be larger than that for Na^{+}.

Table VII not only agrees with the above conclusion,[43] but in addition it shows that qualitatively the gradation of $\Delta_{hydr.}$ is the same for the molar dispersion as for the molar refraction. In a quantitative respect one can only state that relative to the magnitude of R_D and **D** of one mole of water, the hydration effect is considerably greater for dispersion than for refraction. For example, one has for Li^{+}

$$\Delta^{D}_{hydr.}/D_{liq.H_2O} = -0.038/0.082 = -0.46$$

while

$$\Delta^{R}_{hydr.}/R_{liq.H_2O} = -0.33/3.72 = -0.09 \qquad (12)$$

It is of especial interest that for F^{-} a positive value of $\Delta^{D}_{hydr.}$ is obtained, analogous to the

(41) For the evidence that such solution effects exist also for large ions, see XXI and ref. (35), section 6c.

(42) For the apparent molar dispersion of aqueous hydrogen ion one finds $D = -0.05 \pm 0.05$. The large error is due to uncertainties in extrapolating values of D_{acid} to infinite dilution; therefore it is not warranted to place H^{+} in Table VII. However, the plot of hydrogen halides in Fig. 3 is not appreciably affected by such an error.

(43) Concerning Rb^{+} and Cs^{+}, see ref. 26.

TABLE VII

DIFFERENCES $\Delta_{hydr.}$ BETWEEN AQUEOUS AND FREE GASEOUS IONS FOR THE MOLAR REFRACTION R_D AND THE MOLAR DISPERSION D IN CC.

1. Refraction[a] [$(R_D)_{liq.H_2O}$ = 3.72 cc./mole]

$\Delta^D_{hydr.}$	+0.056	+0.018	(−0.05 ± 0.03)	(0.0 ± 0.05)	**0.0**	−0.018	−0.038	−0.05	−0.04	−0.094	−0.12
Ion/Na^+	−3.1	−1.0				1	2.0	2.7	2.2	5.2	6.7

[a] The values of $\Delta^R_{hydr.}$ are taken from XXX, p. 121.

[b] The values of $\Delta^D_{hydr.}$ are based on Tables V (VIII for HO^-) and VI and the assumption (11); concerning Cs^+, see ref. (62.)

corresponding refractometric effect. The positive sign indicates a loosening of the electronic shells of the adjacent water molecules by the action of the field of the small fluoride anion (see the similar result for OH^- in Section 7.)

It would be premature to draw definite conclusions concerning the values of $\Delta^D_{hydr.}$ for the heavier halide ions. A comparison of values in Table V with those in Table VI indicates that the **D** derived from the square relation for gaseous Cl^-, Br^- and I^- is smaller than that for the aqueous ions by 0.05, 0.13 and 0.1 cc., respectively. However, because of the uncertainty in $\mathbf{D}_{g.}$ for the large halide ions (see Section 5) and in $\mathbf{D}_{aq.}$ for Br^- and I^- (see Table II), the above values of the hydration effect are not reliable.

We shall, as was done for refraction, provisionally use the values of $\mathbf{D}_{aq.}$ in Table VI as being equal to those for the free gaseous Cl^-, Br^- and I^- ions. These values of **D** do not lead to contradictions with the regularities expected in the ratios (8) and (9) for gaseous ions; we have, *e. g.*

$$\underset{5.4}{Cl^-/A} > \underset{4.9}{Br^-/Kr} > \underset{4.3}{I^-/Xe}$$

7. The Change of Molar Dispersion by the Addition of Protons.—In Section 3 it was shown that the molar dispersion generally decreases when protons are transferred from the electronic shell of a hydride into the nucleus. Now, having the values of **D** for individual ions, we can discuss the effect of protons being brought from outside

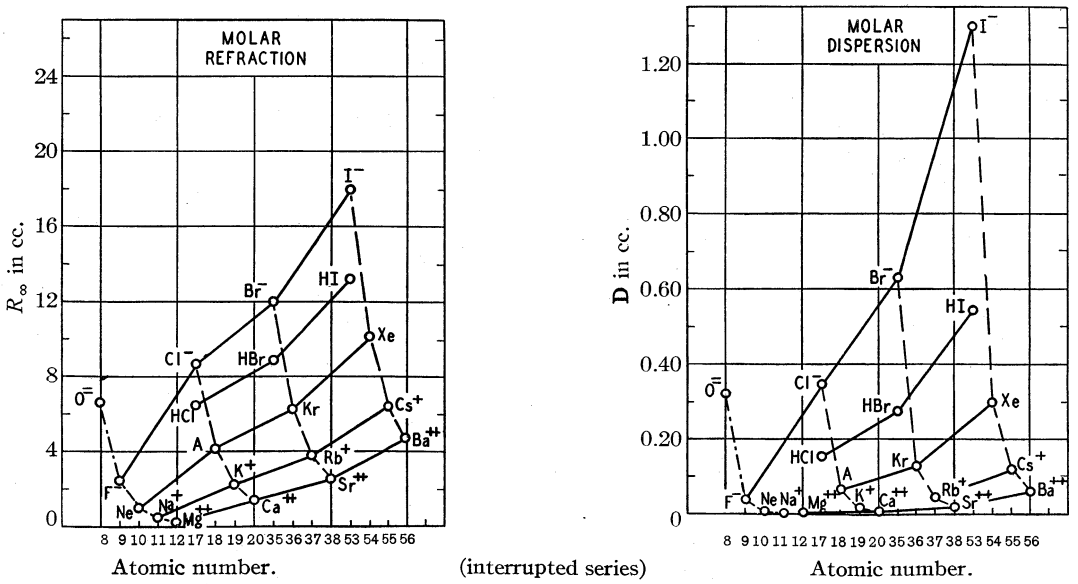

Fig. 4A.—Comparison of the molar refraction for infinite wave length: 1, of ions and atoms of a given noble gas type as a function of the nuclear charge (dashed lines); 2, of analogous ions, atoms, and molecules belonging to different periods (full lines); 3, of hydrogen halide molecules with the corresponding halide ions. Fig. 4B gives the same for the molar dispersion **D** ($\mathbf{D} = R_D - R_\infty$). In all cases the relative changes are larger for dispersion than for refraction.

TABLE VIII

THE CHANGE OF MOLAR DISPERSION BY THE ADDITION OF PROTONS

(I)	I^-	HSe^-	HS^-	Br^-	Cl^-	HO^-
$\mathbf{D}_I$	1.3	(1.14)	(0.75)	0.63	0.346	(0.149)
$\Delta\mathbf{D}$	0.76	(0.66)	(.43)	.36	.188	(.064)
$\mathbf{D}_{II}$	.54	.48	.320	.274	.158	.085
(II)	HI	H_2Se	H_2S	HBr	HCl	H_2O
$Q_I^D = (\mathbf{D}_I - \mathbf{D}_{II})/\mathbf{D}_I$	0.58	(0.58)	(0.57)	0.57	0.54	(0.43)
Q_I^D/Q_I^R	**2.03**	2.04	2.04	**2.05**	**2.04**	2.04

the electronic shell into either (1) the nucleus (*e. g.*, the process $Cl^- \rightarrow A$) or (2) into the electronic system (*e. g.*, $Cl^- \rightarrow HCl$).

The data for case (1) are contained in Table V and represented graphically in Fig. 4B which gives a plot of **D** for ions, atoms and molecules as a function of atomic number, and which is naturally analogous to the corresponding figure for refraction (Fig. 4A). We notice that the absolute change in the molar dispersion caused by the addition of one proton depends on the polarizability of the initial particle; *e. g.*, the decrease is 0.28 cc. (93% of $\mathbf{D}_{Cl^-}$) for the process $Cl^- \rightarrow A$, and 0.046 cc. (72% of $\mathbf{D}_A$) for $A \rightarrow K^+$. The percentage change is, as implied in the square relation, about twice as great for molar dispersion as for refraction.

For case (2) we have a chemical change according to the equation $H^+ + I = II$, in which I is the initial, II the final particle. These changes are simpler than other chemical processes in the respect that the electronic system of only one of the reacting particles is involved. The introduction of positive charge into the electronic system causes the electrons to be more tightly bound, *i. e.*, its polarizability becomes smaller. The observed diminution ΔR of the refraction R_I^D of a charged anion or neutral molecule (I) caused by the addition of protons was found (XXX)[43a] to obey a simple exponential relation

$$Q_I^R = \Delta R/R_I^D = 0.2859\ (1 - e^{-0.2848 R_I^D}) \quad (13)$$

The relative change of refraction Q_I^R increases with R_I^D and reaches the value 0.2847 for I^- ($R_I^D = 19.21$) which is nearly equal to the limiting value 0.2859 for $R_I = \infty$.

Table VIII, for which the unbracketed values are either known experimentally or obtained above (see footnote *c*, Table V) and for which the bracketed ones are derived below, shows that the change of molar dispersion by protons behaves qualitatively in an analogous way. The relative change $Q_I^D = (\mathbf{D}_I - \mathbf{D}_{II})/\mathbf{D}_I$ for dispersion increases from 0.54 for Cl^- to 0.57 for Br^- and 0.58 for I^-.[44] For all three halide ions the ratio Q_I^D/Q_I^R equals 2.04, showing again that the molar dispersion is about twice as sensitive as refraction. This relation can be made the basis for a derivation of ionic dispersions for gaseous HO^- HS^- and HSe^- from the known values of H_2O, H_2S and H_2Se. Assuming the ratio $Q_I^D/Q_I^R = 2.04$ to apply to these substances as well, and using the known values of Q_I^R (XXX, p. 134), one obtains Q_I^D given in Table VIII. Since $\mathbf{D}_{II}$ is known, we have the bracketed values of $\mathbf{D}_I$ in Table VIII at once.

The comparison of $(\mathbf{D}_{OH^-})_{g.} = 0.149$[45] with $(\mathbf{D}_{OH^-})_{aq.} = 0.205$ leads to a positive hydration effect $\Delta_{hydr.}^{D}$ which again fits qualitatively with the idea of a loosening of water molecules due to adjacent anions.

8. Changes in Molar Dispersion of Ions in Crystals and Complex Ions.—The decrease in molar dispersion discussed in Section 7 is caused by the tightening action of protons. This tightening of an electronic system also shows up in cases where the positively charged particle attached to it has an electronic system of its own. Thus for the alkali halides the tightening effect in dispersion is apparent from the regular increase in the absolute values of the negative differences $\mathbf{D}_{cryst.} - \mathbf{D}_{aq.\ ions}$ in Fig. 3[46]; *i. e.*, in the order of increasing polarizability of the anion (from Cl^- to I^-) and of increasing field of the cation (from Cs^+ to Li^+).[26]

In general one expects the tightening effect to be more or less compensated by the loosening action of negatively charged particles. This loosening effect shows up in the refraction of

(43a) See also K. Fajans and N. Bauer, *J. Chem. Phys.*, **10**, 410 (1942).

(44) The quantity $Q_{II}^D = \Delta D/D_{II}$ also shows a regular but more rapid gradation; *i. e.*, Q_{II}^D changes from 1.12 (Cl^-) to 1.41 (I^-). If we use the values of D_{X^-} derived from the square relation (5), the value of Q_I^D is approximately 0.46 for all three ions.

(45) Use of the square relation as an alternative method of calculation gives $(D_{OH^-})_{g.} = 0.148$.

(46) The regularities of Fig. 3 are not affected by comparing $\mathbf{D}_{cryst.}$ with $\mathbf{D}_{g.}$ instead of with $\mathbf{D}_{aq.}$

fluorides of the heavier alkali ions (see Fig. 3). Of these salts, data on the dispersion are available only for potassium fluoride; here, as expected, the molar dispersion of the crystal ($\mathbf{D} = 0.080$) is larger than that of free gaseous ions ($\mathbf{D}_{g.\ ion} = 0.057$).

In the case of compounds of doubly charged noble gas ions (BeO to BaTe), the large deviations from additivity of the molar refraction[30] generally show the expected gradations.[47] An example of similar behavior for the molar dispersion is given by the differences in Table IX, obtained from the most reliable **D** values in Table III. The reason for the large differences between corresponding Δ values can be expressed in the simplest way by stating that the tightening effect is greatest in MgS, as expected.

TABLE IX

DEVIATIONS FROM ADDITIVITY FOR THE MOLAR DISPERSION OF COMPOUNDS HAVING DOUBLY CHARGED IONS

	D in cc.	Δ		D in cc.
CaS	0.71 ± 0.02	**0.54**	CaO	0.17 ± 0.02
Δ	**.33 ± .04**		Δ	**.08 ± .03**
MgS	.38 ± .02	**0.29**	MgO	.09 ± .01

The molar dispersion of oxide ion is the most reliable among the values calculated for doubly charged anions (see Section 5); it is of interest to compare this $\mathbf{D}_{O^-} = 0.32$ cc. with the values of the apparent molar dispersion which $O^=$ shows in compounds. One obtains $\mathbf{D}_{O^-\,app.}$, given in Table X, by subtracting the value of $\mathbf{D}_{g.}$ for the attached positive ion (Table V[48]) from the

TABLE X

THE APPARENT MOLAR DISPERSION OF THE OXYGEN OCTET IN CRYSTALS AND COMPLEX IONS, IN CC.

Attached cation	Ba^{++}	Sr^{++}	None	Ca^{++}	H^+	Mg^{++}	S^{6+}	Cl^{7+}
Apparent $\mathbf{D}_{O^-}$	0.70	0.37	0.32	0.16	0.149	0.09	0.070	0.057
Apparent R_{O^-}	7.91	6.81	6.95	6.03	4.76	4.24	3.68	3.31

corresponding value for the crystal (Table III) or complex ion $SO_4^=$, ClO_4^-, and OH^- (Tables VI and VIII). Concerning the corresponding data for refraction, see refs. (30) and XLIII and Table V. We note from Table X that again the dispersion of a given electronic system subjected to various force fields shows relatively larger changes than the corresponding ones previously found for refraction; *e. g.*, on going from the free ion to the oxygen octet in perchlorate, where $O^=$ is deformed by the field of Cl^{7+}, $\mathbf{D}_{O^-}$ changes by a factor of 5.6, R_{O^-} by a factor of 2.1.

Especially significant in Table X is the high value of $\mathbf{D}_{O^-\,app.}$ in BaO. It gives support to the former conclusion (VII) that the oxygen ion appreciably loosens the barium ion. This conclusion was based on the fact that also the apparent refraction of $O^=$ in BaO (7.91) is higher than the refraction obtained for free oxide ion (6.95) by extrapolation from the R values for other noble gas ions.

(47) K. Fajans, *Z. Krist.*, **66**, 325 (1928).

(48) It is apparent from extrapolating the values in Table V that R and **D** are negligibly small for S^{6+} and Cl^{7+}.

Summary

1. The difference $\mathbf{D} = R_D - R_\infty$ between the molar (Lorentz–Lorenz) refraction for the sodium D line and that extrapolated to infinite wave length from measurements in the visible is used as measure of the *molar dispersion.*

2. For isoelectronic substances, the dispersion of which can be represented by a single term formula in the visible, one is led to expect that **D** is approximately proportional to the square of R_D. It is shown that this *square relation* applies satisfactorily to noble gases (N. G.), hydrogen halides and H_2O, H_2S, H_2Se.

3. The molar dispersion $\mathbf{D}_{g.}$ for free gaseous ions of the noble gas type is obtained by applying the square relation to the corresponding values of molar refraction found previously and to the experimental data on $R_{N.G.}$ and $\mathbf{D}_{N.G.}$ A comparison of the gradations of $\mathbf{D}_{g.}$ with the gradations of the experimental molar dispersions for aqueous electrolytes leads to an estimate of the effect of hydration on the apparent ionic dispersion.

4. The molar dispersion proves to be a property which is even more sensitive to changes in the forces acting on the electronic systems of ions and molecules than is the molar refraction; in general the relative changes in **D** are about twice as great as the corresponding changes in R_D.

The Vapor Pressure of Phenothiazine[1]

BY O. A. NELSON AND L. E. SMITH

During recent years considerable experimental work has been done with phenothiazine for the purpose of establishing the value of this compound as an insecticide. It has been tested as a stomach poison against a great variety of insects,[2] but thus far the most extensive field tests have been aimed at the substitution of this compound for arsenicals for the control of the codling moth larva.

When freshly applied, phenothiazine is more toxic to this insect than lead arsenate at the same dosage. After a few days, however, the deposit loses much of its toxicity. This loss may be due to loss of deposit due to lack of adhesive properties or to decomposition in sunlight. Although the rate of vaporization of phenothiazine is very low, nevertheless it has been suggested that the loss in toxicity might be due to the evaporation of the smaller particles from the surfaces of the sprayed fruits or leaves. For this reason the vapor pressure and the rate of evaporation of this compound were determined.

Method.—It was evident that the vapor pressure of phenothiazine was much too low to be determined by the static method. An apparatus was designed, therefore, whereby the vapor pressure could be determined by the air-saturation method. The apparatus, a modification of the one used by Vanstone,[3] is shown in Fig. 1.

The saturator, about 14 inches long, was loosely packed with glass wool and powdered phenothiazine and suspended in a constant-temperature bath. Packing it in this manner reduced to a minimum the possibility of channeling and also provided an enormous surface, thus facilitating saturation of the air with the compound. The exit tube of the saturator was electrically heated to prevent condensation of the vapors before they reached the thin-walled condenser, cooled in an ice-salt mixture. The weight of the phenothiazine condensed was determined by a colorimetric method developed in the Division of Insecticide Investigations, which is based on the transformation of the compound into a red product by treatment with bromine. The limit of accuracy of this method was 1.0 microgram of phenothiazine, representing an error of less than 5% in most of the determinations. This method is essentially the same as the one described by Eddy and DeEds.[4] For the lower temperatures 11.8 liters of air was drawn through the aspirator, while for the higher temperatures only 2 liters was required. The rate of flow of the air through the apparatus was controlled by means of the capillary tip at the outlet tube from the aspirator.

In determinations of vapor pressure by the air-saturation method it is imperative that the air drawn through or over the sample be completely saturated with the compound under investigation. That the air was saturated with respect to the phenothiazine was evidenced by the observation that air could be drawn through the saturator at a rate twice that used in the vapor-pressure determination without lowering the results.

In order to verify the results obtained in the 14-inch saturator and only one condenser, a second series of vapor pressure determinations was made in which the saturator consisted of three, and later five, 10-inch glass tubes, filled as described above, and heated in an electrically controlled air furnace, and two condensers instead of one. Not a trace of phenothiazine was obtained in the second condenser, thus proving complete absorption in the former experiments. The results of this series are given in Table I, series 2.

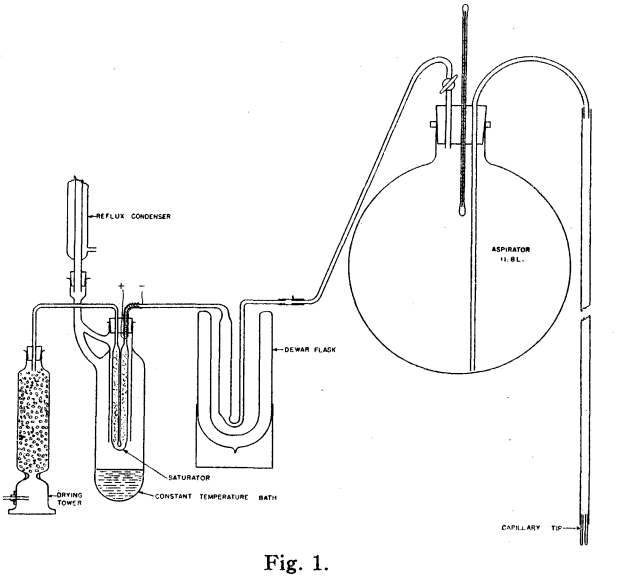

Fig. 1.

