where $T_{t=0}$, T_t, T_e are, respectively, the transmittance for time zero, time t and equilibrium. The complex reaction velocity constant $k_1' + k_2$ is given by the slope of the curve obtained by plotting time in minutes against log (log T_t − log T_e) and was proven to be independent of the direction from which equilibrium is approached.

The equilibrium constant is calculated from

$$K_C = \frac{[\text{Carbinols}]}{[\mathrm{R}^{=}][\mathrm{OH}^-]} = \frac{[\log T_{t=0} - \log T_e]}{[\log T_e][\mathrm{OH}^-]} \quad (5)$$

The concentration of carbinols is the difference in concentration of colored ion initially (when none has faded) and at equilibrium. This value is the ordinate obtained by extrapolating the plot of equation (4) to zero time.

Values of the molar rate constant are calculated from

$$k_1 = \frac{k_1 + k_2}{[OH^-] + 1/K_C} \qquad (6)$$

Results

The colored form of phenolphthalein obeys Beer's law over the range of concentrations considered in this investigation: namely, up to 1.34×10^{-5} m./l. (Table I). The values of $T_t = 0$ are extrapolated values since concentrations of hydroxyl ion, insufficient to convert all phenolphthalein to the colored ion, are sufficient to cause appreciable fading of the latter during the time of observation. The value of $k_B = -1.63 \times 10^{-5}$ m./l. is considered the most accurate, being measured from a specially purified sample of phenolphthalein. The molar extinction coefficient ($E = \frac{1}{Cl}\log(I_0/I)$) is 0.3057×10^{-5} (l = length) (7).

TABLE I

MOLAR EXTINCTION COEFFICIENTS (E) AND CONSTANTS FOR BEER'S LAW (k_B) FOR ALKALINE PHENOLPHTHALEIN SOLUTIONS

NaOH = 0.014 M, λ = 550 mμ, temp. = 25°, layer thickness = 20.054 mm.

Concn. dye, $\times 10^5$ m./l.	$k_1' + k_2$, min.$^{-1}$	$T_{t=0}$, %	E, (m./l.)$^{-1}$ cm.$^{-1} \times 10^{-5}$	$k_B \times 10^5$ m./l.
0.670	0.01209	39.60	0.2992	1.664
1.102	.01195	21.10	.3057	1.630
1.340	.01207	15.75	.2987	1.668

A typical run is given in Table II and plotted in Fig. 2. Equilibrium transmittances measured after twenty-four hours were stable and no irreversible fading[13] was observed. Extrapolated values of $T_{t=0}$ are shown in Table III. The constancy of these extrapolated values over the pH range employed in this study shows that no secondary salt effect is detectable.

Table IV summarizes the molar rate and equilibrium constants, which are reliable to better than 1%. The increase in these constants with concentration is shown in Table V to be due to a primary salt effect.[14]

Discussion

The theory assumes that the kinetics of the reaction may be formulated as $R^{=} + OH^{=} \rightleftarrows X^{=} \rightarrow ROH^{=}$ where $X^{=}$ is the activated complex sensibly in equilibrium with the reactants but not with the product. The influence of the charges of the reactant species and the ionic strength of the solution is given by the Brönsted–Debye limiting law equation (B. D. L. L.)

$$\log k_1 = \log k_0 + 1.02\, Z_R\text{-}Z_{OH^-}\, \sqrt{\mu} \qquad (8)$$

where k_0 is the extrapolated molar rate constant for zero ionic strength.

The equilibrium constant is given by the expression

$$K_a = \frac{a_R\text{-}a_{OH^-}}{a_{ROH^=}} = \frac{C_R\text{-}C_{OH^-}}{C_{ROH^=}} \frac{f_R\text{-}f_{OH^-}}{f_{ROH^=}} \qquad (9)$$

where a is activity and c is concentration. Introducing the Debye–Hückel limiting equation for the activity coefficient (f), yields for the measured stoichiometric constant K_C

$$\log K_C = \log K_a + 1.02\, Z_R\text{-}Z_{OH^-}\, \sqrt{\mu} \qquad (10)$$

Figure (3) shows a plot of log k_1 against $\sqrt{\mu}$. The ionic strength is varied in one series of runs (circles) by increasing the concentration of sodium hydroxide, in the other (crosses) by increasing the concentrations of sodium chloride. A limiting slope of +2 is obtained in accord with formulation (1) and Eq. (8) showing conclusively that carbinol formation in phenolphthalein involves the reaction of an ion of charge −2 with the hydroxyl ion. The forward rate exhibits no anomalous behavior.

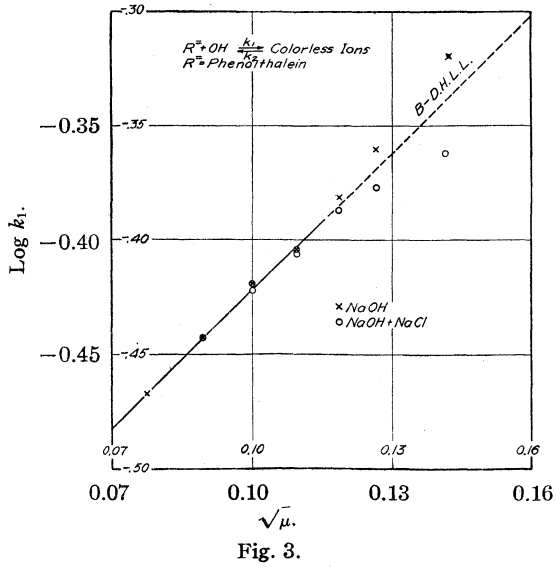

Fig. 3.

The upper curve in Fig. 4 shows the plot of log K_C against $\sqrt{\mu}$. The slope is unity or one-half the value required by the theory for an equilibrium involving doubly charged phenolphthalein, hydroxyl and triply charged carbinol ions. This abnormal behavior has been attributed erroneously by Lund to the variation of the forward rate constant with ionic strength. Failure to measure the equilibrium constant in sufficiently dilute solutions is responsible for this misunderstanding.

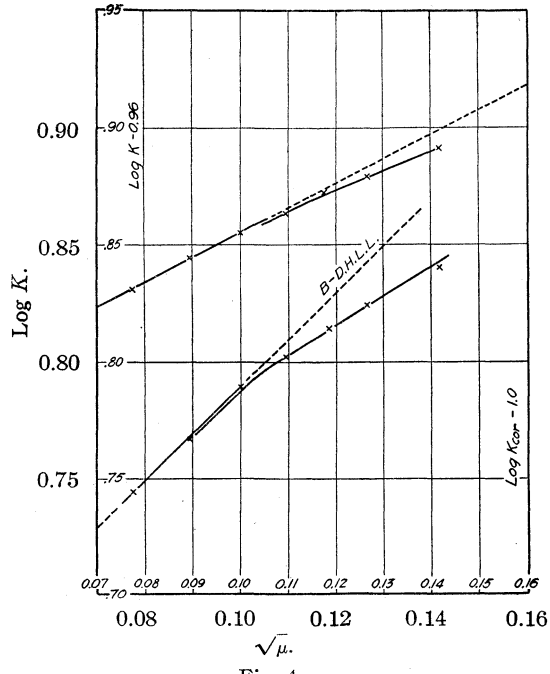

Fig. 4.

The abnormal behavior arises from the fact that the concentration of the triply charged carbinol assumed in (1) cannot be measured directly as is assumed in formulation (1). Over the pH range covered in these experiments (11.8 to 12.3) and particularly at the lower concentration of alkali the triply charged carbinol should be partially hydrolyzed. The equilibrium relationships under such conditions may be formulated

$$R^- + OH^- + H_2O \begin{cases} \overset{K_1}{\rightleftharpoons} ROH^= + H_2O \\ \overset{K_2}{\rightleftharpoons} RHOH^- + OH^- \end{cases} \quad K_3 \qquad (11)$$

(14) For review see V. K. LaMer, *Chem. Rev.*, **10**, 179 (1932).

where RHOH$^{=}$ is also a colorless carbinol. The equilibrium described by K_1 considers the triply charged carbinol as the product in equilibrium with reactants R$^{=}$ and OH^{-}. This equilibrium constant is shown by (10) to be affected by the ionic strength. K_2, however, which considers the doubly charged carbinol and hydroxyl ion in equilibrium with the reactants, is not affected by the ionic strength. K_3 describes the mobile equilibrium existing between these carbinols and is defined as

$$K_3 = \frac{[\mathrm{ROH}^{\equiv}][\mathrm{H_2O}]}{[\mathrm{RHOH}^{=}][\mathrm{OH}^{-}]} \qquad (12)$$

On the basis of this equilibrium formulation, K_c calculated from the data may be separated into K_{1a} and K_2 ($K_{2a} = K_{2c}$). Consideration of (5) and (6) shows that this operation does not affect the calculated values of k_1 which have been shown to obey precisely the predictions of the Brönsted–Debye equation. The separation of K_C into K_{1a} and K_2 is shown by the equations

$$K_C = \frac{[\mathrm{ROH}^{\equiv}] + [\mathrm{RHOH}^{=}]}{[\mathrm{R}^{=}][\mathrm{H_2O}][\mathrm{OH}^{-}]} = \frac{[\mathrm{ROH}^{\equiv}]}{[\mathrm{R}^{=}][\mathrm{H_2O}][\mathrm{OH}^{-}]} + \frac{[\mathrm{RHOH}^{=}]}{[\mathrm{R}^{=}][\mathrm{H_2O}][\mathrm{OH}^{-}]} \qquad (13)$$

$$K_C = K_{1a}10^{2\sqrt{\mu}} + K_2/[\mathrm{OH}^{-}] \qquad (14)$$

TABLE V

RATE AND EQUILIBRIUM CONSTANTS ($\mathrm{R}^{=} + \mathrm{OH}^{-} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{ROH}^{\equiv}$) IN NaOH AND NaCl SOLUTIONS

$T = 25°$

NaOH × 10³	NaCl × 10³	μ × 10³	$k_1' + k_2$, min.$^{-1}$ × 10²	K_C	k_1, min.$^{-1}$ × 10²	k_2, min.$^{-1}$ × 10²
6	0	6	0.7568	61.78	34.12	0.5522
6	2	8	.7794	63.99	36.05	.5634
8	0	8	.8560	63.60	36.09	.5674
8	2	10	.8819	65.20	37.80	.5800
8	4	12	.9065	66.41	39.33	.5944
8	6	14	.9242	68.36	40.86	.5977

8	12	20	.9411	73.43	43.55	.5930

A test of equation (14) is made by selecting values for K_{1a} and K_2 and calculating K_C at different hydroxyl ion concentrations. Comparison of K_C calculated from experimental data and K_C calculated from equation (14), employing $K_{1a} = 40.25$ and $K_2 = 0.038$, is shown in Table VI. The agreement is within experimental error over the range where the Debye–Hückel limiting equation is valid.

Graphically the behavior of K_{1c} expressed in concentrations is shown in the lower curve in Fig. 4. K_{1c} is obtained by solving equation (14)

TABLE VI

EQUILIBRIUM CONSTANTS (EQS. (13) AND (14)): K_c = EXPERIMENTAL EQUILIBRIUM CONSTANT; $(K_c)_{14}$ = EQUILIBRIUM CONSTANT CALCULATED FROM (14)

NaOH × 10³	K_c	$(K_c)_{14}$	ΔK_c, %
6	61.78	62.40	1.0
8	63.60	63.52	0.13
10	65.25	64.98	.43
12	66.52	66.56	.06
14	67.86	68.24	.56
16	69.06	69.87	1.2
20	71.00	73.10	2.8

employing experimental values of K_C and hydroxyl ion and the value of 0.038 for K_2. The Brönsted–Debye equation is obeyed over the range of dilute solution up to $\sqrt{\mu} = 0.11$. The close agreement of the experimental K_C with the K_C calculated from (14) confirms the postulated equilibria.

The ionization constant of RHOH$^{=}$ may be calculated from (12) and the values of K_{1a} and K_2. Using $K_{1a} = 40.25$, $K_2 = 0.038$ and the ion constant for water $K_W = 1 \times 10^{-14}$ (at 25°) the value of the ionization constant is 1.1×10^{-11}.

Summary and Conclusions

1. The kinetics of the reaction of phenolphthalein with hydroxyl ion to produce a colorless carbinol have been investigated spectrophotometrically at 25° for sodium hydroxide solutions (0.006 to 0.020 M) with and without the addition of sodium chloride.

2. Precise values of the transmittances of phenolphthalein solution at 550 mμ have been obtained by extrapolating to zero time. The extinction coefficient is independent of the concentration of alkali showing that no perceptible secondary salt effect exists at these concentrations.

3. The limiting slope of the log k_1 (forward rate constant) *vs.* the square root of ionic strength, $\sqrt{\mu}$ establishes that carbinol formation involves the reaction of a doubly charged negative phenolphthalein ion with a hydroxyl. $\mathrm{R}^{=} + \mathrm{OH}^{-} \rightarrow$ carbinol.

4. The limiting slope of log K (equilibrium constant) *vs.* $\sqrt{\mu}$ is one-half that predicted for the simple formulation $\mathrm{R}^{=} + \mathrm{OH}^{-} \rightleftarrows \mathrm{ROH}^{\equiv}$. An interpretation consistent with established electrostatic principles is obtained on the assumption that the carbinol is partially hydrolyzed, *viz.*, $\mathrm{ROH}^{\equiv} + \mathrm{H_2O} \rightleftarrows \mathrm{RHOH}^{=} + \mathrm{OH}^{-}$.

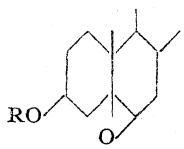
Studies on Cholesteryl Oxides[1]

BY PURNENDU N. CHAKRAVORTY AND ROBERT H. LEVIN

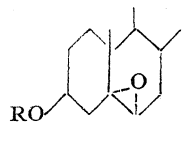
In connection with work in progress, it became necessary to study the properties of the oxide ring in cholesteryl-5,6-oxides. Previous investigators have used perbenzoic acid to prepare the various oxido derivatives of cholesterol, and from their results the nature of the substituent at C_3 appeared to influence the ratio of stereoisomeric products formed. Thus from cholesterol Westphalen and Windaus[2] obtained α-cholesterol oxide (I, R = H) in 50% yield, with some of the β-isomer (II, R = H) being isolable from the crystallization mother liquors. Ruzicka and Bosshard[3] found that treatment of cholesteryl acetate with perbenzoic acid produced largely β-cholesteryl oxide acetate. Spring and Swain[4] reported that cholesteryl benzoate, under the same conditions, formed almost equal amounts of α- and β-cholesteryl oxide benzoates in excellent yield.

In this Laboratory, preparation of oxides has been simplified by the use of monoperphthalic acid.[5] This reagent is readily prepared and is more stable than perbenzoic acid. Further, the phthalic acid which is formed from the perphthalic acid during the reaction can be separated easily from the sterol oxides because of its insolubility in chloroform. Such ease of separation is particularly useful in the preparation of bile acid oxides because it eliminates the need for washing with alkali. However, when using perphthalic acid several precautions are necessary. The chloroform should be freshly distilled over potassium carbonate, since the sterol oxides will react with even traces of hydrogen chloride. In some of our experiments, the perphthalic acid–cholesteryl compound reaction mixture was not worked up immediately but allowed to stand overnight or longer. In these instances the reaction product was quite sticky and uncrystallizable, and the yield was small. This was presumably due to a secondary reaction of the cholesteryl oxide with phthalic acid, giving, very probably, a half phthalic ester as was indicated by the solubility of the product in alkali.

When cholesteryl acetate was treated with perphthalic acid, β-cholesteryl oxide acetate (II, R = Ac) was isolated in 50% yield and the α



I[6]



II[6]

R = H, Ac, Bz

isomer (I, R = Ac) in 20% yield. A similar reaction using cholesteryl benzoate gave α-cholesteryl oxide benzoate (I, R = Bz) in 50 to 70% yield, but no β-oxide benzoate could be obtained. With cholesterol, the same reagent produced α-cholesterol oxide (I, R = H) in 60% yield, and a small amount of the β-isomer.

Several partially successful attempts to rearrange cholesteryl oxides to ketocholestane compounds have been reported. Chinaeva and Ushakov[7] used a Grignard reagent. Spring and Swain[4] employed heat and vigorous dehydrating reagents. In neither instance was the yield of 6-ketocholestanol satisfactory. It was thought that any tendency of the oxido group to isomerize into a ketone might be accelerated through a mass action effect by removing the product from the sphere of reaction as a ketone derivative. Accordingly, β-cholesteryl oxide acetate was heated with semicarbazide hydrochloride in pyridine. The product of this reaction was a halogen containing substance, m. p. 188–190°, which could be recovered unchanged after refluxing with acetic anhydride, and was therefore identified as a 3-acetoxy-5-hydroxy-6-chlorocholestane (III, R = Ac) instead of 3-acetoxy-5-chloro-6-hydroxycholestane (IV, R = Ac, R′ = H). A rational explanation of this reaction became possible when it was found

that a solution of semicarbazide hydrochloride in pyridine has a *p*H of 6.2 and will turn blue litmus red. Since ethylene oxides are, in general, stable to alkaline reagents, but susceptible to acidic substances, this transformation is not surprising.

It has been known for some time that ethylene oxide rings in aliphatic molecules are also opened by heavy metal and even alkaline earth metal halides.[8] In an extension of this reaction to cholesteryl oxides, ferric chloride, zinc chloride and magnesium bromide[9] were found to react with β-cholesteryl oxide acetate to give compounds containing halogen. The ferric chloride reaction product was identified as 3-acetoxy-5-hydroxy-6-chlorocholestane (III, R = Ac). The zinc chloride and magnesium bromide products were not completely characterized.

As indicated above, cleavage of the cholesteryl oxide bond can produce two position isomers (III, IV). Recently some conflicting reports have been published concerning the orientation of products obtained by the action of certain acidic reagents on various cholesteryl oxide derivatives. Ruzicka and Bosshard[3] treated the β-oxide acetate with dry hydrogen chloride in pyridine and obtained 3-acetoxy-5-hydroxy-6-chlorocholestane (III, R = Ac). Hattori[10] reported this same compound resulting from the action of hydrogen chloride on α-cholesteryl oxide acetate, and claimed that very pure β-oxide acetate[11] gave a 5-chloro-6-hydroxycholestane derivative (IV, R = Ac, R′ = H). Spring and Swain[4] have found that α-cholesterol oxide and its benzoate react with benzoyl chloride in pyridine or with hydrogen chloride to give 5-hydroxy-6-chlorocholestane compounds (III), whereas β-cholesterol oxide and its benzoate form 5-chloro-6-hydroxy derivatives (IV, R = Bz, R′ = Bz, H). We treated β-cholesteryl oxide acetate, m. p. 113°, with benzoyl chloride in pyridine and obtained 3-acetoxy-5-hydroxy-6-chlorocholestane (III, R = Ac), which was characterized by mixed melting point, analysis, and its non-reactivity toward acetic anhydride. If the action of benzoyl chloride involves simply a cleavage of the cholesteryl oxide linkage followed by addition of fragments of the benzoyl chloride molecule, then in our reaction, as well as Spring and Swain's reaction with the α-oxide and its benzoate, the 5-benzoxy compound would be expected to form.[12] Since the 5-hydroxy derivative was obtained, it seems that the benzoyl chloride acts like the semicarbazide hydrochloride, that is, merely as a donor of hydrogen chloride. Formation of 6-benzoxy compounds can be explained on the assumption that the primary reaction is fission by hydrogen chloride, followed by benzoylation of the newly formed 6-hydroxy group with excess of the reagent.

It was thought that pyridine might function as a carrier of hydrogen chloride in these experiments. Therefore, the reaction of "pyridine hydrochloride" with β-cholesteryl oxide acetate was undertaken. This reagent was obtained as a hygroscopic white solid by passing dry hydrogen chloride into a solution of pyridine in ether. In petroleum ether there was no reaction, "pyridine hydrochloride" being insoluble in this solvent. In absolute ethanol a reaction readily took place, with the formation of the same 3-acetoxychlorohydrin (III) previously obtained with semicarbazide hydrochloride, ferric chloride and benzoyl chloride.

The reaction of β-cholesteryl oxide acetate with benzoyl chloride was also carried out under anhydrous conditions using carbon tetrachloride as a solvent. The substitution of a completely chlorinated solvent for pyridine, which contains hydrogen, did not alter the course of the reaction, and the same 5-hydroxy-6-chlorocholestane derivative was isolated from the reaction mixture although in a poorer yield. Apparently the elements of hydrogen chloride are obtained from the benzoyl chloride, but the mechanism of the transformation remains quite obscure.

The reaction with "pyridine hydrochloride" was extended to α-cholesterol oxide, its acetate, and benzoate; and β-cholesterol oxide. These substances, to our surprise, uniformly gave 5-hydroxy-6-chlorocholestane derivatives (III) in good yields. "Pyridine hydrochloride" is a convenient reagent to use. It is easily prepared, may be kept indefinitely in a desiccator, reacts smoothly, and any excess is readily disposed of. In the case of α- and β-cholesterol oxides, some trouble was experienced in purifying the reaction products be-

(9) Ushakov and Madaeva, *J. Gen. Chem.* (U. S. S. R.), **9**, 1690 (1939), treated α-cholesterol oxide with magnesium bromide, but did not isolate any compound containing halogen.

(10) Hattori, *J. Pharm. Soc. Japan*, **60**, 334 (1940).

(11) Hattori's value for the m. p. of β-cholesterol oxide, 136°, is at variance with all other published values and our own findings which give a m. p. of 106–107° for the pure substance. However, his oxide acetate has the accepted m. p., 112–113°.

(12) See for example Ehrenstein's acetolysis of the stereoisomeric 5,6-oxides of dehydroandrosterone acetate, *J. Org. Chem.*, **6**, 626 (1941); also Hattori, ref. 10.

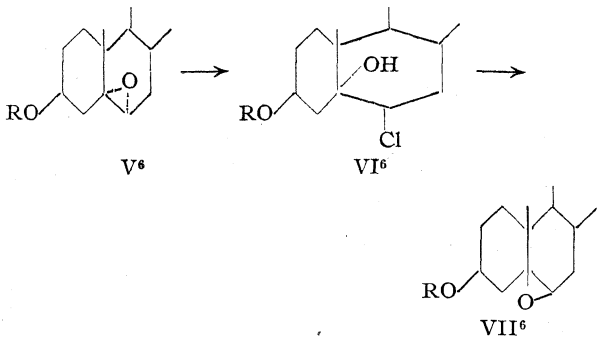
cause of dehalogenation occurring during recrystallization. The difficulty was obviated by benzoylating the crude dry reaction product and then crystallizing. Apparently the presence of a free hydroxyl group at C_3 labilizes the halogen at C_6, forming possibly a 3,6-oxide.

From the results of previous investigators it appeared that the configuration of the oxide and the nature of the substituent at C_3 affected the orientation of the chlorohydrin produced by fission of the oxide ring. Our experiments, however, indicated that the reagent might become a dominant factor in determining the course of the reaction. It became desirable to check Spring and Swain's experiments with benzoyl chloride in pyridine. Using α-cholesterol oxide, its acetate and benzoate, and β-cholesterol oxide, the products again were derivatives of 5-hydroxy-6-chlorocholestane (III). In the reaction of β-cholesterol oxide, a new substance was obtained together with 3-benzoxy-5-hydroxy-6-chlorocholestane. The new product has a m. p. of 197–198° and gave a sharp depression with the 3-benzoxy chlorohydrin obtained above. It was not, however, the expected dibenzoate of 3,6-dihydroxy-5-chlorocholestane, since that compound has a melting point of 184°. Work is in progress to elucidate its structure.

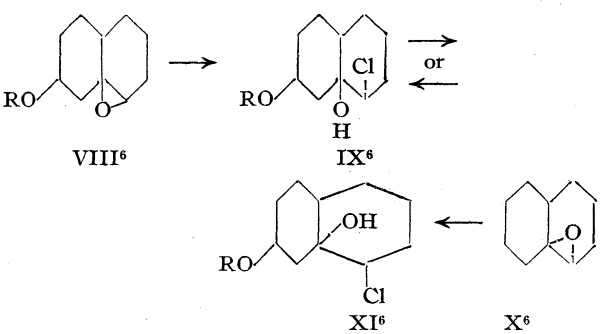
Thus Spring and Swain obtained 5-hydroxy-6-chloro compounds from the α-oxide series and 5-chloro-6-hydroxy derivatives from the β-oxides, while we could isolate only one type, regardless of which oxide we used. Since the experimental procedures were basically similar, this discrepancy, at the moment, seems difficult to explain.

Mild saponification of 3-acetoxy-5-hydroxy-6-chlorocholestane (III, R = Ac) with sodium carbonate gave α-cholesterol oxide, m. p. 141°. This is in accordance with the work of Spring and Swain,[13] who obtained α-cholesteryl oxide benzoate by heating 3-benzoxy-5-hydroxy-6-chlorocholestane (III, R = Bz) with quinoline. Previously Windaus[14] had reported that the 5-chloro compound, 3,6-dihydroxy-5-chlorocholestane, forms β-cholesterol oxide when treated with alkali.