Experimental Results

After the weight of the compound vaporized in a known volume of air had been determined, the vapor pressure was readily calculated from Dalton's law of partial pressures. The expression used by Vanstone, correcting the volume of air for temperature and pressure, is

$$\text{V. P.} = \frac{wV_cTP\ 760}{273pV + 760wV_cT}$$

wherein

V. P. = vapor pressure of phenothiazine, in mm.
w = weight of phenothiazine condensed, in grams
V_c = specific volume of phenothiazine = 22.41 liters/gram-mole = 0.1126 liter per gram
P = pressure of atmosphere, in mm.
p = pressure of air in aspirator, in mm.
V = volume of air aspirated, in liters
T = absolute temperature of air in aspirator

Table I gives the experimental data obtained in this investigation, together with the vapor pressures as calculated by means of the above equation.

TABLE I

EXPERIMENTAL DATA FOR VAPOR PRESSURE OF PHENOTHIAZINE

Temp., °C.	Replications, number	Vapor pressure, mm.	Standard error, mm.
	Series 1		
63	7	0.00008	0.00002
66	3	.00014	.00003
78	6	.00026	.00003
100.5	3	.0016	.0001
111	10	.0038	.0002
121.5	4	.0089	.0004
	Series 2		
78	4	0.0002	
90	1	.00064	
96.5	1	.0014	
99	3	.0018	
100	3	.0019	
110	2	.0037	
112	1	.0042	
121	2	.0085	

Over limited ranges of temperature and pressure the relation between these factors can be expressed by the equation $\log p = 9.265 - 4490.0/T(\text{abs.})$. By means of this equation the vapor pressures of phenothiazine were calculated at 10-degree intervals from 40 to 140°. These data are recorded in Table II.

TABLE II

CALCULATED VAPOR PRESSURES OF PHENOTHIAZINE

Temp., °C.	Vapor pressure, mm.	Temp., °C.	Vapor pressure, mm.

80	.00032	140	.025
90	.00081		

Rate of Vaporization of Phenothiazine

The rate at which phenothiazine vaporized was determined in two series of experiments, in which glass plates were dusted with finely divided phenothiazine. In the first series two glass plates with areas totaling 384 sq. cm. were placed inside a 4-inch glass tube, which in turn was kept at 45° in a constant-temperature air thermostat. A gentle current of air was drawn over the dusted surfaces to carry off the phenothiazine vapors. The runs were continued for two to four days. An absorption bulb filled with ethyl alcohol and kept at ice–salt temperature was inserted in the air line for three to six hours, and the weight of phenothiazine was determined by the colorimetric method. To determine whether all the phenothiazine was absorbed, a second absorption bulb was inserted in the line, and air was drawn through for four hours. No phenothiazine was found in the second bulb.

In the second series of experiments, the finely divided phenothiazine was dusted on 45 by 50 mm. cover glasses, which were then placed at an angle of about 45° in echelon arrangement on a wire rack in the air thermostat at 45°. A moderate current of air was drawn over the dusted surfaces for ninety-six hours. The loss in weight of phenothiazine was determined by direct weighing of the cover glasses, before and after evaporation, on a micro balance sensitive to 0.002 mg.

Table III gives a summary of the results obtained in these experiments.

TABLE III

RATE OF VAPORIZATION OF PHENOTHIAZINE

Series	Replications	Rate of evaporation μg./sq. cm./hr.	Probable error of the mean μg./sq. cm./hr.
1	11	0.019	0.002
2	8	.027	.0027
Average		.023	.0013

The average particle size of the sample used in these experiments, as determined by the air-permeation method,[5] was 3 microns diameter.

The method used in determining the rate of vaporization was designed to yield results comparable to those obtained under field conditions, where the insecticide is sprayed or dusted on the surfaces of fruits and leaves. The weight of phenothiazine per unit area of glass surface in these experiments was about five times the amount applied to fruits or foliage, and because of this difference in density of phenothiazine particles there might possibly be a slight difference in rate of evaporation. The difference is believed to be small, however, and the rates recorded here are considered good estimates of the rate of loss of this compound due to vaporization in actual use.

The original weight of phenothiazine on the glass plates was approximately 200 micrograms per square centimeter. As the average rate of loss amounted to only 0.023 microgram per square centimeter per hour, the loss over a period

(5) E. L. Gooden and C. M. Smith, *Ind. Eng. Chem., Anal. Ed.*, **12**, 479 (1940).

of one hundred hours would be slightly more than 1%.

Summary

The vapor pressure of phenothiazine within the temperature range of 63–121° and the rate of evaporation of the finely powdered compound at 45° have been determined.

The results obtained show that the loss in toxicity of phenothiazine when used for the control of insect pests is not due to evaporation.

Tracer Studies with Radioactive Hydrogen. Some Experiments on Photosynthesis and Chlorophyll

BY T. H. NORRIS, S. RUBEN AND M. B. ALLEN

Since nothing is known regarding the role of chlorophyll in green plant photosynthesis, there has been, and still is, considerable speculation on the subject. The many theories that have been proposed may be divided into two classifications: (1) chlorophyll participates as a reducing agent (hydrogen donor), (2) chlorophyll merely acts as a sensitizer (as certain dyes function on photographic plates, for example). The first category is by far the larger and we may cite a few of the more interesting proposals found in this group.

Dixon and Ball[1] have suggested that chlorophylls *a* and *b* are involved in a reversible oxidation–reduction cycle in which chlorophyll *a* (GH_2) is oxidized to *b* (GO).

$$GH_2 + CO_2 + \text{light} \longrightarrow GO + 1/n(H_2CO)n \quad (1)$$

and *b* in turn is reduced to *a* as follows[2]:

$$GO + H_2O + \text{light} \longrightarrow GH_2 + O_2 \quad (2)$$

The discovery that the chlorophylls contain a readily oxidizable group led Conant[3] and coworkers to propose that the pigment might act as a two electron reducing agent.

$$12GH_2 + 6CO_2 \xrightarrow{\text{enzyme}} 12G + C_6H_{12}O_6 + 6H_2O \quad (3)$$

in a dark reaction,[3] chlorophyll being regenerated by a photochemical process.[4]

$$12G + 12H_2O + \text{light} \longrightarrow 12GH_2 + 6O_2 \quad (4)$$

Stoll[4] and Willstätter[5] independently consider chlorophyll to function as a hydrogen donor in a photochemical reaction producing monodehydrochlorophyll (GH). This free radical is supposed to revert to the original dye via another photochemical process.

$$GH + H_2O + h\nu \longrightarrow GH_2 + OH \quad (5)$$

Franck[6,7] has a somewhat similar point of view, but has formulated the chlorophyll regeneration as

$$GH + R'OH + h\nu \longrightarrow GH_2 + R'O \quad (6)$$

where R'OH is different from water.

It occurred to us that using radioactive hydrogen[8] H^3, as a tracer it might be possible to learn whether or not chlorophyll is participating in photosynthesis as a donor of hydrogen. If photosynthesis is allowed to proceed for a sufficiently long time in water containing HTO[9] chlorophyll containing T should be formed[10] if the idea underlying equations 2, 4, 5, 6 is correct.

Experimental

Eleven cc. of the unicellular green alga *Chlorella pyrenoidosa* was suspended in 220 cc. of 0.05 *M* potassium bicarbonate solution containing HTO and strongly illuminated for three hours. During this period 2.5×10^{-3} mole of oxygen was evolved and a simple calculation shows that if the donor scheme is correct each chlorophyll should have been oxidized and reduced at least 100 times.[10a] The algae were centrifuged and the chlorophyll removed by exhaustive extraction with 95% acetone. All operations from the end of the illumination to the final burning of the chlorophyll were performed in strict darkness. In order to facilitate operations in the dark, the volumes of all solutions and vessels were carefully predetermined. To remove a lower layer from a separatory funnel, an evacuated

vessel of known volume was attached to the bottom. The chlorophyll was transferred by extraction to pentane and this solution washed twice with 80% acetone. The pentane layer was thoroughly washed with water. Under such conditions chlorophyll will usually precipitate, but the solution was too dilute in the present case for this to occur to an appreciable extent. The solvent was distilled off *in vacuo* at room temperature and the chlorophyll[11] carefully dried under high vacuum for several days. It was then burned in a stream of dry oxygen to carbon dioxide and water, the gases being passed over heated cupric oxide and the water collected in a cold trap. This water was converted quantitatively to magnesium oxide and hydrogen with excess fresh magnesium turnings at ~625°.[12] The conversion was carried out in a large test-tube filled with turnings, connected to the vacuum system through a rubber stopper sealed with de Khotinsky cement. The water was frozen in the bottom of the tube by immersion in liquid air. After evacuation the upper section was heated to ~625° electrically and the water then distilled up through the turnings, one distillation usually being sufficient for complete reaction. The evolved hydrogen was dried by passage through a liquid air trap and introduced directly into a Geiger counter containing 1.5 cm. of ethanol vapor and its radioactivity measured.[13] By using a new test-tube and stopper for each conversion the difficulty of decontamination was greatly reduced. The counter and the vacuum line were rid of adsorbed radiohydrogen by repeated flushing with ethanol vapor. The results of three separate experiments are summarized in Table I.

TABLE I

FORMATION OF RADIOACTIVE CHLOROPHYLL DURING CHLORELLA PHOTOSYNTHESIS IN HTO

Expt.	Algae,[b] cc.	Conditions	O_2 evolved (millimoles)	Radioactivity (counts/min.) Found experimentally	Radioactivity (counts/min.) Theoretical[a] for complete exchange
1	11.0[c]	175 min. in light	2.0	< 80	2200
2	3.1[d]	185 min. in light	0.5	< 65	5260
3	5.5[e]	180 min. in dark	...	<100	9350

[a] Calculated on the assumption that each chlorophyll molecule in the algae has one hydrogen atom capable of undergoing photodissociation and moreover that each cycle involves the same C—H bond. [b] 1 cc. of algae contains 2×10^{-5} mole of chlorophyll. [c] Suspended in 220 cc. of 0.05 *M* $KHCO_3$ containing 2.0×10^7 c./min./mole H_2O. [d] Suspended in 55 cc. of 0.05 *M* $KHCO_3$ containing 1.7×10^8 c./min./mole H_2O. [e] Suspended in 50 cc. of 0.05 *M* $KHCO_3$ containing 1.7×10^8 c./min./mole H_2O.

It is apparent from Table I that no evidence for a photochemical exchange between chlorophyll and H^+ (*e. g.*, H_2O, —OH, —NH_2, —COOH) was obtained. Before concluding that chlorophyll does not act as a hydrogen donor in photosynthesis we must consider two possible objections: (1) loss of H^3 from chlorophyll by thermal exchange during the extraction process; (2) an isotope effect—*i. e.*, H^3 is not an ideal tracer for hydrogen of mass 1.

The possibility that chlorophyll contains labile hydrogen which can undergo photochemical or thermal exchange with water, etc., was therefore investigated. Pure chlorophyll was prepared from fresh spinach leaves following the procedure of Mackinney.[14] After drying in high vacuum for several weeks, the final product was analyzed spectrophotometrically[15] and found to be 97 ± 1% pure while the *a*/*b* ratio was 1.77. A weighed portion (40 mg.) of this chlorophyll was dissolved in 8 cc. of absolute ethanol and then 2 cc. of water (HDO) containing HTO and DTO was added.[16] This solution was shaken in the light for thirty minutes and the solvent distilled off *in vacuo* at room temperature. An attempt was made to free the chlorophyll of adsorbed or trapped solvent by maintaining a high vacuum (10^{-6} mm.) over it for several days, after which the chlorophyll and its glass container (crushed) were introduced into a combustion tube and burned in a stream of dry air. In order to obtain sufficient hydrogen for several entirely independent radioactivity determinations, a weighed portion of anhydrous glucose (Merck reagent grade) was added to the chlorophyll just prior to combustion. The resulting water was converted to hydrogen and counted. The results of this and similar experiments are summarized in Table II.

TABLE II

SEARCH FOR EXCHANGEABLE HYDROGEN IN CHLOROPHYLL

Expt.	Chlorophyll, g.	Specific activity of hydroxyl hydrogen in solvent (80% EtOH) counts/min./g. atom H	Experimental conditions	Tritium content of chlorophyll Exptl.	Tritium content of chlorophyll Theoretical[a]
1	0.040	2.78×10^8	30 min. light	187 ±30	3820
2	.095	0.53×10^8	60 min. light[b]	51 ±20	2430
3	.034	2.78×10^8	30 min. light[c]	100 ±25	3240

[a] Calculated on the assumption that each chlorophyll molecule has one exchangeable hydrogen atom. In experiments (1) and (3) 30.8% of the total H_2 generated was introduced in the Geiger counter; in (2) 43.4% of the H_2 was counted. [b] O_2 excluded at all times during experiment. After removing active solvent (25 cc.) the chlorophyll was dissolved in 10 cc. of 95% ethanol (inactive) which after ~five minutes was distilled off *in vacuo* at room temperature. This operation was repeated twice, the intention being the removal of firmly adsorbed or trapped radio-active solvent. [c] Washed once with 10 cc. of inactive 95% ethanol.

Since the small amount of radiohydrogen found in Experiments 1–3 was approximately 10^{-6} of the T used in each experiment, it was of interest to determine if exchange with the glass occurred. To this end Experiment (1) was repeated except that the chlorophyll was omitted. The hydrogen obtained in this experiment gave 30 ± 10 counts/minute in the Geiger counter.

(11) This probably contained small amounts of yellow pigments, etc., *cf.* Mackinney, *J. Biol. Chem.*, **132**, 91 (1940).

(12) In order to avoid any isotope separation it is essential that this conversion be quantitative. This method was found to be more rapid than the reaction with hot zinc.

(13) For a brief discussion of counting radiohydrogen see Allen and Ruben, THIS JOURNAL, **64**, 948 (1942).

(14) Mackinney, *J. Biol. Chem.*, **132**, 91 (1940).

(15) We are indebted to Dr. S. Aronoff for this analysis.

(16) Radio-water of this composition was obtained by condensation of the exhaust gases from the acceleration chamber of the 60" Berkeley cyclotron.

Discussion

It would appear from Tables I and II that $< 5\%$ of the chlorophyll has exchanged one hydrogen. However, due to the possibility of an appreciable isotope separation, the low values shown in Tables I and II do not exclude the possible existence of a cycle (Equations (7) and (8)) in which a photoactivated chlorophyll (G^*H_2) acts as a donor of

$$h\nu + GH_2 + A \longrightarrow G^*H_2 + A \longrightarrow GH + HA \quad (7)$$

hydrogen to some unknown substance (A)[17] and the chlorophyll free radical (GH) formed in this process is reduced to native chlorophyll (GH_2) by a thermal reaction such as (8).

$$GH + ROH \longrightarrow GH_2 + RO \quad (8)$$

Process (8) very likely has a lower activation energy than the analogous reaction (9) involving an oxygen–tritium bond.

$$GH + ROT \longrightarrow GHT + RO \quad (9)$$

The difference in energies of activation could be of the order of 2 kcal. and consequently the specific reaction rate for (8) would be ~20 times greater than that of (9).

It might be of interest to mention some simple reactions involving hydrogen and deuterium in which the differences in activation energies have been obtained by kinetic studies. Rollefson[18] found a difference of 1630 calories in the energies of activation for the following

$$Cl + H_2 \longrightarrow HCl + H \quad (10)$$
$$Cl + D_2 \longrightarrow DCl + D \quad (11)$$

Farkas and Farkas[19] studied

$$Cl + H_2 \longrightarrow HCl + H \quad (12)$$
$$Cl + HD \longrightarrow DCl + H \quad (13)$$

and found the difference to be 600 calories.

In the photochemical reaction (7) the absorption of a light quantum would raise the photoactivated chlorophyll to an energy level well over the top of the energy barrier and therefore the specific reaction velocities for (7) and (14) would be the same and no isotope separation would occur.

$$h\nu + GHT + A \longrightarrow GH^*T + A \longrightarrow GH + TA \quad (14)$$

This seems to be a reasonable assumption since the quantum yield of photosynthesis is essentially the same[20] for wave lengths of light from 4500 to 6900 Å.

On the other hand, if (7) and (14) were thermal or if the photoactivated compound dropped to a lower energy level (by fluorescence or by a tautomeric change such as suggested by Franck and Livingston[21] such that the energy content was within say 1 kcal. of the activation energy of (7), the isotope separation would result in which GHT would tend to accumulate over GH_2. Moreover, if (8) and (9) were photochemical no isotope separation would occur.

It should be noted that Trelease and coworkers[22,23,24] have found the rate of photosynthesis in pure deuterium oxide (heavy water) to be 0.41 the rate in water. They have also shown that the thermal reactions and not the photochemical processes are slowed by the deuterium. If a reaction such as (8) is the rate determining step the difference in activation energies of (15) and (8)

$$GH + ROD \longrightarrow GHD + RO \quad (15)$$

is ~600 calories. Assuming the difference in energies of activation is due primarily[25] to the difference in zero point energies, one calculates that the difference in activation energies in rupturing a carbon–tritium and a carbon–hydrogen bond is ~25% greater than the corresponding difference between a carbon–deuterium and a carbon–hydrogen bond. However, it is possible that photosynthesis involves several thermal reactions in which isotope separations may occur. Therefore, in the tritium experiments where there is competition between ROH and ROT the isotope separation may be greater or less than one would expect from a simple consideration of the rate in pure deuterium oxide.

If the experiments described in this communication were repeated using 100% D_2O and the chlorophyll analyzed for deuterium content, all uncertainties due to isotopic effects would be completely eliminated and an unequivocal conclusion regarding the role of chlorophyll in photosynthesis could be reached. We hope to do this experiment in the near future.

It is evident that the results obtained in this research cannot be considered as definite evidence for or against the hydrogen donor hypothesis, but we may reasonably conclude that *either no isotope separation accompanies (7) and does take place in*

(17) Equation (7) is essentially similar to the formulation by Franck and Gaffron

$$GH_2\text{-}CO_2 \text{ complex} + h\nu \longrightarrow GH + \text{intermediate.}$$

(8) or else the hypothesis that chlorophyll acts as a donor of hydrogen in photosynthesis should be abandoned.

Acknowledgments.—We wish to thank Professors G. K. Rollefson and J. Franck for many helpful suggestions and discussions. We are indebted to Professor E. O. Lawrence and members of the Radiation Laboratory, particularly Dr. M. D. Kamen, for the tritium samples.

Summary

1. The formation of chlorophyll containing T could not be detected during photosynthesis of *Chlorella pyrenoidosa* in HTO + H_2O.

2. No (<5%) thermal exchange was observed between purified chlorophyll and 80% ethanol containing HTO.

3. The implications of these results for the theory that chlorophyll acts as a hydrogen donor in photosynthesis are discussed.

4. It is pointed out that repetition of the experiments herein described using 100% D_2O would avoid the question of isotope separation and make possible an unequivocal conclusion regarding the role of chlorophyll.

NOTES

Characteristics of β-[2,5-Dimethoxyphenyl]-β-hydroxyisopropylamine Hydrochloride

BY RICHARD BALTZLY AND JOHANNES S. BUCK

This compound was reported recently[1]; subsequent investigation makes it evident that the substance to which that formula was attributed is actually β-[2,5-dimethoxyphenyl]-β-oxoisopropylamine hydrochloride. This could have been anticipated[2] but was not at the time. The error arose partly from the difficulty of interpreting small absorptions of hydrogen when using a catalyst (palladized charcoal) that itself binds relatively large amounts of hydrogen and partly from adverse conditions over which the analyst had no control.