The stereochemical aspects of these reactions should be pointed out. In the above case, for example, an oxide with a β-configuration (V) combined with the elements of hydrogen chloride to form a 5-hydroxy-6-chloro compound (VI),



which, on losing hydrogen chloride, gave an oxide of the opposite configuration (VII). Windaus[14] started with an α-oxide and obtained a 5-chloro-6-hydroxycholestane derivative which lost halogen acid and formed a β-oxide. Furthermore, we have obtained the same chlorohydrin from oxides of different configuration. The current theory states that in the cleavage of an oxide linkage a *trans*-compound is formed.[15] However, if an α-oxide (VIII) forms a *trans*-5-hydroxychlorohydrin (IX), and a β-oxide (X) similarly produces a *trans*-5-hydroxy compound (XI), then the two will neces-



sarily be of opposite configuration at C_5,C_6. Even assuming that the α-oxide may give a 5-hydroxy-6-chloro derivative of a geometrical configuration different from IX, then the β-oxide, following the same route, would still give the opposite stereoisomer. Thus, it is necessary to postulate additional Walden inversions in one case but not in the other or an entirely different mechanism to explain how the same steric configuration is obtained by cleavage of the stereoisomeric oxides of cholesterol, or how the stereoisomers are interconverted through an intermediate chlorohydrin.

Further studies on the oxides of cholesterol will be reported in a subsequent communication.

Experimental[16]

Monoperphthalic acid was prepared according to the method of Böhme[5] and kept in the refrigerator for as long as a month without appreciable decomposition.

β- and α-Cholesteryl Oxide Acetates.—Ten grams (0.023 mole) of cholesteryl acetate, m. p. 112–114°, dissolved in 50 cc. of ether, was mixed with 8.4 g. (0.046 mole) of monoperphthalic acid in 266 cc. of ether. The solution was allowed to reflux for six hours and the solvent removed by distillation. The residue was dried *in vacuo* and digested with 250 cc. of chloroform dried over potassium carbonate. Filtration gave a residue of 6.7 g. (87% recovery) of phthalic acid and a clear colorless solution which was taken to dryness *in vacuo*. The residue was crystallized from 30 cc. of methanol, giving 6.0 g. (58%) of β-cholesteryl oxide acetate, which on recrystallization from methanol gave the pure product, m. p. 111–112°, $[\alpha]^{25}D$ −21.8°; mixed m. p. with cholesteryl acetate, 97–101°. Concentration of the filtrate gave 1.55 g. (15%) of α-cholesteryl oxide acetate. The α-isomer was purified by crystallization from ethanol and found to have a m. p. of 101–103°, $[\alpha]^{25}D$ −44.6°. The m. p. is 5° higher than previously reported values.[2,10] However, it gave a depression (m. p. 88–104°) when mixed with pure β-oxide acetate. Saponification with methanolic potassium hydroxide and crystallization from dilute alcohol gave α-cholesterol oxide, m. p. 141–143°, $[\alpha]^{25}D$ −44.5°.[2]

In several runs the reaction mixture was left over the week-end. The yield of oxides in these instances was very poor and a considerable amount of alkali soluble substance was formed. Since this product remained dissolved in alkali after saponification, it is assumed to be a 5-half-phthalate derivative of cholestane.

α-Cholesteryl oxide benzoate was similarly prepared. Cholesteryl benzoate (16.7 g., 0.034 mole) reacting with perphthalic acid (12.7 g., 0.07 mole) gave 8.7 g. (50%) of α-cholesteryl oxide benzoate, m. p. 164–166°, $[\alpha]^{25}D$ −28.0.[4] No β-oxide benzoate could be isolated.

α-Cholesterol Oxide.—In the same manner, 5 g. (0.013 mole) of cholesterol (Wilson) and 4.7 g. (0.026 mole) of perphthalic acid gave 3.1 g. (61%) of α-cholesterol oxide, m. p. 141–143°. A small amount of the β-isomer was obtained from the mother liquors.

β-Cholesterol oxide, m. p. 105–107°, $(\alpha)^{25}D$ −12.7, was also obtained by saponification of the β-oxide acetate.

Reaction of β-Cholesteryl Oxide Acetate with Semicarbazide Hydrochloride.—A solution of 2.3 g. of β-cholesteryl oxide acetate in 10 cc. of pyridine was treated with 2.0 g. of semicarbazide hydrochloride and warmed on the steam-bath for six hours. The solution was concentrated to half its volume and poured over crushed ice. The precipitate was separated by filtration, digested with methanol, and filtered while hot to remove a small amount of disemicarbazide. Concentration and cooling gave colorless needle-like crystals, m. p. 183–186°, which gave a strong Beilstein test. These were combined with crystals recovered from the mother liquor and recrystallized twice from dilute acetone, giving 0.8 g. of cholesteryl acetate chlorohydrin, m. p. 187.5–189.5°.

Anal. Calcd. for $C_{29}H_{49}O_3Cl$: C, 72.4; H, 10.3; Cl, 7.38. Found: C, 72.2; H, 10.1; Cl, 7.31.

(16) Microanalyses by H. Emerson and W. Struck.

A portion (200 mg.) of the chlorohydrin, refluxed for fifteen minutes with acetic anhydride, was recovered unchanged, hence it was characterized as 3-acetoxy-5-hydroxy-6-chlorocholestane (III).

β-Oxide Acetate and Ferric Chloride.—β-Oxide acetate (0.40 g.) was treated with 1.0 g. of ferric chloride in alcohol. The solution was allowed to reflux for three hours, then concentrated to half its volume and water added. Ether extraction and isolation in the usual manner gave a chlorohydrin which was purified by repeated crystallization from dilute methanol and dilute acetone. The final product melted at 183–185°, and was recovered unchanged after refluxing with acetic anhydride. There was no depression of the m. p. on admixture with authentic 3-acetoxy-5-hydroxy-6-chlorocholestane.

β-Oxide Acetate and Benzoyl Chloride. 1. In Pyridine.—To a solution of 0.45 g. of β-cholesteryl oxide acetate in 5 cc. of dry pyridine was added 0.5 cc. of benzoyl chloride. The mixture was allowed to stand at room temperature for one-half hour, then heated on the steam-bath for the same period. The solution was poured into ice water and the semi-crystalline precipitate separated by decantation. Crystallization from dilute methanol gave 0.42 g. of chlorohydrin, m. p. 150–161°. Two recrystallizations from dilute acetone gave 0.25 g. of 3-acetoxy-5-hydroxy-6-chlorocholestane, m. p. 183–185°, which showed no depression of the m. p. on admixture with the product of the semicarbazide hydrochloride reaction.

Anal. Calcd. for $C_{29}H_{49}O_3Cl$: C, 72.4; H, 10.3; Cl, 7.38. Found: C, 72.3; H, 10.7, Cl, 7.26.

The compound was recovered unchanged after refluxing with acetic anhydride.

2. In Carbon Tetrachloride.—A solution of 0.60 g. of β-oxide acetate in 30 cc. of carbon tetrachloride distilled over potassium carbonate was treated with 0.50 cc. of benzoyl chloride under anhydrous conditions. The solution was allowed to reflux for three hours, then kept at room temperature for thirty-six hours. After distilling the solvent, the excess benzoyl chloride was removed *in vacuo*. Crystallization from dilute methanol gave a product which sintered at 100° and melted at 135–155°. A Beilstein test for halogen was positive. Four crystallizations from dilute acetone gave colorless needles of 3-acetoxy-5-hydroxy-6-chlorocholestane, m. p. 182–185°. There was no depression of the m. p. on admixture with an authentic sample.

Anal. Calcd. for $C_{29}H_{49}O_3Cl$: C, 72.4; H, 10.3; Cl, 7.38. Found: C, 72.3; H, 10.2; Cl, 7.17.

β-Oxide Acetate and "Pyridine Hydrochloride."—**"Pyridine Hydrochloride"** was prepared by passing dry hydrogen chloride into a solution of pyridine in ether and allowing the saturated solution to stand for one-half hour. The white solid was separated by filtration and found to be very hygroscopic. It is insoluble in dioxane and petroleum ether and soluble in alcohol. Crystallization from absolute alcohol–ether gave colorless platelets, m. p.: s. 81; m. 141–146°. It can be kept for months in a desiccator over calcium chloride with no evidence of decomposition.

To a solution of 1.0 g. of β-cholesteryl oxide acetate in 30 cc. of absolute ethanol was added 1.0 g. of pyridine hydrochloride. The solution was allowed to reflux for fifteen

minutes, then concentrated to half its volume and the sterol precipitated by the addition of water. Crystallization from dilute acetone gave 0.85 g. (77%) of crude 3-acetoxy-5-hydroxy-6-chlorocholestane, m. p. 148–168°. A Beilstein test was positive. After several crystallizations from dilute acetone, colorless needles, m. p. 184–186° were obtained. The product was recovered unchanged after treatment with acetic anhydride, and gave no depression in m. p. on admixture with authentic 3-acetoxy-5-hydroxy-6-chlorocholestane.

Reaction of Pyridine Hydrochloride with the Other Oxides of Cholesterol.—**α-Cholesteryl oxide benzoate** is sparingly soluble in alcohol, so it was necessary to dissolve it in benzene. One gram of the oxide in benzene was mixed with 2.0 g. of pyridine hydrochloride in ethanol. The solution was refluxed for fifteen minutes, the solvent evaporated, and the reaction product crystallized from methanol as a halogen containing compound, m. p. 193–196°. Recrystallization from ethyl acetate–methanol, and dilute acetone gave 0.60 g. (56%) of 3-benzoxy-5-hydroxy-6-chlorocholestane, m. p. 196–198°. It was recovered unchanged after refluxing with acetic anhydride.

Anal. Calcd. for $C_{34}H_{51}O_3Cl$: C, 75.2; H, 9.46; Cl, 6.53. Found: C, 75.0; H, 9.40; Cl, 6.33.

α-Cholesteryl oxide acetate (0.80 g.) and 1.0 g. of pyridine hydrochloride in alcohol gave 0.65 g. (74%) of 3-acetoxy-5-hydroxy-6-chlorocholestane, m. p., and mixed m. p., 185–187°. It was recovered unchanged after treatment with acetic anhydride.

α- and β-Cholesterol oxides also reacted smoothly with pyridine hydrochloride. However, the product lost halogen easily, thereby hindering its purification. Thus 0.30 g. of the **α-oxide** gave 0.25 g. of crude chlorohydrin, m. p. 154–160°; Beilstein test positive. Recrystallization from methanol–acetone gave feathery needles, m. p. 99–105°. This product no longer contained halogen.

Benzoylation of the crude product gave an easily purifiable substance. Using 0.45 g. of α-oxide and 1.0 g. of pyridine hydrochloride, a chlorohydrin was obtained. It was dried and benzoylated with 0.50 cc. of benzoyl chloride in pyridine. The product was isolated in the usual way and crystallized from ethyl acetate–methanol, giving 0.35 g. (58%) of 3-benzoxy-5-hydroxy-6-chlorocholestane, m. p. 193–196°. Recrystallization from dilute acetone, and again from ethyl acetate–methanol, gave colorless needles, m. p. 196–198°, which showed no depression on admixture with an authentic sample.

Similarly, from 0.40 g. of the **β-oxide** there was obtained 0.28 g. (52%) of 3-benzoxy-5-hydroxy-6-chlorocholestane, m. p. 192–195°. When mixed with an authentic sample the m. p. was not depressed.

Reaction of Benzoyl Chloride with the Other Oxides of Cholesterol.—Reactions with benzoyl chloride did not proceed as smoothly as the corresponding reactions with pyridine hydrochloride and the products were less pure. Treatment of 0.70 g. of **α-oxide** acetate with 0.60 cc. of benzoyl chloride gave 0.42 g. (55%) of a product, m. p. 160–170°. After heating with acetic anhydride and recrystallizing twice from dilute acetone, 3-acetoxy-5-hydroxy-6-chlorocholestane was obtained as colorless needles, m. p. 178–183°. A mixed m. p. with authentic acetoxychlorohydrin, however, was 179–184°.

Anal. Calcd. for $C_{29}H_{49}O_3Cl$: C, 72.4; H, 10.3. Found: C, 72.6; H, 10.1.

Starting with 0.50 g. of **α-oxide benzoate**[4] and 0.50 cc. of benzoyl chloride, 0.45 g. (84%) of 3-benzoxy-5-hydroxy-6-chlorocholestane, m. p. 191–195°, was obtained. Recrystallization from dilute acetone gave a pure product, m. p. 197–198.5°. A mixed m. p. with authentic benzoate chlorohydrin gave no depression.

Anal. Calcd. for $C_{34}H_{51}O_3Cl$: C, 75.2; H, 9.46; Cl, 6.53. Found: C, 75.0; H, 9.29; Cl, 6.46.

Using 0.15 g. of **α-cholesterol oxide** and 0.20 cc. of benzoyl chloride, the benzoate chlorohydrin was obtained in fair yield. After several recrystallizations its m. p. and mixed m. p. with authentic 3-benzoxy-5-hydroxy-6-chlorocholestane was 193–196°.

The reaction of **β-cholesterol oxide** with benzoyl chloride was also carried out according to Spring and Swain.[4] The results were, however, different, so the details of the experiment are given. The β-oxide (0.30 g.) in 4 cc. of dry pyridine was warmed for an hour with 0.50 cc. of benzoyl chloride. The solution was poured into ice-water and the precipitate separated by filtration. The residue was crystallized from 30 cc. of acetone–methanol, giving 0.15 g. of 3-benzoxy-5-hydroxy-6-chlorocholestane, m. p. 190–193°. Recrystallizations from acetone–methanol and dilute acetone brought the m. p. up to 195–197°.

Anal. Calcd. for $C_{34}H_{51}O_3Cl$: C, 75.2; H, 9.46; Cl, 6.53. Found: C, 74.9; H, 9.50; Cl, 6.47.

Concentration of the first mother liquor gave 0.14 g. of a crystalline compound, m. p. 176–182°. It was recrystallized twice from acetone–methanol, in which it seemed to be more soluble than the previously obtained benzoate chlorohydrin. It had a m. p. of 197–198°, and its mixed m. p. with authentic 3-benzoxy-5-hydroxy-6-chlorocholestane was 179–186°. This compound is not 3,6-dibenzoxy-5-chlorocholestane.

Anal. Calcd. for 3,6-dibenzoxy-5-chlorocholestane, m. p. 184°, $C_{41}H_{55}O_4Cl$: Cl, 5.48. Found: Cl, 7.01, 7.11.

α-Oxide from 5-Hydroxy-6-chlorocholestane Derivatives.—A solution of 0.7 g. of 3-acetoxy-5-hydroxy-6-chlorocholestane in 30 cc. of dilute alcohol was treated with 10 cc. of 2 *N* sodium carbonate and warmed on the steam-bath for thirty minutes. The addition of water gave a precipitate of 0.40 g. of **α-cholesteryl oxide** which was recrystallized twice from ethyl acetate, m. p. 141–143°. A mixed m. p. with an authentic sample of α-oxide showed no depression.

A similar reaction was carried out with 3-benzoxy-5-hydroxy-6-chlorocholestane and methanolic potassium hydroxide, again giving α-cholesterol oxide, m. p. 141–143°.

Summary

α- and β-cholesterol oxide, α- and β-cholesteryl oxide acetate and α-cholesteryl oxide benzoate have been conveniently prepared through the action of perphthalic acid on cholesterol and its derivatives.

Semicarbazide hydrochloride and ferric chloride react with β-cholesteryl oxide acetate to form 3-acetoxy-5-hydroxy-6-chlorocholestane.

All five of the cholesteryl oxides prepared react with "pyridine hydrochloride" and benzoyl chloride to give 5-hydroxy-6-chlorocholestane derivatives.

β-Cholesterol oxide, as its acetate, has been converted to α-cholesterol oxide through the 5-hydroxy-6-chloro compound.

The stereochemical implications of these reactions have been pointed out.

Synthesis of *p*-Hydroxyphenyl Amyl Sulfide

BY ELLIS MILLER, FRANK S. CROSSLEY AND MAURICE L. MOORE

A previous publication from these Laboratories[1] confirmed the report[2] that the hydroxyphenyl alkyl sulfides were more powerful in their bactericidal activity than the corresponding alkylphenols. These results prompted us to seek a practical method for the preparation of *p*-hydroxyphenyl *n*-amyl sulfide, which had been shown to possess maximum activity for the compounds in this series.

The hydroxydiphenyl sulfides have been prepared by Hilbert and Johnson[3] by use of the Ziegler[4] reaction between diazotized anisidine and thiophenol. The diazothio ether thus formed breaks down at 70° to give a methoxydiphenyl sulfide which is converted into the desired product by dealkylation. They reported that an attempt to prepare *p*-hydroxydiphenyl sulfide by treating diazotized *p*-aminophenol with sodium thiophenate was unsuccessful. Suter and Hansen[2] treated diazotized anisidine with potassium ethyl xanthate and decomposed the intermediate diazonium ethyl xanthate to obtain *p*-methoxythiophenol which then reacted with amyl bromide and the product was dealkylated to give *p*-hydroxyphenyl *n*-amyl sulfide. They also reported an unsuccessful attempt to combine the sodium salt of butanethiol-1 with diazotized *p*-aminophenol.

In the previous publication,[1] a more satisfactory procedure was developed which involved the synthesis of thiohydroquinone and subsequent reaction of this with amyl bromide to give the desired *p*-hydroxyphenyl *n*-amyl sulfide. The success of the thiohydroquinone synthesis suggested that diazotized *p*-aminophenol should react with the sodium salt of *n*-amyl mercaptan, even though previous workers[2,3] had been unsuccessful with similar reactions. An extensive study of possible experimental conditions for the reaction has shown that it can be used to prepare the compound in yields of 25–30%.

The diazotization was carried out at a temperature of 0–10° and the diazothio ether decomposed by heating at 60°. The resulting product was distilled and gave a yield of 50–60% of a material which solidified at room temperature. However, on crystallizing the material from solvent naphtha the yield of *p*-hydroxyphenyl *n*-amyl sulfide dropped to 25–30%. Careful fractionation of the reaction mixture disclosed that two definite products were formed during the reaction and permitted the isolation of the second product with its purification. The product was identified by preparation of derivatives and synthesis as di-*n*-amyl disulfide. The reaction has been applied to *n*- and isoamyl mercaptan with comparable results.

Experimental Part

***p*-Hydroxyphenyl *n*-Amyl Sulfide.**—*p*-Aminophenol, 21.8 g. (0.2 mole), was dissolved in 110 cc. of 4 *N* hydrochloric acid (0.44 mole) and diazotized in the usual manner by the slow addition of a solution of 15 g. (0.23 mole) of sodium nitrite in 30 cc. of water. The mixture was stirred until the diazotization was complete (starch–iodide paper test) and the deep purple solution of *p*-hydroxyphenyldiazonium chloride rapidly filtered from a small amount of insoluble material. The solution was then added slowly to a cold (10°) sludge of 24 g. (0.23 mole) of *n*-amyl mercaptan in 75 cc. of water containing 37.5 g. (0.94 mole) of sodium hydroxide. The temperature was maintained at 10° throughout the addition and frothing was controlled by the addition of small amounts of *n*-butanol. After the reaction had subsided, the cooling bath was removed and stirring continued at room temperature until the diazonium salt disappeared (R-salt test). The mixture was then heated to 60° to complete the decomposition of the diazothio ether and allowed to stand overnight at room temperature, after which it was diluted with five volumes of water, acidified with concentrated hydrochloric acid and extracted with 500 cc. of toluene. The extract was washed three times with 500-cc. portions of water, dried over anhydrous

(2) Suter and Hansen, *ibid.*, **54**, 4100 (1932).
(3) Hilbert and Johnson, *ibid.*, **51**, 1526 (1929).
(4) Ziegler, *Ber.*, **23**, 2469 (1890).

sodium sulfate, and the toluene removed by distillation at atmospheric pressure. The residue was distilled rapidly at about 2 mm. pressure to separate the distillable portion (20 g. of orange-yellow oil which solidified on standing) from a heavy tar. A slow redistillation of this product gave 16 g. of a light yellow oil, boiling over a range of 110–140° (1 mm.), which solidified immediately.

Material (120 g.) from several of the above runs was carefully fractionated, through a 12″ indented column, insulated with a glass air-jacket, into two main fractions:

Fraction A, 45 g., b. p. 89–91° (1 mm.), $n^{20}D$ 1.4876, d^{25}_{25} 0.9224, was identified as di-*n*-amyl disulfide.[5] Reduction with metallic sodium in anhydrous ethanol[6] gave a solid sodium salt of *n*-amyl mercaptan which reacted with 2,4-dinitrochlorobenzene on refluxing in anhydrous ethanol to give 2,4-dinitrophenyl *n*-amyl sulfide, m. p. 79.5–80°, identical with the product, m. p. 80°, prepared from *n*-amyl mercaptan,[7] and by the reduction of synthetic di-*n*-amyl disulfide. The material also readily formed a crystalline derivative, m. p. 134–136°, which resolidified and did not remelt up to 250°, when treated with mercuric chloride in an alcohol solution at room temperature for seven hours which was identical with the derivative from synthetic di-*n*-amyl disulfide.

Fraction B, 45 g., b. p. 142–145° (1 mm.), was recrystallized twice from solvent naphtha and gave 37 g. of *p*-hydroxyphenyl *n*-amyl sulfide, m. p. 62–62.5°.[1]

p-Hydroxyphenyl isoamyl sulfide,[1] a red oil, b. p. 134–136° (1 mm.), $n^{25}D$ 1.5523, was prepared by the above reaction using isoamyl mercaptan and di-isoamyl disulfide, b. p. 94–96° (1 mm.), isolated as the by-product.

Di-*n*-amyl Disulfide.—(A) This compound was prepared by the method described in "Organic Syntheses" for *p,p'*-dinitrodiphenyl disulfide.[8] To 180 g. (0.75 mole) of sodium sulfide, dissolved in 750 cc. of 95% ethanol with refluxing, was added 24 g. (0.75 atom) of sulfur and the mixture stirred until dissolved. *n*-Amyl bromide, 151 g. (1 mole), dissolved in 250 cc. of 95% ethanol, was placed in a two-liter, three-necked flask, and the hot sodium disulfide solution was added at such a rate as to maintain gentle refluxing.[9] The addition was complete in about twenty minutes and the mixture refluxed on the steam-bath for three hours, after which it was allowed to stand overnight at room temperature. Alcohol was removed to about one-third volume by distilling at reduced pressure (water pump), two volumes of water added and the mixture extracted with 500 cc. of benzene. The extract was washed several times with water, dried over anhydrous sodium sulfate, and, after removing the benzene, the di-*n*-amyl disulfide distilled through the 12″ column as a colorless liquid, b. p. 90–92° (1 mm.); yield 62 g., $n^{25}D$ 1.4875; d^{25}_{25} 0.9212.

(B) *n*-Amyl mercaptan, 52 g. (0.5 mole), was dissolved in a solution of 22 g. (0.55 mole) of sodium hydroxide in 125 cc. of water and oxidized by the addition of 60.3 g. (0.475 atom) of iodine in small portions over a period of twenty minutes according to the method of Kekulé and Linnemann[10] for the preparation of diethyl disulfide. The mixture was stirred until all of the iodine dissolved and then extracted with 200 cc. of benzene. The extract was washed three times with water, dried over anhydrous sodium sulfate and the benzene removed by distillation. The yield of di-*n*-amyl disulfide was 36 g., b. p. 101–103° (2 mm.), $n^{25}D$ 1.4868.

Summary

p-Hydroxyphenyl *n*-amyl sulfide has been prepared in yields of 25–30% by the diazotization of *p*-aminophenol, coupling with sodium *n*-amyl mercaptide, and decomposition of the diazothio ether. A second product was obtained from this reaction in a yield of 25% and has been identified as di-*n*-amyl disulfide by preparation of derivatives and synthesis.

p-Hydroxyphenyl isoamyl sulfide was prepared in the same manner and di-isoamyl disulfide obtained as a second product.

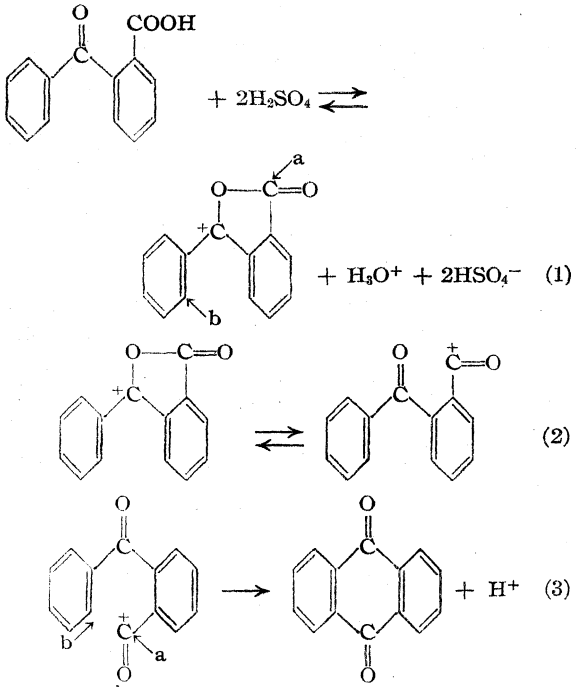
A Mechanism for the Formation of Anthraquinone from *o*-Benzoylbenzoic Acid

BY MELVIN S. NEWMAN

The facile ring closure of *o*-benzoylbenzoic acid to anthraquinone under the influence of sulfuric acid has never been satisfactorily explained.[1] Although ring closure condensations with acids of the *o*-benzylbenzoic and γ-arylbutyric type take place fairly readily in sulfuric acid, anthraquinone formation remains a reaction unique in organic chemistry. The ease and the high yield with which this condensation takes place ortho to a ketonic function are indeed remarkable.

It is the object of this communication to present a plausible mechanism for the formation of anthraquinone from *o*-benzoylbenzoic acid. The proposed mechanism is outlined in the following equations.



Arguments Advanced in Favor of the Proposed Mechanism

Equation 1.—The chief support for equation 1 was obtained in the following experiments.

A. A solution of 5.0 g. of *o*-benzoylbenzoic acid in 98–99% sulfuric acid was poured into 500 cc. of absolute methanol in a one-liter Claisen flask. During this addition the flask was cooled externally by ice-water and internally by dry-ice. About 300 cc. of methanol was rapidly removed under reduced pressure at low temperature and the residue was poured on ice. The organic matter was rapidly taken into ether and separated into acid and neutral fractions by sodium carbonate extraction. From the acid fraction was isolated 1.48 g. (30%) of *o*-benzoylbenzoic acid. The neutral fraction consisted of 3.17 g. (60%) of a mixture of the normal and pseudo methyl esters of *o*-benzoylbenzoic acid. This mixture was analyzed by dissolving in 32 cc. of 98–99% sulfuric acid and pouring on ice. After such treatment it is known that the normal ester is recovered unchanged while the pseudo ester is converted into *o*-benzoylbenzoic acid.[2] By this means the 3.17 g. of mixed esters was converted into 1.19 g. (40%) of *o*-benzoylbenzoic acid and 1.78 g. (56%) of methyl *o*-benzoylbenzoate, thus indicating that the ester mixture consisted of 40% of pseudo ester and 56% normal ester.

B. This experiment was carried out just as experiment A, except that instead of dissolving *o*-benzoylbenzoic acid in sulfuric acid and pouring into cooled methanol, 60 cc. of 98–99% sulfuric acid was poured into a solution of 5.0 g. of the pseudo methyl ester of *o*-benzoylbenzoic acid in 500 cc. of methanol. There was then obtained 0.18 g. (3.6%) of *o*-benzoylbenzoic acid and 4.92 g. (92.5%) of mixed esters which, by analysis as above, was shown to consist of 35% of pseudo ester and 63% of normal ester.

Before drawing any conclusions from these experiments, it is desirable to point out certain facts. From the studies cited by Hammett,[3] it seems well established that most organic acids behave as monoacid bases on ionization in solvent sulfuric acid, as follows

$$RCOOH + H_2SO_4 \rightleftharpoons RCO_2H_2^+ + HSO_4^- \quad (4)$$

When sulfuric acid solutions of such acids are poured into absolute methanol, no appreciable amount of esterification occurs other than the slow normal acid catalyzed esterification.[4] Likewise, when sulfuric acid solutions of the methyl esters of such acids are poured into water, the methyl esters are recovered almost completely unchanged.[4,5] The normal methyl ester of *o*-benzoylbenzoic acid represents such an ester.

Certain acids, chiefly 2,4,6-trialkylbenzoic acids, ionize in sulfuric acid in a more complex way,[3b] as follows

(1) Gleason and Dougherty, THIS JOURNAL, **51**, 310 (1929), and Fieser, "Experiments in Organic Chemistry," D. C. Heath and Co., New York, N. Y., 1935, p. 189, discuss briefly the possibility of cyclic intermediates.

$$RCOOH + 2H_2SO_4 \rightleftharpoons R{-}\overset{+}{C}{=}O + H_3O^+ + 2HSO_4^- \quad (5)$$

When sulfuric acid solutions of such acids are poured into methanol, almost complete esterification takes place.[4] Similarly when sulfuric acid solutions of the methyl esters of such acids are poured into water the free acid is obtained.[4,5] The pseudo methyl ester of *o*-benzoylbenzoic acid represents such an ester.

Since *o*-benzoylbenzoic acid is largely esterified by dissolving in sulfuric acid and pouring into methanol (experiment A) it seems quite likely that in sulfuric acid solution *o*-benzoylbenzoic acid ionizes according to equation 1. The cyclic form of the positive ion is the preferred structure as indicated because the pseudo methyl ester is formed on pouring the sulfuric acid solution into methanol. The fact that the ester isolated after such treatment contains a large amount of normal ester should not confuse the picture because experiment B shows that during the isolation of the reaction products considerable isomerization of pseudo ester to normal ester occurs. Furthermore, no cyclic ester could have been formed from the normal ester or from free *o*-benzoylbenzoic acid because the normal ester is stable in acid methanol and is the ester formed on acid catalyzed esterification of *o*-benzoylbenzoic acid.[2,6] To summarize briefly, then, the fact that *o*-benzoylbenzoic acid is largely esterified on pouring its sulfuric acid solution into methanol constitutes evidence that *o*-benzoylbenzoic acid undergoes a complex ionization in solvent sulfuric acid. Furthermore, the fact that the pseudo ester is first formed on pouring a sulfuric acid solution of *o*-benzoylbenzoic acid into methanol indicates that the positive ion present in the sulfuric acid solution is cyclic in nature, as shown in equation 1.

(6) Plaskuda, *Ber.*, **7**, 987 (1874); Haller and Guzot, *Bull. soc. chim.*, (3) **25**, 54 (1901); H. Meyer, *Monatsh.*, **25**, 475 (1904).

Equations 2 and 3.—Since great chemical reactivity is generally associated with positive ions in organic molecules, it would appear strange that such an ion as indicated in equation 1 did not immediately react to form anthraquinone. However, it is a fact that sulfuric acid solutions of *o*-benzoylbenzoic acid must be heated before anthraquinone is formed to any appreciable extent. Recourse to atomic models shows that in a cyclic form carbon atom *a* is far removed from carbon atom *b* with which it must join to form anthraquinone. It seems necessary, therefore, to postulate that the cyclic positive ion on heating absorbs energy and cleaves to a new open chain acyl ion of higher energy content (equation 2). This acyl ion can then rotate so that carbon atom *a* approaches carbon atom *b*. At some stage a proton is lost from carbon *b*, a new carbon–carbon link is formed between carbons *a* and *b*, and anthraquinone results (equation 3).

With the above mechanism as a working hypothesis, it is proposed to study the rate of anthraquinone formation under various conditions and to study, if possible, the effect of substituents on steps 1, 2 and 3.

Summary

A mechanism for the formation of anthraquinone from *o*-benzoylbenzoic acid in sulfuric acid is proposed. Experimental evidence in favor of the proposed mechanism is presented.

Studies on Argentine Plants. V.[1] Identification and Characterization of Some Alkaloids in Fagara Coco (Gill) Engl.

BY V. DEULOFEU, R. LABRIOLA AND J. DE LANGHE

In 1925 Stuckert[2] and his collaborators undertook the isolation of alkaloids from the leaves and young twigs of *Fagara coco* (Gill) Engl., a tree growing in central and northern Argentina and in Bolivia, and which apparently has been used in those regions as a drug. They obtained several crystalline substances of which the three best characterized were named and described as follows: α-fagarine, $C_{18}H_{22}NO_4$, m. p. 169°; β-fagarine, $C_{12}H_{26}NO_6$, m. p. 176°; and γ-fagarine, $C_{15}H_{15}NO_3$, m. p. 139°. At Stuckert's request, Merck and Company (Darmstadt) carried out a large-scale preparation of alkaloids from *Fagara coco* and isolated: fagarine I, melting at 163°, $C_{19}H_{23}NO_5$ which is probably identical with Stuckert's α-fagarine, and fagarine II, apparently new, which melted at 202° and had a composition corresponding to $C_{18}H_{20}NO_4$.

By extraction and purification of the alkaloids from the end twigs and leaves of a sample of *Fagara coco* kindly supplied to us by Dr. Stuckert, we have obtained three well-defined substances corresponding to the α, β and γ-fagarines mentioned above. Revised formulas and melting points are given in the experimental part. In addition, small fractions of a higher-melting material which may correspond to Merck fagarine II have been obtained, but not in sufficient quantity for complete purification.

Our investigation of the properties of these alkaloids shows that two of them bear a very close relationship to substances already described in the literature. β-Fagarine is identical with skimmianine which was discovered by Honda[3] in *Skimmia japonica*, a plant belonging like *Fagara* to the family of Rutaceae. The structure of skimmianine has been established by Asahina and Inubuse[4] who showed that this alkaloid is a dimethoxy derivative of *dictamine* which was found by Thoms[5] in *Dictamus albus* and by Asahina, Ohta and Inubuse[6] in *Skimmia repens*. The identity of β-fagarine and skimmianine is proved by the close correspondence of their melting points and the melting points of a series of six derivatives and degradation products which were prepared from β-fagarine by the present authors according to the method originally described by Asahina for skimmianine.

COMPARISON OF PROPERTIES

Substance	Melting points, °C. From β-fagarine	From skimmianine[4]
Free base, $C_{14}H_{13}NO_4$	178	176
Picrate of base, $C_{14}H_{13}NO_4 \cdot C_6H_4N_3O_6$	195	195–197
Iso-skimmianine, $C_{14}H_{13}NO_4$	188–9	185
Dimethoxy-isoskimmianine	218–220	218
Skimmianic acid	248	248
Skimmianal	238	238
2,4-Dihydroxy-7,8-dimethoxyquinoline	250	250

It is recommended that the name β-fagarine be eliminated and the name skimmianine be used henceforth.

γ-Fagarine apparently has not been described under another name and the retention of the present term is therefore recommended. Nevertheless, this alkaloid is very similar to skimmianine, from which it differs by having one less methoxyl group. It forms a series of derivatives and degradation products entirely analogous to those described for skimmianine but not identical. On oxidation by permanganate, γ-fagarine yields γ-fagaric aldehyde and γ-fagaric acid. The latter, which also is derived from the aldehyde by further oxidation, on decarboxylation yields a 2,4-dihydroxymethoxyquinoline in which the position of the methoxyl group is unknown. Since none of the four isomeric dihydroxymethoxyquinolines has yet been synthesized, we have begun their synthesis in order to make these key reference compounds available for direct comparisons.

α-Fagarine is a substance quite different from these compounds and since it has not been de-

scribed under another name as far as we know, we recommend retaining the present term. We have assigned to it the formula $C_{13}H_{21}NO_4$. Of the four oxygens, two belong to the methoxyl groups. It possesses a methylimino group and is a stronger base than skimmianine or γ-fagarine from which it may be separated easily by exploiting this difference. Preliminary experiments indicate that its behavior with methyl iodide or oxidizing agents is completely different from that of the other two bases. We are continuing its investigation.

Experimental Part

Acid Extraction.—Ten kg. of leaves and twigs of *Fagara coco* was soaked for four days in 60 liters of 10% hydrochloric acid, and this extraction was twice repeated at four-day intervals. On evaporation *in vacuo* to about 10 l., a precipitate formed which was filtered off and freed from alkaloids by repeated maceration with 20% hydrochloric acid. The combined alkaloidal extract was neutralized with dilute sodium hydroxide and extracted with trichloroethylene. The washed extract was evaporated to dryness and the residue was extracted repeatedly with 13% hydrochloric acid. The combined acid extracts were neutralized and extracted with chloroform. The residue from the washed chloroform extract was again extracted with 13% hydrochloric acid. This acid extract was treated with dilute sodium hydroxide until the weaker bases precipitated at *p*H 3.5–4.0. After twenty-four hours, the precipitate containing skimmianine and γ-fagarine was recrystallized from alcohol yielding skimmianine. Concentration of the mother liquors gave a product, 120–150°, in which γ-fagarine predominates and from which it can be crystallized in large prisms from alcoholic solution.

The alkaline mother liquor was brought to *p*H 9 with sodium hydroxide and exhaustively extracted with chloroform. Evaporation of the extract and recrystallization of the residue from alcohol yielded α-fagarine.

Acid extraction of 10 kg. of leaves gave 54 g. of impure alkaloidal residue yielding 13 g. of skimmianine, m. p. 178°; 6 g. of γ-fagarine, m. p. 139°; and 7 g. of α-fagarine, m. p. 163°.

Alcoholic Extraction.—Two kg. of leaves was boiled first with 8 l. of 96% ethanol for four hours and the extraction repeated three times with 5-l. portions of alcohol and, finally, with a 5-l. portion of alcohol to which 250 cc. of concentrated ammonium hydroxide had been added. The combined extracts from 10 kg. of leaves, after neutralizing with hydrochloric acid and drying, gave a residue of about 1.5 kg. After cooling this was extracted with 4 successive portions of cold, dilute hydrochloric acid, the combined extracts neutralized with 30% sodium hydroxide solution and then extracted exhaustively with trichloroethylene. The residue was then extracted with 2 l. of very dilute hydrochloric acid and the combined extracts were rendered alkaline, extracted with chloroform, the product washed with water, dried, and the residue again extracted with very dilute hydrochloric acid. Water was added up to 2 l., a fine suspension removed by filtration, and sodium hydroxide slowly added to *p*H 2. At this point a precipitate which did not give the alkaloidal reaction was formed and this was removed by filtration. The *p*H of the solution was brought to 3.5–4 and the procedure was continued as given for the acid extraction. The yield from the 10 kg. of leaves was 41.5 g. of skimmianine, m. p. 178°, 2.5 g. of γ-fagarine, m. p. 139°, and 5 g. of α-fagarine, m. p. 162°.

Characterization of γ-Fagarine as a Methoxy-dictamine.—When γ-fagarine of m. p. 139° was recrystallized several times from alcohol, prismatic crystals of m. p. 142° were obtained, soluble in chloroform, benzene and ether, slightly soluble in petroleum ether, and very slightly soluble in water. Alcohol was the best solvent for recrystallization.

Anal. Calcd. for $C_{13}H_{11}NO_3$: C, 68.12, H, 4.80; N, 6.11; two methoxyl, 27.03. Found: C, 68.14, 68.39; H, 4.99, 5.11; N, 6.22; —OCH_3, 27.12, 27.09.

γ-Fagarine Picrate.—Prepared in the usual way[4] in alcohol solution and recrystallized from the same solvent, the picrate was obtained in the form of yellow needles of m. p. 177°.

Anal. Calcd. for $C_{13}H_{11}NO_3 \cdot C_6H_3N_3O_7$: N, 12.22. Found: N, 12.50.

γ-Fagarine Picrolonate.—Prepared in the usual way,[4] and recrystallized from alcohol, the picrolonate formed yellow needles melting at 174–175°.

Anal. Calcd. for $C_{13}H_{11}NO_3 \cdot C_{10}H_8N_4O_5$: N, 14.60. Found: N, 14.84.

The Rearrangement of γ-Fagarine to Iso-γ-fagarine.—A sample of 500 mg. of γ-fagarine was treated in a closed tube at 100–105° with 3 ml. of methyl iodide for three hours. When the heating was over, the solution was filtered and evaporated to dryness. The residue thus obtained was crystallized from methanol, after decolorization by carbon. There was obtained 300 mg. of colorless needles, melting at 179°.

Anal. Calcd. for $C_{13}H_{11}NO_3$: C, 68.12; H, 4.80; N, 6.11. Found: C, 67.93; H, 5.18; N, 6.36.

γ-Fagaric Aldehyde.—A sample of 800 mg. was dissolved in 60 ml. of acetone heated almost to the boiling point and a hot acetone solution of 1.6 mg. of potassium permanganate was slowly added. Oxidation occurred easily. After cooling, the manganese dioxide was filtered off, and the solution was evaporated to dryness. The residue (100 mg.), recrystallized from alcohol, yielded fine, yellow needles, melting at 185°.

Anal. Calcd. for $C_{12}H_{11}NO_4$: C, 61.80; H, 4.72. Found: C, 61.94; H, 5.08.

γ-Fagaric Aldehyde Phenylhydrazone.—The phenylhydrazone of the preceding aldehyde was prepared by heating the latter in alcohol solution for twenty minutes with a slight excess of phenylhydrazine and acetic acid. Upon addition of water at the end of heating, a precipitate was formed which was filtered off and, when recrystallized from alcohol, yielded yellow needles melting at 207°.

Anal. Calcd. for $C_{18}H_{17}N_3O_3$: N, 13.00. Found: N, 13.37.

γ-Fagaric Acid.—The manganese dioxide precipitate obtained during the oxidation of fagarine was digested with 10% sodium hydrate and filtered. The resultant solution was acidified with hydrochloric acid which yielded a precipitate of γ-fagaric acid. It was quite insoluble in ordinary organic solvents. It recrystallized from a large volume of boiling acetone to which carbon had been added. There was obtained 100 mg. of colorless needles, melting at 215°.

Anal. Calcd. for $C_{12}H_{11}NO_5$: N, 5.62. Found: N, 5.68.

The same acid was obtained by oxidizing with potassium permanganate a hot acetone solution of γ-fagaric aldehyde. The crystals obtained also melted at 215° and were not distinguishable from those obtained by direct oxidation of the base.

2,4-Dihydroxymethoxyquinoline.—A sample of 380 mg. of γ-fagaric acid was suspended in 40 ml. of dilute hydrochloric acid[7] and boiled until a clear solution was obtained. On cooling, a crystalline precipitate, melting at 225° and weighing 320 mg. was obtained. Recrystallized from alcohol, it yielded long prisms melting at 250°.

Anal. Calcd. for $C_{10}H_9NO_3$: C, 62.82; H, 4.71; N, 7.33. Found: C, 63.10; H, 5.12; H, 7.59.

(7) Strong acid of density 1.19 diluted 1:2.

Nitrous Derivatives of 2,4-Dihydroxymethoxyquinoline.—An alkaline solution of the quinoline derivative mentioned, containing the necessary amount of sodium nitrite, was poured slowly into a solution of 10% sulfuric acid with stirring. There was obtained a reddish precipitate which was filtered and was recrystallized several times from acetic acid, yielding intensely red needles which melted and decomposed at 216–217°.

Anal. Calcd. for $C_{10}H_8N_2O_4$: N, 12.72. Found: N, 13.02.

α-Fagarine.—The fraction precipitating at *p*H 9 was purified by repeated recrystallization from alcohol. Two kinds of crystals have been obtained: prismatic, melting at 163°, and octahedral, melting at 169°. Recrystallized from chloroform-petroleum ether, long prisms were obtained, melting at 169°. These are the crystals which were finally analyzed. They were soluble in benzene, chloroform, ether and acetone, slightly so in petroleum ether. When pure, they were slightly soluble in water. The substance has no optical activity.

Anal. Calcd. for $C_{18}H_{21}NO_4$: C, 68.57; H, 6.42; N, 4.44; two methoxyls, 19.68; one $-NCH_3$ group, 9.23. Found: C, 68.58, 68.47; H, 6.36, 6.25; N, 4.33, 4.28; $-OCH_3$, 18.45; $-NCH_3$, 12.80.

α-Fagarine treated for twenty minutes with 40% sulfuric acid and phloroglucinol in a boiling water-bath yielded a red precipitate which, according to Gadamer, is characteristic of dioxymethylene groups.

Summary

The study of the alkaloids in the twigs and leaves of *Fagara coco* (Gill) Engl. has confirmed the presence of those described by Stuckert as α-, β- and γ-fagarines.

β-Fagarine has been identified with skimmianine.

γ-Fagarine has been degraded to a 2,4-dihydroxymethoxyquinoline, and it has been established that it is a methoxydictamine.

α-Fagarine is a base of a different type from the preceding ones. Some of its functional groups have been determined.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE OHIO STATE UNIVERSITY]

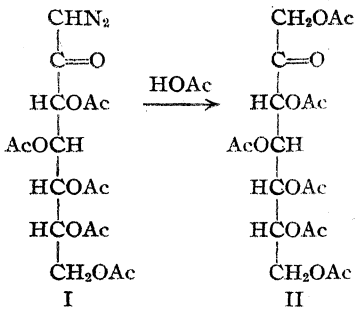
The Action of Diazomethane upon Acyclic Sugar Derivatives. III.[1] A New Synthesis of Ketoses and of their Open Chain (*keto*) Acetates

BY M. L. WOLFROM, S. W. WAISBROT AND ROBERT L. BROWN

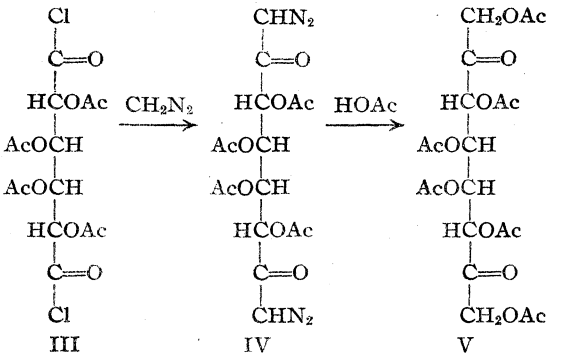
Bradley and Robinson[2] described the reaction of a diazomethyl ketone with acetic acid to produce an acetoxymethyl ketone, although analogous reactions for the acylation of diazoacetic ester had been noted earlier by Staudinger and coworkers.[3] The recent availability of the diazomethyl ketones in the sugar series[4] makes feasible the application of this reaction to the synthesis of ketoses in their open chain or *keto*-acetate structure.

The reaction was first established for the known fructose derivative and the diazomethyl ketone obtained[1] from *d*-arabonyl chloride tetraacetate and diazomethane was found to react smoothly with glacial acetic acid to produce the open chain or *keto*-form of *d*-fructose pentaacetate, a derivative that had been synthesized by Hudson and Brauns[5] by direct acetylation procedures and whose open-chain structure is established.[6] Reaction of I, designated 1-diazo-1-desoxy-*keto*-*d*-glucoheptulose pentaacetate,[4] with acetic acid produced *keto*-*d*-glucoheptulose hexaacetate (II), isomeric with and convertible (by saponification and reacetylation) to the one known cyclic hexaacetate of *d*-glucoheptulose.[7]

Utilizing the acetolysis procedure of Tambor and Du Bois,[8] 1-bromo-1-desoxy-*d*-glucoheptulose pentaacetate[1] was converted into II in somewhat lower yield than from the diazomethyl ketone I and acetic acid. This new acyclic derivative (II) exhibited no mutarotation in either chloroform or methanol solution and its ultraviolet absorption spectrum in U. S. P. chloroform revealed a pronounced absorption maximum at 2830 Å. ($\log \epsilon_{max.} = 1.60$ at 2830 Å.) which corresponds closely to the value reported by Baldwin, Wolfrom and Lowry[9] for *keto*-*d*-fructose pentaacetate ($\log \epsilon_{max.} = 1.59$ at 2830 Å.) and by Khouvine and Arragon[10] for *keto*-*l*-sorbose pentaacetate (absorption maximum at about 2800 Å.). Inasmuch as it has been shown that the cyclic acetates do not exhibit an absorption maximum in the region of that for the ketonic carbonyl group,[10] these data constitute proof that no ring closure has occurred during the series of reactions leading to the formation of the new derivatives and confirm the assignment of the acyclic or *keto* structure to our compound.



I II



The series of reactions recorded above provide a general method for the synthesis of acyclic ketose acetates and represent a transformation of an aldose to the next higher ketose. It was then of interest to apply these reactions to a dibasic sugar acid and for this purpose the long-known mucyl dichloride tetraacetate (III)[11] was selected. From III the bisdiazomethyl ketone IV was obtained. Treatment of IV with hydrogen chloride yielded

the dichloro derivative and treatment with acetic acid produced the well-crystallized diketose acetate V, designated 1,8-dihydroxy-mucyldimethane hexaacetate. This is an open chain acetate of a diketose, a new type of derivative in the sugar field.

Extension of this work is in progress in this Laboratory.

Experimental

keto-d-**Fructose Pentaacetate.**—1-Diazo-1-desoxy-*keto-d*-fructose tetraacetate[1] (1 g.) was dissolved in glacial acetic acid (25 cc.) and refluxed for one hour. The dark brown solution was poured on crushed ice, and the resulting solution was extracted with three 25-cc. portions of chloroform. The combined extracts were washed free of acetic acid with water and the solution dried. Upon solvent removal under reduced pressure, a dark sirup was obtained which was dissolved in 20 cc. of absolute ethanol, decolorized repeatedly with charcoal and concentrated under reduced pressure to 8 cc. Upon standing in the ice-chest the concentrate yielded 0.5 g. of pale yellow crystals; m. p. 63–67°. Several recrystallizations from ethanol yielded a pure product identified by melting point, mixed melting point and rotation as *keto-d*-fructose pentaacetate for which Hudson and Brauns[5] record the constants; m. p. 69–70°, spec. rot.[12] +35° ($CHCl_3$).

keto-d-**Glucoheptulose Hexaacetate** (II).—1-Diazo-1-desoxy-*keto-d*-glucoheptulose pentaacetate[4] (I, 5.0 g.) was dissolved in glacial acetic acid (100 cc.) and the solution refluxed to the cessation of nitrogen evolution (ten to fifteen minutes; delivery tube from condenser top placed in water as indicator). The hot reaction mixture was poured on crushed ice (400 g.) and the resulting solution extracted with four 50-cc. portions of chloroform. The extract was washed free of acetic acid with water, dried over Drierite and decolorized (Darco). Upon solvent removal under reduced pressure the product crystallized spontaneously as light yellow needles. The crystalline mass was dissolved in 60 cc. of hot 1:4 ethanol–water, decolorized and diluted with an equal volume of warm water. Upon cooling, the product separated as long, white prismatic needles; yield 3.7 g. (70%), m. p. 103.5–105°, spec. rot. +18° (abs. $CHCl_3$). Three additional crystallizations were effected by solution in 15 parts of hot 1:4 ethanol–water and dilution with an equal volume of water to yield pure *keto-d*-glucoheptulose hexaacetate; m. p. 104–105°, spec. rot. +18.7° (22°, *c* 2.7, U. S. P. or abs. $CHCl_3$). These constants remained unchanged on further crystallization from aqueous ethanol or acetone–petroleum ether.

The substance was soluble in ethanol, acetone, acetic acid and warm ether but was insoluble in water and petroleum ether. The compound exhibited no detectable mutarotation in either chloroform or methanol solution. An absorption spectrum analysis[13] of the substance in chloroform (U. S. P.) solution (0.0377 molar) revealed an absorption maximum at 2830 Å. ($\log \epsilon_{max.} = 1.60$ at 2830 Å.).

(12) All rotations are recorded to the D-line of sodium light.

(13) We are indebted to Professor W. R. Brode and Mr. John Patterson of this Laboratory for this analysis.