The substance previously obtained (m. p. 176° dec.) when dissolved in water and reduced with hydrogen and platinum-black absorbed 1 mole of hydrogen. A new hydrochloride was isolated melting at 215°.

Anal. Calcd. for $C_{11}H_{18}O_3N$: C, 53.31; H, 7.33. Found: C, 53.43; H, 7.53.

When the corresponding base was acetylated with acetic anhydride a diacetyl derivative was formed melting at 120° and crystallizing from ethyl acetate–hexane in parallelogrammatic plates.

Anal. Calcd. for $C_{15}H_{21}O_5N$: C, 60.98; H, 7.17. Calcd. for $C_{13}H_{17}O_4N$: C, 62.12; H, 6.83. Found: C, 61.09; H, 7.30.

Identification of *o*- and *p*-Sulfobenzoic Acids[1] as their S-Benzylthiuronium Salts

BY E. CAMPAIGNE[2] AND C. M. SUTER[3]

The structure of the alkylated benzenesulfonic acids may be partially clarified by oxidation to the sulfobenzoic acids. The identity of the *o*-, *m*- and *p*-sulfobenzoic acids may be determined by conversion to the acid chlorides and to the amides.[4] This involves separation and drying of the salts of the sulfobenzoic acids, and the somewhat tedious conversion to the chlorides with a phosphorus halide. The use of S-benzylthiuronium chloride as an analytical reagent for sulfonic acids[5] has recently been reported. Since the benzylthiuronium derivatives are prepared in water solutions, the use of this reagent should give a quick and easy method for the identification of the oxidation products of alkylbenzenesulfonic acids and related compounds.

The S-benzylthiuronium salts of *o*- and *p*-sulfobenzoic acid were obtained in good yield from water solutions of the acid sodium or ammonium salts, but the derivative of the *m*-sulfobenzoic acid was found to be quite soluble in water, and could not be isolated conveniently. The *o*-sulfo-

benzoic acid gave an immediate precipitate from hot dilute acid. This salt was extremely insoluble, and analysis showed it to be the di-(S-benzylthiuronium) *o*-sulfobenzoate. The *p*-sulfobenzoic acid gave a derivative which was more soluble, crystallizing slowly from cold dilute acid. Analysis shows this to be the acid salt, S-benzylthiuronium hydrogen *p*-sulfobenzoate. The difference in solubilities of these three salts gives a convenient method of identification of the three acids. A solution of the free acid, or a solution of a salt of the acid which has been acidified with a few drops of concentrated hydrochloric acid, is heated to boiling and the calculated quantity of a 10% solution of S-benzylthiuronium chloride is added. An immediate precipitate indicates *o*-sulfobenzoic acid. A precipitate which crystallizes slowly on cooling indicates *p*-sulfobenzoic acid, and if no precipitate, or an oil, is obtained, the acid is *m*-sulfobenzoic acid.

Experimental

***p*-Sulfobenzoic Acid.**—Two grams of *p*-toluenesulfonic acid was oxidized with 5 g. of potassium permanganate in basic solution. The precipitated manganese dioxide was filtered off, and hydrochloric acid was added until the solution became acidic. The addition of barium chloride caused an immediate precipitate of white flakes of the barium salt of *p*-sulfobenzoic acid, which was soluble in base and reprecipitated by acid. One gram of this salt was digested in 30 ml. of hot water with excess sodium sulfate and 1 ml. of concentrated hydrochloric acid. The precipitate of barium sulfate was removed, and 10 ml. of 10% S-benzylthiuronium chloride was added. The clear solution, on cooling, gave flat plates of S-benzylthiuronium hydrogen *p*-sulfobenzoate which were recrystallized with difficulty from ethyl alcohol, m. p. 212.6–214.4° (cor.).

Anal. Calcd. for $C_{15}H_{16}N_2O_5S_2$: N, 7.61; Found: N, 7.80.

***m*-Sulfobenzoic Acid.**—This acid was prepared in the usual manner by sulfonating benzoic acid in 30% fuming sulfuric acid and salting out the acid sodium salt. One gram of this salt was dissolved in 20 ml. of distilled water containing 1 ml. of concentrated hydrochloric acid and 10 ml. of 10% S-benzylthiuronium chloride was added. No precipitate formed on cooling. At freezing temperatures an emulsion formed which redissolved as it warmed to room temperature. No further attempt was made to isolate this salt.

***o*-Sulfobenzoic Acid.**—The acid ammonium salt of this acid was prepared from saccharin according to the method of Clarke and Dreger.[6] One gram of the crude salt was dissolved in 30 ml. of hot water, 1 ml. of concentrated hydrochloric acid and 10 ml. of 10% S-benzylthiuronium chloride were added. An immediate precipitate was formed in the hot solution. After cooling, the di-(S-benzylthiuronium) *o*-sulfobenzoate was recrystallized from 70% alcohol as fine white needles, m. p. 205.5–206.5° (cor.). When mixed with the derivative from *p*-sulfobenzoic acid the melting point was 194–196°.

Anal. Calcd. for $C_{28}H_{26}N_4O_5S_3$: N, 10.25. Found: N, 10.35.

The Formation of Insoluble Sulfur in the Presence of Gases Other than Sulfur Dioxide

BY EDWARD A. FEHNEL

The work of Smith and Holmes[1] and, more recently, of Das and Ghosh[2] would indicate that the plasticity and insolubility of certain forms of sulfur are dependent upon the presence of at least a trace of sulfur dioxide. The former investigators considered the presence of this compound an essential condition for the formation of plastic sulfur; the latter believe that all insoluble forms of the element owe their distinctive property to the presence of an insulating film of sulfur dioxide about the minute crystallites. On the other hand, suggestions have been made by various investigators, notably Deines[3] and Meyer,[4] that possibly other foreign substances might also be capable of causing the formation of insoluble forms of sulfur.

In order to decide between these two conflicting points of view, an improved quenching method was devised in this Laboratory for the preparation of insoluble, plastic sulfur in a closed system which permitted contact with any desired gas while eliminating all possibility of contact with air. Under these conditions the formation of traces of sulfur dioxide by aerial contact is avoided, and it becomes possible to ascribe the various effects to their true causes.

It was found that while air and sulfur dioxide gave the expected results, yielding clear, amber, plastic masses analyzing about 36% insoluble sulfur after 6 days, and while nitrogen and ammonia gave opaque, yellow, brittle masses analyzing less than 4% insoluble sulfur, both hydrogen chloride and hydrogen sulfide were capable of producing clear, amber, plastic masses analyzing 36% and 8% insoluble sulfur, respectively. The plasticity of these latter forms was, it is true, rela-

tively short-lived, lasting about twenty minutes in the case of the HCl-produced material and only two minutes in the case of the H_2S-produced material. Nevertheless, the plastic state was observed to exist, and in contrast to the immediate solidification of the material formed in the presence of the inert gases nitrogen and ammonia, its life in this state was quite appreciable. The corresponding increases in the proportion of insoluble sulfur present in the hardened samples is also indicative of the ability of hydrogen chloride and hydrogen sulfide to act similarly to sulfur dioxide in the formation of the plastic and insoluble modifications.

Thus, theories postulating the indispensability of sulfur dioxide in the formation of plastic sulfur or for the maintenance of insolubility in the hardened mass appear, on the basis of these facts, to be untenable. The suggestions by Deines and by Meyer that foreign substances other than sulfur dioxide might be effective in causing similar results are upheld by the experimental evidence.

Preparation of Germanium Tetrachloride, $GeCl_4$

BY LAURENCE S. FOSTER, J. W. DRENAN AND A. F. WILLISTON

When germanium dioxide, GeO_2, is boiled with hydrochloric acid, germanium tetrachloride, $GeCl_4$, volatilizes if the concentration of hydrogen chloride approaches 6 *N*.[1] It has been observed in this Laboratory and elsewhere, however, that if the concentration of hydrogen chloride is too high, germanium tetrachloride vapor is carried uncondensed through a water cooled condenser.[2] The loss of germanium is readily explained. When the acid concentration is high, germanium tetrachloride is not hydrolyzed and, in addition, is not very soluble in such acid solutions. Its vapor pressure, furthermore, is quite high at the temperature of the cooling water in the condenser. When 6 *N* hydrochloric acid, approximately the constant boiling mixture, is used, both the acid and the germanium tetrachloride are completely condensed; when mixtures with higher concentrations of hydrogen chloride are boiled, however, gaseous hydrogen chloride passes through the condenser and carries considerable germanium tetrachloride along with it.

Aitkenhead and Middleton[2b] took advantage of this phenomenon in the analysis of minerals for small amounts of germanium; germanium tetrachloride was distilled in a stream of hydrogen chloride gas, thus removing the germanium completely from the rest of the dissolved sample. The gases which escaped from the top of a reflux condenser were absorbed in a small volume of water and the germanium content readily determined.

At very low temperatures (−72°) no complexes form between germanium tetrachloride and hydrogen chloride[3] so that it is possible to separate the two by judicious cooling. It has been found that if the vapors which emerge from the top of a reflux condenser, after being dried, are cooled in a "dry-ice"–isopropyl alcohol mixture, the hydrogen chloride (b. p. −85°) escapes uncondensed and the germanium tetrachloride freezes out as a pure white solid (m. p. −49.5°). The method has the added advantage that the germanium dioxide is more readily dissolved in the boiling flask when the concentration of hydrogen chloride is kept high.

Procedure.—Germanium oxide is suspended in 6 *N* hydrochloric acid and the suspension is boiled gently under a reflux condenser. Hydrogen chloride is passed into the flask at a rapid rate at first so that some of it escapes slowly through a sulfuric acid trap at the end of the train. Later, when the absorption in the boiling flask nears completion, the rate of flow is reduced. As the gases pass through the reflux condenser, condensed germanium tetrachloride and constant boiling hydrochloric acid return to the flask, but the gases escaping through the condenser carry a high percentage of germanium tetrachloride and gradually all of it is volatilized. The gas mixture, having been cooled to the dew point of the germanium tetrachloride at the temperature of the cooling water, will be unsaturated at room temperature and will not deposit liquid germanium tetrachloride in the calcium chloride tower used to remove residual moisture. When passed through the tube cooled by means of dry-ice, however, the germanium tetrachloride is completely removed and entrains very little hydrogen chloride. An all glass apparatus is preferable, but no difficluties are encountered if rubber connections are used. By this procedure 5 to 10 g. of GeO_2 may be converted to the tetrachloride within an hour. Residual hydrogen chloride may be removed by allowing the product to stand over sodium carbonate, filtering and distilling in dry apparatus.[1b]

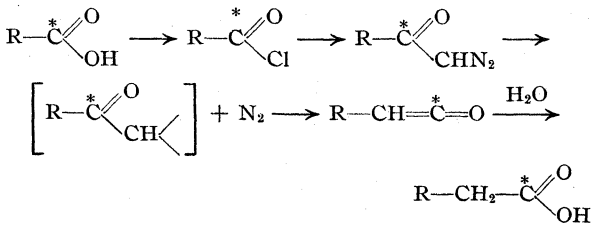
The Mechanism of the Arndt-Eistert Reaction[1]

BY CLAYTON HUGGETT, RICHARD T. ARNOLD AND T. IVAN TAYLOR

The conversion of an acid to its next higher homolog by the Arndt–Eistert procedure is of considerable value to organic chemists. The most reasonable mechanism[2] for the reaction proposes the formation and decomposition of a ketene.



This mechanism readily explains the type of products formed under varying experimental conditions, and the analogy to the Curtius and Hofmann rearrangements has been recognized.[3]

From the above equation it is seen that the carbonyl carbon atom of the starting acid becomes the carbonyl carbon atom in the final product; the newly introduced carbon atom then occupies the alpha position.

We have found substantial evidence to support this formulation of the mechanism by using C^{13} isotopes as tracer elements. Heavy benzoic acid prepared by the carbonation of ordinary phenylmagnesium bromide with carbon dioxide[4] containing a high per cent. of C^{13} was converted to phenylacetic acid by the method of Arndt and Eistert. The heavy isotope was found in the carbonyl group of the phenylacetic acid as shown by decarboxylation with copper chromite and quinoline.

The carbon dioxide from the heavy benzoic acid contained 2.51 per cent. C^{13} and that from the phenylacetic acid measured 2.53 per cent. C^{13}. Within experimental error these values are identical and support the ketene mechanism.[2]

Of necessity this work has been discontinued but will be renewed when conditions permit.

The Ionization Constant of Morpholine in Water[1]

BY ALVIN R. INGRAM[2] AND W. F. LUDER

In connection with an investigation of the conductivity of morpholine solutions, it seemed desirable to know the strength of morpholine as a base. Accordingly, the ionization constant of morpholine in water was measured by the conductivity method.

Since great accuracy was not required, no special precautions were taken in the preparation of conductivity water. This, together with the low conductance of morpholine solutions, resulted in solvent corrections of several per cent. at the most dilute concentrations. Another source of error entered into the determination of Λ_0. In order to find Λ_0 it was necessary to measure the conductance of morpholinium chloride. The slight hydrolysis of this salt was not taken into account in the extrapolation for its Λ_0.

However, analysis of the results indicates that the value for the ionization constant of morpholine in water at 25° is 2.44×10^{-6} within the limits of error to which most ionization constants in the literature are given.

Experimental

Materials, Apparatus, and Procedure.—The bridge[3] and procedure[4] have been described previously. The temperature of the oil thermostat was kept at 25 ± 0.01° by an electronic relay. The water used was ordinary distilled water once redistilled and usually had a specific conductance of about 1×10^{-6} mho. Morpholine was dried over barium oxide and aluminum oxide, then fractionated three times off aluminum oxide, the constant boiling portion being used for runs. The best conductance for morpholine treated in this way was 6×10^{-10} mho. Morpholinium chloride (m. p. 177°) was prepared by passing dry hydrogen chloride over the surface of purified morpholine, washing the product with redistilled petroleum ether and diethyl ether, and pumping in a vacuum desiccator over phosphorus pentoxide.

Results.—Values of Λ are given in Tables I and II. Plots of $1/\Lambda$ against $c\Lambda$ for morpho-

line and Λ against $\sqrt{c}$ for morpholinium chloride indicate, by their deviations from the expected curves,[5] that the values of Λ for the most dilute points have been somewhat over-corrected for solvent conductance. The extrapolation to Λ_0 for morpholinium chloride takes this into account, but may be a few per cent. in error because of hydrolysis. This determination seems to be the source of greatest error. However, it seems unlikely that it can be more than two or three per cent. Assuming it to be 3% the error in K would be slightly less, about 2.8%. The value of Λ_0 was taken as 115.

Using this value and 261.5[6] for NaOH and 126.4[7] for NaCl, Λ_0 for morpholinium hydroxide is 250. Plotting the straight line form of the Arrhenius conductance ratio equation for the ionization constant, $1/\Lambda = c\Lambda/K\Lambda_0^2 + 1/\Lambda_0$, the graphically determined slope $1/K\Lambda_0^2$ gives a value of 2.44×10^{-6} for K.

(5) The ionization constant of morpholine is low enough so that in view of the two sources of error previously mentioned, it was considered unnecessary to use the more accurate forms of the $1/\Lambda - c\Lambda$ plot proposed by Fuoss (THIS JOURNAL, **57**, 488 (1935)) and Shedlovsky (*J. Franklin Inst.*, **225**, 739 (1938)).

Action of Macerans Enzyme on a Component of Corn Starch

BY RALPH W. KERR

The origin of the Schardinger dextrins, when starch is treated in the presence of *B. Macerans* or the enzyme prepared from this bacillus[1] has been a matter of speculation for many years. In another paper[2] the writer sought to show that, in procedures which might ordinarily be used to convert corn starch with this enzyme, the yield of Schardinger dextrins, precipitable with trichloroethylene, arose almost entirely from a degradation of the most permanently dispersed fraction of the starch, which latter amounts to approximately 55% of the total starch. It was concluded that these dextrins were probably formed by synthesis from the more simple configurations in this product.

We are now able to elaborate on these conclusions. In another communication[3] we discussed the isolation of an amylose in yields of 5 to 6% of starch, by crystallizing the product from a warm water extract of corn starch with butanol. The amylose quickly changes to an insoluble form, however, in concentrations over 1 g. per 100 cc. in water solution. In this condition it might be expected to be rather inert in the presence of starch splitting enzymes. It may, however, be held in a relatively stable solution at *p*H 6.0 at lesser concentrations, *e. g.*, 0.30 g. per 100 cc.

A conversion of such a solution of the amylose was attempted adding 40 cc. of a *Macerans* enzyme preparation of 0.3 unit activity[2] to 2 l. of water containing 6 g. of the amylose in its soluble form. The conversion was made at *p*H 6.0 and 45° for forty-eight hours. The liquors were then concentrated by vacuum distillation to 400 cc. at 45° and allowed to stand at this temperature for another twenty-four hours at *p*H 6.0. Practically no insolubles were in evidence. The liquors were concentrated to 130 cc., a small amount of floc filtered off and 130 cc. of trichloroethylene added. The mixture was allowed to stand for forty-eight hours at room temperature, with intermittent stirring, and then for forty-eight hours in the refrigerator. The dextrins were filtered off, washed with ice water, then with methanol, dried and weighed: 4.2 g. of mixed dextrins, precipitable with trichloroethylene resulted, a yield of 70%. Further quantities precipitated when the mother liquors were concentrated.

Inasmuch as the crystalline amylose gives a conversion limit[3,4] of 93% maltose with β-amylase

and hence is essentially linear in configuration, and inasmuch as β-amylase produces no reducing sugars whatsoever from the Schardinger dextrins,[2] it would seem evident that the *Macerans* enzyme was able to synthesize the cyclo amyloses from linear arrangements of glucopyranose units.

An explanation as to why the enzyme normally produces no greater yield of dextrins from whole corn starch might be that the more linear chains, which are probably coils in water solution, become enmeshed or oriented, thus blocking the approach of the enzyme to the individual molecules and possibly inhibiting the closing of the cycle to form the dextrin; whereas the linear configurations in our highly branched fraction,[3] which are principally the side branches in this case, are held more or less rigidly into space, thus greatly reducing the number that become enmeshed, one with the other. This condition would favor the production of large yields of the Schardinger dextrins from this latter component according to this viewpoint, and would, incidentally, account for the greater colloidal stability of solutions of this constituent, which we have called, provisionally, the more alcohol-soluble fraction.

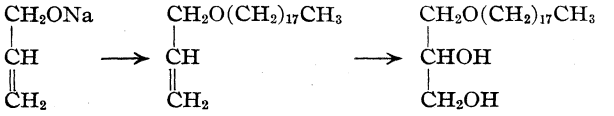
Batyl Alcohol[1]

BY N. KORNBLUM[2] AND HARRY N. HOLMES

An earlier communication from this Laboratory described the isolation and identification of batyl alcohol $CH_2OH\text{-}CHOH\text{-}CH_2O(CH_2)_{17}\text{-}CH_3$, from the non-saponifiable fraction of yellow bone marrow.[3] Preliminary tests carried out by Dr. Roy Kracke of Emory University with a crystalline product obtained by us from yellow bone marrow indicated that batyl alcohol might be of value in the treatment of agranulocytosis. In order to permit of an extended program of physiological testing, a substantial quantity of pure batyl alcohol was needed. The synthesis employed here is that of Davies, Heilbron and Owens,[4] modified to give better yields of pure products.