Anal. Calcd. for $C_7H_8O_7(CH_3CO)_6$: C, 49.35; H, 5.67; CH_3CO, 12.97 cc. 0.1 *N* NaOH per 100 mg. Found: C, 49.33; H, 5.53; CH_3CO, 12.90 cc.

keto-d-Glucoheptulose hexaacetate could also be prepared from 1-bromo-*keto-d*-glucoheptulose pentaacetate[1] by the general acetolysis procedure of Tambor and Du Bois.[8] The bromo derivative (2 g.) was dissolved in acetic anhydride (10 cc.) containing fused potassium acetate (3 g.). After shaking for five minutes the mixture was heated for thirty minutes at 70° and then allowed to stand overnight. The crystals obtained on pouring the reaction mixture into ice and water were removed by filtration and washed with a small amount of cold ether; yield 0.9 g., m. p. 102°, spec. rot. +17° ($CHCl_3$). Further purification yielded pure material identified by melting point, mixed melting point and rotation as *keto-d*-glucoheptulose hexaacetate.

The nature of the sugar portion in the above compound was verified by transformation into the one known cyclic hexaacetate of *d*-glucoheptulose.[7] *keto-d*-Glucoheptulose hexaacetate (1.0 g.) was treated for an hour at 0° with a dry methanol solution of anhydrous ammonia. The sirup obtained on solvent removal under reduced pressure was acetylated at 100° with acetic anhydride and sodium acetate, and the product obtained on pouring the cooled reaction mixture into water was recrystallized (decolorizing charcoal) from 75% ethanol; yield 0.2 g., m. p. 114.5–115.5°, spec. rot. +86° (23°, *c* 3, U. S. P. $CHCl_3$). A mixed melting point with an authentic specimen of *d*-glucoheptulose hexaacetate (m. p. 114.5–115°) was unchanged. Austin[7] recorded the following constants for *d*-glucoheptulose hexaacetate: m. p. 112°, spec. rot. +87° ($CHCl_3$). Wolfrom and Thompson[7] found the constants: m. p. 115–116°, spec. rot. +87° ($CHCl_3$). The present product is therefore identified as the *d*-glucoheptulose hexaacetate of Austin.

1,8-Bisdiazo-mucyldimethane Tetraacetate (IV).—Mucyl dichloride tetraacetate[11] (III, 4 g.) was suspended in anhydrous ether and added slowly with continuous stirring to a solution of diazomethane (4 g.) in 200 cc. of anhydrous ether, previously cooled in an ice–salt bath. The reaction was maintained at the temperature of the ice–salt bath for two hours, whereupon the product was removed by filtration and washed with ether. Pure material was obtained on further crystallization from ethanol; yield 3.5 g., m. p. 179–180° (dec.). The crystals were soluble in acetone, chloroform and dioxane.

Anal. Calcd. for $C_{16}H_{18}O_{10}N_4$: C, 45.07; H, 4.25; N, 13.14. Found: C, 45.13; H, 4.31; N, 12.82.

1,8-Dichloro-mucyldimethane Tetraacetate.—1,8-Bisdiazomucyldimethane tetraacetate (IV, 1 g.) was suspended in ether (40 cc.) and treated, under cooling, for thirty minutes with a stream of dry hydrogen chloride, whereupon the chloro compound formed was removed by filtration and purified by crystallization from ether; yield practically quantitative, m. p. 174–175°.

Anal. Calcd. for $C_{16}H_{20}O_{10}Cl_2$: C, 43.35; H, 4.55; Cl, 16.0. Found: C, 43.47; H, 4.67; Cl, 15.4.

1,8-Dihydroxy-mucyldimethane Hexaacetate (V).—1,8-Bisdiazo-mucyldimethane tetraacetate (IV, 1 g.) was refluxed for thirty minutes with glacial acetic acid (10 cc.),

whereupon the cooled solution was poured on ice (25 g.) and the separated solid removed by filtration and purified by crystallization from ethanol; m. p. 193–195° (dec.).

Anal. Calcd. for $C_{20}H_{26}O_{14}$: C, 48.98; H, 5.34. Found: C, 48.76; H, 5.31.

We acknowledge the assistance rendered in a portion of this work by Messrs. Ralph S. Klopper and Stephen Olin.

Summary

1. The known *keto-d*-fructose pentaacetate has been synthesized by the reaction between acetic acid and 1-diazo-1-desoxy-*keto-d*-fructose tetraacetate.

2. Acetic acid was reacted with 1-diazo-1-desoxy-*keto-d*-glucoheptulose pentaacetate (I) to produce *keto-d*-glucoheptulose hexaacetate (II), also obtainable by the acetylation of 1-bromo-*keto-d*-glucoheptulose pentaacetate.

3. Mucyl dichloride tetraacetate (III) was treated with diazomethane to produce the bisdiazomethyl ketone (IV) from which the 1,8-dichloride and the 1,8-diacetoxy (V) derivatives were formed. The latter is an acetate of a diketose, a new type of structure in the sugar field.

4. The above reactions establish a new synthesis of *keto*-acetates from aldose derivatives of lower (one or two carbon atoms) carbon content.

Structure of the Dextrins Isolated from Corn Sirup[1]

BY MELVIN LEVINE, JOSEPH F. FOSTER AND R. M. HIXON

The structural differences between the different starches and starch fractions, especially with regard to the questions of branching and non-reducing fractions, would appear to be somewhat clarified by a more complete study of the structure of the low molecular weight products of hydrolysis. In the older literature Brown[2] concluded that these products consist essentially of maltose and a "stable dextrin" of definite molecular size (about 40 glucose units) with a specific rotation of about 196° and a reducing power equivalent to 5.5% maltose, or about the value which would be expected for a molecule of this size if it terminated in a reducing glucose molecule. These results have been partially accepted in the corn sirup industry where "dextrin" is considered to be a definite substance having the rotation reported by Brown, but considered to be non-reducing.[3] From a theoretical standpoint these degradation products would be expected to consist of a mixture of glucose polymers of varying chain length, and with reducing power and specific rotation[4] depending on the chain length. If the original starch contains branching, as the present evidence indicates, these molecules might be expected to be further complicated.

The method which we are reporting in this paper for isolating the dextrins from corn sirup was developed primarily to make these materials available in relatively large quantities for physiological investigations. The availability of such dextrins together with the theoretical importance of a more complete knowledge of their structure has encouraged a rather detailed investigation of these materials, especially with regard to the questions of branching and the presence of any non-reducing fractions.

Experimental

Isolation of Crude Dextrins from Corn Sirup.—The conditions used for the isolation of the dextrins were selected after a study of the solubilities of glucose and maltose in aqueous alcohol (Fig. 1). Fifteen pounds of corn sirup[5] was weighed into a five-gallon container. Enough absolute methyl alcohol to bring the concentration to 80–85% was added, the mixture heated to 55° in a water-bath and stirred thoroughly until a homogeneous mixture was obtained, which was allowed to stand at approximately 45° until the supernatant alcoholic extract was clear (twenty-four to forty-eight hours) and was then decanted. The residual heavy sirup was again extracted with approximately three volumes of 80% alcohol by stirring at 55°, allowing to settle at 40°, and decanting the clear supernatant liquor. This extraction process was repeated four times.

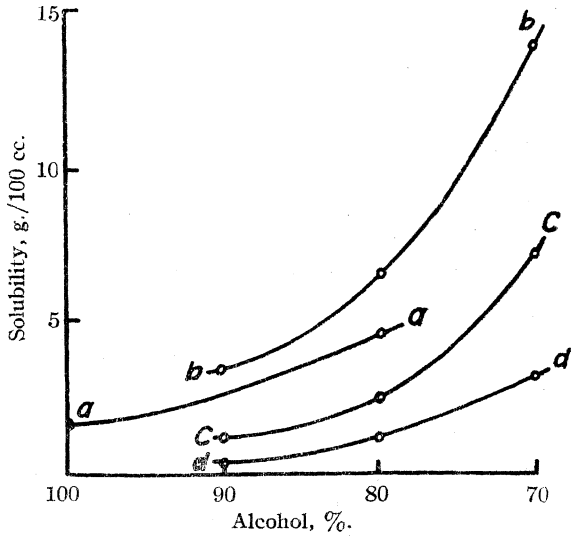

Fig. 1.—Solubility of maltose and glucose in aqueous alcohol: a, glucose in C_2H_5OH at 20°; b, maltose in CH_3OH at 40°; c, maltose in CH_3OH at 25°; d, maltose C_2H_5OH at 25°. The data for glucose are from Hudson and Yanovsky, THIS JOURNAL, 39, 1013 (1917). The data for maltose were determined in this Laboratory by averaging the values calculated from rotation and reducing value.

The heavy, sticky residue was thinned somewhat with water, heated to 60° and filtered through a cotton filter cloth with the aid of suction. Absolute methanol was added to the filtrate to bring the concentration up to 85%, the sirup allowed to settle, then dehydrated and pulverized with absolute methanol. The powdered dextrin was recovered by filtering with the aid of suction and dried in a vacuum oven at 45° for forty-eight hours. The final products were slightly hygroscopic white powders having a slightly sweet taste, specific rotation of about 175°, and reducing value (R_{Cu}) by the alkaline ferricyanide method[6] of about 750 to 850 (maltose = 1900).

(6) Farley and Hixon, *Ind. Eng. Chem., Anal. Ed.*, **13**, 616 (1941).

Fractionation of Dextrins.—A weighed amount of crude dextrin was dissolved in twice its weight of distilled water, filtered, precipitated by the addition of four volumes of absolute methanol, allowed to stand till clear and the supernatant liquid poured off. The soluble fraction was recovered by evaporating under reduced pressure, and both soluble and insoluble fractions dried. Reducing power and rotation were run on the fractions, after which they were subjected to further fractionation by the same method. A typical fractionation is shown graphically in Fig. 2. The fractions used in the chemical studies discussed below were prepared by this method of fractionation.

To determine the completeness of removal of maltose in this method of fractionation, a mixture consisting of 3 g. of maltose and 10 g. of dextrin V (mol. wt. 1800 by iodine titration) was subjected to a single fractionation in 80% methanol. The insoluble fraction consisted of 7.2 g., mol. wt. 1950; the soluble fraction 4.5 g., mol. wt. 530. If the latter fraction be assumed to contain all of the maltose plus 1.5 g. of the dextrin, the mean molecular weight would be about 490.

Acetylation of Dextrins and Fractionation of the Acetates.—Satisfactory acetylation could be attained by any of the variations of the pyridine–acetic anhydride method.[7,8,9] A 100-g. sample of a dextrin having a reducing value of 850 was dissolved in 400 cc. of pyridine and allowed to stand for forty-eight hours. Then 500 cc. of pyridine and 500 cc. of acetic anhydride were added and the mixture shaken. After standing for forty-eight hours the solution was poured into about 10 liters of water, the precipitate collected on a filter and washed well with about 5 liters of water; yield 220 g. of white powder.

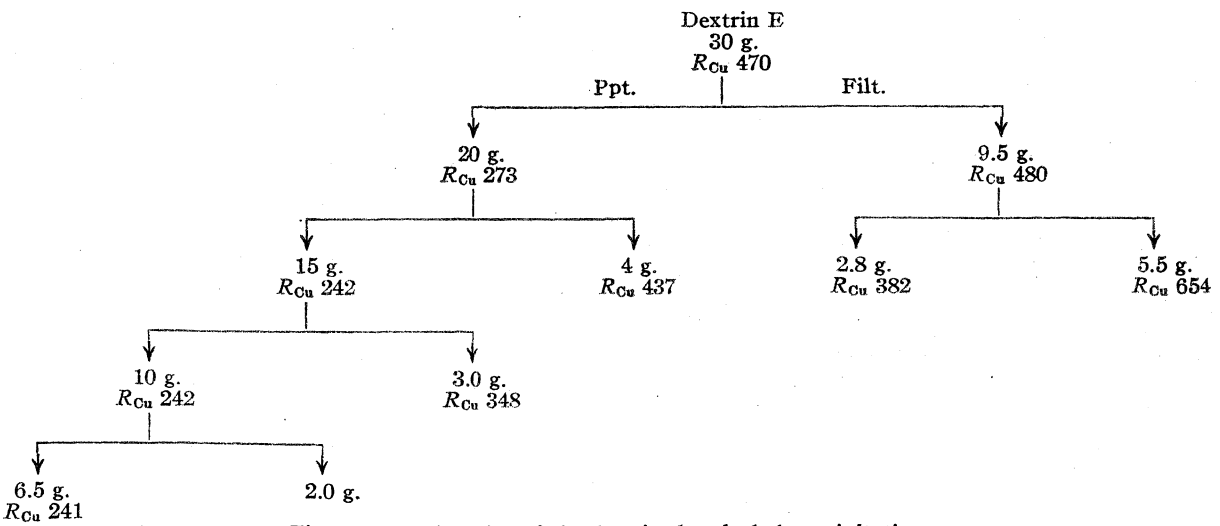

Fig. 2.—Fractionation of the dextrins by alcohol precipitation.

This material was repeatedly fractionated by dissolving in boiling absolute methanol and then cooling the solution in an ice-bath for about three hours until the dextrin acetate had settled. This came down as a white, very heavy

sirup which hardened on standing and was broken up and pulverized with a glass rod. The solution was filtered, the filtrate evaporated to dryness, and both the soluble and insoluble fractions dried and pulverized. Results of this type of fractionation are given in Fig. 3.

Oxidation of Dextrins and Isolation of the Dextrinic Acids.—It was found that these dextrins could be converted quantitatively to the potassium salts of the dextrinic acids by a large-scale modification of the Kline and Acree method for determining aldose sugars.[10] A small sample of the dextrin was first titrated with iodine and alkali according to their directions to determine the exact reducing value. Then a sample of from 10 to 20 g. was dissolved in a small volume of water, placed in a three-neck reaction flask equipped with a mechanical stirrer and two dropping funnels, and the calculated amount of iodine and potassium hydroxide (each approximately 0.1 *N*) added, the caustic being permitted to drop continuously and the iodine being added in about 5-ml. portions as the solution became colorless. The addition required two or three hours and an additional three hours with stirring was allowed for completion of the reaction. The solution was concentrated to a thick sirup under reduced pressure, and the oxidized dextrin isolated by repeatedly adding methyl alcohol to a concentration of 85%, centrifuging out the solid, which at this point was rather gummy, taking up in water and repeating the alcoholic precipitation until the aqueous solution gave no test for iodide. The solid was then shaken up several times with ether, and finally ground in a mortar and dried, giving a perfectly white powder. Yields were usually 90 to 95% of the theoretical.

The potassium salts were analyzed for potassium by ashing 20–30-mg. samples with a drop of concentrated sulfuric acid in a small electric muffle, and weighing the sulfate formed. The chain length calculated from per cent. of potassium was found to agree very well with that calculated from the amount of iodine and caustic used in the oxidation. For example, one fraction having a chain length of 14.2 glucose units by iodine titration was oxidized and the derivative found to contain 1.67% potassium, from which the chain length was calculated to be 14.4 glucose units.

Maltose was also oxidized to potassium maltobionate by the above method, but the derivative was found to be very hygroscopic and much harder to work with than in the case of the larger molecules.

Methylation of Dextrins.—Attempts to methylate these dextrins by the various methods which have been used for carbohydrates showed that by far the best results could be obtained by means of sodium and methyl iodide in liquid ammonia, which was first applied to starch by Freudenberg and Boppel.[11] By this method the theoretical per cent. of methoxyl could be attained in one treatment, and recovery was practically quantitative. However, due to the greater solubility of these materials in both water and ammonia, it was found impracticable to change solvent during the methylation, and recovery of the methylated product had to be effected by evaporating off the ammonia, and exhaustively extracting the thoroughly dried and pulverized residue in a Soxhlet extractor with chloroform, instead of adding the residue to boiling water as was done by these workers.

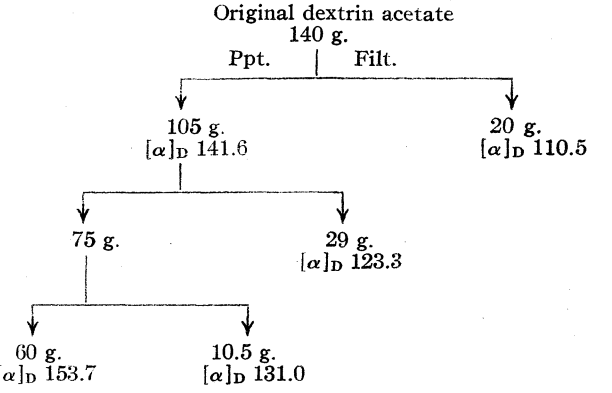

Fig. 3.—Fractionation of dextrin acetates.

Ten grams of a dextrin having an average chain length calculated from iodine titration of eleven glucose units was methylated by this procedure: yield, 12.5 g. of cream colored powder or 99% of theoretical (45.5% methoxyl, calculated for an 11 glucose dextrin, 46.3). Five grams of this material was hydrolyzed and the di-, tri- and tetramethyl glucose separated by the method of Bell,[12] which involves partition of tri- and tetramethyl glucose between chloroform and water. In this way, 0.515 g. of crystalline tetramethyl glucose was isolated (52.3% methoxyl, calculated 52.5). This corresponds to a chain length of 10.6 glucose units assuming no tetramethyl glucose to be lost. The amount of dimethyl glucose obtained was very small (about 30 mg.).

To check this result 3.8 g. of the methylated dextrin was hydrolyzed, converted to the glucosides, and analyzed for tetramethyl glucose by the method of fractional distillation.[13] By this method, 0.424 g. of tetramethyl methylglucoside was found in the distillate, and the chain length calculated to be 10.3 glucose units.

The molecular weight of the methylated dextrin was determined by two physical methods. By viscosity in chloroform, using Staudinger's equation and his value of K_m (namely, 1×10^{-4}),[14] the value obtained was 9700; cryoscopically, using bornyl bromide as solvent, 1530. This last value is in reasonable agreement with the value calculated from the chain length, or about 2000.

The salts of the dextrinic acids have also been methylated completely and in good yields following the same procedure as with the dextrins. To date no study of the methylated derivatives has been carried out.

Reaction of the Dextrins with Phenylhydrazine.—The procedure first tried was essentially that used by Bergmann and Machemer with the acetylated cellulose dextrins,[15] which involves preparation of the derivative in liquid phenylhydrazine, isolation by pouring into ether, and purification by solution in 50% acetic acid and precipitation with absolute methanol. Much better results were obtained in the case of the unacetylated materials by

(15) Bergmann and Machemer, *Ber.*, **63**, 322 (1930).

eliminating the use of acetic acid and using benzene instead of ether as the precipitant. The procedure finally established was as follows. One gram of the dextrin was dissolved in 5 cc. of phenylhydrazine by heating under reflux at 130° for two hours. The reaction mixture, after cooling, was poured with stirring into 50 cc. of benzene. The precipitate was recovered by filtration, washed several times with ether, thoroughly dried, pulverized, and extracted with ether in a Soxhlet extractor for twenty-four hours. By this procedure the recovery of the derivative was more complete and the results more consistent. The derivatives were analyzed for nitrogen by the micro Dumas method, and the molecular weight of the carbohydrate residue calculated.

These derivatives are amorphous powders, characteristically yellow in color in contrast to true phenylhydrazones, and are extremely susceptible to hydrolysis. When dissolved in water they give off a very noticeable odor of phenylhydrazine, and ether extraction of the aqueous solution or boiling with activated charcoal results in the removal of from 25 to as high as 85% of the nitrogen. For this reason it was at first thought that the materials were simply adsorption complexes; however, the fairly close agreement in the case of the smaller fractions between the molecular weight from nitrogen and iodine titration indicated that a definite reaction did take place.

To further investigate this question the derivatives of glucose and maltose were prepared following exactly the procedure used for the dextrins. The maltose derivative had the same characteristic yellow color as the dextrin derivatives and had the same amorphous appearance under the microscope. The glucose derivative was somewhat more orange in color and was essentially amorphous although there did seem to be some small crystals present which were birefringent. The rotations could not be determined accurately due to the dark color of the aqueous solutions, but the values were about −40° for the glucose derivative and +70° for the maltose derivative. Both derivatives melted over a wide range, indicating them to be non-homogeneous (maltose derivative, 115–118°; glucose derivative, 111–120°). Nevertheless the nitrogen analysis was in both cases very close to the theoretical (maltose derivative 6.46%, calculated 6.48; glucose derivative, 10.2, calculated 10.4). The maltose derivative showed the same instability in water as the dextrin derivatives, at least 25% of the phenylhydrazine being extractable. It is interesting to note that if the aqueous solution is exhaustively extracted with ether and then allowed to stand a few days, more phenylhydrazine can be removed, indicating that a reversible equilibrium is involved. The glucose derivative gave an odor of phenylhydrazine when dissolved, but the amount extractable was negligible.

The phenylhydrazine derivative of an acetylated dextrin was also prepared, following essentially the procedure of Bergmann and Machemer.[15] It was found that part of the acetyl groups were removed by the phenylhydrazine so that the derivative had to be reacetylated. The derivative was found to contain 1.70% nitrogen and 43.2% acetyl, from which the molecular weight of the carbohydrate residue was calculated to be 862, in good agreement with the value calculated from iodine titration, namely, 850.

Specific Rotations of the Dextrins.—Before running specific rotations the dextrins were carefully dried in a vacuum oven at 60° for twenty-four hours. Rotations were run at 25° on 1% solutions in water, using sodium D light. In Table I these results are compared with the values calculated assuming the additivity of molecular rotations as has been done by Freudenberg with the smaller molecules.[4] A value of 46,000 was assigned for the molecular rotation of maltose (or the sum of the reducing and non-reducing terminal glucoses in the dextrins) and 32,400 for the intermediate glucoses, the value for maltose being obtained from the observed rotation and iodine molecular weight and the value for the intermediate units by assuming a rotation of 200° for an infinitely long chain. The equation used is thus

$$\alpha_M = 46000 + \frac{M - 348}{162}(32400)$$

where α_M is the molecular rotation and M the molecular weight. The specific rotation is of course obtained by dividing the molecular rotation by the molecular weight.

TABLE I

COMPARISON OF SPECIFIC ROTATION CALCULATED FROM IODINE AND R_{Cu} REDUCING VALUES WITH THE OBSERVED VALUES

Fraction	Molecular wt. I_2	Weight from R_{Cu}	$[\alpha]_D$ calcd. from I_2	$[\alpha]_D$ observed	$[\alpha]_D$ calcd. from R_{Cu}

E	1902	1450	188	185	183

Discussion

As can be seen from Fig. 2 the results of alcohol fractionation are not very satisfactory. The recovery is poor, the fractionation is slow and the materials very hard to work with. Nevertheless, from the crude dextrin, fractions were obtained having mean molecular weights ranging from less than the value of maltose up to about 26 glucose units, as calculated from iodine reducing value. The fractions are obviously heterogeneous since in no case was a fraction obtained which could not be further fractionated, although, in most cases, by the time the molecular weight had reached a value corresponding to about 25 glucose units the amount of the fraction was too small to permit further treatment. The result of the fractionation of the known mixture of maltose and dextrin V indicates that the higher fractions could not contain any appreciable amount of maltose or glucose, and it seems probable that the distribution of molecular sizes is fairly narrow.

Haworth and associates[16] have investigated the fractionation of the dextrins through their acetates with satisfactory results. The results obtained here indicate a fairly sharp fractionation as evidenced by the large difference in rotation between the fractions. The advantage of more rapid fractionation is, however, offset by the necessity of acetylating and regenerating the dextrins.

The excellent check between the per cent. potassium in the dextrinic acids and the iodine reducing value of the original dextrins indicates that the reaction is, as formulated by Kline and Acree,[10] a simple oxidation of aldehyde groups to the carboxylic acids, and that no iodine is used otherwise (for example, adsorbed). From this it would seem that iodine titration is the best criterion of chain length in these low molecular weight dextrins. In Fig. 4 the molecular weights calculated from R_{Cu} are compared with the corresponding values calculated from iodine reducing power. Results obtained in this Laboratory with higher molecular weight fractions indicate that the R_{Cu} molecular weights are too low by an almost constant value and hence it would appear that the curve bends upward and becomes parallel with the theoretical as is also indicated in the figure. It should be mentioned also that iodine methods are not very reliable in the case of very high molecular weight materials where tenacious adsorption occurs.

The reliability of the iodine values in this range is further indicated by the agreement between the specific rotations and the values calculated from the apparent molecular weights (Table I). Low observed values can be explained by moisture. In several cases the observed values are below those calculated from iodine molecular weight, but above those calculated from R_{Cu} molecular weight. Obviously specific rotation is not a very sensitive function for a high molecular weight fraction; nevertheless, even in the highest fractions studied here the calculated increase of specific rotation is approximately 1.5° per glucose unit.

The close agreement between the chain length calculated from reducing value and tetramethyl glucose analysis, even when we consider the limited accuracy of the available methods for separation of the methyl glucoses (the maximum relative accuracy is probably not more than about 5–10%) indicates the chains to be essentially linear. The almost complete lack of dimethyl glucose, which would arise at the points of branching, supports this conclusion (30 mg. of dimethyl glucose would permit a maximum of one branch to about 160 glucose units, or about 6% of branched molecules). This result is to be expected for fractions of this size from simple probability considerations, if we assume the 1–4 and 1–6 linkages to be broken at the same rate. It should perhaps be pointed out that the method of tetramethyl assay is not a very sensitive criterion for ascertaining whether or not a small portion of the molecules are branched. For example, a straight-chained fraction of ten glucose units would give 10% of tetramethyl glucose, whereas if even 25% of the molecules were branched only about 12.5% of tetramethyl glucose would be obtained. Hence the absence of dimethyl glucose is, perhaps, a safer criterion.