Substitution of octadecyl iodide for the chloride (used by Davies, *et al.*) and a reaction temperature of 60–65° instead of reflux conditions resulted in a significant increase in the yield of pure allyl octadecyl ether. This is a consequence of the fact that the lower operating temperature minimizes the conversion of allyl alcohol to high boiling products which contaminate the desired allyl octadecyl ether. This auto-condensation of allyl alcohol containing sodium allyl oxide, which apparently has not been hitherto reported, proceeds in the presence or absence of oxygen and gives a complex series of unsaturated neutral and acidic compounds.

Conversion of the allyl ether to the glycerol derivative was best effected by the improved hydroxylation procedure of Scanlan and Swern,[5] except that it was found necessary to heat the reaction mixture in batches of the size employed here.

Experimental

Octadecyl Iodide.—This substance was prepared by the procedure of Bleyberg and Ulrich.[6] The product was purified by distillation *in vacuo;* b. p. 194–197° (2 min.); yield 70–75%. Upon recrystallization from acetone white plates melting at 33–34° were obtained.

Allyl *n*-Octadecyl Ether.—To a solution of 31 g. of sodium in 450 g. of allyl alcohol was added 150 g. of *n*-octadecyl iodide. The mixture was maintained at 60–65° for twenty hours and when cold was diluted with water and, *without* being acidified, extracted with ether. After washing the extracts with water the major portion of the solvent was distilled, approximately 25 ml. of benzene added, and the residual ethyl ether, benzene and entrained moisture then removed by distillation. A final bath temperature of about 160° was required. The yellow oil which remained was fractionally distilled *in vacuo* through a Widmer column. After an appreciable forerun which separated into two layers, there was obtained 85–96 g. (70–79%) of a colorless liquid, b. p. 150–152° (2 mm.); m. p. 28.5–29° (thermometer in melt); $n^{32}D$ 1.4441. Recrystallization from ethanol did not alter the refractive index. Davies, Heilbron and Owens[4] reported m. p. 27.5–28.5°.

Octadecyl Glyceryl Ether (Batyl Alcohol).—A mixture of 41.7 g. of 30% hydrogen peroxide solution and 500 ml. of glacial acetic acid was heated at 80–85° for one hour, at which point 49.5 g. of allyl *n*-octadecyl ether dissolved in 420 ml. of glacial acetic acid was added and the resulting

(1) Presented in part before the division of Biological Chemistry of the American Chemical Society, St. Louis meeting, April, 1941. At this same meeting Erich Baer and H. O. L. Fischer announced an alternate synthesis of batyl alcohol and subsequently published the details in *J. Biol. Chem.*, **140**, 397 (1941).

solution maintained at 70–80° for 20–22 hours. When cold, the mixture was rendered alkaline with dilute ammonium hydroxide, extracted with ether and the ether distilled off. The residue obtained upon removal of the ethyl ether was treated at 60° for seven hours with a solution containing 220 g. of potassium hydroxide, 660 ml. of water and 2500 ml. of ethanol. The solution was then concentrated to approximatley 750 ml. at 40° under reduced pressure. The resulting mixture was extracted with ether, the extracts washed with water and the ether removed. The product was purified by two recrystallizations from ethanol; white crystals, which sinter at 69° and melt 70–71° (cor.); yield 30–37 g. (55–67%). Hydroxylation of 50 g. of allyl *n*-octadecyl ether according to the procedure described by Davies, Heilbron and Owens[4] gave only 19 g. (34%) of pure glyceryl ether.

Allyl Alcohol and Sodium Allyl Oxide.—A solution of sodium (45 g.) in allyl alcohol (700 cc., Eastman Kodak Co. white label quality) was protected by a soda-lime guard tube while it was refluxed gently for forty-eight hours. The turbid mixture was cooled, diluted with water and extracted thoroughly with ether. The aqueous alkaline solution was then acidified with sirupy phosphoric acid and again extracted with ether. In this way the product was separated into a neutral (A) and an acidic (B) fraction. The ether solutions were washed with water, dried and distilled at 2 mm. From (A) was obtained 66 g. of material boiling at 63–140° with $n^{25}D$ ranging from 1.4696 to 1.5148. (B) gave 90 g. of material boiling at 73–155° with $n^{25}D$ ranging from 1.4673 to 1.5021. In each instance the first portion of the distillate was colorless and very fluid; with rising boiling point the distillate gradually becomes light yellow and quite viscous. Both (A) and (B) were insoluble in water, but soluble in ethanol, and both gave negative fuchsin tests. Both absorbed hydrogen over Adams catalyst and gave positive tests for unsaturation with bromine in carbon tetrachloride. (A) reacted with sodium, evolving a gas.

This experiment was repeated several times with substantially the same results. In one run allyl alcohol which had been dried over Drierite was employed and the reaction carried out in an atmosphere of nitrogen with results essentially the same as those described above. Conversion of allyl alcohol to high boiling products under these conditions has apparently not been reported previously.

The neutral and acidic fractions were not investigated further.

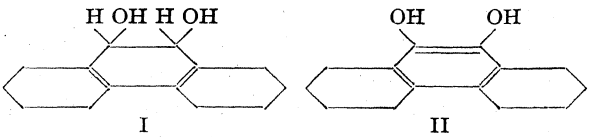
The Structure of Skita's "Decahydro-9,10-dihydroxyphenanthrene"

BY PHILIP LEVINE[1]

In a previous article,[2] reference was made to the preparation of a compound identical with that described by Skita[3] as decahydro-9,10-dihydroxyphenanthrene (I). Further investigation of this substance has now shown that the meso positions have not been hydrogenated and that the compound in question is *s*-octahydro-9,10-dihydroxyphenanthrene (II).



I II

The reasons for questioning the structure proposed by Skita were the resistance of the compound to hydrogenation over Raney nickel at 120°, the failure to undergo dehydration to *s*-octahydro-9-phenanthrol, and the readiness with which the compound is oxidized by the atmosphere. Also Skita's only evidence for the glycol structure (I) was the analytical data for the compound itself and for its diacetate. A comparison of Skita's figures with the calculated values for (II) and its derivative shows that the analytical data do not suffice to distinguish between (I) and (II).

Oxidation of the compound to the octahydroquinone requires only one equivalent of lead tetraacetate. Assuming Skita's formula, one might expect either normal cleavage to the dialdehyde or the consumption of *two* equivalents of lead tetraacetate for oxidation to the quinone.

The question was unequivocally settled in favor of the hydroquinone structure (II) by reductive acetylation of the quinone obtained by oxidizing the compound. The diacetate thus obtained was identical in appearance and melting point with the diacetate from the original compound and no depression of the melting point was observed on mixing the two samples. The method used for the reductive acetylation of the quinone was that which normally converts a quinone into the diacetate of the corresponding hydroquinone without effecting any further reduction.

Experimental[4]

Lead Tetraacetate Oxidation of Octahydrophenanthrenehydroquinone.—To 0.7 g. of the hydroquinone in 15 cc. of benzene was added in small portions 1.4 g. (one equivalent) of lead tetraacetate. The solution became deep red. Additional lead tetraacetate was unreacted as shown by tests with starch–iodide paper. A small amount of glycerol was added to remove excess oxidizing agent. The benzene solution was washed twice with water, dried over magnesium sulfate, and evaporated almost to dryness. The brilliant red crystals, melting at 139–141°, were evi-

(4) All melting points are corrected.

dently identical with the quinone obtained by Skita, m. p. 142°. Needles melting at 142–144° were obtained by crystallization from methanol.

Silver Oxide Oxidation of Octahydrophenanthrenehydroquinone.—A mixture of 0.42 g. of hydroquinone (m. p. 133–137°), 1 g. of silver oxide, and 1 g. of magnesium sulfate in absolute ether was shaken for one-half hour and filtered. The quinone proved to be soluble with difficulty in ether and was therefore extracted from the solids with benzene. Most of the benzene was evaporated and the product (0.338 g., m. p. about 137°) precipitated from the remaining solvent with hexane. Red needles melting at 142° were obtained by crystallization from acetone, which proved to be the best solvent for the purpose.

Reductive Acetylation of Octahydrophenanthraquinone.—Two drops of triethylamine was added to 0.1 g. of quinone with 0.1 g. of zinc dust in 2 cc. of acetic anhydride. The mixture was allowed to stand for ten minutes, heated to boiling, filtered, and the residue washed with hot acetic acid. Water was added to the boiling filtrate and washings to the cloud point. On cooling, the solution deposited 0.134 g. of white needles melting at 162–163°.

Acetylation of the Hydroquinone.—Addition of a drop of triethylamine to some of the hydroquinone (m. p. 135–137°) with a pinch of zinc dust in acetic anhydride caused slight warming. The mixture was allowed to stand a few hours and boiled for five minutes. The mixture was worked up in the same way as the product from the reductive acetylation of the quinone. The white needles melted at 161.5–163°. The mixed m. p. with the diacetate from the quinone was 162–163°.

Atomic Weight of Lead from a Second Sample of Pitchblende, Great Bear Lake, N. W. T., Canada

BY JOHN PUTNAM MARBLE

In a continuation of the geochemical studies on the pitchblende ores of Great Bear Lake, the atomic weight of the lead in a second sample has been determined. This sample, from the 800-foot section of the No. 2 vein, Eldorado mine, Labine Point, Great Bear Lake, N. W. T., Canada, was received from H. S. Spence, Esq., of the Canada Department of Mines and Resources, for whose coöperation we are deeply grateful. The material is of the pitchblende-silica type ore, came from depth (below 100 feet), and carried no visible alteration products. Microscopic studies show a very small amount of galena, estimated at a fraction of one per cent.

The lead–uranium ratio uncorrected for "common lead," with an autoradiograph showing little evidence of alteration[1] and a complete analysis[2] have been previously published. While the results of this present work are admittedly incomplete, it was thought worth while to put them on record, as they are in virtual agreement with those of the first sample[3] and the carrying out of further atomic weight determinations, or preferably of the determination of the isotope ratios of this sample, have necessarily had to be deferred. Since the pitchblende is virtually thorium-free, the atomic weight indicates the approximate correction to be made for "common lead," which cannot be done for thorium-rich minerals.

The preparation of the material for analysis, the extraction and purification of the lead, and the method of analysis were essentially the same as in the case of the first sample of Great Bear Lake lead.[3] The work was done in the T. Jefferson Coolidge Memorial Laboratory of Chemistry at Harvard University, by kind permission of Dr. Gregory P. Baxter, for whose interest and assistance we are deeply grateful. The results of the analysis are as follows

Vac. wt. $PbCl_2$	1.56541 g.
Vac. wt. Ag	1.21935 g.
Wt. Ag added in solution	0.00010 g.
Vac. wt. Ag $\equiv$ $PbCl_2$	1.21945 g.
Ratio $PbCl_2/2Ag$	1.28370
Atomic weight Pb	206.057

(Ag = 107.880; Cl = 35.457)

This value agrees so closely with that of the work on the earlier sample (Pb = 206.054), that we may conclude that the lead in the Great Bear Lake pitchblende ore shows no appreciable variation in isotopic composition in different parts of the deposit, and also that a correction of about 4 per cent. should be applied to the "uncorrected" lead–uranium ratio of the second analyzed sample, as was done for the first. Further work may confirm these conclusions.

Saponins and Sapogenins. XX. Some Color Reactions of Triterpenoid Sapogenins

BY C. R. NOLLER, R. A. SMITH, G. H. HARRIS AND J. W. WALKER

While attempting to prepare the acid chlorides of some triterpenoid acids by means of thionyl

chloride, it was noted that one of two commercial preparations of thionyl chloride caused the formation of highly colored solutions, for example burgundy red with echinocystic acid and a brilliant blue with hederagenin, while the other lot gave only colorless, yellow or red solutions. When the first lot of thionyl chloride was purified by the usual procedure over quinoline and linseed oil, it no longer gave the brilliant colors. Fractional distillation using a packed column gave no appreciable separation of the impurity. Accordingly a systematic qualitative analysis was made of the impure sample. This indicated a considerable amount of tin to be present, some iron and a trace of phosphorus. Quantitative analysis showed amounts equivalent to 0.007% stannic chloride, 0.004% ferric chloride and less than 0.001% phosphorus. When a solution of 0.01% of anhydrous stannic chloride and 0.005% of sublimed ferric chloride in purified thionyl chloride was allowed to react with various triterpenoids, the colors produced by the impure thionyl chloride were practically duplicated. Differences may be attributed to traces of phosphoric acid in the commercial sample.

Pure stannic chloride dissolved in pure thionyl chloride produced characteristic colors but stannic chloride dissolved in benzene, petroleum ether, ethyl ether, carbon tetrachloride, chloroform or cyclohexane was without effect. Ferric chloride, antimony trichloride, antimony pentachloride, phosphoric acid, or phosphorus oxychloride which has been exposed to moisture, and concentrated sulfuric acid in thionyl chloride produced colors but purified phosphorus oxychloride, phosphorus trichloride, phosphorus pentachloride, silicon tetrachloride, chlorine, sulfur dioxide and hydrogen chloride, when dissolved in thionyl chloride, do not give a color-producing reagent.

The colors produced vary with the reagent and with the compound used. Sometimes a sequence of colors is produced, which may be so rapid at first that the solution must be observed continuously in order to note them. Usually the color changes are complete after an hour although sometimes they are not complete after twenty-four hours. In the case of the hydroxy acids, the intense colors are produced only if at least one free hydroxyl group is present; if all the hydroxyl groups are esterified the intensity of the colors is greatly decreased. Esterification of the carboxyl group is without effect. In the case of the α- and β-amyrins, which lack a carboxyl group, the intensity of the colors is little changed by esterification. Differences between isomeric compounds, for example echinocystic acid and hederagenin, or α-amyrin and β-amyrin, may be sufficiently great to distinguish readily between them.

Little can be said concerning the cause of the colors. The inorganic compounds producing the color all may be considered as electron accepting reagents but we see no reason why stannic chloride should be effective only in thionyl chloride solution and not in other anhydrous solvents. The colored compounds might be looked upon as halochromic salts but the intensity and brilliance of the colors, particularly the blues and purples with stannic chloride, would seem to call for a chromophoric group with greater possibilities of resonance than are afforded by a single unconjugated carbon–carbon double bond, a carboxyl group and two hydroxyl groups.[1]

The color changes produced on treating 0.02 g. each of a wide variety of triterpenoids and their derivatives with 0.5 cc. of 0.01% anhydrous stannic chloride in pure thionyl chloride in a small test-tube which was kept stoppered during observation, may be summarized as follows:

Hederagenin, light pink → violet → light blue → deep orange after one hour.

Hederagenin methyl ester, pink → purple → violet → deep yellow after eight hours.

Hederagenin diacetate, light yellow → yellow after eight hours.

Echinocystic acid, pink → purple → blue → light red → very deep red after twenty-four hours.

Methyl echinocystate, red → blue-green → purple → very deep red after one hour.

Echinocystic acid diacetate, colorless → light violet → light orange after twenty-four hours.

Methyl echinocystate diacetate, colorless → light violet → deep yellow after twenty-four hours.

Echinocystic acid monoacetate (by esterification), pink → violet → deep blue → red after two hours.

Echinocystic acid monoacetate (by hydrolysis), violet → deep green → very deep red after twenty minutes.

Isonorechinocystenedione, yellow → orange → red after twenty-four hours.

Ursolic acid, light pink → deep red → light red → very deep red after eight hours.

Oleanolic acid, light pink → very deep red after one hour.

Methyl oleanolate, light pink → very deep red after one hour.

Methyl oleanolate acetate, light yellow → light violet → deep yellow after twenty-four hours.

Betulin, colorless → light pink → light violet → dark muddy green after one hour.

(1) One of the referees states, "There is no question but that we are dealing here with some very complex adsorption reactions."

α-Amyrin, orange → very deep red → very deep purple after twenty-four hours.
β-Amyrin, purple → very deep red after five minutes.
α-Amyrin benzoate, light pink → deep red after one hour.
β-Amyrin benzoate, light yellow → red → deep yellow → orange after twenty-four hours.
α-Amyrone, colorless → yellow → orange after twenty-four hours.
β-Amyrone, colorless → light blue → purple → deep red after eight hours.

The color changes of a limited group of triterpenoids with (A) pure thionyl chloride, (B) 0.01% anhydrous ferric chloride in thionyl chloride, (C) 0.01% antimony trichloride in thionyl chloride, (D) 0.01% antimony pentachloride in thionyl chloride, (E) 10% phosphorus oxychloride + 0.5% water in thionyl chloride, (F) 0.01% stannic chloride + 0.005% ferric chloride in thionyl chloride and (G) commercial thionyl chloride may be summarized as follows:

Hederagenin, (A) colorless → light amber (B) orange → red → green → amber (C) orange → violet → blue → green → red → brown (D) yellow → red → green → yellow → orange (E) blue → green → orange → red (F) violet → purple → blue → green → amber (G) red → blue → green → amber.
Echinocystic acid, (A) colorless → pink → red (B) orange → red → violet → red (C) pink → violet → blue-green → red (D) pink → violet → blue → violet → red (E) violet → blue-green → violet → red (F) red → purple → blue-green → red (G) violet → blue → blue-green → red.
Oleanolic acid, (A) pink → violet → red (B) violet → purple → red (C) violet → red (D) violet → blue → red (E) pink → red (F) violet → red (G) violet → purple → red.
Ursolic acid, (A) yellow → orange → red (B) violet → purple → red (C) violet → red (D) yellow → orange → red (E) orange → red (F) red (G) violet → blue → purple → red.
α-Amyrin, (A) pink → purple → red (B) orange → red (C) yellow → orange → red (D) yellow → red (E) colorless → yellow → orange → red (F) yellow → red (G) red.
β-Amyrin (A) colorless → pink → violet → red (C) purple → blue → red (D) red → blue → purple → red (E) blue → opaque.
Betulin, (A) colorless → yellow → green (F) yellow → red → purple → green (G) yellow → red → purple → green.

Peroxides in Isopropanol

BY C. ERNST REDEMANN

While it is a widely known fact that ethyl ether, isopropyl ether, and dioxane readily form peroxides when stored in contact with air or oxygen, there seems to be no mention of the formation of peroxides in isopropanol when stored under similar conditions.

A sample of 99.5% isopropanol, which had been stored for many months in strong daylight in a clear glass bottle only about one-third filled, was observed to have a strong unpleasant odor. Since this odor greatly resembled the odor of isopropyl ether when it is badly contaminated with peroxides, the isopropanol was investigated for the presence of peroxides. The following tests for peroxides were strongly positive: (1) immediate liberation of iodine from acidified potassium iodide solution, (2) the formation of blue peroxychromic acid, soluble in ether, from chromic acid solutions, (3) the production of chemiluminescence from 3-amino-phthalhydrazide catalyzed by hemoglobin,[1] (4) precipitation of Prussian blue from a solution containing ferric chloride and potassium ferricyanide,[2] (5) reduction of black nickelic oxide to pale green nickelous hydroxide,[3] (6) decolorization of lead sulfide.[4]

Quantitative iodometric determinations were made of the peroxide content of all samples of isopropanol available in this Laboratory with the results shown in the table.

Sample	Peroxide, mole/l.	Conditions of storage
1	0.36	Clear glass bottle, 1/3 full, strong light
2	.13	Clear glass bottle, 2/3 full, strong light
3	.04	Clear glass bottle, 5/6 full, strong light
4	.05	Clear glass bottle, 5/6 full, strong light
5	.003	Tin can, nearly full, dark
6	.007	Redistilled, stored about four years, largely in the dark

This reaction appears, in part, to be a photochemical process. The following brief experiment was designed to indicate the comparatively rapid rate of formation of peroxide in strong light. Twenty-five ml. of isopropanol was placed in a 500-ml. Pyrex glass flask fitted with a capillary tube to equalize external and internal pressure. The flask was left on the roof in full daylight for two days. Initial peroxide content 0.003 mole/l.; after two days 0.026 mole/l.