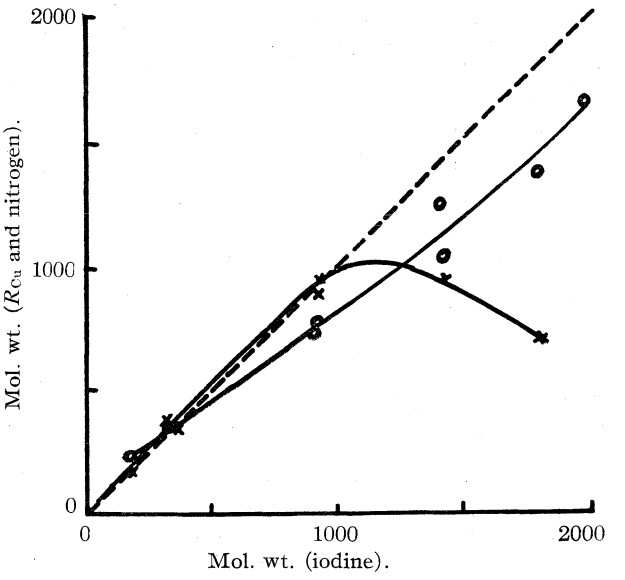

Fig. 4.—Comparison of molecular weights calculated from R_{Cu} and per cent. nitrogen in the phenylhydrazine derivatives, with the values obtained from iodine reducing values. Molecular weights were calculated from R_{Cu} by assuming the value for maltose (1900) to be correct and using the equation $M = 342 \times 1900/R_{Cu}$. The crosses are nitrogen values; the circles R_{Cu} values.

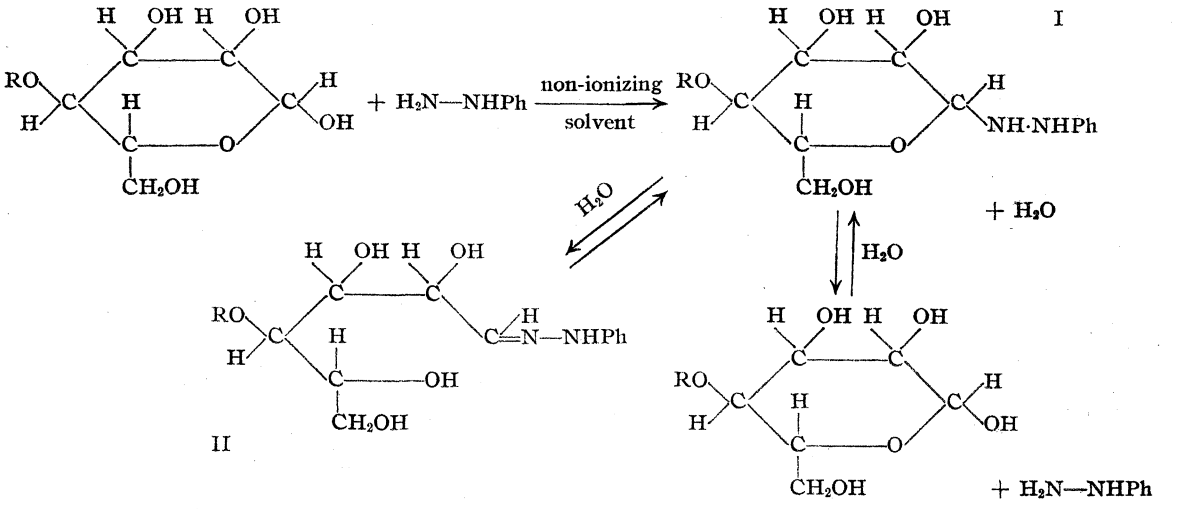
In considering the possible presence of non-reducing dextrins, two distinct types must be considered. In the first place, there is the possibility of dextrin structures in which the terminal aldehyde group is bound in a non-reducing fashion but the non-reducing end is free. This type of molecule would be detected by the tetramethyl end-group analysis since it would lead to a preponderance of tetramethyl groups over reducing groups. Conclusions based on this evidence are, of course, subject to the same experimental inac-

(16) Haworth, Hirst and Plant, *J. Chem. Soc.*, 1214 (1935).



curacies discussed above; however, it seems safe to conclude that at most not more than 10% of non-reducing material of this type could be present, and probably none. The other possibility which must be considered is the presence of ring dextrins of the Schardinger type which have neither reducing nor non-reducing ends and would hence not be detected by the tetramethyl glucose analysis. However, this possibility is completely eliminated by the agreement of the rotations with the calculated values. The Schardinger dextrins have rotations about 20–25° lower than that calculated for an open chain of equal molecular weight, and their presence would have to be offset by low-molecular weight dextrins to bring up the reducing power; the net effect would be a marked lowering of the rotation of the fraction. Thus the suggestion that these materials consist of glucose, maltose and non-reducing dextrins is completely out of the picture, and the possibility of the presence of even a small amount of non-reducing material seems dubious.

The reaction of phenylhydrazine with cellulose dextrins has been investigated by Staud and Gray[17] and by Bergmann and Machemer,[15] who concluded that nitrogen analysis of the reaction product is more trustworthy than copper numbers as a basis for estimating molecular size. The application of the method to the starch dextrins was investigated in the hope of using it as another criterion of chain length, and also in the hope that the derivatives might possess some advantages for fractionation in that any non-reducing material would not react. The results indicated that the reaction is quantitative but that the derivatives are unstable. These conclusions were substantiated by the preparation of the derivatives of glucose and maltose.

Both hydrazide and hydrazone forms of the phenylhydrazine derivatives of glucose have been reported.[18] The glucose derivative obtained here was apparently a mixture of the two forms but predominantly the hydrazide. Obviously rather complicated equilibria are involved, but the following simplified mechanism would seem to explain the phenomena so far observed.

The equilibrium between the phenylhydrazide form (I) and the phenylhydrazone form (II) has been recognized.[18] The fact that a large amount of the phenylhydrazine is immediately released from the maltose derivative upon solution in water, followed by a slow hydrolysis of the remainder, would seem to indicate that the hydrolysis of the phenylhydrazide is quite rapid whereas the shift between the two tautomeric forms is slow. The hydrolysis is evidently inhibited by acid, as is shown by the fact that derivatives prepared using 50% acetic acid for purification were found to contain about the same per cent. nitrogen as the derivatives prepared by the modified method.

Figure 4 shows reasonable agreement of the per cent. nitrogen with the calculated values up to a molecular weight of about 1000, corresponding to about six glucose units. From this point on the per cent. nitrogen is much too high, indicating adsorption of phenylhydrazine by the carbohydrate. There is considerable evidence that the chains in starch and its derivatives are coiled in the form of a helix with a periodicity of about six

(17) Staud and Gray, *Ind. Eng. Chem., Anal. Ed.*, **1**, 80 (1929).

(18) For a review of these compounds see Tollens and Elsner, "Kurzes Handbuch der Kohlenhydrate," Fourth Ed., J. A. Barth, Leipzig, 1935, pp. 231–232.

glucose units.[19,20] If the adsorption of phenylhydrazine is due to entrapment in the center of these helices, it might be expected that no noticeable amount of adsorption[21] would occur until the average chain length of the dextrin was approximately six to eight glucose units, as is observed. It is conceivable that by varying the solvents used and by controlling the conditions of precipitation it might be possible to eliminate adsorption and to obtain the derivatives in the more stable hydrazone form.

Summary

1. A method for isolating the dextrins from corn sirup in large quantities is given.

2. Repeated alcohol fractionation gives fractions ranging in mean molecular weight from less than two glucose units to 26 units, and the higher fractions are concluded to be relatively free of maltose and glucose.

3. Oxidation of the dextrins to the potassium salts of the dextrinic acids can be carried out in good yields and the potassium content of the products checks with the reducing value of the original dextrin, indicating the iodine reaction to be quantitative and a true measure of molecular size.

4. The specific rotations of the dextrins agree with the values calculated from iodine molecular weights, lending further evidence to the reliability of iodine values.

5. The Freudenberg and Boppel method of methylation is found to be very satisfactory for both the dextrins and dextrinic acids.

6. Tetramethyl glucose assay of the methylated dextrins indicates the chains to be essentially unbranched, and non-reducing fractions to be absent. The former conclusion is substantiated by the almost complete absence of dimethyl glucose, the latter, by the agreement of the rotations with the calculated values.

7. The reaction of phenylhydrazine with the smaller starch dextrins is found to be quantitative, but the derivatives are unstable and postulated to be largely of the phenylhydrazide type.

8. The dextrin fractions averaging greater than about six glucose units in length show a strong tendency to adsorb phenylhydrazine and a possible explanation is given.

Antioxidants and Autoxidation of Fats. XIV. The Isolation of New Antioxidants from Vegetable Fats[1]

BY CALVIN GOLUMBIC

The tocopherols have been found in a wide variety of vegetable fats but are generally absent from animal fats.[2,3] The observations of Olcott and Emerson[4] and later those of Golumbic[5] have shown that they and related compounds function as fat antioxidants and they are responsible in part for the greater stability of vegetable fats toward oxidative deterioration.

When added to animal fats that are exposed to air or oxygen, tocopherols are rapidly oxidized during the period in which they exert their antioxygenic action and their complete disappearance practically coincides with the end of the induction period of the fat.[6] At this point there is a readily detectable increase in the rate of oxygen uptake and of peroxide formation[6] (Table I). In an autoxidizing hydrogenated vegetable fat, on the other hand, the pronounced acceleration of peroxide formation does not occur until a considerable time after the total disppearance of tocopherol (Table I). This observation suggested the presence of hitherto unrecognized antioxidants which were less susceptible to oxidation than the tocopherols. They were obviously not phenolic in nature because the oxidized fat gave no test with the ferric chloride–dipyridyl reagent of Emmerie and Engel.[7]

In some respects, the oxidized vegetable fat behaved as though it contained quinoid substances.

[a] Determined by the Emmerie–Engel method as modified by Parker and McFarlane, *Can. J. Res.*, **18**, 403 (1940). [b] Millimoles of peroxide oxygen per kg. of fat. [c] This amount of synthetic α-tocopherol was added to the fresh lard. [d] Naturally occurring tocopherol.

Thus, the light yellow color of the fresh fat gradually deepened to an orange-yellow during the course of the autoxidation. The oxidized fat was decolorized by treatment with reducing agents but its color soon reappeared after removal of the reducing agent and re-exposure to air. Upon continued exposure to air, no further change was noted until the period of accelerated peroxide formation was reached, whereupon the color of the fat faded out rapidly. Vegetable fats in general exhibit this decolorization at the point of extreme rancidity.[8] It seemed pertinent, therefore, to separate the substances responsible for the color production and to study their antioxidant and chemical properties.

For this purpose, hydrogenated vegetable fats were allowed to undergo sufficient atmospheric oxidation to destroy all the tocopherols and petroleum–ether solutions of these partially oxidized oils were twice chromatographed on permutit. This operation gave a red zone whose eluate yielded a red oil from which most of the sterols and fat were removed by cooling in alcoholic solution. Upon repeated adsorption of the residual oil on silicic acid, a homogeneous red zone was obtained which yielded a red oil possessing definite antioxygenic and quinoid properties (Table II).

The red concentrates prepared in this manner were subjected to the action of reducing, acetylating and cyclizing agents in order to gain further information as to the chemical nature of their antioxygenic constituents. In addition, their absorption spectrum was measured and their biological (vitamin E) activity was determined. In all these properties and reactions, these red anti-

TABLE II

ANTIOXYGENIC ACTION OF THE QUINONE CONCENTRATES

Substrate	% of inhibitor added	Antioxygenic index[a]
Lard	0.05 Quinone concentrate[b]	3
	.02 Red oxidation product of α-tocopherol	2–4
Purified ethyl esters of hydrogenated cottonseed oil	.80 Quinone concentrate	3

[a] Ratio of the induction period of stabilized fat to that of control. [b] Analytically equivalent to 0.025–0.035% red oxidation product of α-tocopherol.

oxygenic concentrates showed a marked similarity to the chroman-5,6-quinones resulting from the treatment of tocopherols with nitric acid.[9] Previous attempts[9] and our own efforts to purify these latter compounds have been unsuccessful, hence no direct qualitative comparison can be made between them and the antioxygenic quinoid concentrates just described. Until this is accomplished, the definitive chemical structure of the active constituents of the quinoid concentrates will remain open to question.

The red quinoid substances were found in oxidized cottonseed and soybean oils as well as in mixed hydrogenated vegetable fats. They do not occur as such in the fresh fats but are gradually formed in increasing amounts from colorless precursors as the fats undergo autoxidation. When the oxidized fats were dissolved in a butanol chloroform mixture[10] and compared colorimetrically with similar solutions of the chroman-5,6-quinone derived from α-tocopherol, the maximum amounts appearing in oxidized hydrogenated vegetable fats were of the order of 0.02 to 0.03%. Even at these low concentrations, chroman-5,6-quinones exhibit marked antioxygenic properties.[11]

The colorless precursors of these quinoid compounds are not the tocopherols. The quinoid compounds were never detected in autoxidizing animal fats or in purified fat substrates containing only added tocopherol. Furthermore, the addition of α-tocopherol or of α-tocoquinone to a fresh hydrogenated vegetable fat did not increase the amount appearing during the induction period.

Both the red quinoid substances and their precursors are destroyed by alkaline saponification; hence, methods analogous to those usually employed for concentrating vitamin E had to be

(9) Smith, Irwin and Ungnade, THIS JOURNAL, **61**, 2424 (1939).

(11) Golumbic, THIS JOURNAL, **63**, 1163 (1941).

abandoned. The quinoid precursors could be separated with little apparent destruction by chromatographic adsorption on activated alumina according to the method introduced by Moss and Drummond for the isolation of tocopherols from wheat germ oil.[12] To secure selective adsorption of all the antioxygenic constituents of hydrogenated vegetable fats, it was first necessary to convert them to their crude ethyl esters by acid alcoholysis.[2] Petroleum ether solutions of these esters were adsorbed on activated alumina and afforded a yellow zone containing the quinoid precursors in association with the tocopherols. The antioxygenic activity of this adsorbed fraction was lost after acetylation but not after quantitative oxidation with gold chloride.

Tocoquinones, the expected oxidation products if tocopherols alone were present, are devoid of stabilizing action[5]; hence, the adsorbed zone contained phenolic inhibitors other than tocopherols. By repeated chromatographic adsorption on silicic acid, of the fraction oxidized by gold chloride, a homogeneous red zone was obtained which yielded a red antioxygenic oil exhibiting the chemical behavior of the chroman-5,6-quinones. The most likely source of these quinoid substances is thus their corresponding hydroquinones, possibly 5-hydroxy tocols.

Quackenbush, Gottlieb and Steenbock[10] found that the application of the Furter–Meyer method[13] to the determination of tocopherols in vegetable oils sometimes gave high results because of the presence of a chromogen other than tocopherol, which produced a color not unlike that obtained by vigorous oxidation of tocopherol. The fact that this unidentified chromogen was mainly lost upon saponification of the vegetable oils strongly suggests that it is the alkali-labile precursor of the red quinoid substances whose isolation is here reported.

These antioxygenic compounds are also responsible for certain characteristics of the autoxidative behavior of vegetable fats; a discussion of these relations will be presented elsewhere.

Experimental

Preparation of the Antioxygenic Quinoid Concentrates.—Hydrogenated vegetable fats were the most satisfactory starting materials; crude vegetable oils introduced complications because of the difficulty of removing the carotenoid pigments

(12) Moss and Drummond, *Biochem. J.*, **32**, 1953 (1938).

(13) Furter and Meyer, *Helv. Chim. Acta*, **22**, 240 (1939).

The hydrogenated vegetable fat (500 g.) was subjected to acid alcoholysis by refluxing with absolute alcohol containing 2–3% hydrogen chloride.[2] The crude ethyl esters obtained by this process were dissolved in sufficient petroleum ether (b. p. 60–70°) to make a 20% solution and chromatographed on 500 g. of activated alumina. The column exhibited one or two yellow zones depending on the kind of alumina used. When two bands were obtained, as with Brockmann's alumina, all the antioxygenic substances were confined to the second (lower) of the two bands whereas with other commercial aluminas, all the antioxygenic compounds were adsorbed in the single zone. The elutions were made with chloroform and evaporation of this solvent left a semi-solid residue. This was taken up in ethyl alcohol, cooled at −5° and the fat and sterols which crystallized were filtered off. Repetition of this process yielded a concentrate containing about 10% tocopherol (Emmerie–Engel analysis). It was quantitatively oxidized in alcoholic solution with gold chloride.[3] The precipitated gold was filtered off and the clear orange-red solution concentrated *in vacuo* to a small volume. This was taken up in ether, washed with water and dried. The ether residue was dissolved in petroleum ether (b. p. 60–70°) and chromatographed on 60 g. of silicic acid–hyflosupercel mixture (2 : 1). Two highly colored zones were obtained which were eluted with chloroform. The lower yellow band afforded an oil which gave a positive Furter–Meyer test but a negative Emmerie–Engel test and thus contained tocoquinones. The upper red zone yielded a red oil which on a colorimetric basis was equivalent to about 50 mg. of the chroman-5,6-quinone prepared from α-tocopherol. This fraction was cooled in alcoholic solution to remove further amounts of fats and sterols and the recovered oil was again adsorbed on the silicic acid–hyflosupercel mixture. Repetition of these last two steps yielded a concentrate which exhibited a chromatographically homogeneous zone upon adsorption and which contained 5–10% of the quinone, based on colorimetric comparison with the chroman-5,6-quinone from α-tocopherol.

To secure the red antioxygenic substance from incipiently rancid hydrogenated vegetable fats, these were allowed to undergo atmospheric oxidation, usually at 60°, until all the tocopherol had disappeared as determined by Emmerie–Engel analysis. Petroleum ether solutions of the partially oxidized oils were twice chromatographed on permutit, a process which afforded one red zone. Further purification of this adsorbed fraction was secured in essentially the same manner as with the gold chloride oxidized fractions, namely, by crystallization of fats and sterols from alcoholic solution and chromatographic adsorption on silicic acid. The antioxygenic red oil finally obtained was indistinguishable in properties from the concentrates secured from the fresh fat.

Another though less successful means of separating the antioxygenic quinoid substances from tocopherols was to extract petroleum ether solutions of their concentrates with Claisen alkali. It has previously been established that the reduced forms of the red oxidation products of the tocopherols are somewhat soluble in Claisen's alkali whereas according to Scudi and Buhs,[14] tocopherols themselves are not extracted by this reagent. Although this

(14) Scudi and Buhs, *J. Biol. Chem.*, **141**, 451 (1941).

method permits only partial recovery of the red antioxygenic substances, it was of some value in detecting their presence in highly pigmented vegetable oils.

Chemical and Biological Properties.—The absorption spectrum of the concentrates in the visible region, as measured in alcoholic solution by a Bausch and Lomb spectrophotometer, is identical with that of authentic chroman-5,6-quinones[9] and shows maximal absorption in the range 560–570 mμ.

The quinone concentrates are efficient stabilizers for lard and other fat substrates (Table II). They are instantly decolorized by reducing agents but quickly regain their initial color after separation from the reducing agent and re-exposure to air. Reductive acetylation, however, yields stable colorless oils which possess no antioxygenic properties. When the quinone concentrates react with *o*-phenylenediamine, they form products whose ether solutions exhibit the greenish fluorescence in daylight and in ultraviolet light, characteristic of the phenazines of authentic chroman-5,6-quinones.[9] The antioxygenic quinoid substances are destroyed when the concentrates are saponified. Their lability to alkali, first noted by John and Emte[15] with the authentic compounds, is markedly diminished when sodium hydrosulfite is present. However, when the quinone concentrates were saponified in the presence of this reducing agent, only a small proportion of the total quinone was isolated from the unsaponifiable matter. The greater proportion of it appeared to remain in the saponified fraction. Likewise, only partial recovery of the chroman-5,6-quinone oxidation product of α-tocopherol was secured when it was subjected to the same treatment.

(15) John and Emte, *Z. physiol. Chem.*, **261**, 24 (1939).

Conflicting statements have appeared regarding the vitamin E activity of the chroman-5,6-quinone derived from α-tocopherol. Evans, as reported in a paper of Smith and co-workers,[9] found that it was inactive in doses up to 6 mg. whereas Ridgway, Drummond and Wright[16] reported that it showed some activity in amounts of 5 mg. In our hands, the red oxidation product of α-tocopherol as well as its hydroquinone diacetate and the red quinoid substances obtained from vegetable oils were devoid of biological activity in doses of 10–15 mg. (eight animals).

The author is indebted to Lever Brothers Company, Cambridge, Massachusetts for a grant in support of this work.

Summary

Cottonseed and soybean oils and mixed hydrogenated vegetable fats contain alkali-labile antioxygenic substances other than the tocopherols. The chemical behavior of these fat antioxidants showed that they are similar to, if not identical with, the chroman-5,6-quinones and occur in fresh vegetable fats in a colorless, possibly quinol form. Their isolation and concentration were accomplished by chromatographic adsorption and the use of selective solvents. These antioxygenic quinoid substances, like the chroman-5,6-quinone product of α-tocopherol, were devoid of vitamin E activity.

N^1-Sulfanilylamino-alkyl-pyrimidines

BY GEORGE W. RAIZISS AND MORRIS FREIFELDER

The substitution of an amide hydrogen in sulfanilamide by some heterocyclic nuclei has resulted in compounds with increased therapeutic activity. In continuing our work[1] in this field, we have synthesized a series of sulfanilylamino alkylpyrimidines. Some of these were prepared concurrently by other investigators and have been described[2]; in addition, we have mentioned herewith several which were previously unpublished.

The 4-alkyl and 4,5-dialkyl substituted 2-aminopyrimidines reacted readily with *p*-acetsulfanilyl chloride, forming the acetsulfanilyl derivatives which were subsequently hydrolyzed to the sulfanilylaminoalkylpyrimidines. Our attempts to combine the acid chloride with amino hydroxypyrimidines, such as isocytosine (2-amino-4-hydroxypyrimidine) or divicine (2,5-diamino-4,6-dihydroxypyrimidine), and purines such as adenine or guanine, failed.

Most of the aminopyrimidines used were prepared according to Benary's method[3] by treating guanidine carbonate with sodium oxymethylene ketones; these were obtained by condensation of methyl alkyl ketone and ethyl formate in presence of sodium methylate. 2-Amino-4-ethyl-5-methylpyrimidine was prepared from sodium oxymethylene-α-methyl-methyl ethyl ketone (derived from diethyl ketone and ethyl formate); 2-amino-4-isobutylpyrimidine from sodium oxy-

methylene methyl isobutyl ketone (derived from methyl isobutyl ketone), 2-amino-4-*n*-amylpyrimidine from sodium oxymethylenemethyl-*n*-amyl ketone (derived from methyl *n*-amyl ketone). 2,5-Diaminopyrimidine was prepared in excellent yield by catalytic reduction of 5-nitro-2-aminopyrimidine[4] using platinum oxide catalyst; 2-amino-4-hexylpyrimidine was prepared by combining guanidine carbonate with the sodium oxymethylene alkyl ketone derived from ethyl formate and methyl *n*-hexyl ketone. A product was obtained which melted at 92–93° (after several recrystallizations). This is in agreement with the pyrimidine) and the melting point reported by Sprague, Kissinger and Lincoln[2c] (named as 2-amino-4-hexylpyrimidine). Oxidation with nitric acid was performed by Caldwell,[2b] with the result that some material was obtained which he considered to be 2-amino-4-carboxy-5-*n*-amylpyrimidine. We carried out a number of oxidations with the hexylpyrimidine, which we obtained, and never had yields above 2–3% of the carboxy compound. It is our belief that the 2-amino-4-methyl-5-*n*-amylpyrimidine reported by Caldwell is essentially 2-amino-4-hexylpyrimidine (as reported by Sprague) containing a small amount of the isomeric 4-methyl-5-*n*-amyl derivative. Employing the same technique we were unable to obtain any oxidation of either 2-amino-4-isobutylpyrimidine or 2-amino-4-*n*-amylpyrimidine.

In Table II, it is interesting to note the solubilities of acetsulfanilylpyrimidines in urine, which may have some relationship to the deposition of crystals in the kidneys and the genito-urinary tract with the formation of urinary concretions. The acetyl-4,5-dimethylpyrimidine derivative is considerably more soluble in urine than any of the

effect in mice infected with pneumococcus type II (method described in publication)[5] disclosed good therapeutic results for sulfanilylamino 4,5-dimethyl- and 4-monomethylpyrimidines. The ethyl derivative showed slight therapeutic effect, while higher homologs and other derivatives were found to be inactive.

Experimental

The compounds in Table I were prepared according to Benary's method as has been previously mentioned.

2,5-Diamino-pyrimidine: 5.6 g. of 2-amino-5-nitropyrimidine (4) was suspended in 150 cc. alcohol and reduced in presence of 0.2 g. of platinum oxide by hydrogen at 3 atmospheres pressure. The reduction was complete in one hour and the almost clear solution was filtered and evaporated to dryness. The yield was quantitative. After two recrystallizations from water the yield was 3.5 g. (80%).

The acet-sulfanilylaminopyrimidines were all prepared and subsequently hydrolyzed according to the method described in the following example. All of the compounds were recrystallized from 50% alcohol.

2-Sulfanilylamino-4-*n*-amylpyrimidine: 3.3 g. (0.02 mole) of 2-amino-4-*n*-amylpyrimidine was dissolved in 4.8 cc. (0.06 mole) of pyridine and 4.7 g. (0.02 mole) of *p*-acetsulfanilyl chloride added gradually with mixing, keeping temperature below 60°. The mixture was then warmed at 60° for one hour and then stirred into 50 cc. of ice-water. The precipitate was filtered and washed with water and dried; yield 6.2 g. (84%). This material can be recrystallized from 50% alcohol, but for further hydrolysis to the amino compound, recrystallization was not necessary. The acetyl product was hydrolyzed by refluxing in ten volumes of 5% sodium hydroxide for two hours. The solution was cooled and neutralized by the addition of dilute hydrochloric acid. The precipitate was filtered, washed with water and dried. After two recrystallizations from 50% alcohol, the yield was 3 g. (48%).

Summary

1. We have prepared and described the chemical and biological properties of various sulfanilylamino-mono- and dialkylpyrimidines and their corresponding acetyl products.

2. The sulfanilylamino-methyl and dimethylpyrimidine derivatives proved to have good therapeutic effect in the treatment of mice infected with Type II pneumococcus.

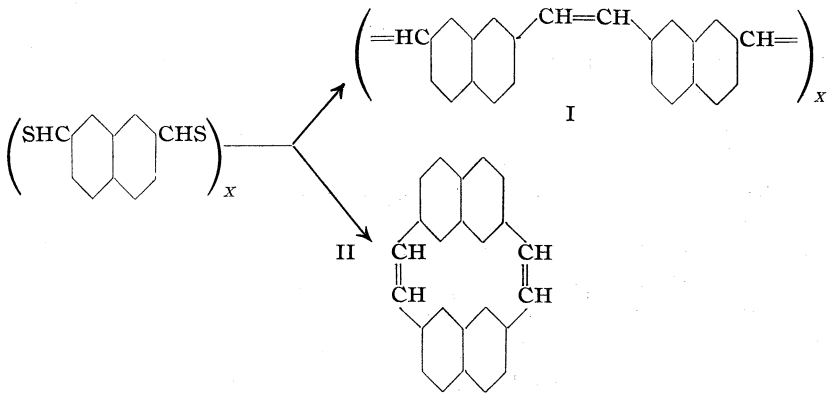
The Synthesis of 2,7-Naphthalenedialdehyde; an Attempted Synthesis of Coronene

BY J. H. WOOD AND J. A. STANFIELD

Although most of the 2,7-derivatives of naphthalene have been known for some time, the 2,7-dialdehyde has not been previously prepared. This aldehyde was synthesized by the Stephen[1] method wherein the corresponding 2,7-dinitrile was converted into the aldimine hydrochloride by the action of stannous chloride and hydrogen chloride in an ether solvent. The aldehyde was then obtained by hydrolysis. The structure of the aldehyde was established by the method of preparation, by oxidation by alkaline permanganate to the known 2,7-dicarboxylic acid, and by analysis of the aldehyde and its 2,4-dinitrophenylhydrazone.

The conversion of aryl thioaldehydes into stilbene analogs and homologs by heating with copper powder has been previously reported.[2] Such a conversion of 2,7-naphthalenedialdehyde might lead to two different types of ethylene derivatives as indicated



Ring closure of II by dehydrogenation at the alpha positions would give coronene.

Several attempts were made to prepare coronene as outlined above but all resulted in reaction products from which nothing definite was obtained. In this work, the thioaldehyde was readily prepared by the action of hydrogen sulfide upon naphthalenedialdehyde in the presence of hydrogen chloride. Upon heating the thioaldehyde with copper, non-sulfur containing materials were obtained. Attempts to convert this into coronene by heating alone and with selenium failed.

(2) Wood, Bacon, Meibohm, Throckmorton and Turner, THIS JOURNAL, **63**, 1334 (1941).

Experimental

Preparation of 2,7-Naphthalenedinitrile.—The method of Ebert and Merz[3] was followed, whereby the dinitrile was obtained by heating sodium 2,7-naphthalenedisulfonate with potassium cyanide. The yields in general were poor (10 to 15%).

Preparation of 2,7-Naphthalenedialdehyde.—Twelve grams of anhydrous stannous chloride and 150 ml. of dry ether were placed in a liter, three-necked flask equipped with a stirrer, reflux condenser, and an inlet for hydrogen chloride. Hydrogen chloride was bubbled in with stirring until solution of the stannous chloride was complete. This was indicated by the separation of a heavy, oily layer and the time required was about two and one-half hours. A suspension of 2 g. of 2,7-naphthalenedinitrile in 100 ml. of dry ether was then added with stirring over a period of forty minutes. Hydrogen chloride was passed in during this time. A viscous, yellow mass resulted. Stirring and the passage of hydrogen chloride were continued for a period of twenty-four hours by which time a yellow precipitate of the aldimine hydrochloride had formed. The mixture was cooled to zero before filtering to ensure as complete precipitation as possible. After filtration, the aldimine hydrochloride was hydrolyzed by refluxing in 250 ml. of water for twenty minutes. Upon cooling and filtering, the impure aldehyde mixed with inorganic material was obtained. Purification was partly accomplished through the bisulfite addition compound. Final purification was accomplished by two recrystallizations from water–alcohol solution which gave long, white needles, m. p. 142° (cor.). The yield was 0.5 g. (24.3%). 2,7-Naphthalenedialdehyde is soluble in methanol, ethanol, ether and benzene.

Anal. Calcd. for $C_{12}H_8O_2$: C, 78.26; H, 4.35. Found: C, 78.98; H, 4.19.

2,7-Naphthalenedialdehydedi-(2,4-dinitrophenylhydrazone).—The hydrazone was prepared from alcoholic solution catalyzed by a few drops of concd. hydrochloric acid. Recrystallization was not accomplished; color, orange; m. p., slight decomposition at 295°, complete decomposition at 312–313°.

Anal. Calcd. for $C_{24}H_{16}O_8N_8$: N, 20.59. Found: N, 20.13.

Summary

1. 2,7-Naphthalenedialdehyde was prepared by the action of stannous chloride on the corresponding dinitrile.

(3) Ebert and Merz, *Ber.*, **9**, 592 (1876).

2. The 2,4-dinitrophenylhydrazone of this aldehyde was prepared.

3. Attempts were made to obtain coronene by heating 2,7-polythionaphthalenedialdehyde with copper powder.

Factors Influencing the Cresolase Activity of Tyrosinase. The Effect of Gelatin and *p*-Cresol Concentration

BY WILBUR H. MILLER[1] AND CHARLES R. DAWSON

Previous workers[2,3,4] have demonstrated that tyrosinase preparations from the cultivated mushroom *Psalliota campestris* show a marked variation in ratio of catecholase to cresolase activity,[5] depending on the procedure used to isolate the enzyme. Since during the process of purification, unless special precautions are taken, the major portion of the cresolase activity is apt to be lost, the ratio of the catecholase to the cresolase activity in the purified preparation is often high (greater than 2). In these so-called "high catecholase" preparations, the catecholase activity is proportional to the copper in the preparation whereas the cresolase activity is not.[3,7] Until recently it was this type of preparation that was used for several investigations in this Laboratory concerning the nature, properties and mode of action of the enzyme tyrosinase.[2,7,8] In 1940 Parkinson and Nelson[4] reported the development of tyrosinase preparations in which the ratio of catecholase to cresolase activity was low (2 or less), and in which both enzymic activities were proportional to the copper content of the preparation. Such preparations have been called "high cresolase" preparations.

The development of different type tyrosinase preparations, having different ratios of catecholase to cresolase activities, has resulted in conjecture as to whether or not the enzyme is in reality one copper protein possessing two types of enzymic action, or is a mixture of two copper proteins each with its own activity. Before any considerable progress can be made toward a solution of this interesting and fundamental problem, it is necessary to have reliable means of characterizing the different type preparations on the basis of their catecholase and cresolase activities. Because of the marked inactivation of the enzyme that is observed particularly during the oxidation of catechol, it has been the practice to measure the enzyme activities in the presence of a "protecting" agent, gelatin being commonly used for this purpose.[2,9] Thus previous studies designed to compare the two types of tyrosinase preparations on the basis of their catecholase and cresolase activities have been made with gelatin present in the reaction medium.[4,10]

Recently, however, it has been found that the presence of gelatin in the reaction medium during the enzymatic oxidation of catechol (catecholase activity) tends to obscure fundamental differences between the different type preparations,[11] and it has been found that gelatin need not be present in the reaction medium in order to obtain a reliable measurement of catecholase activity.[12] These observations made it seem advisable to reinvestigate, from the same point of view, the effect of gelatin on the other characteristic activity of the different type tyrosinase preparations, *i. e.*, the cresolase activity.

The results of such a study, described in detail below, reveal that the increase in rate of oxidation of *p*-cresol (increase in cresolase activity), that is observed when tyrosinase is used in the

presence of gelatin, is dependent on the type of tyrosinase preparation employed and also on certain environmental factors such as the substrate concentration. The variable effect of gelatin in these *p*-cresol–enzyme systems has been found to be complex in nature, and may be such as to obscure or unduly accentuate certain fundamental characteristics of the particular enzyme preparation.

The Enzymatic Oxidation of *p*-Cresol

When a typical high catecholase preparation is used, with and without gelatin in the reaction medium, the enzymatic oxidation of *p*-cresol, as followed by manometric measurements of oxygen consumption, proceeds as shown by the curves of Fig. 1. In these experiments a constant amount of the enzyme was employed and the substrate (*p*-cresol) concentration was varied tenfold, that is from 2.5 to 25 mg. in an 8.0-cc. reaction volume. In contrast to the enzymatic oxidation of catechol which starts at a maximum rate,[11] it can be seen from Fig. 1 that the enzymatic oxidation of *p*-cresol is characterized by an initial lag or induction period in the rate of oxygen absorption. The length of this induction period can be varied in a number of ways and this phase of the reaction has been studied[6,8] in attempts to distinguish more clearly the differences between cresolase and catecholase activity. From Fig. 1 it is apparent that a tenfold variation in *p*-cresol concentration has no pronounced effect on the length of the induction period, either in the presence or absence of gelatin. Only in the case where gelatin is present in the reaction medium (Curves I-G, II-G, etc.) might it be inferred that the induction period is significantly less with the lower substrate concentrations.

With the high catecholase preparation, the rate of oxygen absorption after the initial lag period in the *p*-cresol reaction reaches a maximum value, usually in twenty to thirty minutes. This rate then continues at nearly a constant value whether gelatin is used or not. Thus, in the case where 2.5 mg. of *p*-cresol was used (Curves I and I-G of Fig. 1) it can be seen that the maximum value was maintained until about 75% of the *p*-cresol was completely oxidized.[13]

When a typical high cresolase preparation is used, the general course of the reaction is some-

(13) The complete enzymic oxidation of *p*-cresol results in the absorption of three atoms of oxygen per mole of *p*-cresol,[8] which for 2.5 mg. of *p*-cresol corresponds to an oxygen uptake of 785 cu. mm.

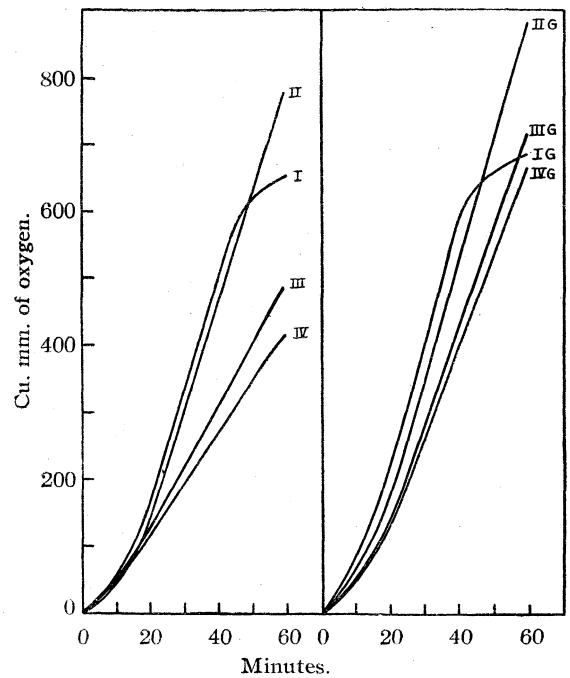

Fig. 1.—Showing the effect of gelatin and substrate concentration on the enzymatic oxidation of *p*-cresol by a high catecholase tyrosinase preparation. Oxygen absorption determined in Warburg Respirometer using flasks of 50-cc. capacity; 120 oscillations per minute; temperature 25°; *p*H 7.1. Total reaction volume was 8.0 cc., consisting of 1.0 cc. 0.2 *M* citrate–0.4 *M* phosphate buffer, 1.0 cc. (5 mg.) of gelatin solution where indicated, 1.0 cc. of *p*-cresol solution of indicated concentration (see data below), 1.2 cc. of a diluted (1:100) high catecholase tyrosinase preparation C144 added from the flask side arm to initiate the reaction, and water to bring to volume. Preparation C144 from the common mushroom, *Psalliota campestris*, had a catecholase to cresolase activity ratio of 13.8 and dry wt. (undiluted) of 2.6 mg. per cc.; contained 0.105% copper and 693 catecholase units per γ copper. Catecholase and cresolase activity were determined using methods previously described.[6,12] Each of the above curves is an average curve obtained from 3 to 5 experiments with readings taken at five-minute intervals. Such experiments are generally more reproducible when gelatin is a component of the system, *i. e.*, the points making up the average curve show less deviation. To compensate for this a greater number of experiments was employed in the systems containing no gelatin. The maximum rate values indicated below are obtained from the average curves over the time range where the oxygen uptake per five-minute interval was maximum and constant to within ±3 cu. mm.

what different. This is apparent from Fig. 2 where the data plotted have been obtained from experiments exactly analogous to those described in Fig. 1, except that a constant amount of a high cresolase preparation was used. It is to be noted that in a reaction medium containing no gelatin (Curves I, II, etc., of Fig. 2), the length of the induction period is changed rather appreciably by change in substrate concentration. A longer induction period results from the use of lower *p*-cresol concentrations. Gelatin in the reaction medium practically eliminates this effect of substrate concentration on the length of the induction period (Curves I-G, II-G, etc., of Fig. 2). These results are in contrast to the effects of gelatin and substrate concentration on the induction period of a high catecholase preparation (Fig. 1).

With a high cresolase preparation the rate of oxygen absorption, after the initial lag period, approaches a maximum more rapidly, and maintains this rate constant for a much shorter period of time than is the case when a high catecholase preparation is employed (compare Figs. 1 and 2). This is true whether gelatin is present in the reaction medium or not, although gelatin does tend to increase somewhat the time a nearly constant rate of oxygen uptake is maintained with the high cresolase preparation.

For both types of preparations, the most pronounced effect of a tenfold variation in original substrate concentration is, on the maximum rate of oxygen absorption, obtained after the initial lag period (see maximum rate data Figs. 1 and 2). Thus, considering the data obtained using the high catecholase preparation (Fig. 1), it can be seen that when there is no gelatin in the reaction medium (Curves I, II, etc.), a marked lowering of the maximum rate of oxidation results when the original amount of *p*-cresol is increased from 2.5 to 25.0 mg. However, when gelatin is a component of the system (Curves I-G, II-G, etc.), the effect of increasing the original substrate concentration is much less pronounced. Gelatin appears to prevent, to an appreciable extent, inhibition of enzyme action caused by excessive amounts of *p*-cresol. The data obtained with the high cresolase preparation (Fig. 2) show qualitatively the same thing. It should be noted, however, that the inhibitory effect of excessive amounts of *p*-cresol in the absence of gelatin (Curves I, II, etc.) is considerably less pronounced for this type of preparation.

The manner in which the rate of enzymatic oxidation of *p*-cresol varies with the substrate concentration for both types of tyrosinase preparations, and the influence of gelatin on this variation, is shown more strikingly in Fig. 3. The data in Fig. 3 are those of Figs. 1 and 2 (see legend Fig. 3) plotted to show the rates as percentages of the optimum rate obtained in each series of experiments. It is apparent that in the absence of gelatin the rate of oxidation of *p*-cresol with a high catecholase preparation (Curve I) is considerably more sensitive to change in original substrate concentration than is the rate obtained with a high cresolase preparation (Curve II). Of particular interest is the quite different picture obtained when gelatin is present in the reaction medium. Although gelatin does not shift the position of the optimum substrate concentration for either type preparation, its effect on the substrate-rate curve is not the same for both type preparations.

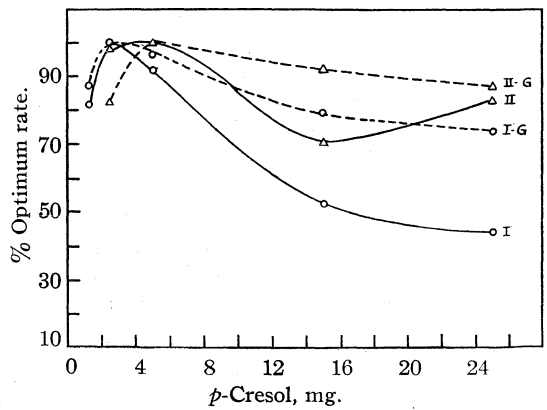

Fig. 3.—Showing the relationship between substrate concentration and cresolase activity when measured in the presence and absence of gelatin. The percentages of the optimum rates obtained with and without gelatin for each type preparation are calculated from the maximum rate data given in legends of Figs. 1 and 2 with one exception. Data obtained as indicated in the legend of Fig. 1 for 1.25 mg. of *p*-cresol have been added to show the optimum *p*-cresol concentration for the high catecholase preparation. Experimental points on the curves are: O, high catecholase; Δ, high cresolase; — — —, gelatin; ———, no gelatin.

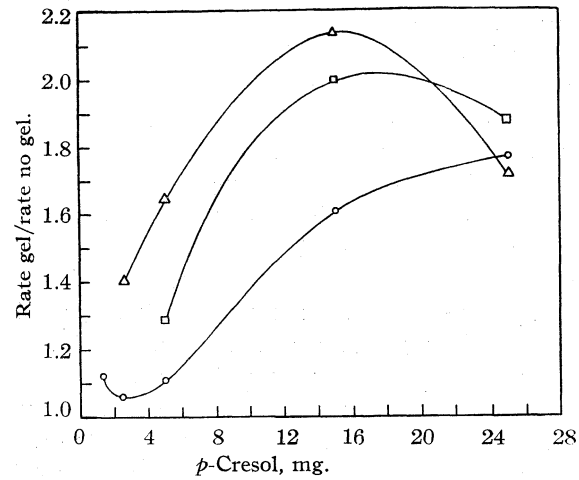

Fig. 4.—Showing that the effect of gelatin on cresolase activity varies markedly with the type of tyrosinase preparation and with the *p*-cresol concentration. For the high catecholase and the high cresolase preparations the ratios (rate gelatin/rate no gelatin) are calculated from the maximum rate data given in legends of Figs. 1 and 2 except for 1.25 mg. of *p*-cresol (see legend Fig. 3). The data shown for the intermediate preparation[14] were obtained as indicated in the legend of Fig. 1 using 0.8 cc. of the diluted (1:100) enzyme preparation C144PbAl. This preparation had a catecholase to cresolase activity ratio of 4.1 and a dry weight (undiluted) of 1.2 mg. per cc. contained 0.106% copper and had 690 catecholase units per γ of copper. Experimental points are: O, high catecholase; Δ, high cresolase; □, intermediate.

This difference in effect of gelatin is particularly noticeable on the low concentration side of the optimum.

Inspection of the rate data in Figs. 1 and 2 shows that when gelatin is present in the reaction medium, the maximum rate of the enzymatic oxidation of *p*-cresol is in all cases greater than that obtained when gelatin is not present. Gelatin causes an apparent increase in cresolase activity. The important point to note in this connection is the fact that the boosting effect of gelatin is not constant, but is variable, depending not only on the type of tyrosinase preparation, but also on the substrate concentration. This statement is emphasized by the data as shown in Fig. 4.

Discussion

Just how gelatin causes the effects described above is not clearly understood at the present time. The mechanism whereby one protein influences the state and action of another presents an interesting and fundamental problem, but it is a problem that cannot be solved until more data on the phenomena are available and more is known about protein structure. A study of the effect of inert protein material on the catalytic action of protein enzymes offers one of the most direct attacks on the problem, for the effects produced by the inert protein can be easily measured. It has been the purpose of this study to emphasize the fact that the effect of gelatin on tyrosinase cresolase activity and characterizing features of that activity is variable and markedly dependent on the type of tyrosinase preparation, *i. e.*, on the state of the tyrosinase protein material.

It has been suggested that the effect of gelatin results from the fact that it tends to prevent inactivation of the enzyme during the course of the oxidation,[9] primarily by preventing the enzyme from entering the air–liquid interface where surface denaturation of the protein–enzyme may occur.[15] Although it is probable that gelatin does "protect" the enzyme to some extent in this manner, certain of the data presented here, and elsewhere,[11] indicate that the function of gelatin is considerably more complex, and involves factors in addition to those which merely prevent inactivation of the enzyme. For the "protection" view of gelatin action to be completely logical and

(14) Tyrosinase preparations having a ratio of catecholase to cresolase activity in the range of 3.5–4.0 frequently are found to have properties intermediate to those characterizing the high catecholase and high cresolase preparations. Such enzyme preparations have been termed "intermediate" preparations.[11, 12]

(15) L. Tenenbaum, Dissertation, Columbia University, 1940.

satisfactory in explaining the very significant increase in cresolase activity that is observed when gelatin is employed in the measurements, one would expect to find considerable evidence of inactivation of the enzyme when gelatin is not employed. Furthermore, one would expect to find correspondingly less evidence of inactivation of the enzyme when gelatin is a component of the system. Yet when the cresolase activity of a high catecholase preparation is measured with no gelatin in the system (Curves I, II, etc., Fig. 1), constant rates of oxidation are observed for periods of over a half hour with the surface of the system changing at least 120 times per minute, *i. e.*, there is no evidence of serious inactivation of the enzyme in the absence of gelatin. With the other type of tyrosinase preparation (high cresolase preparation) there is evidence (short period of constant rate) indicating possible inactivation of the enzyme, when the activity measurements are made in the absence of gelatin (Curves I, II, etc., Fig. 2). However, the change toward a linear oxidation curve, effected by making gelatin a component of the system (compare Curves II and II-G, Fig. 2) appears to be hardly enough to explain a 65% increase in cresolase activity (compare maximum rate data for Curves II and II-G, Fig. 2).

Certain of the data obtained in this study suggest that gelatin increases the enzyme activity by perhaps modifying the enzyme molecule, or more likely by modifying the enzyme substrate relationships during the course of the reaction. Thus the influence of gelatin on the initial phase of the reaction, the induction period, was found to vary with the type of enzyme preparation and the substrate concentration. These same two factors were found also to influence the boosting effect of gelatin on the rate of oxidation obtained after the induction period (see Fig. 4).

It is possible that much may be learned in the future about the enzyme tyrosinase by studying its action in the presence of added protein material, such as gelatin. However, it would appear that when studies are made for the purpose of comparing the various type tyrosinase preparations, in reference to either their cresolase or catecholase activity, the use of gelatin is not to be recommended, at least not until more is known about its complex role in the system. With gelatin present, certain fundamental differences between the various type preparations are likely to be masked or possibly accentuated.

Summary

1. The effect of gelatin and *p*-cresol concentration on the cresolase activity of different type tyrosinase preparations from *Psalliota campestris* has been studied.

2. Over a tenfold range of substrate concentration, gelatin causes an increase in the rate of *p*-cresol oxidation as catalyzed by the enzyme tyrosinase.

3. The increase in rate of oxidation caused by gelatin varies markedly with the type of enzyme preparation and the substrate concentration.

4. The different type tyrosinase preparations show characteristic relationships of substrate concentration to cresolase activity and these relationships are affected differently by gelatin.

5. It appears that the role of gelatin in these systems is considerably more complex than just preventing inactivation of the enzyme during the course of the oxidation.

Some Physical Chemical Characteristics of Glycogen

BY WILBUR B. BRIDGMAN

The research described in this report was undertaken with a two-fold purpose. First, the particle size of glycogen has not been studied by sedimentation methods, and further information regarding its physical characteristics may be of value to the biological worker in understanding the relationship of glycogen to animal metabolism. Second, it was desired to gain experience and information in the application of ultracentrifuge experiments to inhomogeneous systems where the particle size varies continuously in contrast to the discrete size classes generally found in protein systems.

Much of the literature about glycogen is concerned with its determination in tissue and its relation to metabolism. While glycogen is widely distributed throughout the bodies of animals, about one-half of the total amount is concentrated in the liver. This organ is therefore the logical raw material for the preparation of glycogen. Two principal methods have been used for its extraction. The older method involves heating with concentrated alkali as the primary step. More recently the first extraction has been made with a dilute solution of trichloroacetic acid. Both methods have been shown to agree in the amount of glycogen obtained and no differences have been shown between the materials prepared by these two methods.[1] The properties of the glycogen samples that were compared were rotatory power, ash content, iodine color and reducing power. It seemed possible that the ultracentrifuge might be used to show differences in particle size that would not affect the properties previously studied.

In previous attempts to measure the particle size, osmotic pressure determinations[2] on glycogen or its derivatives have indicated high molecular weights (500,000 to 3,500,000). Early attempts to deduce the molecular size from substitution and end-group reactions were interpreted as indicating a much smaller molecule. In recent years these data have also been shown to be consistent with macro-molecules.[3] The only previous account of ultracentrifuge measurements with glycogen that the author has found in the literature is a statement by Mystkowski[4] that in preliminary experiments sedimentation of glycogen occurred at speeds of 17,000 to 25,000 r. p. m. and that it was very polydisperse.

Preparation

The glycogen used in this research was prepared from rabbit livers.[5] Two methods of preparation were used. Method A used 3% trichloroacetic acid to extract the glycogen from the liver and was essentially the same as that described by Sahyun and Alsberg.[6] In method B small pieces of liver were digested in concentrated solutions of potassium hydroxide on a steam-bath.[7] In both cases the glycogen was purified by dissolving in water and reprecipitating with ethyl alcohol three or four times.