These data are presented to call the attention of experimenters to the need for making sure that isopropanol is peroxide free when working with easily oxidizable material. Likewise, some care should be exercised when evaporating old isopropanol solutions to dryness as an explosion

Tracer Studies with Radioactive Carbon. The Exchange between Acetic Anhydride and Sodium Acetate

BY S. RUBEN, M. B. ALLEN AND P. NAHINSKY

In connection with some tracer studies in these Laboratories it was desired to develop a rapid method for the synthesis from labelled carbon dioxide of an unsaturated acid containing C* only in the carboxyl group. The Perkin synthesis, in which the unsaturated acid is formed by reaction of an aldehyde with an acid anhydride in the presence of a salt (Equation (1)), seemed well suited to our needs.

$$2R_1CHO + R_2CH_2C(=O)-O-C(=O)-CH_2R_2 \xrightarrow{R_2CH_2COONa} 2R_1C(H)=C(R_2)-COOH + H_2O \quad (1)$$

Since we wished to obtain the unsaturated acid with the highest possible specific radioactivity, it was desirable to measure the rate of exchange between the salt and the anhydride. Michael[1] and more recently Breslow and Hauser[2] have shown that within several hours at 100° the exchange reaction between sodium acetate and butyric anhydride has come to equilibrium. We have found that the exchange between acetic anhydride and labelled sodium acetate *at room temperature* is surprisingly rapid.

Experimental

Labelled sodium acetate was prepared by shaking 10^{-3} mole of C^*O_2[3] with 5 cc. of 1 *M* CH_3MgI in ether at room temperature for ~ten minutes. After hydrolysis with dilute sulfuric acid the ether was removed by evaporation. Excess solid silver sulfate was added to precipitate silver iodide and the acetic acid distilled off *in vacuo*. The yield was ~95% based upon carbon dioxide. The acetic acid distillate was carefully neutralized with sodium hydroxide solution and evaporated to dryness. A small amount of dilute acetic acid was added and the solution again evaporated to dryness to free the sodium acetate from traces of base. This preparation was thoroughly dried at 100° *in vacuo* until a vacuum of better than 10^{-5} mm. of mercury could be maintained over the solid without pumping.

The dry labelled sodium acetate was shaken with acetic anhydride[4] for twenty minutes at room temperature and the anhydride distilled off at room temperature *in vacuo*. The anhydride was converted into sodium acetate and counted as such.[5] The results of this and a similar experiment employing C^{14} are summarized in Table I.

TABLE I

EXCHANGE BETWEEN NaAc* AND $(Ac)_2O$ AT ROOM TEMPERATURE

Expt.	Equivalents of NaAc	Equivalents of Ac_2O	Time of exchange, min.	Per cent. of random distribution of Ac*[6]
1	$2\cdot10^{-3}$	$95\cdot10^{-3}$	20	55
2	$1\cdot10^{-3}$	$4.8\cdot10^{-3}$	30	62

In view of the fact that sodium acetate is very insoluble in acetic anhydride it was surprising to find such rapid exchange at room temperature in this two-phase system.

A similar result was obtained with sodium butyrate and acetic anhydride. 4.7 grams of carefully dried sodium butyrate[6] was shaken with 17.6 cc. of acetic anhydride for ~forty minutes at room temperature, after which the anhydride was distilled off at room temperature *in vacuo*.

When the distillate was fractionally distilled it was found that 4.6 cc. had a boiling point above that of acetic anhydride. The acetic and butyric acid content of the high boiling fraction was determined by means of a Duclaux distillation. This fraction consisted of 72% butyric and 28% acetic acid. Thus 18.7% of the acid equivalent in the total anhydride fraction is butyric acid. For random distribution of butyrate between the sodium salt and the anhydride one would expect 10.3% for the above experiment. The marked tendency of butyrate to concentrate in the anhydride at room temperature is in keeping with the results of Michael[1] and Breslow and Hauser.[2]

Preparation of β-(2-Methyl-6-oxo-1-cyclohexen-1-yl)-propionic Acid

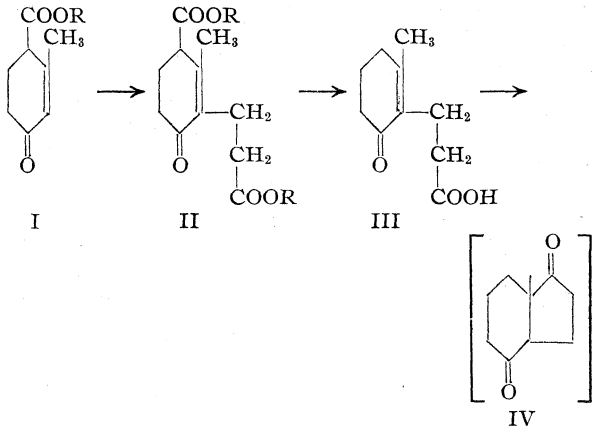
BY ERWIN SCHWENK AND EDITH BLOCH

Unsaturated cyclic ketoesters of the type of 3-carbomethoxy-2-methyl-6-oxo-1-cyclohexene (I) contain the same atomic grouping as α,β-dialkylglutaconic acids and like the latter can be alkylated with alkyl halides and sodium ethoxide,[1] but apparently only simple alkyl halides have been studied.[2]

(1) Richter-Taylor, "The Chemistry of the Carbon Compounds," 3rd English ed., Vol. II, p. 139.

(2) See, for instance, Koetz, *et al.*, *Ann.*, **400**, 83 (1913); E. Bergmann and A. Weizmann, *J. Org. Chem.*, **4**, 266 (1939).

We were interested in the introduction of a side-chain bearing a carboxyl group into the ester I because the propionic acid III finally obtainable as indicated should be useful in the synthesis of cyclic diketones with an angular methyl group of the type IV. So far we have not been able to effect the ring closure.



Experimental

3-Carbomethoxy-2-methyl-6-oxo-1-cyclohexene (I, R = CH_3).—This substance was obtained by a modification of the procedure described for the corresponding ethyl ester (Hagemann ester), I, R = C_2H_5.[3]

Nine hundred and twenty grams (8 moles) of freshly distilled methyl acetoacetate and 35 cc. of piperidine were warmed to 60°. One hundred and twenty grams (4 moles) of trioxymethylene was added in small portions under stirring while keeping the temperature at 60–80°. The mixture was cooled to room temperature, 200 g. of anhydrous sodium sulfate was added and the flask left standing in the refrigerator overnight. The product was filtered from the sodium sulfate and the residue washed well with ether. The combined filtrate and washings were washed in a separatory funnel with small portions of water, 10% hydrochloric acid and again with water. The ether solution was dried over sodium sulfate, the solvent removed and the residue of crude 1,3-dicarbomethoxy-2-methyl-6-oxo-1-cyclohexene was saponified partially by refluxing for two hours in an oil-bath with a solution of 96 g. of sodium (4 moles) in 2.5 liters of absolute alcohol. After standing overnight the alcohol was removed *in vacuo*, the residue taken up in 500 cc. of ice-water and acidified under cooling with 25% sulfuric acid. The resulting oil was taken up in ether, the ether solution washed with water, dried over anhydrous sodium sulfate and the ether evaporated. The residue was distilled *in vacuo*, b. p. 135° (2 mm.), yield, 240 g. (37%). A considerable low boiling fraction was obtained (b. p. 70° (2 mm.)) consisting chiefly of 2-methyl-6-oxo-1-cyclohexene.

Anal. Calcd. for $C_9H_{12}O_3$: C, 64.3; H, 7.2. Found: C, 64.7; H, 7.2.

The semicarbazone was prepared as usual, m. p. 168–170°.

Methyl β-(3-Carbomethoxy-2-methyl-6-oxo-1-cyclohexen-1-yl)-propionate (II, R = CH_3).—Twenty-three grams of sodium was dissolved in 500 cc. of absolute methyl alcohol (dried over magnesium methylate) and 168 g. of 3-carbomethoxy-2-methyl-6-oxo-1-cyclohexene was added, followed by 168 g. of methyl-β-bromopropionate. The mixture was refluxed for one hour; the alcohol removed *in vacuo*, the residue taken up in ether, washed, dried over sodium sulfate and the solvent evaporated. The ether residue was distilled in vacuum. Thirty-two grams of low boiling material was obtained, consisting mostly of unchanged starting material. The main fraction boiled at 170–180° (1 mm.), yield, 170 g. (83% considering recovered starting material).

Anal. Calcd. for $C_{13}H_{18}O_5$: C, 61.4; H, 7.1. Found: C, 61.5; H, 7.4.

The semicarbazone was prepared by refluxing 1 g. of the ester with 1 g. of semicarbazide hydrochloride and 1 g. of sodium acetate; recrystallized from dilute alcohol, it melted at 145–148°.

Anal. Calcd. for $C_{14}H_{21}N_3O_5$: N, 13.5. Found: N, 13.9.

Ethyl β-(3-Carbethoxy-2-methyl-6-oxo-1-cyclohexen-1-yl)-propionate.—This ester was prepared from Hagemann's ester and ethyl-β-bromopropionate as described above; b. p. 184–186° (2 mm.), yield, 70%. No satisfactory analysis could be obtained from this material but the 2,4-dinitrophenylhydrazone obtained as usual crystallized from ethanol in orange-red prisms, m. p. 120–122°.

Anal. Calcd. for $C_{21}H_{26}O_8N_4$: N, 12.0. Found: N, 12.1.

β-(2-Methyl-6-oxo-1-cyclohexen-1-yl)-propionic Acid.—One hundred grams of II (R = CH_3) was refluxed for six hours with 200 cc. of hydriodic acid (42%). After cooling the mixture was carefully made alkaline by adding it to excess concentrated sodium carbonate solution under cooling and stirring. All neutral material was removed by repeated extraction with ether and the dark brown solution was acidified again. The acid was taken up in ether and the ether solution washed with dilute sodium thiosulfate solution and with water. After drying over anhydrous sodium sulfate the ether was evaporated and the residue was distilled *in vacuo* at about 1 mm.; yield, 40 g. The distillate crystallized on standing. Recrystallization from ligroin (b. p. 70–90°) yields the acid in long feather-shaped crystals; m. p. 79–81°. The same acid was obtained from II (R = C_2H_5).

Anal. Calcd. for $C_{10}H_{14}O_3$: C, 65.9; H, 7.7. Found: C, 65.6; H, 7.7.

A New Modification of Willgerodt's Reaction

BY ERWIN SCHWENK AND EDITH BLOCH

It was first shown by Willgerodt[1] that treatment of aryl methyl ketones with yellow am-

(1) Willgerodt, *Ber.*, **20**, 2467 (1887); **21**, 535 (1888).

monium sulfide yields the amides of arylacetic acids which by saponification with aqueous alkali give arylacetic acids. The method would probably find more use if it were not necessary to heat the reagents in a closed vessel to 150°. This disadvantage of the method has not been eliminated by recent modifications.[2,3,4,5]

We have tried to avoid the use of an autoclave by replacing the ammonium sulfide with higher boiling amines and sulfur. Morpholine[6] now made technically in very pure form and at a cheap price has been found to be most suitable. The process differs from the reaction as described by Willgerodt in that first the morpholides of

$$ArCOCH_3 \longrightarrow ArCH_2CSC_4H_8ON$$

the arylthioacetic acids are formed. The reason for this course of the reaction is probably the absence of water in the reaction mixture similar to Kindler and Tsauping Li's procedure[5], who also obtained derivatives of the arylthioacetic acids. The morpholides of the arylthioacetic acids often can be isolated in crystalline form. If that is not possible because of the oily consistency of these morpholides, even the crude oily morpholides may be submitted to a saponification with either aqueous or alcoholic alkali, which will afford the arylacetic acids after acidification of the alkaline solution.

The reaction apparently is applicable to all aryl methyl ketones in which the aryl part of the molecule is either unsubstituted or substituted by a stable group like the alkoxy group or halogen. To substances containing nitro-, amino-, hydroxy- or acetoxy- groups, the reaction seems not to be applicable in this form.

As an example, we describe the preparation of the as yet not known *o*-benzyloxyphenylacetic acid with our new method. In general, it may be said that the aryl thioacetmorpholides crystallize easily. In cases where they remained oily, we have taken the crude material and submitted it, without purification, to the saponification step. Some of the morpholides are quite difficult to saponify; we have not made an investigation of this part of the method and believe that study of the saponification in special cases may improve the final yield considerably.

Yields, melting points (not corrected) and analyses of some arylthioacetmorpholides of known arylacetic acids which we have prepared are given in the table.

TABLE I

Change in Potential of Silver–Silver Chloride Electrodes with Time

By Edgar Reynolds Smith and John Keenan Taylor

An aging effect with freshly prepared silver–silver chloride electrodes was first noted by MacInnes and Parker,[1] who found it to be always in the same direction. This effect was investigated by Smith and Taylor,[2] who attributed its origin to concentration-polarization and made tests, the results of which harmonized with this explanation. When silver electrodes are coated electrolytically with silver chloride, the solution within the pores of the silver chloride becomes more dilute than the surrounding solution and these electrodes, freshly prepared, therefore, act as cathodes toward electrodes previously aged in the solution, since the latter have had the electrolyte within their pores replenished. Because the aging behavior is always in the same direction and, for relatively thick coatings of silver chloride, amounts at least to several tenths of a millivolt, it appears to be an effect different from the fluctuating bias of a few hundredths of a millivolt frequently observed after the electrodes have apparently come to equilibrium. If sufficient time is allowed, the freshly prepared electrodes attain the same average potential as the aged electrodes. The time required for this equilibrium to be attained depends on several factors, among which are the amount of silver chloride deposited per unit area, *i. e.*, the thickness of the layer through which the diffusion must occur, and the current density at which the layer is formed. The smaller the current density of silver chloride formation, the nearer is the concentration within the pores of the layer kept to equilibrium with the surrounding solution and consequently the smaller is the aging effect.

In some recent work, Hornibrook, Janz and Gordon[3] made experiments, the results of which they consider to contradict the conclusions of Smith and Taylor. Their results, however, instead of being contradictory to these conclusions are in agreement with what is to be expected for thin films of silver chloride formed at low current densities. It should be emphasized that no dispute as to the facts is involved and no criticism of the validity of the technique and results of the excellent work of Hornibrook, Janz and Gordon is intended.

From the dimensions of the electrodes and the time and current used for coating with silver chloride, it appears that the thickness of the coatings and the magnitude of the current density used by Smith and Taylor were, respectively, about 13.4 and 5.6 times as large as those used by Hornibrook, Janz and Gordon. The latter point out that concentration differences tend to disappear with exp $(-\pi^2 kt/x^2)$, where k is the diffusion constant, t the time, and x the distance from the plane where the concentration is constant. The time required for the exponential to fall to a given value increases as the square of the distance, x, which can be taken as the thickness of the layer of silver chloride. Hornibrook, Janz and Gordon found no indication of aging after twenty-five minutes in one experiment and after forty minutes in another. If the time of aging with their relatively thin layer was of the order of ten minutes, it would escape detection, while with a layer 13 times as thick, about twenty-eight hours would elapse before the aging was over, and the effect would be readily found.

Present conditions of work make it unjustifiable for us to spend the time required to show experimentally how the aging period of freshly prepared silver–silver chloride electrodes varies from a negligible time for a very small thickness of silver chloride deposited at a low current density to an appreciable time for a thicker layer deposited at a higher current density. Our previous work, however, has shown the latter, and the results of Hornibrook, Janz and Gordon not only show the former, but are what would reasonably be expected on the basis of our explanation of the aging effect.

Because of the various factors, such as film thickness, current density, temperature, concentration and agitation of the solution, which affect the time of aging, different investigators using different conditions of preparation of their silver–silver chloride electrodes will find marked differences in the magnitude and duration of the aging effect. In any case, however, it is important to recognize the possibility of the occurrence of the effect and to make sure it has been eliminated from the results of the final measurements.

The Alkylation of Linseed Oil

BY JUDSON G. SMULL AND JOHN S. SAYLOR

The structures of linoleic and linolenic acids which are present in linseed oil, have been indicated as having the $=CHCH_2CH=$ grouping.[1,2,3] It occurred to the authors that the CH_2— portion of the grouping might be active enough to show the reactions of active methylene groups, as shown by such compounds as cyclopentadiene, malonic ester and others.

The first evidence of reaction which it is desired to report at this time is a reaction analogous to that of malonic ester. For this purpose an alkali-refined neutral linseed oil was converted to the mixed methyl esters directly by alcohol interchange. An excess of absolute methanol, containing hydrogen chloride was added to dry linseed oil and refluxed until the reaction was complete. The mixed methyl esters after purification were distilled at 200° under 6 mm. pressure.

Approximately 0.1 mole of these mixed methyl esters was treated with 0.1 mole of sodium ethoxide dissolved in excess absolute ethanol, and refluxed at 60° for about ten minutes. To the cooled mixture in the flask, 0.13 mole of ethyl iodide was added gradually, with thorough shaking. This reaction mixture after heating at 90° on the water-bath for forty minutes, was allowed to stand overnight. The excess ethanol and ethyl iodide were distilled and the remaining solution filtered. The filtrate was dissolved in ether, washed with brine, then water, and dried. After removal of the ether, the major portion distilled at 205° and 14 mm. pressure, as a very pale, highly mobile liquid. This procedure was followed closely on two other runs. All of the samples were kept under nitrogen to prevent oxidation. The analytical data are given in the tabulation.

		Iodine No. (Wijs) Determined	Theoretical[a]	Refractive index
Linseed oil		192.0	...	1.4811
Mixed methyl esters		186.0	...	1.4632
Alkylated esters				
Samples	A	170.9	167.0	1.4616
	B	178.1		1.4619
	C	183.1		1.4613
	Av.	177.4		1.4616

[a] The theoretical iodine number was calculated on the assumption that linseed oil contains 60% linoleic acid, with one active CH_2— group and 25% linolenic acid, with two active CH_2— groups.

With an average of 1.1 active CH_2— groups, condensation with 1.1 ethyl groups should be expected, forming an ethylated methyl ester of the mixed acids. The fair agreement of the determined iodine number with the calculated value (an approximation) is evidence of reaction. The lower values for refractive index are also evidence of reaction. Furthermore, it was believed that if alkylation had occurred, the alkylated esters should give a negative fulvene reaction whereas unalkylated ester should be positive. This actually was the case. Again, confirmation of the fulvene test was obtained by oxidation tests, where a dark red color was produced in the original methyl ester but no appreciable darkening in the alkylated methyl ester. The oxidation presumes the formation of a —CO— group, according to Scheiber.[4] The oxidized portion should in turn condense with unoxidized oil to give the fulvene color reaction.

This study is being continued on pure methyl linoleate and pure methyl linolenate.

The Oxidation of Amino Acids by Hydrogen Peroxide in Formic Acid

BY GERRIT TOENNIES AND RICHARD P. HOMILLER

It has been shown[1] that the action of hydrogen peroxide on casein dissolved in formic acid causes a selective oxidation of its tryptophan, methionine and (partly) cystine units. As regards the effect of other acid oxidizing agents on the natural amino acids Williams and Woods[2] stated that of 16 samples tested only cystine, tyrosine and tryptophan were oxidized by iodic acid (at 100°), and Nicolet and Shinn[3] showed that periodic acid selectively attacks tryptophan, methionine and cystine, as well as the α-hydroxy amino acids. Since, however, according to the same authors the latter type of compound seemed to be protected against the oxidation by acylation or by peptide formation through the amino group, and since our own observations[1] on the action of performic acid (the product of interaction of hydrogen peroxide and formic acid), which showed

[a] Where more than one compound of the same designation is listed, products of different origin were used. [b] Solution prepared from the monohydrochloride with the aid of silver acetate. [c] Solution prepared from the dihydrochloride with the aid of silver acetate.