The glycogen was kept in two forms. Some of the material was dried to constant weight in a vacuum desiccator over calcium chloride at room temperature. In other cases water solutions were dialyzed against distilled water to remove traces of salts or alcohol. The concentration of these stock solutions was determined by evaporation to dryness, assuming all non-volatile material to be glycogen. The following paragraphs describe the treatments applied to the individual samples of glycogen used in this investigation.

Glycogen II.—Five rabbit livers were treated by method A. About half of the material from the last precipitation was dried. This gave 2.4 g. of glycogen, designated as IIADd. The remainder was dissolved and dialyzed. This made a 7.14% stock solution, IIADl.

Glycogen IIIA.—Four rabbit livers were treated by method A. About half of this glycogen was dried from the last precipitation, giving 1.2 g. of IIIADd. The remainder, IIIADl, was used for the dialyzed stock solution of concentration 2.07%.

Glycogen IIIB.—Three livers obtained at the same time as those used in IIIA were worked up by method B, using 50% potassium hydroxide as solvent. The yield from this preparation was very small. All of the material obtained was dissolved to form a stock solution, IIIBDl, of 0.4% concentration.

Glycogen VA.—A single liver was frozen in dry-ice as soon as it was removed from the rabbit. The liver was crushed in the frozen state and divided into two approximately equal portions. One portion was treated by method A. All of the material was dialyzed in this case.

(7) M. Sahyun, *ibid.*, **93**, 227 (1931); N. R. Blatherwick, P. J. Bradshaw, M. E. Ewing, H. W. Larson and S. D. Sawyer, *ibid.*, **111**, 537 (1935).

A 25-cc. sample of the dialyzed solution was evaporated to dryness. This gave 0.3966 g. of a residue which was designated VADd. The bulk of the solution was used as stock solution VADl.

Glycogen VB.—The other half of the liver used in preparation VA was treated by method B, using 30% potassium hydroxide as solvent. After the initial treatments with acid and alkali, respectively, the two samples VA and VB were purified simultaneously. Each sample received identical treatment in the process of purification. Drying 25 cc. of dialyzed solution gave 0.3884 g. of VBDd. The bulk of the solution was used for VBDl. Glycogen VBDd had an orange discoloration while VADd was clear white in appearance.

Experimental Results

Sedimentation Constants.—Sedimentation velocity experiments were performed in both the Svedberg oil turbine "velocity" ultracentrifuge and the Svedberg electrically driven "equilibrium" ultracentrifuge. At a speed of 18,000 r. p. m., which can be obtained with either centrifuge, sedimentation was rapid. In both centrifuges the solution was at a distance from 5 to 7 cm. from the center of rotation. Observation of the redistribution of the components of the solution was made by the Lamm scale displacement method. The sedimentation constant, s, was calculated by the procedure given by Svedberg and Pedersen.[8] Because of the heterogeneity of the material, the graphs of scale displacement, Z, against distance from the center of rotation had quite broad peaks, making it difficult to locate the maxima accurately. As a result, individual calculations of s for successive time intervals during a given experiment fluctuated widely. Average values of s from separate experiments on the same or comparable solutions show agreement with $\pm 5\%$ in most cases. Satisfactory agreement was found between sedimentation constants measured with the two centrifuges. However, the velocity centrifuge was considered to be more reliable. In some of the experiments in the equilibrium ultracentrifuge, very sharp boundaries were observed that were attributed to convection rifts because of their abnormal behavior and because of the failure to observe them in duplicate experiments in the velocity machine. The results obtained with the various samples are summarized below.

Glycogen II.—Ten measurements were carried out on solutions of this preparation. The concentration of glycogen was varied from 0.8 to 2.86%. Nine experiments were performed in the velocity ultracentrifuge, five at 42,000 r. p. m. and four at 18,000 r. p. m. One experiment was performed in the equilibrium ultracentrifuge at 17,500 r. p. m. The first two experiments made on the dialyzed material indicated the presence of two boundaries. Only the slower moving peak was sufficiently well-defined to permit the calculation of a sedimentation constant. All the remaining experiments showed one broad peak. The average values of s_{20} for these ten experiments varied from 60 to 70 S (one Svedberg unit, S, $= 1 \times 10^{-13}$ c. g. s. units). The average for the ten experiments was $s_{20} = 64.8\ S$. One of the measurements with glycogen IIDd was made more than a year after the preparation of the sample. This experiment gave $s_{20} = 60.2\ S$. An attempt to correlate s_{20} with the concentration of glycogen indicated a slight increase of s as the concentration was decreased. This trend was so small in comparison to the fluctuations of the individual values of s_{20}, that no significance was attached to it and no attempt was made to extrapolate s_{20} to infinite dilution. Likewise the solvent was varied from distilled water to 1% sodium chloride without producing any significant change. It was thus concluded that s_{20} was independent of the concentration of glycogen or of salt in the range studied within the accuracy of the observations. Subsequent experiments used 0.1% sodium chloride as solvent.

Glycogen IIIA.—Two experiments with glycogen IIIAdl and two with glycogen IIIADd were carried out at 17,000 r. p. m. in the equilibrium ultracentrifuge. These experiments showed two boundaries that gave s_{20} values in the range 65 to 88 S. A duplicate experiment in the velocity centrifuge at 18,000 r. p. m. indicated a single broad peak with $s = 61\ S$. It was concluded that convection must have occurred in the earlier observations and that this last value is the best that can be obtained under present conditions.

Glycogen IIIB.—Five experiments were performed in the equilibrium ultracentrifuge during the interval from eleven to forty-five days after the livers were obtained. The first two experiments indicated double peaks. The slower peak corresponded to values of $s_{20} = 138$ and 152 S, respectively, and the faster peak gave $s = 296$ and 441. The third experiment, carried out a week later than the first, gave a single broad peak with $s_{20} = 244\ S$. The next two experiments,

(8) T. Svedberg and K. O. Pedersen, "The Ultracentrifuge," Oxford University Press, New York, N. Y., 1940.

performed at approximately two week intervals, gave single broad peaks, with $s_{20} = 120$ and 92 S. A check experiment in the velocity ultracentrifuge with this last sample gave the same type of peak with $s = 105$ S. This behavior suggests a change had taken place in the material on standing, with the final state being a single maximum distribution with the maximum corresponding to $s_{20} = 100$ S.

Glycogen VA.—Two solutions of glycogen VADl gave values of $s_{20} = 85$ and 81 S. There was a suggestion of a second peak of lighter material (s_{20} of the order of magnitude of 10 S) (see Figs. VI and VII). Two experiments were also made with solutions of glycogen VADd. One of these gave $s_{20} = 79$ S. The other was inconclusive as the first two exposures showed a single maximum peak but in later pictures this had broken up into a series of four peaks that bore no resemblance to any of the other three experiments. The average of the three experiments is $s_{20} = 82$ S.

Glycogen VB.—Two solutions of glycogen VBDl and one of glycogen VBDd gave values of $s_{20} = 67$, 75, and 77 S, respectively. The average is $s_{20} = 73$ S. All experiments with glycogen VA and VB were made in the velocity ultracentrifuge.

Diffusion Constants.—Five diffusion experiments were performed in a glass Lamm diffusion cell. Observations of the blurring of the boundary were made by the scale line displacement method. The diffusion constant was calculated by means of the expression

$$D = \sigma^2/2t$$

where t is the time and σ is the standard deviation of the curve obtained by plotting the scale displacement, Z, against position in the cell. A method of second moments was used for evaluating σ. Values of D_{20} calculated from individual exposures during these five experiments are shown graphically in Fig. 1. The abscissas are times after the formation of the boundary. The observed values of D are seen to fall into two groups. The results for glycogen IIIB are distinctly lower than the other values which are fairly consistent among themselves. The three values for glycogen IIIB have an average $D_{20} = 0.69 \times 10^{-7}$. The average of all the remaining values is $D_{20} = 1.42 \times 10^{-7}$. Figure 1 shows that there is a definite trend toward lower values as time increases. It is often observed that diffusion constants decrease from an initial value to a limiting value that is considered to be the true value.

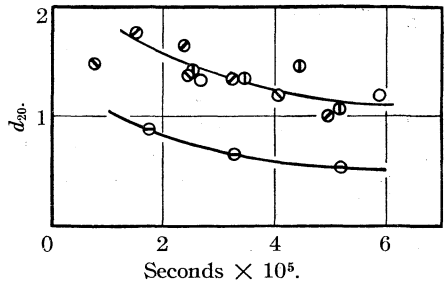

Fig. 1.—Variation of diffusion constant with time after formation of boundary: O, glycogen IIDd; ⊘, glycogen IIIADl; ⊖, glycogen IIIBDl; ⊘, glycogen IIDd; ⊕, glycogen VADd.

While no limiting value is clearly indicated by the values in Fig. 1, they can be interpreted as approaching a value of $D_{20} = 1.1 \times 10^{-7}$ for the main group and $D_{20} = 0.5 \times 10^{-7}$ for glycogen IIIB. If the individual values are plotted against the reciprocal of the time and extrapolated by a straight line to infinite time, lower values of $D_{20} =$ 0.8 and 0.35×10^{-7}, respectively, are obtained. This extrapolation may overcorrect the value since the diffusion constants should eventually become constant, instead of continuing to decrease. It is thought that the values obtained from Fig. 1 represent the best interpretation of the data.

The experimental line displacement–distance curves were compared to a normal distribution curve by a transformation of coördinates. In Figs. 2 and 3 the points represent experimental data obtained with glycogens IIIB and VA, respectively, and the solid line is the ideal distribution curve plotted on the same scale. The other three experiments gave results similar to those which form Fig. 2, *i. e.*, good agreement with the ideal curve. For a curve of ideal shape the value of D calculated from the area and maximum height

$$D = A^2/tH^2_{\text{max.}}$$

should be the same as that calculated by the first method. Good agreement was found between the values of D calculated by the two methods in all cases except for glycogen VA. In this case the height–area method gave consistently lower values.

Partial Specific Volume.—Densities of a series of water solutions of glycogen IIDd were determined pycnometrically at 25°. The most concentrated solution contained 1% glycogen. The apparent partial specific volume calculated from the density was 0.65.

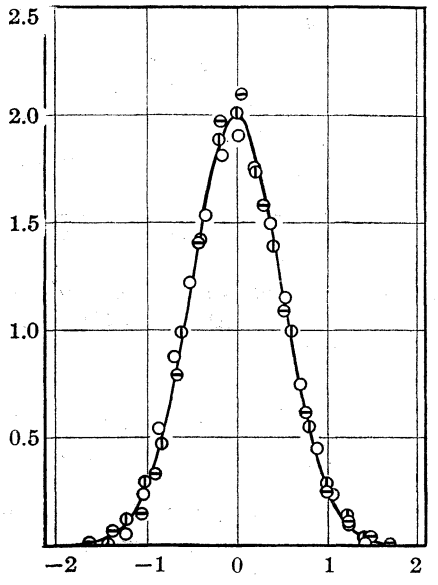

Fig. 2.—Comparison of normal distribution curve with scale line displacements obtained from diffusion experiment on glycogen IIIBDl. Solid line is theoretical curve. Points are calculated from experimental data at various times after the formation of the boundary: ⊖, 174,000 sec.; ⊕, 329,000 sec.; O, 521,000 sec.; arbitrary units.

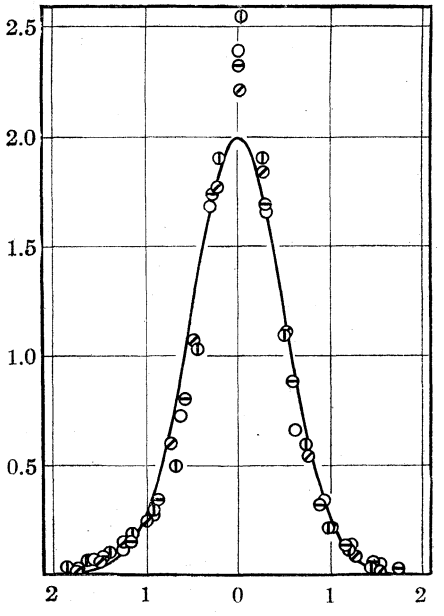

Fig. 3.—Comparison of normal distribution curve with the scale line displacements obtained from diffusion experiment on glycogen VADd. Solid line is theoretical curve. Points are calculated from experimental data at various times after the formation of the boundary: O, 254,000 sec.; ⊖, 347,000 sec.; ⊕, 432,000 sec.; ⊘, 518,000 sec.; arbitrary units.

Refractive Index.—Refractive indices of the solutions used in the density determinations were measured with a dipping refractometer. The value of the refractive index increment,[8] α, was found to be 1.38×10^{-3} for the sodium D line at 25°.

Discussion of Results

Sedimentation.—Sedimentation experiments with glycogen II performed at different centrifuge speeds appeared to give peaks of the same width when the boundary had moved a given distance from the meniscus. This suggested that the blurring of the boundary was due to inhomogeneity of the material and that diffusion was negligible during the time of the experiment. In such a case the shape of the sedimentation curve can be used to obtain the particle size distribution in the sample.

Mathematical functions relating the Z *vs.* x curves obtained at different times during the same experiment have been derived on the assumption of no diffusion taking place during the experiment.[8,9] If the experimental curves can be superimposed when transformed to the same basis by these relationships, that is proof that diffusion has been negligible.

These transformations were applied to the data from two of the experiments. The results are shown graphically in Figs. 4 and 6. In the

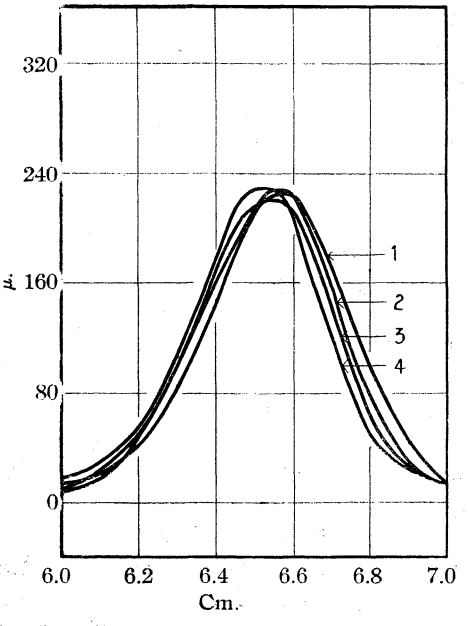

Fig. 4.—Scale line displacement *vs.* distance from center of rotation for a sedimentation experiment on glycogen IIDd. Curves corresponding to different times after the start of sedimentation have all been transformed to the same time (60 min.) assuming diffusion to be negligible: 1, 30 min.; 2, 40 min.; 3, 50 min.; 4, 60 min.

(9) R. Signer and H. Gross, *Helv. Chim. Acta*, **17**, 726–735 (1934).

case of Fig. 4 (a 1% solution of glycogen IIDd at 18,000 r. p. m.) the agreement is very satisfactory. The maximum heights of the four curves agree very well. The horizontal shifting of the curves may be due to error in the determination of the position of the meniscus or the starting time of the experiment. Both of these quantities are important in the calculations. The beginning of sedimentation was taken as the time when the ultracentrifuge had reached operating speed. Actually some sedimentation has probably occurred during the period when the machine is coming up to speed (about seven minutes in this case). The agreement of these curves is taken as proof of the absence of diffusion during this experiment. In Fig. 5 is given a distribution curve indicating the relative concentrations of components as a function of the sedimentation constant. This distribution curve has been constructed from the last curve of Fig. 4 by using the expressions

$$s = \ln \frac{x}{x_0} \Big/ t\omega^2$$

and

$$\frac{dc}{ds} = \left(\frac{x}{x_0}\right)^2 xt\omega^2 \frac{dc}{dx}$$

The scale displacement, Z, is used to evaluate dc/dx.[8]

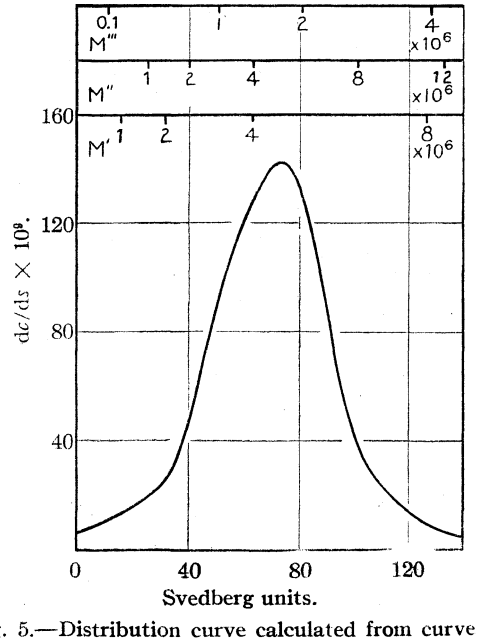

Fig. 5.—Distribution curve calculated from curve 4 of Fig. 4 showing variation of concentration as a function of the sedimentation constant.

Figure 6 shows the results of attempting to superimpose the data from an experiment with

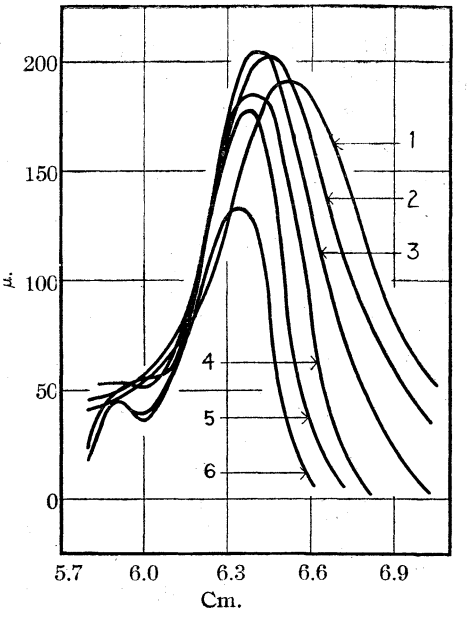

Fig. 6.—Scale line displacement *vs.* distance from center of rotation for a sedimentation experiment on glycogen VADd. Curves corresponding to different times after the start of sedimentation have all been transformed to the same time (53 min.) assuming diffusion to be negligible: 1, 13 min.; 2, 23 min.; 3, 38 min.; 4, 53 min.; 5, 68 min.; 6, 83 min.

glycogen VBDl. With the exception of the first and last curves, the agreement is quite satisfactory on the left side of the peak. Toward the bottom of the cell there is a marked decrease with increasing time. This may be accounted for in several ways. These curves were obtained during the period from thirteen to eighty-three minutes after the centrifuge had reached operating speed. The curves of Fig. 4 cover the interval from thirty to sixty minutes. Thus any error in the position of the meniscus or the initial time will be much more apparent in Fig. 6 than in Fig. 4. Furthermore, the calculations show that positions corresponding to size classes in the leading edge of the peak in the early pictures will fall beyond the bottom of the cell in the last exposures (*i. e.*, the time is sufficient for some of the material to have sedimented to the bottom of the cell). This fact makes questionable the usual practice of using the z values at the bottom of the cell to determine the base line. In the later exposures of this experiment no portion of the cell could be expected to have the original unchanged concentration present. The curves given in Fig. 6 were obtained by drawing in a base line in the conventional manner. Another cal-

culation in which the displacements measured in the comparator were used directly without any base line correction gave somewhat more erratic results but did not show any essential differences from Fig. 6.

In spite of the failure of the curves to superimpose exactly there is considerable indication that diffusion is not the cause of the discrepancy. The maximum heights of the curves (omitting the last two) agree within 10%. The heights of the original experimental curves, *i. e.*, before the transformation was made, varied tenfold. The original curves of Z against x without any base line correction are shown in Fig. 7. The first two curves have been corrected for differences in the optical arrangement so as to be comparable with the rest. The broken lines in Fig. 7 are the theoretical functions for the variation of the height of the peak with position in the cell. The upper one is for the case of a homogeneous material, the blurring being entirely due to diffusion. The lower one represents the case of no diffusion. The observed heights of the curves agree very well with the prediction for no diffusion. If blurring is due to diffusion, the application of the transformation

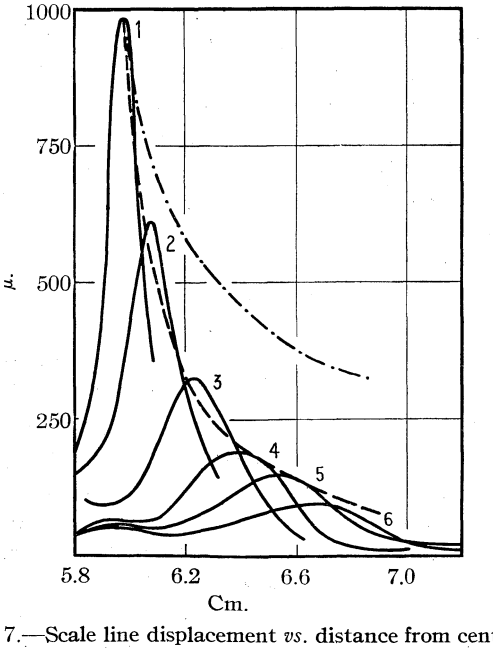

Fig. 7.—Scale line displacement *vs.* distance from center of rotation for a sedimentation experiment on glycogen VADd. Solid lines are observations of the boundary at various times: 1, 13 min.; 2, 23 min.; 3, 38 min.; 4, 53 min.; 5, 68 min.; 6, 83 min. Broken lines are the theoretical functions for the decrease in maximum height of the curves based on different assumptions: · — · — · — homogeneous material with diffusion; — — — inhomogeneous material with negligible diffusion.

equations will result in the later curves being higher than the curves obtained from exposures at an earlier time.[9] Actually the trend of Fig. 6 is in the opposite direction. In spite of the evidence pointing to the absence of diffusion in this experiment, the failure of the individual curves to superimpose completely makes it undesirable to calculate a size distribution curve from any one of them.

The later curves in both Figs. 6 and 7 show a small but definite peak of lighter material that was not resolved in the earlier exposures.

Analysis of the transformation equations shows that the scale line displacements corresponding to the more rapidly moving components decrease more rapidly than those for the components which move more slowly. This means that as sedimentation proceeds the maximum of the Z curve shifts toward the lighter components. Thus a sedimentation constant calculated from the maxima of successive Z curves might be expected to decrease as the length of the experiment increases and it would not represent the specific sedimentation constant for a particular component. The extent of this effect would depend upon the shape of the distribution curve, being greatest for a curve with a very broad maximum. A calculation applied to the data for the thirty-minute and sixty-minute curves in Fig. 4 showed that in this case the apparent sedimentation constant calculated from the maximum points would differ by less than 2% from the actual sedimentation constant of the component in the maximum at one time. In view of the experimental error in determining the position of the maximum this effect is not considered for correction. This effect does not explain the shifting of the maxima in Figs. 4 and 6 since the transformations should correct the apparent shift of the maximum caused by the more rapid separation out of the heavier components.

By combining values of the sedimentation constant, diffusion constant and partial specific volume, molecular weight and shape factor data for glycogens can be obtained.[8] In Table I are summarized average values of s_{20} and D_{20} for each of the samples of glycogen which were studied, together with the values of molecular weight and shape factor calculated from them. Aside from glycogen IIIB the variations between the samples are not considered significant. In preparation IIIB a glycogen of definitely greater particle size was ob-

tained. This may be connected with the small yield of glycogen obtained in this preparation. It seems likely that an unintentional fractionation may have occurred in the extraction or purification of this sample. It is of interest in showing that glycogen exists or can be prepared in samples of varying size.

TABLE I

MOLECULAR KINETIC DATA FOR GLYCOGENS

Glycogen	S_{20} (S units)	$D_{20} \times 10^7$	f/f_0	$M \times 10^{-6}$
II	65	1.1	1.90	4.1
IIIA	61	1.1	1.94	3.9
IIIB	100	0.5	2.78	13.9
VA	82	1.1	1.76	5.2
VB	73	1.1	1.83	4.6

Some experiments, particularly those with glycogen IIIB, suggested that when first prepared larger sized particles were present. On standing in water solution, the distribution changed to a function with a single maximum at a lower molecular weight. The evidence for this is, however, not conclusive. This possibility is of interest in the light of K. Meyer's conclusion that starch undergoes a continual aggregation in water solution.[10]

Samples of glycogen VA and VB, which should provide the most critical test for any differences in the products obtained by the acid method or basic method, do not show significant differences.

A shape factor of 1.9 corresponds to an ellipsoid of revolution having an axis ratio of 1 to 18 for a prolate ellipsoid or a ratio of 1 to 25 for an oblate ellipsoid. This dissymmetry is much greater than other investigations of glycogen have indicated. A larger value of the diffusion constant would lower the shape factor.

In order to translate the sedimentation constants used as abscissa in Fig. 5 into molecular weight, it is necessary to make assumptions regarding the particle shape. At the top of Fig. 5 are three molecular weight scales based on different assumptions. M' is calculated on the assumption that the diffusion constant, 1.1×10^{-7}, is the same for all components. M'' is based on the assumption that the shape factor 1.9 is constant for all species. M''' is the value for spherical particles. Probably no one of these scales represents the actual relationship exactly, but together they give an indication of the range of sizes possible.

(10) K. H. Meyer (see ref. 3), p. 146–165.

An interpretation of diffusion measurements on polydisperse material has been made by Gralén.[11] His investigation shows that for a polydisperse system the value of the diffusion constant calculated will be greater, the higher the moments used in its calculation. This difference in diffusion constant, calculated by the different moments, can be used as a measure of polydispersity but requires very accurate data. The results with glycogen lead to the conclusion that comparison of the observed scale line displacement curve with the Gaussian error curve is not a sensitive test of homogeneity. The one diffusion experiment which did not show good agreement with the normal distribution curve was with sample VA where the ultracentrifuge also had indicated some lighter material grouped about a second maximum (see Figs. 6 and 7).