α-hydroxy amino acid units to be resistant, had been obtained on unhydrolyzed protein, it became of interest to examine the action of performic acid on the free amino acids.

In order to obtain insight into the interaction of hydrogen peroxide and formic acid,[4] 1 cc. of 30% hydrogen peroxide was diluted to 10 cc. with 88% formic acid, and one-half-cc. samples of the resulting solution were titrated both for active peracid and for the sum of peracid and hydrogen peroxide. The iodometric method employed was that previously used by one of us[5] for the determination of permonosulfuric acid and hydrogen peroxide. The results (Fig. 1) show that under the stated conditions the concentration of performic acid approaches its maximum after one hour and changes little during the next hour.

The action of the per-compounds on the amino acids was examined as follows. 2 mM. of the compound was dissolved in 88% formic acid, 1 cc. of 30% hydrogen peroxide was added and the volume was completed with the formic acid to 10 cc. A similar blank solution, without amino acid, was prepared at the same time. One-half-cc. samples of each solution were pipetted at intervals, during a total period of approximately two hours, into 20 cc. of a solution containing 5 mM. potassium iodide, 0.1 mM. $(NH_4)_2MoO_4$ and 5 mg. of starch, and the liberated iodide was at once titrated with 0.024 *N* thiosulfate solution. The blank solutions showed an approximately linear loss of 4 ± 1% per hour while in the presence of the majority of the amino acids the resulting curves were similar except that in most cases they fell somewhat more rapidly. Only in the case of methionine, tryptophan and cystine were curves similar to C (Fig. 1) obtained, showing consumption of 2, 3 and 5 atoms of oxygen, respectively, per molecule. Most of the amino acids were used as purchased; some had been prepared or purified by us. All had been analytically identified. The results are summarized by the data of Table I. The arrangement is in the approximate order of increasing susceptibility to oxidation as revealed by these experiments.

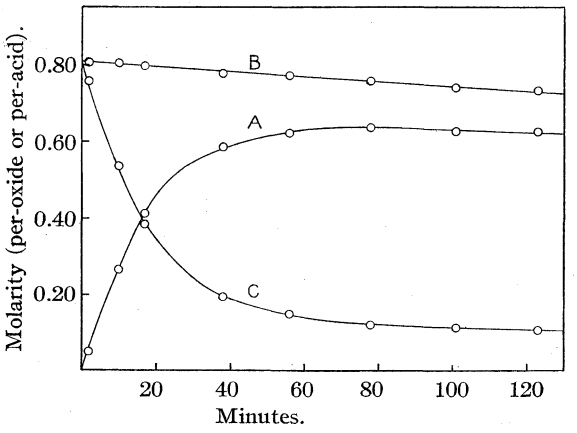

Fig. 1.—The behavior of hydrogen peroxide in formic acid: 1 cc. of superoxol dissolved to 10 cc. with 88% HCOOH; temperature 26.5°. Curve A represents peracid (HCOOOH), curve B the sum of peracid and hydrogen peroxide, and curve C (obtained by calculation from A and B) hydrogen peroxide (*cf.* text for analytical procedures).

From the results obtained on the first 4 or 5 compounds listed one might conclude that the typical structural elements of amino acids are quite stable toward the oxidizing agent used. The further data show, however, that depending on the structure and, perhaps, on the presence of impurities, some amino acids are slowly attacked. Three amino acids stand definitely apart, in that they show a rapid, stoichiometrically well-defined reaction. The data indicate that within one hour (when the majority of the amino acids consume one-third atom of oxygen or less) methionine is oxidized to the sulfone[6] level, while during the same time the oxygen consumption of cystine corresponds to the requirements for conversion to cysteic acid.

(5) Toennies, THIS JOURNAL, **59**, 552 (1937).

(6) Toennies and Kolb, *J. Biol. Chem.*, **140**, 131 (1941).

The apparently stoichiometric oxidation of tryptophan by 3 atoms of oxygen leaves room for different interpretations which cannot be evaluated without further work. In addition to the behavior of these three compounds it seems worth noting that in contrast to their behavior with periodic acid, the hydroxy amino acids are not distinguished by a special reactivity toward performic acid.

Density and Refractive Index of Cumene

BY JAMES E. TROYAN

In a recent investigation of alkyl benzenes at this Laboratory, the variation with temperature of density and refractive index of cumene (isopropyl benzene) was determined. Previous data on these properties had been found in the literature, but the inconsistency in published values led to the new measurements reported in this article.

The plots of densities and of refractive indices against temperatures defined curves which were fitted to the general equation, d^t_4 or $n^t_D = a + bt + ct^2$, by the method of least squares. The following expressions were obtained

$$\text{Density} - d^t_4 = 0.8777 - 0.73 \times 10^{-3}t - 2.8 \times 10^{-6}t^2$$
$$\text{R. I.} - n^t_D = 1.5017 - 0.54 \times 10^{-3}t + 0.46 \times 10^{-6}t^2$$

Densities were determined by means of pycnometer weighings between 6.1° and 37.8°. The close agreement between experimental data and the calculated curve is shown in Fig. 1. The

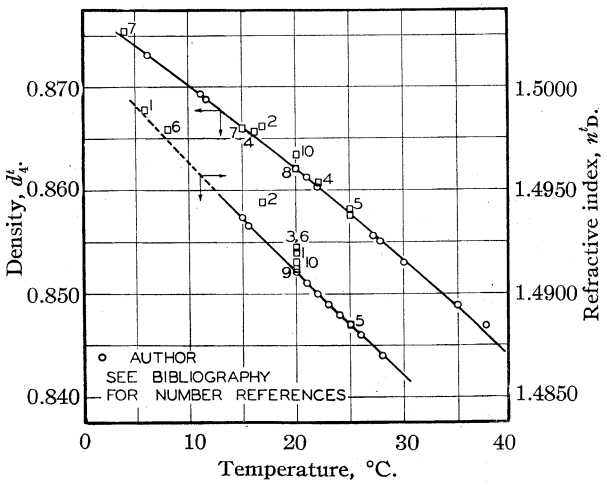

Fig. 1.

average deviation of individual points from this curve is ±0.0001 or about 0.01%. Refractive indices were measured with an Abbé refractometer at temperatures ranging from 15–28°. Experimental points, which are likewise plotted in Fig. 1, show an average deviation of only 0.002% from values indicated by the curve of the R. I. equation given above. Density and R. I. data reported by other investigators are included for comparison with the author's results.

Best grade Eastman Kodak Company cumene was used in these measurements without any further purification. This was considered acceptable since the density and refractive index of the middle cut of a redistillation (b. p. 152–153°) were not significantly different from those of the original material, which had the following properties: b. p. 151–153°, f. p. −95.2°, d^{20}_4 0.8620, $n^{20}D$ 1.4911. By comparison, best values in the literature are: b. p. 152.5°, f. p. −96.2°, d^{20}_4 0.8620, $n^{20}D$ 1.4912–1.4920.

Although the author's data may be limited somewhat in accuracy by the purity of the cumene used, it is assumed that the equations offered here are sufficiently reliable for general use in industry.

NEW COMPOUNDS

4-Nitrodiphenyl Ether-4′-Sulfonyl Chloride and -4′-Sulfonamide

p-Nitrodiphenyl ether was sulfonated by heating and stirring with concentrated sulfuric acid until test portions were completely soluble in water. The sodium salt was isolated, dried and converted to the sulfonyl chloride with phosphorus pentachloride. The light cream-colored sulfonyl chloride was recrystallized from isopropyl ether: m. p. 84–85° (cor.). It was analyzed by refluxing a weighed portion in 50% ethanol for three hours, evaporating to dryness repeatedly on the steam-bath to remove hydrogen chloride, and titrating the residual sulfonic acid with standard alkali.[1]

Anal. Calcd. for $C_{12}H_8O_5NSCl$: equiv. wt., 314. Found: equiv. wt., 322.

(1) *Cf.* Davis and Davies, *J. Chem. Soc.*, **123**, 2976 (1923).

To prove the structure of this compound, diphenyl ether was converted to diphenyl ether-4-sulfonyl chloride by the directions of Suter.[2] This compound was nitrated by dissolving 1 g. of it in 5 ml. of glacial acetic acid, adding 4 ml. of concentrated nitric acid, and then adding portionwise 2 ml. of concentrated sulfuric acid while keeping the temperature at about 60–70°. After the reaction mixture had stood several hours it was poured into water and the oily nitro compound was seeded to cause crystallization. Recrystallization from ethyl ether gave a product, m. p. 85.5–86.5°, indicated by melting point and mixture melting point to be identical with that made by sulfonating *p*-nitrodiphenyl ether.

The sulfonamide was obtained from either sulfonyl chloride as very light yellow crystals from dilute ethanol, m. p. 130–131°. Before Kjeldahl digestion the sample was allowed to stand with cold sulfuric acid and zinc dust.[3]

Anal. Calcd. for $C_{12}H_{10}O_5N_2S$: N, 9.5. Found: N, 9.4.

Since this work indicates that 4-nitrodiphenyl ether sulfonates mainly in the 4′-position, as might be expected, the 4-nitrodiphenyl-ether-*x*-sulfonic acid of Jones and Cook[4] may now be concluded to have been the 4′-sulfonic acid.

N,N-Di-*n*-butylhydroxylamine and its Oxalate

This hydroxylamine was made by substantially Wieland's procedure.[5] A 5% solution of nitrogen dioxide in anhydrous ether was prepared and cautiously dropped into a well-stirred solution of *n*-butylmagnesium bromide in ether. As soon as starch–iodide paper indicated the presence of excess nitrogen dioxide, the mixture was let stand for two hours and then decomposed with a little water. The N,N-di-*n*-butylhydroxylamine was extracted with ether and precipitated therefrom by adding a solution of oxalic acid in ether. The oxalate, recrystallized from methanol, melted at 144.0–144.5°.

Anal. Calcd. for $C_{10}H_{21}O_5N$: N, 5.94; equiv. wt. (dibasic acid), 118. Found: N (Kjeldahl), 5.95; equiv. wt., 118.

(2) Suter, THIS JOURNAL, **53**, 1112 (1931).

(4) Jones and Cook, THIS JOURNAL, **38**, 1534 (1916).
(5) Wieland, *Ber.*, **36**, 2315 (1903).

The free N,N-di-*n*-butylhydroxylamine was obtained by warming the oxalate with concentrated alkali solution, chilling, and isolating the product by filtration. After recrystallization from aqueous ethanol it melted at 52.5–53.0°. It was very soluble in all organic solvents tested, but only slightly soluble in water, giving a neutral solution; its weakness as a base is indicated also by the fact that the acid in the oxalate may be titrated as if free. When warmed with solutions of silver, cupric or auric salts, it exhibits the expected reducing power.

Anal. Calcd. for $C_8H_{19}ON$: N, 9.66. Found: N, 9.59.

4-Toluenesulfonates of the Nitro-4-phenylphenols

2,6-Dinitro-4-phenylphenyl 4-Toluenesulfonate.—This compound was prepared by the treatment of 2,6-dinitro-4-phenylphenol in pyridine solution with tosyl chloride. The crude, faintly yellow product was obtained in quantitative yield and, after crystallization from propanol, from which 88% was recovered as colorless prisms, it melted at 186–187°.

Anal. Calcd. for $C_{19}H_{14}O_7N_2S$: S, 7.73. Found: S, 7.69.

2,6-Dinitro-4-(4-nitrophenyl)-phenyl 4-Toluenesulfonate.—For the preparation of this compound it was necessary to dissolve the 2,6-dinitro-4-(4-nitrophenyl)-phenol and the tosyl chloride in warm 1,4-dioxane and then to add the pyridine. The crude product was obtained in quantitative yield, and after crystallization from methanol the recovery was 80%. The crystals so obtained were faintly yellow prisms, but after drying at 130° and 15 mm. the color disappeared; m. p. 219–220°.

Anal. Calcd. for $C_{19}H_{13}O_9N_3S$: S, 6.97. Found: S, 6.85.

COMMUNICATIONS TO THE EDITOR

THE TOXIC PRINCIPLES OF POISON IVY

Sir:

We have investigated the active principles of poison ivy and find that the toxic oil is a complex of at least three active components and several innocuous concomitants.

Hill and his co-workers[1] isolated a toxic yellow oil from poison ivy with the stated boiling point of 210° (0.5 mm.), and presented evidence to prove that it was identical with urushiol, the boiling point of which was quoted as 210° (0.4–0.6 mm.). From this toxic oil they prepared a series of derivatives, identical when crystallizable with those prepared from urushiol, but no yields were reported.

"Urushiol" is a name first applied by Majima[2] to an extract of Japan lac which boiled over a range of 210–222° ((0.4–0.6 mm.), and, upon redistillation, from 195° to "above 210°." It was shown to consist of four components[3] the structures of which were partially elucidated.

Since it is known that plants of the *Anacardiaceae* family, to which both poison ivy and Japan lac belong, elaborate a number of vesicant mono- and dihydric alkyl phenols with fifteen and seventeen carbon side chains, the derivatives prepared by Hill only prove the presence of a compound or compounds with a 3-pentadecacatechol skeleton in the distillate. This is a property it possesses in common with urushiol.

Essentially we followed Hill's method of isolation; our concentrate boiled over a range, the major portion distilling at 185–250° (2 microns) with considerable resinification. Redistillation in a Hickman molecular still yielded three fractions at bath temperatures up to 125°, 165° and 170°, the principal superficial difference being one of color. The products, although containing innocuous concomitants, were all toxic, 0.5 gamma of oil per sq. cm. of hypersensitive skin being sufficient to elicit a strong characteristic poison ivy reaction.

Chromatographed under nitrogen on barium carbonate–Hyflo Super Cel (Johns Mansville Sales Corporation), fraction 1 was separated into an unsaturated acid (or acids, hydrogenation yielding a solid, m. p. 66–67°, depressed by palmitic but not stearic acid; C, 75.4; H, 12.5; amide m. p. 105–106°, depressed by palmitamide but not stearamide; therefore stearic acid[4]) and a phenolic oil, log ϵ 265 mμ = 3.02, log ϵ 273 mμ = 3.09 in absolute ethanol. In twenty-four hours absorption decreased to log ϵ 265 mμ = 2.72 and the ferric chloride test became negative in the original concentration, 6 mgm./100 cc. This suggests that the presence of drying oils in the vesicant-bearing sap accounts at least in part for the extraordinary stability of the toxic principles in their natural environment.

Chromatographed on alumina (Alorco) deactivated with 90% ethanol, fraction 1 yielded *six* bands, from the top: orange, four colorless with bright blue-white fluorescence under ultraviolet light, and yellow. One fluorescent band, eluted with 90% ethanol, was phenolic and autooxidized with extreme rapidity. The other fluorescent bands could not be removed without major destruction, but were shown to be highly toxic, while the remaining fractions were not. We conclude that at least three toxic components are present, and are engaged in improving this technique and elucidating the structures of the toxic compounds. The exigencies of the day have required this short report at this time.

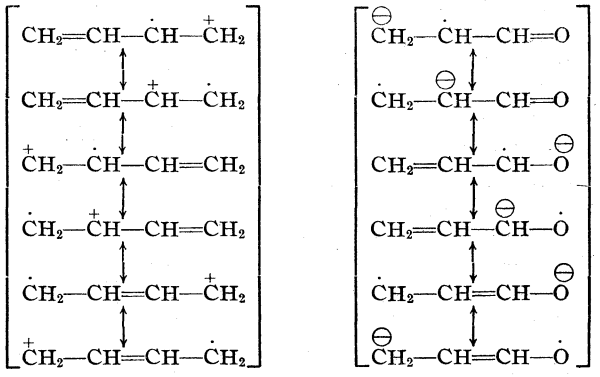
THE MECHANISM OF THE DIELS-ALDER REACTION

Sir:

It is noteworthy that in the usual case the Diels–Alder reaction involves, on the one hand, a substance, *e. g.*, a diene, of relatively low ionization potential and, on the other, a molecule of high electron affinity, *e. g.*, an α,β-unsaturated carbonyl compound. We may therefore expect an electron-transfer from the diene to the dienophile with the formation of an ion-pair intermediate of the type recently postulated in general for molecu-

lar compound formation by Weiss.[1] Both components, after the electron exchange, will be hybridized, *viz.*, in the simplest case, the reaction between butadiene and acrolein,



We thus arrive at a mechanistic picture in which collision results in electron transfer followed by formation of a dipolar aggregate, held together

$$A + B \rightleftharpoons [A\cdot]^+\,[B\cdot]^- \longrightarrow \left[\begin{array}{cc} A & B \end{array}\right]$$

by ionic forces (and possibly further by interparticular overlapping of the orbitals of the nonbonded electrons in each half; in this event, the link could be described as an *intermolecular semipolar bond*,[2] *cf.* $[A^+]:[B^-]$). Stereochemically, the aggregate would consist of two parallel charged (usually flat) surfaces, oriented in such wise as to take maximum advantage of electrostatic attractive forces. The first step is probably in most cases rapid and reversible, the rate-controlling process being the usually (but not always) substantially irreversible rearrangement of the ion-pair complex to the product $\left[\begin{array}{cc} A & B \end{array}\right]$ *above*.

This picture is in complete conformity with the large body of observed phenomena attendant upon the reaction. There may be cited: (i) transient color formation, (ii) steric course of the reaction, (iii) effect of substituents of divers electrical character on the ease of reaction both of the diene and the dienophile, (iv) observed molecular compound formation preceding reaction in certain cases, (v) the occasional abnormal course of the reaction (notably in the case of heterocyclic nitrogen bases, and ketenes), (vi) solvent effects.

The procession of the reaction by the above course further indicates the possibility of catalysis by donor or acceptor molecules which cannot themselves participate in the diene-addition reaction. Preliminary experiments designed to test this possibility give some qualitative indication that dimethylaniline and 1,3,5-trinitrobenzene exert such an accelerating effect.

The situation will be considered in detail in a forthcoming publication.

(1) Weiss, *J. Chem. Soc.*, 245 (1942).

(2) (Note added in proof, November 25, 1942.) This concept is a logical extension (or modification) of the theory of molecular complex formation which is not implied in Weiss' paper.[1] I intend to develop these ideas further; meanwhile, I note that Dr. L. C. Bateman (*Chemistry and Industry*, **61**, 453 (1942), received November 23) has independently proposed a similar picture during a discussion at the Chemical Society (London) on October 15, 1942. On this side these ideas were first embodied in Dr. J. J. Leavitt's Dissertation, "Some Properties and Reactions of Unsaturated γ-Lactones," Harvard University, September 1, 1942.

NEW BOOKS

Elementary Physical Chemistry. By MERLE RANDALL, Professor of Chemistry in the University of California, and LEONA ESTHER YOUNG, Professor of Chemistry in Mills College. Randall and Sons, 2512 Etna St., Berkeley, California, 1942. (Photolith reproduction.) xiv + 455 pp. Illustrated. 15.5 × 23.5 cm. Price, $4.50.

Physical Chemistry. By FRANK THOMSON GUCKER, JR., Associate Professor of Chemistry, Northwestern University, and WILLIAM BUELL MELDRUM, Professor of Chemistry, Haverford College. American Book Company, 88 Lexington Avenue, New York, N. Y., 1942. xii + 683 pp. 262 figs. 14.5 × 22.5 cm. Price, $4.00.

As physical chemistry has advanced beyond its historic preoccupation with aqueous solutions of electrolytes, an adequate grasp of its subject matter has become increasingly difficult to obtain in a single year-course. An "introductory" course in the third, or even second, year of college is a frequent answer to this problem as well as to the needs of students majoring in other sciences or preparing for medicine. Such a course, covering one or two semesters, is the province of the two text-books with which we are concerned. They both deal mainly with "classical" principles; both stress experimental facts and the deductive approach, with a minimum of mathematics and thermodynamics. Parallel or previous study of the calculus would be desirable but not essential. In both cases the problems of beginning students have been kept clearly in mind; extensive use of illustrations, graphs, exercises and applications should go far to stimulate interest and

assure comprehension. Both books can be recommended as sound, carefully written and well made contributions to the teaching of *introductory* physical chemistry.

The Randall and Young book has several unique features. It introduces the physico-chemical method of treatment by analyzing a familiar process—vaporization of a liquid. Gradually, and quite naturally, *concepts* are developed, *e. g.*, boiling point, vapor pressure, equilibrium, heat content, temperature scale, escaping tendency, partial pressure, activity, activity quotient, cycles. Soon important relations begin to appear as experimental facts, such as the Clausius–Clapeyron equation, Trouton's rule, and Raoult's law. The first third of the book is devoted to this kind of analysis of phenomena encountered in analytical or organic laboratory. The remainder of the book develops the basic principles in a more quantitative and fairly systematic manner. The emphasis is strongly on equilibrium, and particularly heterogeneous equilibrium, including distillation, freezing point, solubility and distribution. There are brief sections on flow of fluids and reaction rates, but almost no mention of atomic, molecular or crystal structure, isotopes, colloids, surface phenomena or photochemistry. Though much briefer than most such texts, it is notable for the extensive use of figures (279). Many of these excellently illustrate principles by graphs of experimental data (with copious references); others show laboratory or industrial apparatus. All figures are supplied with explanatory paragraphs which of themselves give a good descriptive picture of physico-chemical behavior. Another important feature are the 690 exercises distributed in small groups at appropriate points throughout the text. They are original and stimulating, and often serve to extend the textual discussions or to apply them to other fields.

The Gucker and Meldrum book is more conventional in plan. After brief discussions of fundamental chemical theory, atomic structure and valence, it takes up in order the states of aggregation (123 pp.), thermochemistry (27 pp.), solutions (55 pp.), kinetics (19 pp.), equilibrium with particular reference to solutions of electrolytes (about 200 pp.), colloids and surface phenomena (78 pp.), phase equilibrium (31 pp.), and thermodynamics (34 pp.). Structure and its relation to properties, reaction mechanisms, and quantitative aspects of hetereogeneous equilibrium receive only minor attention. The book owes much to "Introduction to Theoretical Chemistry" by the same authors, but covers much more of the "classical" ground and at a somewhat more advanced level. The development is largely empirical, with little aid from thermodynamics or calculus, although such aids are available in the final chapter if use can be made of them there. There is strong emphasis throughout on the application of chemical principles in biological phenomena. There is contained an unusual amount of well-selected experimental data (262 figures, 124 tables). The numerous figures showing how well, or sometimes how badly, theories accord with actual facts are particularly commendable. An adequate number (258) of problems and review questions is provided; several of a given type are usually included, but there is fair variety and range of difficulty. Each chapter closes with a carefully prepared reading list of books and review articles, frequently with specific page references and helpful comments on scope and character.

ARTHUR F. BENTON

The Electron Microscope. By E. F. BURTON, Head of the Department of Physics, University of Toronto, and W. H. KOHL, Development Engineer, Rogers Radio Tubes Limited, Toronto. Reinhold Publishing Corporation, 330 West 42nd Street, New York, N. Y., 1942. 233 pp. Illustrated. 15.5 × 23.5 cm. Price, $3.85.

Great things are expected of the electron microscope as a tool of the investigator in pure and applied research. Like all things not well understood, it has sometimes been the subject of over-enthusiastic expectations. On the other hand, a lack of comprehension of the instrument operates to delay the useful applications to which it may be put.

In this volume, the authors by simple steps lead the reader gradually to a comprehension of the nature of vision and the elements of optical science, through a brief course in electronics and its branch called electron optics, the basis of taking magnified pictures without light.

This is a book for the thoughtful reader, not a picture book. Copiously illustrated, however, with homely diagrams, adequate although executed with non-professional draftsmanship, and with half-tone reproductions of photo and electron micrographs, it presents a physicist's explanation of the theory and operation of this modern instrument in a manner easily comprehended by scientists in fields other than that of electronics. For the lay reader who enjoys a certain amount of homework the thoughtful study of this volume will present much that is authentically and interestingly informing in various fields of life of today and of tomorrow.

JOHN W. M. BUNKER

Introduction to Semimicro Qualitative Chemical Analysis. By LOUIS J. CURTMAN, Professor of Chemistry, The City College, The College of the City of New York. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1942. x + 377 pp. 38 figs. 14.5 × 22 cm. Price, $2.75.

This book is a follow-up of the author's earlier "Qualitative Chemical Analysis," based on experimental testing of modifications of macro methods to semi-micro scale, and containing some relatively new procedures, also. The first 130 pages (Part I) are a discussion of the usual background topics of modern qualitative analysis, ranging from coördination theory and acid–base theory, through solutions, equilibrium, ionization, solubility product, and oxidation–reduction, to buffer solutions, hydrolysis and colloids. Part II (75 pp.) takes up the reactions of the metal ions, followed by a much shorter section on the anions, with copious equations. Part III (16 pp.) deals with calculations, and includes many simple weight relation and normality problems. Part IV on laboratory work (87 pp.) devotes several pages to general advice, directions and warnings on semi-micro work, followed by orientation and practice tests on various metal ions. Then come the systematic procedures for the metal ions, followed by tests

on anions. Part V gives the systematic detection of the anions, preparation of the solution for metal analysis, the phosphate separation. The 30-page Appendix gives recording notes for data, desk equipment lists, reagent lists, and specifications for stock solutions, with a long table of solubilities.

The background section seems to be well written and adequate, while the sections on the characteristics of the various ions give a variety of tests on each ion. The cation analysis scheme has a few departures from the usual procedures: the separation of the copper and tin subgroups using potassium hydroxide; an extra step for complete separation of arsenate ion in strongly acid solution; ammonium sulfide precipitation of the iron–nickel family with immediate separation of manganese with nitric acid and potassium chlorate; partial precipitation of magnesium with the calcium group. The anion analysis is worked out in some detail. The typography, design and mechanical execution are good; a few small details which might have been improved are the lack of style consistency in the literature citation footnotes, the use of unattractive full capital abbreviations (such as E. M. F. instead of e. m. f.), a few old-fashioned spellings (sulphur, in particular), and the hyphenation of such words as silver-ion (as nouns).

ALLEN D. BLISS

Introduction to the Microtechnique of Inorganic Analysis. By A. A. BENEDETTI-PICHLER, Dr. Techn. Sc., Assistant Professor of Chemistry, Queens College, Flushing, N. Y. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1942. vii + 302 pp. 84 figs. 15.5 × 23.5 cm. Price, $3.50.

In the 1920's Dr. Benedetti-Pichler came to New York from Austria, where he had been a student of the chief founder of inorganic microchemistry, Friedrich Émich, and inaugurated one of the first, if not the first, systematic course in that subject at an American university. At that time microchemistry was very young indeed, and untried; now it has matured and its standing in the science is secure, and it has a place in most educational curricula that emphasize analysis and manipulative technique; moreover, there is nowadays scarcely an industrial laboratory of any pretensions that does not have some facilities for microchemical work. Dr. Benedetti-Pichler deserves much of the credit for these developments.

The book under review "is intended as an introduction to the microtechnique of chemical experimentation." Briefly summarized, it purports to do two things: describe, in the manner of a laboratory manual, certain of the basic manipulative and observational techniques that have been developed for or adapted to microchemistry, in order to facilitate operations on a reduced scale; and illustrate the application of these techniques to qualitative and quantitative inorganic analysis. Thus this volume, which is presented as a college textbook, is divided into three parts: I, Apparatus for General Use; II, Qualitative Analysis, A, Confirmatory Tests, B, Microtechnique of Qualitative Analysis; III, Quantitative Analysis, A, Gravimetric Determinations, B, Titrimetric Determinations; followed by a bibliography and the usual appendices.

The present book replaces an earlier work, "Introduction to the Microtechnique of Inorganic Qualitative Analysis," by Professor Benedetti-Pichler and Dr. W. F. Spikes. Readers familiar with the older book will be interested in a comparison of its subject matter with that of the new one. The three parts in the older were: I, The Microscope; II, Qualitative Analysis (Apparatus and Technique); III, Microqualitative Scheme. Thus the most important addition in the volume under review is the inclusion of microquantitative analysis; some may feel that the most important omission is the systematic scheme for microqualitative analysis. Many writers make a rather vague distinction between "micro-" and "semimicro-" procedures. The present volume carries this a step further and describes typical "centigram, milligram and microgram procedures." The reviewer believes that this is a useful pedagogical device.

The reviewer believes that the book will serve very satisfactorily for the purposes intended. But he cannot refrain from deploring the lack in this book, as in most other texts on microchemistry, of any material that will qualify the student to apply microtechniques in a practical way when he sets up as a microchemist in an industrial or a research laboratory. Deplorable especially is the lack of emphasis on the fact, so palpably real to supervisors of microlaboratories in industry, that more often than not the selection, isolation and preparation of the sample for microanalytical attack requires at least as much effort and skill as the actual microanalysis. The reviewer does not quarrel with what is in this book: clearly the student must learn all of this before he is even competent to microanalyze pure substances; but it is contended that the book would have had a great deal more value in orienting the student of microchemistry into the "world of things as they are," if another fifty pages, giving some applications of microtechniques to practical problems, had been added. There is no dearth of these, as the author is well aware. Doubtless the author would reply that his book is not a compendium but an introduction, and that he deliberately chose to cover only those aspects of the subject that he did cover, leaving to others the industrial applications. That is a valid reply, which the reviewer would have to accept; but he still deplores the fact that the "others" have not arisen, and he hopes for their early emergence.

Minor criticisms are the absence of an author index, and of a presentation of the increasingly versatile and important electrographic technique.

BEVERLY L. CLARKE

Physical Chemistry for Students of Biochemistry and Medicine. By EDWARD STAUNTON WEST, Ph.D., Professor of Biochemistry in the University of Oregon Medical School. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1942. xiv + 368 pp. 24 figs. 16 × 24 cm. Price, $5.75.

The jacket informs us: "The primary aim of this book is to present the selected phases of physical chemistry recognized as basic to an understanding of biological phenomena." In doing so, the author has treated the following topics: the structure of matter, including atomic structure; valence, including in his discussion electro-

valence, covalence, coördinate valence, and the hydrogen bond; the gas laws; theories of solutions, including solubility, osmotic pressure, electrolytic dissociation, diffusion, and the mass law; acids and bases, including buffer solutions; the determination of *p*H by various methods; the colloidal state and membrane phenomena including surface phenomena, size of colloidal particles, adsorption and the Donnan equilibrium; oxidation and reduction, including reference to the theory of oxidation-reduction potentials and the mechanisms of biological oxidations; and finally, the velocity of reactions.

These topics have, on the whole, been chosen with discrimination and have generally been treated in the light of contemporaneous theory. Omission of any reference to the theory of Debye and Hückel is surprising to this reviewer, as is the bare statement that: "Neutralization of toxins by antitoxins seems to proceed according to the laws of adsorption." Whereas the very elementary treatment presupposes only a low level of preparation in mathematics, physics, and chemistry, the insertion of numerous simple problems, and pertinent questions should help the reader to coördinate his knowledge on an elementary, quantitative plane. The more inquisitive reader is referred to more extended summaries, but rarely to original definitive literature. The relations of physical chemical principles to biology are well illustrated and stressed.

In these days when inadequate preparation is likely to become more general, this book can be used profitably by both premedical and medical students.

RONALD M. FERRY

Organic Reactions. Volume I. ROGER ADAMS, Editor-in-Chief, WERNER E. BACHMANN, LOUIS F. FIESER, JOHN R. JOHNSON and H. R. SNYDER. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1942. vii + 391 pp. 15.5 × 23.5 cm. Price, $4.00.

Organic chemists will welcome this first volume of the series with more than ordinary enthusiasm, for it is a landmark in the literature of organic chemistry. The series is a new departure, and will make available extremely valuable information in a readily applicable form. Perhaps the nearest approaches to the present series are the still useful but quite out-of-date special parts of Houben–Weyl and Lassar–Cohn on general organic reactions such as condensation, nitration, etc.

Primarily, the work is concerned with the scope and limitations of important laboratory reactions. "The subjects are presented from the preparative viewpoint, and particular attention is given to limitations, interfering influences, effects of structure, and the selection of experimental techniques. Each chapter includes several detailed procedures illustrating the significant modifications of the method." The textual material, tables and extensive bibliographies provide a coverage that is as nearly complete as one might wish.

The twelve chapters have been written by authors who have had particular experience with the reactions or processes described: (1) "The Reformatsky Reaction" (Ralph L. Shriner); (2) "The Arndt–Eistert Synthesis" (W. E. Bachmann and W. S. Struve); (3) "Chloromethylation of Aromatic Compounds" (Reynold C. Fuson and C. H. McKeever); (4) "The Amination of Heterocyclic Bases by Alkali Amides" (Marlin T. Leffler); (5) "The Bucherer Reaction" (Nathan L. Drake); (6) "The Elbs Reaction" (Louis F. Fieser); (7) "The Clemmensen Reduction" (Elmore L. Martin); (8) "The Perkin Reaction and Related Reactions" (John R. Johnson); (9) "The Acetoacetic Ester Condensation and Certain Related Reactions" (Charles R. Hauser and Boyd E. Hudson, Jr.); (10) "The Mannich Reaction" (F. F. Blicke); (11) "The Fries Reaction" (A. H. Blatt); and (12) "The Jacobsen Reaction" (Lee Irvin Smith).

Some of the chapters have many more formulas in the tables than others. A strictly uniform pattern of presentation may not be the best procedure for a work of this kind, but a more extensive use of formulas instead of names in some of the chapters would be preferred by students and others.

It is interesting to note the occasional cases where "name" reactions bear the name not of the original discoverer, but of one who subsequently explored the broad aspects of the reaction.

The series, separate volumes of which will appear periodically, will form something more than a mere adjunct to laboratory procedures. It is the sort of work that not only stands alone, but that will prove an invaluable supplement to every text or reference work in organic chemistry. With the appearance in recent years of a wide variety of excellent books on organic chemistry, the content of some seminar and special topics courses may be revised to place added emphasis on immediately current articles instead of extensive surveys which are increasingly available.

Although this work appears in war times, the general idea was conceived several years ago and in this respect is unlike "Organic Syntheses," the origin of which is directly traceable to meeting the needs for research chemicals in the last war. The editors and authors are to be complimented and thanked for a splendid work which must have made unusual demands on them in these strenuous times.

HENRY GILMAN

Chemical Refining of Petroleum, the Action of Various Refining Agents and Chemicals on Petroleum and its Products. By VLADIMIR A. KALICHEVSKY, Research and Development Laboratories, Socony-Vacuum Oil Co., Inc., and BERT ALLEN STAGNER, Ph.D., Consulting and Research Chemist. Revised edition. Reinhold Publishing Corporation, 330 West 42nd St., New York, N. Y., 1942. 550 pp. Illustrated. 23.5 × 15 cm. Price, $7.50.

The rapid advances which have been made in the refining art during the past decade have made necessary revision of this well-known book which was first published in 1933. Much of the book was rewritten (apparently in 1940) and the material rearranged with improved results. The subjects covered include the composition of petroleum; treatment with sulfuric acid; sulfuric acid sludge and hydrogen sulfide; recovery and manufacture of sulfuric acid; treatment with alkaline reagents; sweetening operations; refining by adsorption; refining with solvents; deterioration and anti-detonants; inhibitors of atmospheric oxidation; gums and cracked petroleum products;

and deterioration of lubricating and similar oils. A very useful supplementary list of U. S. patents on petroleum refining is presented, patents issued up to January, 1940, being listed. The glossary of terms which occupied some 23 pages in the first edition is now omitted; definitions of such terms as aldol, alkyl, amine, anthracene, bauxite, benzoyl, etc., are certainly superfluous in an A. C. S. Monograph.

The authors have written a very readable treatise. The style and makeup are excellent; subheadings are used liberally. The chemical reactions which occur in the various refining processes are discussed briefly but perhaps adequately for the purpose of the book.

Although the book will appeal chiefly to the refiner and to the petroleum technologist, it can be read with profit by chemists who are interested in the application of chemical procedures to the refining of petroleum.

V. N. IPATIEFF

Organic Syntheses. An Annual Publication of Satisfactory Methods for the Preparation of Organic Chemicals. Vol. 22. LEE IRVIN SMITH, Editor-in-Chief, HOMER ADKINS, C. F. H. ALLEN, W. E. BACHMANN, NATHAN L. DRAKE, R. L. SHRINER, H. R. SNYDER, and A. H. BLATT, Secretary. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1942. 114 pp. 15.5 × 23.5 cm. Price, $1.75.

The addition of this new book to the series of publications in the field of synthetic chemistry entitled "Organic Syntheses," must be considered as filling a useful service. We have now available for reference twenty-two volumes of this practical organic text. The organic preparations recorded have been selected, approved and checked by a competent editorial board experienced in the modern technique of synthetic organic chemistry, and the new volume should prove to be just as helpful as any of the editions already published.

In this volume are described satisfactory methods for the laboratory preparation of thirty-four different organic compounds representative of the aliphatic, aromatic and heterocyclic series. Several of these will prove of immediate service as key substances in new research programs.

The very complete literature references are extremely useful for workers interested in the different fields represented by the preparations recorded. The practical nature of the work should prove very helpful to those workers who do not have access to good library facilities and the literature of chemistry. A subject index for volumes 20–22 is printed in this volume.

TREAT B. JOHNSON

Technical Report Writing. By FRED H. RHODES, Professor of Chemical Engineering, Cornell University. McGraw-Hill Book Company, Inc., New York, N. Y., 1941. vii + 125 pp. 8 figs. including one of conventional symbols. 15.5 × 23.5 cm. Price, $1.50.

The author, struck, as many others have been, "by the appalling lack of ability of students and graduates to write effective reports," and having concluded that they are unlikely to learn in courses in English how to construct and write a good report, decided that it was up to him to train his students in technical writing by requiring that the reports in his courses be written in good English and subjected "to the same careful criticism that is exercised in the editing of articles for publication in the better technical journals." As there was no satisfactory textbook covering this precise field, he proceeded to write one, and has succeeded admirably in what he set out to do. In a series of brief chapters he outlines the importance of effective presentation, written or oral, of the results of an investigation, particularly where this presentation is to reach the less strictly technical members of an organization, and discusses the characteristics and proper organization of a good technical report, with pertinent remarks on many details of style and usage to which the writer of a report should, but usually does not, pay attention. In these pages I saw no statement with which I do not fully concur, nor any significant omission; and noted only a single error which might puzzle the reader, namely, that on page 99 in the columns headed "deviation" the numbers are the square of the deviation. The last few chapters, occupying more than half of the book, deal briefly with some of the simpler methods of analyzing, correlating, and depicting experimental data; references are given to other books which treat these matters more fully. If ways can be found to induce students—and not only students, but graduates—to absorb, and make use of, the teachings of this book, there should be fewer complaints of poor organization of reports and articles and of sloppy writing which makes it more difficult for the reader to grasp what the writer is trying to convey.

JOHN JOHNSTON

A Shorter Course in Organic Chemistry. By J. C. COLBERT, Associate Professor of Chemistry in the State University of Oklahoma. Second Edition. D. Appleton–Century Company, Inc., 35 West 32nd Street, New York, N. Y., 1942. xvii + 355 pp. 15 × 23 cm. Price, $3.75.

Introductory Organic Chemistry. By E. WERTHEIM, Professor of Organic Chemistry in the University of Arkansas. The Blakiston Company, 1012 Walnut Street, Philadelphia. Penna., 1942. vii + 482 pp. 82 figs. 15.5 × 23.5 cm. Price, $3.00.

These two books are intended for students who are in related sciences of biology, medicine, home economics, etc. Both aim to give a student a well grounded appreciation of the graphic formula and of the structural theory of organic chemistry. The means by which each attains this end are, however, widely different and represent two views on the method of instruction. The book by Colbert begins with a chapter on the theoretical basis of organic chemistry which includes such topics as the Bohr atom, the coördinate and covalent bond, the valence of carbon, resonance, isomerism (structural, dynamic, optical and geometrical), classification as aliphatic, aromatic, and heterocyclic, and the importance of analysis and physical constants of organic compounds. After this introduction there is (part one) a sequence of fourteen chapters (246 pages) on aliphatic compounds, in which hydrocarbons, halogen alkyls, alcohols, acids, the lipids (fats, phosphatides, waxes and

sterols), amino acids and proteins and other topics are described. In part two, there are five chapters (68 pages) which describe aromatic compounds, monosubstituted benzene derivatives and heterocyclic compounds. The aim of the author is to develop the fundamental theory slowly but thoroughly in about the first third of the book and then give the remainder as a rapid survey. The book contains many excellent charts, directions for study and numerous questions. A short appendix gives the methods of calculating yields and the formulas of compounds.

The opening chapter of the text by Wertheim emphasizes the special fields covered in organic chemistry, the elements present in organic compounds, the industrial value of organic products such as leather, oils, chemicals, resins, etc.; the sources of organic compounds, the general methods by which the chemist analyzes them, the skeleton structure, the carbon atom and structural isomerism. After this introduction there follows a series of twenty chapters on hydrocarbons, halogen derivatives, alcohols, etc., in which the chemistry of functional groups and aromatic compounds are discussed. This material is divided into about 227 pages on aliphatic and 92 pages on aromatic and heterocyclic compounds. The concluding four chapters are, respectively, on digestion and absorption of foods, metabolism, nutrition and foods. Throughout the work the author has chosen to omit technicalities while stressing points of fundamental importance. The commercial and social aspects of organic chemistry are emphasized. Numerous illustrations of such subjects as the processing of soap, uses of cellophane and synthetic resins, synthetic rubber, animals showing the effect of diet deficiency, and respiratory apparatus are included. The photographs of molecular models are especially good. A generous supply of study questions is included with each chapter. The forty pages of appendix contain a glossary of terms in chemistry, biology and medicine, a discussion on the removal of stains, a list of reference books and analytical data on foods.

This review does not argue the merits of the two methods of instruction. The opening chapter of each text probably presents a pretty good picture of the principle which each author proposes to use with students who desire only a short course in organic chemistry. A conscientious student who will study either text and solve the problems can undoubtedly acquire a good knowledge of the subject.

AVERY A. MORTON

Equilibrium and Kinetics of Gas Reactions. An Introduction to the Quantum-Statistical Treatment of Chemical Processes. By ROBERT N. PEASE. Princeton University Press, Princeton, New Jersey, 1942. ix + 236 pp. Illustrated. 15.5 × 23.5 cm. Price, $3.75.

This is a textbook designed for first year graduate students. The first part, about one-third of the book, is a review of the fundamental thermodynamics of equilibrium in gaseous systems. Nearly half of this part is devoted to the formulation of thermodynamic quantities in terms of partition functions and illustrations of their use. Only sufficient theory is developed as is needed in the numerous practical applications.

The rest of the book treats the rate and mechanism of gas reactions. This part begins with a brief description of the theory of the absolute rate of reactions. Chapters on reactions of simple order, quasi-unimolecular, chain, and oxidation reactions follow. The book closes with a brief account of surface-catalyzed reactions.

It is unfortunate that there are few gas reactions even moderately free of complications, as much might be learned from them. The reluctance of chemical reactions to proceed in a straightforward way is in itself remarkable, and the result is that the theory of reaction rates is far ahead of experimental confirmation. Indeed, it is almost true that the reactions which are least understood are those which have been studied most. While the reviewer does not agree with all of the conclusions of the author, the evidence for and against particular mechanisms is presented fairly. Such help in interpreting the mechanism of complex reactions as can be given by the theory of absolute reaction rates is freely used. The complicated behavior of oxidation reactions is particularly well presented.

Typographical errors are few and unimportant. The book emphasizes a common viewpoint of equilibrium and the approach to equilibrium in gas reactions, and the author is to be congratulated on his clear and readable survey of a complicated and fascinating field of study.

DARRELL V. SICKMAN

Introductory College Chemistry. By HORACE C. DEMING, Professor of Chemistry, and B. CLIFFORD HENDRICKS, Professor of Chemistry, University of Nebraska. Second edition, completely revised. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1942. xii + 521 pp. 176 figs. 15.5 × 23.5 cm. Price, $3.00.

This revision of Deming's popular and widely used "Introductory College Chemistry" should be of interest to anyone teaching a group who are either less advanced or do not need a detailed and comprehensive course in general chemistry. In the preparation of this revision the original text has been largely rewritten. A few changes in order of presentation have been made and new questions and exercises have been added. However, in this rewriting there has been no loss of clarity or logical presentation. The practical aspects of chemistry are stressed, but not to the exclusion of fundamental principles.

The order of treatment is the fairly standard: Introduction—Oxygen—Water—Atomic Structure—Hydrogen—Acids—Bases—Salts—Non-metals—Metals—Organic Chemistry. Although the order may not appeal to some teachers, the authors seem to have maintained excellent continuity.

All in all, the book would seem to be worthy of the careful consideration of anyone interested in a well-written, up-to-date, and readable, but less comprehensive textbook.

C. H. SORUM

Du Pont—One Hundred and Forty Years. By WILLIAM S. DUTTON. Charles Scribner's Sons, New York, N. Y., 1942. x + 396 pp. 16.5 × 23.5 cm. Price, $3.00.

This book presents the story of a chemical enterprise through which from remote beginnings in colonial days runs

unbroken for seven score years the red thread of a family name and a spirit which as the years went by became a cherished tradition to be passed on from generation to generation. It is to a notable degree a biography of an institution. The outstanding figure of the earlier chapters is Eleuthère Irénée du Pont, one of two sons of Pierre Samuel du Pont de Nemours, who had been elevated to the nobility because of distinguished services to his country, and his work in connection with the Peace of Paris between the United States and England. At the country estate of his father he met many notable visitors, among them Benjamin Franklin, Lafayette, Talleyrand, and Lavoisier. The latter became interested in the boy of fourteen and two years later gave him a position in the gunpowder factory of which Lavoisier was chief. After four years there he became first assistant to Lavoisier in his laboratory. Then followed the French Revolution, the reign of terror, the migration of the du Pont family to America, and the erection of the little gunpowder factory on the Brandywine near Wilmington in 1802 based on the training given by Lavoisier and financed by French and American capital.

The close connection of ammunition and explosives with the pioneering development of the West, and the wars, of the last century gives historical interest to the large section of the book which covers that period in which nitroglycerine and dynamite and nitrocellulose and smokeless powder gave a new trend to the explosive industry. With the present century there began an era of expansion which in its broader outlines reflects the progress of the chemical industry in America over the past forty years. The reader finds here much which appeals to his imagination. In no field of human endeavor more than in chemistry is the spirit of the pioneers more clearly reflected, and adventure and discovery and individual initiative and resourcefulness become the keys to accomplishment. The concluding chapters dealing with the development of a broad program of research, dyestuffs, cellulose products, plastics, synthetic rubber, nylon, high pressure reactions, and the management and policies of the Company, although presented in popular vein, are informative and interesting. The book is written in excellent literary style, and bears evidence of a painstaking effort on the part of the author to write with authority and accuracy, without sending his bucket too often to the well of sentimentality.

ROBERT E. SWAIN

Practical Physical Chemistry. By ALEXANDER FINDLAY, Professor of Chemistry, University of Aberdeen. Seventh edition, revised and enlarged. Longmans, Green and Co., 55 Fifth Avenue, New York, N. Y., 1942. x + 335 pp. 124 figs. 14 × 22 cm. Price, $3.00.

The most recent edition of this well-known book embodies few innovations. Six new experiments and a number of alternative applications of the previously used experimental methods have been added.

The book has sixteen sections; the first three of which are general in nature—Calculation of Results and Errors, Determination of Weight and Volume and Thermostats. The first two of these present very satisfactory discussions of the material covered. Chapter III on Thermostats is a useful compendium of temperature control mechanisms. The discussion of circulation of the bath fluid—an extremely important factor in constant temperature control—is rather inadequately treated.

The thirteen chapters following cover convenient groupings of experiments. The chapter headings, showing the range of topics, are: Density of Gases and Vapours, Density and Vapour Pressure of Liquids, Viscosity and Surface Tension, Optical Measurements, Osmotic Properties of Solutions, Distribution of a Substance between Two Non-Miscible Solvents, Conductivity of Electrolytes, Transport Numbers, Measurements of Electromotive Force, Velocity of Chemical Reaction in Homogeneous Systems, Thermochemistry, Heterogeneous Equilibria, and Colloids. Each chapter includes a short discussion of the underlying principles, then a rather complete description of the apparatus used and the technique of measurement, and finally several alternative experiments illustrating each method. Under each heading the more important types of apparatus are described and experiments suitable to each are suggested.

A good feature of this manual is the unusually large number (approximately 90) of experiments included in this edition. This gives the user wide latitude in the selection of exercises adapted to his needs.

The use of the concept of activity and the application of the Debye–Hückel theory to conductance experiments are evidences of the author's modernity in viewpoint. This edition includes experiments on absorption spectra, the glass and antimony electrodes for *p*H measurements, and the tungsten electrode for redox reactions. The author explains that he has been "reluctantly compelled to omit" certain subjects such as unimolecular films, dielectric constants, colorimetry, and photochemical reactions.

The book is well written and should be found thoroughly satisfactory by most users. It is to be hoped that the publishers will make new cuts for the next edition, some of the cuts in this edition being so old that they detract considerably from the appearance of the book.

ELIJAH SWIFT, JR.

Experimental Physical Chemistry. By W. G. PALMER, M.A., Sc.D., D.Sc., Fellow of St. John's College, Cambridge, University Lecturer in Chemistry in the University of Cambridge. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1942 (Cambridge: at the University Press). xi + 321 pp. 89 figs. 13.5 × 21.5 cm. Price, $2.75.

Some seventy-five experiments divided into eight sections comprise the contents of this new volume. Most of the experiments are the result of the author's experience over a number of years in the Physical Chemistry Laboratory at the University of Cambridge. As a result, the directions given are rather detailed and allow for the mistakes in technique and understanding which the average student might be expected to make. The author includes sufficient theoretical material in each section so that reference to other texts is usually not necessary, though references for further reading are suggested. Carefully worked out sample calculations are included with each experiment.

An unusual section in this book is the chapter on Crystallization and Properties of Crystals. Several experiments are given, illustrating supersaturation, influence of foreign substances on crystal habit, isomorphism and isodimorphism, alternative systems being suggested in each case.

The author has confined the experiments to those requiring apparatus "simple enough to be assembled or constructed by the students themselves from ordinary laboratory equipment." While many of the fundamental principles taken up in the elementary course in Physical Chemistry are illustrated by such equipment, the limitation imposed cuts out a large group of experiments which not only demonstrate alternate methods, but also offer invaluable experience to the student. Experiments using more costly equipment should not be scorned—thus, most students find the Abbé refractometer an easily handled piece of equipment giving them excellent results as an analytical tool when working with minimum boiling mixtures. The use of the polarimeter, refractometer, spectrometer, bomb calorimeter, oil film balance, tensiometer, etc., show the student more refined methods of measurement which do not offer too great difficulties in manipulation and which produce results satisfactory in every sense.

The author is apparently unaware of the work of Grinnell Jones and collaborators on conductance measurements and on the redetermination of the conductance standards (see p. 187). It is also surprising to find no mention of the parachor in this book.

In spite of the poor binding and paper, which are to be expected in these times, the type is clean and very legible and the cuts clear and well drawn. Laboratories without the more expensive facilities mentioned above will find that the directions for assembling equipment given in this text will enable them to carry out a very satisfactory program of experiments covering the fundamental principles of physical chemistry.

ELIJAH SWIFT, JR.

General Chemistry. By HARRY N. HOLMES, Professor of Chemistry in Oberlin College. Fourth edition. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1941. viii + 720 pp. 198 figs. 16 × 24 cm. Price, $3.75.

The fourth edition of General Chemistry by Harry N. Holmes has not lost any of the values that made the text so teachable in the first edition.

The arrangement of the non-metals is just the same as in the previous editions but there is a decided improvement in the arrangement of the metals. These are studied according to the metallurgy of various groups. They are then taken up again according to their position in the Periodic system. This seems to be a decided improvement over the usual method of presenting the metals.

The historical method of presenting chemistry has been fairly well preserved although enough of the modern concept of the atom has been given in the first few chapters to permit the use of the modern theories if one desires.

The exercises at the end of each chapter as well as the references are very well done. The chapter outline and the review suggestions in the early part of the book should be quite a help to the conscientious student.

The application of chemistry to industry and to ordinary living has been brought up to date and should help to create an interest in the science of chemistry.

It is a text that should be examined in order to be appreciated.

Page 2860. Col. 1, line 1 of last paragraph, for "(1 mole)" read "(0.1 mole)," and same below for diethyl sulfate and sodium nitrate.

T. Q. Chou and T. T. Chu. The Preparation and Properties of Peimine and Peiminine.

Page 2936. Col. 1, line 5, for "wereas signed" read "were assigned."

George Wash, Billie Shive and H. L. Lochte. Normal and Abnormal Alkylation of 2-Methylcyclopentyl Methyl Ketone.

Page 2975. In the title, for "Methyl" read "Phenyl."—H. L. LOCHTE.

W. D. Larson and W. J. Tomsicek. The Activity Coefficients of the Undissociated Part of Weak Acids. II. Oxalic Acid.

Page 3330. Equation (4) should read

$$E^0 = E + 0.02957 \log_{10} K_1 K_2 C \left(1 - \frac{-K_1 + \sqrt{K_1^2 + 4K_1 c}}{2c}\right)$$

—W. D. LARSON.

1942, VOL. 64

W. R. Forsythe and W. F. Giauque. The Entropies of Nitric Acid and its Mono- and Tri-hydrates. Their Heat Capacities from 15 to 300°K. The Heats of Dilution at 298.1°K. The Internal Rotation and Free Energy of Nitric Acid Gas. The Partial Pressures over its Aqueous Solutions.

Pages 60 and 61. The authors call attention to the following arithmetical errors:

$$^1/_2N_2 + {}^3/_2O_2 + {}^1/_2H_2 = HNO_3 \quad (1)$$

$\Delta F^0_{298.1}$ should be −19030 cal. instead of −11,539 cal.

$$^1/_2N_2 + {}^3/_2O_2 + {}^1/_2H_2 = HNO_3 \quad (g)$$

$\Delta F^0_{298.1}$ should be −17948 cal. instead of −10.457

$$^1/_2N_2 + {}^3/_2O_2 + {}^1/_2H_2 = HNO_3 \quad (a = 1)$$

$\Delta F_{298.1}$ should be −26345 cal. instead of −18854 cal.

The above errors are repeated in the summary.

Also in the summary

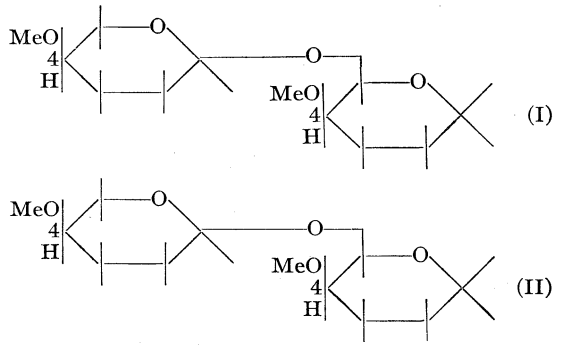
$$^1/_2N_2 + {}^3/_2O_2 + {}^1/_2H_2 = HNO_3 \quad (g)$$

$\Delta H_{298.1}$ should be −31994 cal. instead of −3199 cal.

—W. R. FORSYTHE and W. F. GIAUQUE.

E. V. White. The Constitution of Arabo-galactan. II. The Isolation of Heptamethyl- and Octamethyl-6-galactosidogalactose through Partial Hydrolysis of Methylated Arabo-galactan.

Page 303. The author writes "Formulas 1 and 2 representing octamethyl-6-*d*-galactosidogalactose and heptamethyl-6-*d*-galactosidogalactose are incorrect in the relative positions of the methoxyl and hydrogen groups at position 4 in all the monosaccaride units, which should be reversed as indicated



Page 304. In col. 1 of the Experimental, line 30, in the formula, for "Hg" read "H_8."—E. V. WHITE.

Emmett R. Barnum and Cliff S. Hamilton. 5-Amino- and 1-Aminobenzo(f)-quinolines and Derivatives.

Page 542. Col. 2, lines 11 and 20, for "*p*-dimethylaminobenzaldehyde" read "*p*-diethylaminobenzaldehyde."—C. S. HAMILTON.

H. J. Lucas and Clark W. Gould, Jr. Brucine as a Reagent for Partially Resolving Bromoalkanes; the Configurations of Some Diastereomeric Dibromoalkanes.

Page 602. In footnote (7) for "(+1.0016)" read "(0.0016)," for "compound" read "compared" and in the citation, for "1471" read "147."

N. Howell Furman and Clark E. Bricker. A Polarographic Study of *o*-Phthalic Acid and Phthalates.

Page 665. In the legend for Fig. 6, the last four lines should read "Curve a at *p*H 4.02; curve b at *p*H 3.94; curve c at *p*H 3.75; curve d at *p*H 3.57; curve e at *p*H 3.48; curve f at *p*H 3.25; curve g at *p*H 3.06; curve h at *p*H 2.60; polarogram was made with capillary no. 3."—N. H. FURMAN.

S. C. Schumann, J. G. Aston and Malcolm Sagenkahn. The Heat Capacity and Entropy, Heats of Fusion and Vaporization and the Vapor Pressures of Isopentane.

Page 1041. The authors write "In Table IV the molal heat of vaporization of isopentane at 298.16°K. calculated from Eq. (1) and the modified Berthelot equation at 298.16°K. with T_c = 461°K. and P_c = 32.9 atm. is 5965 calories (Berthelot correction = 239 calories), instead of the value given."

Page 1043. "In Table VII the free energy of neopentane was accidentally computed using the free rota-

tional entropy. Using the correct value for this quantity [Aston and Messerly, THIS JOURNAL, **58**, 2354 (1936)] Table VII should then be:

FREE ENERGY OF FORMATION OF THE PENTANES AT 298.16°K.

	ΔF_{298}, calories	% in equilibrium mixture	% if no neopentane
Neopentane	-3289 ± 320	48.7	...
Isopentane	-3243 ± 300	48.3	93.7
n-Pentane	-1647 ± 270	3.0	6.3

These changes do not affect the rest of the paper, since no other numerical values or conclusions were derived from the erroneous values.—S. C. SCHUMANN, J. G. ASTON AND M. L. SAGENKAHN.