Apparently, polydispersity of the degree observed here is not sufficient to cause marked deviation from the ideal case as long as the particle size distribution can be described by a simple curve with a single maximum.

There is no proof that the principal component in sedimentation would be the principal factor in determining the diffusion constant. The molecular weight calculated from sedimentation and diffusion may be questioned on this basis that the two average values do not necessarily apply to the same component. A process of fractionation followed by sedimentation and diffusion studies with the more homogeneous fractions should be very helpful in interpreting data of this type.

Acknowledgment.—The author wishes to express his appreciation to Professor J. W. Williams for his coöperation and advice in the preparation of this report.

Summary

Glycogen solutions prepared by either the acidic or basic method give an inhomogeneous product. The bulk of the material prepared by the methods used lies in the range of sedimentation constant from 20 to 120 S with the maximum component having a value of $s_{20} = 70$ S. This maximum corresponds to a molecular weight of 2,000,000 if the particle is spherical or a molecular weight of 4,000,000 if the measured diffusion constant can be used to evaluate the frictional resistance to sedimentation. It has not been proven that the glycogen in the tissue is of this same par-

(11) N. Gralén, *Kolloid. Z.*, **95**, 188 (1941).

ticle size or that this particle represents the chemical molecule rather than an aggregate. This investigation indicates the possibility of further work on the natural state of glycogen, methods of its preparation and the interpretation of experimental results on inhomogeneous systems in general.

The Structure of Copolymers of Vinyl Chloride and Vinyl Acetate[1]

BY C. S. MARVEL, GIFFIN D. JONES, T. W. MASTIN AND G. L. SCHERTZ

It is widely recognized that the simultaneous polymerization of two monomers in a mixture leads to products that are quite different from the mixtures obtained by polymerizing the two monomers separately and then combining the polymers. The copolymerization of the monomers thus must lead to mixed units of two monomers in a single polymer chain.

Considerable experimental evidence supporting this generally accepted fact can be cited. Hill, Lewis and Simonsen[2] have made copolymers of butadiene and methyl methacrylate and then ozonized them. The ozonolysis products were such as to show that in general the methyl methacrylate units were sandwiched between butadiene units and that the latter were usually attached by the 1 and 4 carbon atoms in the chain. There was also evidence of direct union between butadiene units and between methyl methacrylate units in the polymer chain. Thus in this particular case almost every possible type of union between the monomers seems to have occurred when the mixture of monomers was polymerized.

Staudinger,[3] Norrish,[4] and others[5] have shown by their studies of copolymers of styrene and *p*-divinylbenzene that cross-linking of chains occurs due to the participation of the divinylbenzene in the reaction. Hence real copolymers must form.

Staudinger and Schneiders[6] have shown that a copolymer of vinyl chloride and vinyl acetate can be separated into products containing varying amounts of chlorine by means of fractional precipitation. This suggests considerable non-homogeneity of product.

Previous work in this Laboratory has shown that vinyl chloride when polymerized alone gives a 1,3 product[7] and likewise when vinyl acetate alone polymerizes,[8] a 1,3 product results. The present work on the copolymers of these two compounds was undertaken to see whether the two monomers entered the copolymer chains in the same arrangement. The first samples examined were some high-chlorine experimental "Vinylites" prepared in the research laboratories of Carbide and Carbon Chemicals Corporation and furnished to us with that Company's permission by Dr. G. H. Young at Mellon Institute. An attempt was made to study the distribution of chlorine in the polymer chain by statistical methods using the dehalogenation of the polymer by zinc.[7] The results of these experiments seemed to be what was expected for a chance distribution in the polymer chains of vinyl chloride and vinyl acetate units.[9]

Next an attempt was made to apply the same procedure to some low-chlorine vinyl chloride–vinyl acetate copolymers made in our own Laboratory. In early results we found the chlorine was removed in far greater quantities than should have been the case if the vinyl chloride units were distributed in the polymer chains according to chance alone. The dehalogenation experiments did not prove to be too satisfactory and were, in fact, not readily reproducible but they did prove that the chlorine atoms were closer together than chance alone would explain.

At this stage of our work, Wall[10] pointed out that two monomers may have quite different tendencies to enter the growing chain of the copolymer. If the two monomers do enter the chain at different rates the polymer found will not have a uniform composition. Wall's equation[10] can be used to express this relation. When α is 1, the

$$\frac{dn_x}{dn_y} = \alpha \frac{n_x}{n_y}$$

two monomers enter the chain at the same rate and the polymer formed at any instant will be of the same composition as the mixture of monomers from which it is produced.

Since our low chlorine copolymer of vinyl chloride and vinyl acetate lost more chlorine than was expected when treated with zinc, it was thought that the α value for this pair of monomers was probably not unity for the experimental conditions used in preparing the samples studied. To test this we ran some interrupted polymerizations to see how the chlorine content of the growing copolymers change. A wide variety of mixtures of vinyl chloride and vinyl acetate were prepared. These mixtures were polymerized under different conditions and for different lengths of time. The complete details are recorded in the experimental part but one example here shows the general trend. A mixture of vinyl chloride and vinyl acetate containing 12.48% of chlorine was divided into four sealed tubes. A little benzoyl peroxide was added and the tubes were allowed to stand for various times. The tubes were opened and the polymers isolated. The molecular weights of the polymers formed at different stages were not markedly different as indicated by viscosity measurements. The tube opened first gave a 49% yield of a copolymer containing 17.65% of chlorine; the second tube gave a yield of 65% containing 15.08% of chlorine; the third tube gave a yield of 78% containing 13.90% of chlorine and the last tube gave a 95% yield of polymer containing 12.48% of chlorine. It is thus obvious that vinyl chloride enters the polymer chain much more rapidly than does vinyl acetate when these two monomers are copolymerized from a mixture. It is also obvious that each polymer chain laid down from this mixture is probably different from every other one, for as the composition of the monomer changes, the ratio of units which enter the polymer will change.

From the examination of a wide variety of copolymerization mixtures of vinyl chloride and vinyl acetate the value of α in Wall's equation at 40° seems to be between 1.5 and 2 and the ratio seems to approach 1 as the temperature of the polymerization is increased.

Once these facts were established, it was clear that the suggestion contained in certain patents[11] that copolymers of improved uniformity could be obtained by the addition of portions of one constituent during the polymerization was based on information of the same sort which we have rediscovered.

Likewise, it has been shown in other cases that the composition of a copolymer is not necessarily related to the composition of the monomer mixture from which it is produced. Thus, in a thorough study of copolymers of vinylidene chloride, it has been found that in general, vinylidene chloride enters the growing polymer chain faster than do vinyl esters,[12] various esters of allyl alcohol derivatives[13] and vinyl ethers.[14] In the case of the copolymers of vinylidene chloride and the acrylate esters, temperature appears to be an important factor since at 45° vinylidene chloride enters the chain faster than ethyl acrylate, whereas at 30° methyl methacrylate and methyl acrylate enter the growing chains more rapidly than does vinylidene chloride.[15] In the case of copolymers of styrene and vinylidene chloride, a copolymer containing 60% by weight of styrene has been obtained from a monomer mixture containing about 30% by weight of styrene.[15]

Further experiments on the removal of chlorine from copolymers of vinyl chloride and vinyl acetate have yielded results which are not as readily reproducible as would be desired. Yet they are of interest when compared with the statistical calculations made by Wall.[9,10]

In Fig. 1 we have reproduced certain curves which Wall has published[9,10] and have superimposed on them certain points which were arrived at by averaging the results of many dehalogenation experiments on different copolymers. While the degree of accuracy of the dehalogenation is not all that one may desire yet the apparent trend is for these points to follow the curves based on a "head to tail" arrangement of the monomer unit in the chain.

The dehalogenated product did not decolorize a dilute solution of potassium permanganate in acetone but did decolorize a solution of bromine in carbon tetrachloride. These reactions indicate that dehalogenation may have produced cyclopropane units in the chain and do not indicate an

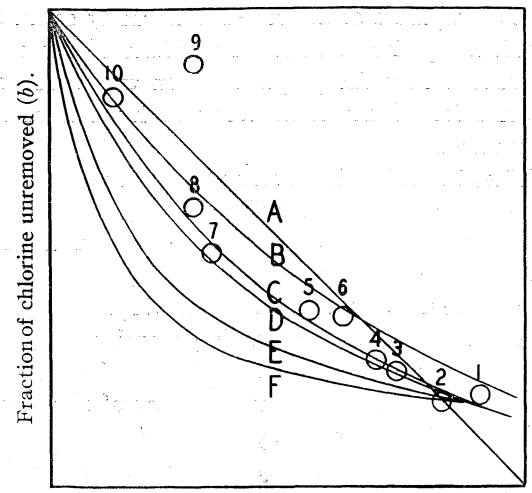

Fig. 1.—A, $f = l - x$ "head to head" arrangement of monomer units; B, $f = e^{-x(1-(x/2))}$ random arrangement of monomer units; C, $f = e^{-2x}$ "head to tail" arrangement of monomer units, $\alpha = 1$; D, $f = \left(\frac{R+2}{2}\right)^2 e^{-4/(2\ R)} - \left(\frac{R}{2}\right)^2$, where R is the ratio of vinyl acetate to vinyl chloride in the completed polymer and $\alpha = 2$; E, f as function of x for $\alpha = 5$; F, f as a function of x for $\alpha = 10$.

olefin structure. Further evidence of the absence of 1,2-chlorine atoms was the fact that no iodine was produced when a sample of "Vinylite" was refluxed in acetone with potassium iodide.

Careful hydrolysis of a copolymer of vinyl acetate and vinyl chloride by treating the ester with water, ethyl alcohol and hydrochloric acid in dioxane solution has given the chlorohydrin.[16] This product is not oxidized by periodic acid. The best available evidence thus indicates that the vinyl chloride and the vinyl acetate enter the copolymer chain to give "head and tail" units just as they do when polymerizing alone. The fact that the chlorohydrin is actually obtained is further proof that a real copolymer is in hand and that the reaction does not merely produce mixtures of individual polymers.

The relative homogeneity of some of these copolymers has been further tested by solubility methods. 1-Heptyne will dissolve polyvinyl acetate[17] but does not dissolve "Vinylite." Phenylacetylene will dissolve low-chlorine "Vinylites" but will not dissolve high-chlorine "Vinylites" or polyvinyl chloride. Mixtures of polyvinyl acetate, polyvinyl chloride and the copolymer were separated into different fractions but due to the non-homogeneity of the copolymer the separation was not 100%. These solubility experiments showed that none of the copolymers tested in this work was strictly homogeneous.

It should be pointed out that most of the molecular weights reported in this manuscript were determined by viscosity methods and are, therefore, only of relative value. Since the results of Staudinger and Schneiders[6] do not permit an unequivocal choice of a K_m for "Vinylite" in dioxane solution and since viscosity molecular weights are of comparative significance only, an approximate K_m value was used in this work. This value was obtained by determining the viscosity of a single polymer in dioxane and in methyl *n*-propyl ketone. Douglas and Stoops[18] have determined that K_m has the value 3.2×10^{-4} for "Vinylites" in ketone solvents. Our comparisons indicated a value 4.1×10^{-4} would be an approximate K_m in dioxane.

Experimental

Molecular Weight Determination.—All molecular weights were obtained by making viscosity measurements on solutions containing 0.1 g. of polymer in 50 cc. of pure dioxane at 20° in an Ostwald viscometer, and then calculating the molecular weight by the Staudinger equation using the K_m value 4.1×10^{-4}. This value was ascertained by determining the relative viscosities of a given polymer in dioxane and in methyl propyl ketone. Only this one experiment is recorded in detail.

An experimental "Vinylite" containing 37.7% chlorine was used. The following results were obtained at 20° using a 5-cc. Ostwald viscometer.

Liquid	Time in seconds
Pure dioxane	122.2 122.6 122.5
0.10 g. of polymer in 10 cc. of dioxane	132.2 133.2 132.5 132.2
0.10 g. of polymer in 10 cc. of dioxane	131.2 132.3 132.8 132.8
Pure methyl *n*-propyl ketone	65.5 65.5 65.1 65.1 65.3
0.10 g. of polymer in 10 cc. of methyl *n*-propyl ketone	69.5 69.5
0.10 g. of polymer in 10 cc. of methyl *n*-propyl ketone	69.5 69.6

$\eta_{rel.}$ in dioxane 1.0817; $\eta_{rel.}$ in methyl *n*-propyl ketone 1.064

$$\underset{\text{(dioxane)}}{\frac{\eta_{rel.} - 1}{K_m C}} = M = \underset{\text{(methyl } n\text{-propyl ketone)}}{\frac{\eta_{rel.} - 1}{K_m C}}$$

$$\frac{0.0817}{K_m(\text{dioxane})} = \frac{0.064}{3.2 \times 10}$$

$$K_m \text{ (dioxane)} = 4.08 \times 10^{-4}.$$

This figure was rounded off to 4.1×10^{-4} for further use.

(16) The hydrolysis of such a copolymer by means of sulfuric acid, alcohol or benzene has been reported in French Patent 724,910 (1931).

TABLE I

PREPARATION AND PROPERTIES OF LOW-CHLORINE COPOLYMERS OF VINYL CHLORIDE AND VINYL ACETATE

Reagents used, g.			Time of experiment in hr.	Yield of product, g.	Chlorine,[20] %	Mol. wt. (viscosity)
Vinyl chloride	Vinyl acetate	Benzoyl peroxide				
0.86	3.06	0.03	63	3.72	12.48	14,000
2.53	2.24	none	100	3.82	30.2	8,100
3.45	4.79	0.03	100	7.29	23.9	14,000
1.27	3.85	none	70	4.17	13.7	21,000
1.10	2.97	0.03	40	3.20	15.4	12,000

Higher Chlorine Copolymers.—Four experimental "Vinylites"[19] containing 87, 77, 65 and 60% vinyl chloride, respectively, were used in the early part of this work. These polymers were white powders which softened at about 110° and were reported to have molecular weights in the range of 28,000. Chlorine analyses in our Laboratory confirmed the compositions reported. In the interrupted polymerizations reported later in this manuscript a few other high-chlorine "Vinylites" were obtained.

Low-Chlorine Copolymers.—Copolymers containing less than 50 mole per cent. of vinyl chloride (42% vinyl chloride or 23.9% chlorine) were prepared by adding freshly distilled vinyl acetate to liquefied vinyl chloride and adding a small amount of benzoyl peroxide ("Lucidol"). The mixture was cooled in dry-ice and sealed in a glass tube. The mixture was allowed to come to room temperature and in most cases irradiated with ultraviolet light at about 40°. The tubes were usually exposed at this temperature for about thirty hours or until they contained a milky opaque solid. Longer exposure to ultraviolet light gave deeply colored products.

After polymerization had apparently stopped, the tubes were opened and the contents dissolved in dioxane to give a solution containing from 0.5 to 2% of polymer. The lower concentrations were used for the lower chlorine polymers. This solution was then aspirated in a fine spray on the surface of vigorously stirred running water. The outfit used is shown in the diagram (Fig. 2). The right-hand tube carried water and the left-hand tube compressed air. Only in this way could low-chlorine copolymers be isolated as solids which could be handled. The precipitation of one lot of polymer usually required about eight hours per liter of dioxane solution. The polymer which was collected in the filter cloth was dried by squeezing out most of the water and then heating at 55° (boiling acetone) in a drying pistol over phosphorus pentoxide at about 20 mm. until the weight was constant.

Copolymers having more than 10% chlorine can be isolated easily as fluffy powders by this method. Copolymers with less than 10% chlorine are very hard to get in a powdery form. They adhere together in a tough mass but these tough masses seem to give constant analyses if carefully dried.

Table I shows the results of some of these experiments. All the experiments were carried out at 40°.

Interrupted Polymerizations.—Various mixtures of vinyl chloride and vinyl acetate containing benzoyl peroxide were prepared and divided into tubes. The mixtures were allowed to polymerize for various lengths of time and then the polymer isolated as above and examined. In other cases a solution of vinyl chloride and vinyl acetate of known chlorine content was allowed to polymerize for a certain period and then the polymer isolated to determine the yield and chlorine content. Other experiments were made with solutions and emulsions. In every case where polymerization was stopped before the yield of polymer was essentially quantitative the polymer contained a higher percentage of chlorine than had been present in the original polymerization mixture. The results of these experiments are summarized in Table II.

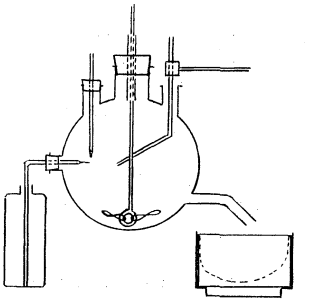

Fig. 2.—Apparatus.

Dehalogenation Experiments on "Vinylites."—In general, the zinc dehalogenation experiments were carried out as described previously[7] except that the solutions were only one-half as concentrated in this work. Usually, 0.2 g. of polymer was dissolved in 50 cc. of dioxane. In some runs large amounts of solute and solvent were used but this ratio was always maintained. That boiling alone did not affect the polymer was shown by refluxing a sample of "Vinylite" having 26.5% chlorine and a molecular weight of 17,000 for five days in dioxane. After isolation of the polymer the molecular weight was found to be 17,000 and the chlorine content 25.9%.

Boiling a "Vinylite" sample (1 g.) having 15.4% chlorine in dioxane (750 cc.) containing 0.148 g. of zinc chloride for five days gave a red-brown solution. On isolation the polymer contained only 9.18% chlorine after this treatment. In a similar experiment the following analyses before and after treatment, respectively, were obtained: C, 48.3; H, 6.23; Cl, 23.9; and C, 52.8; H, 5.8; Cl, 15.0.

These experiments indicate that dehalogenation by zinc may be accompanied by other reactions which account for the erratic results in some experiments recorded in Table III.

No evidence that acetate groups were removed by the zinc treatment was obtained by applying the lanthanum nitrate test[21] or by comparing the analyses of the polymer before and after the treatment.

There is some indication that the dehalogenation does not cause as much degradation and side reaction as does the zinc chloride treatment. For example, in the zinc

chloride treatment, the solution becomes red, but the dehalogenation solution does not; also the color of the former solution is destroyed by refluxing an hour with zinc. Furthermore, analyses indicate that loss of chlorine is the major result of the dehalogenation treatment. For example, a polymer which had been 35% dehalogenated (the dehalogenation was incomplete, since the theory would have predicted 65% removal) had the composition before treatment: C, 47.45; H, 5.83; Cl, 27 (ratio, C:H:Cl:O = 1.00:1.46:0.193:0.312) and after treatment: C, 52.9; H, 6.5; Cl, 17.5; (ratio: C:H:Cl:O = 1.00:1.46:0.112:0.328).

In a theoretically complete dehalogenation of a polymer having initially 26.1% chlorine, there was obtained a product that had poorer agreement with the calculated composition. Calcd.: C, 58.7; H, 7.4. Found: C, 58.3; H, 6.31; Cl, 9.5.

The results of a large number of dehalogenation experiments are summarized in Table III. It should be pointed out that it is not entirely correct to obtain from Wall's formulas[9, 10] values for the calculated mole fraction of chlorine remaining in the case of polymers isolated after incomplete polymerization.

There were dozens of other similar experiments performed but these can be taken as illustrative. In some of these experiments polymer precipitated; in others it did not. In a few experiments the reactions were carried on for as long as thirteen days. In general, this made little difference in the results. The reaction does not seem to be sufficiently quantitative to be useful.

The polymer remaining after the zinc treatment of a "Vinylite" having a chlorine content of 43.7% was soluble in dioxane, did not decolorize a cold dilute potassium permanganate solution in acetone, but did decolorize a solution of bromine in carbon tetrachloride.

Solubility Experiments.—A mixture made up of 2.010 g. of polyvinyl acetate, 2.018 g. of polyvinyl chloride and 1.986 g. of a "Vinylite" containing 36.9% chlorine was extracted with 40 cc. of 1-heptyne. After filtering and evaporating the solution 1.589 g. of residue was obtained. This residue was purified by dissolving in dioxane and precipitating the polymer in water. The chlorine content was 1.49%. The residue from the first extraction was then treated with 25 cc. of phenylacetylene. This solution on evaporation gave 1.480 g. of polymer containing 18.7% chlorine. The material insoluble in the two acetylenes weighed 3.154 g. and contained 50.9% chlorine. The weight of the total recovered material is somewhat higher than that used, because the surplus amount of solvent is held by the polymer under the conditions of the experiment. This is lost in the purification of the product, but also a considerable amount of polymer is lost, and that introduces a still greater error into the figures.

This experiment was typical of several which showed that only a small amount of very low chlorine "Vinylite" would be found in the heptyne extract whereas "Vinylite" containing up to 65% vinyl chloride was soluble in phenylacetylene. By using these two solvents on samples of copolymers separation into fractions was obtained. Some of these separations are listed in Table IV.

The last two samples of copolymer reported in Table IV were prepared by the interrupted technique. The last one which was obtained by stopping polymerization at a 51% yield seems to be more homogeneous than the preceding sample which was made by stopping the polymerization after an 83% yield.

Hydrolysis of "Vinylite" to a Polychlorohydrin.—To a solution of 10 g. of "Vinylite" in 1 l. of dioxane was added 25 cc. of concentrated hydrochloric acid and 25 cc. of 95% ethyl alcohol. The mixture was heated to 50° for twelve hours and a deep red color developed. An additional 25 cc. of alcohol was added and the solution was boiled under a reflux condenser for eleven hours. The polymer was then precipitated by spraying the solution into water. A brownish polymer was obtained which was richer in chlorine than was the original. Two different copolymers were hydrolyzed by this procedure. The analytical figures before and after hydrolysis indicate conversion of the acetate groups to hydroxyl groups.

	Sample 1			Sample 2
	% C	% H	% Cl	% Cl
Anal. before hydrolysis	47.45	5.83	26.5	46.6
Anal. after hydrolysis	45.65	6.48	34.0	49.4
Calcd. for polychlorohydrin	44.4	6.42	35.8	51.1

The polychlorohydrin obtained in this manner did not show reduction of periodic acid solution. The chlorine atoms could not be hydrolyzed to hydroxyl by moist silver oxide or by treatment with mercuric acetate. The polychlorohydrin did not liberate iodine from an acetone solution of potassium iodide.

Contrary to the statements in the literature[22] we could not hydrolyze by means of aqueous alkali a copolymer of vinyl chloride and vinyl acetate prepared by exposing a methanol solution of the monomers and uranyl nitrate to sunlight.

Summary

1. Vinyl chloride and vinyl acetate copolymerize to produce polymer chains containing both units. However, the polymer molecules produced in a given case differ widely in composition and the first chains produced are richer in vinyl chlo-

(22) German Patents 362,666, 516,996.

ride than is the monomer mixture from which they are formed. The copolymers made by complete polymerization of a given starting mixture of monomer vary in composition from chain to chain.

2. The monomer units appear to be oriented in a 1,3-fashion in the polymer chain.

3. Some reactions of these copolymers have been described.

The Acid Catalyzed Hydrolysis of Phenyl Substituted Aliphatic Esters[1]

BY HILTON A. SMITH AND R. R. MYERS

In a recent publication[2] a study of the effect of the character of an alkyl chain on the reaction velocity of acid hydrolysis was reported for a number of esters of aliphatic acids. It was demonstrated that the effects were similar to those produced in the processes of esterification[3] and of saponification of the same (ethyl) esters.[4]

The purpose of the present paper is to report the results of a study of the velocity of hydrolysis of a number of phenyl substituted aliphatic esters, and to compare these results with those previously reported for saponification of the same esters[5] and for the acid-catalyzed esterification of phenylacetic, hydrocinnamic and γ-phenylbutyric acids in absolute methanol.[6]

Experimental

All of the esters were prepared by esterification of the corresponding organic acid with absolute ethanol using sulfuric acid as a catalyst. The esters were purified by fractionation in efficient distillation columns. Each sample used for rate measurements distilled at a constant head temperature and was also shown by analysis using the method already described[4] to be, within the precision of the method, 100% pure.

Phenylacetic, hydrocinnamic, phenylethylacetic and **diphenylacetic** acids were obtained from Eastman Kodak Co.; γ-phenylbutyric, δ-phenylvaleric, cyclohexylacetic and hydratropic acids were all prepared by methods which have been previously described.[5,6,7]

The hydrolyses were all carried out in 70% acetone solution, the concentration of both ester and catalyst (hydrochloric acid) being 0.1 *M*. The acetone used in making up the medium was carefully purified by fractionation from alkaline permanganate in a five-foot, one-inch diameter column packed with glass helices. The fraction retained distilled at constant head temperature. The method employed in making up the reaction mixtures was the same as that already described by Smith and Steele,[2] and the general experimental procedure was also the same. Corrections were made for the contraction in volume which occurs when acetone is mixed with water and also for thermal expansion of the solvent. The reactions were run in electrically heated water thermostats which gave temperatures constant to ±0.01°.

Experimental Calculations and Results

The rate constants were calculated using the expression for a first order reaction

$$k = \frac{2.303 \log a/(a - x)}{(\text{catalyst})t}$$

where a is the initial ester concentration, x is the concentration of organic acid formed after time t, and the (catalyst) is the concentration of added

hydrochloric acid. Table I gives the results of a typical run.

For each run, the individual rate constants were averaged over the range of about 20–50% reaction. These limits were set in order to avoid any possible effects due to errors in making up the reaction mixture, due to loss of solvent as samples were withdrawn from the reaction flask, or caused by the reverse esterification reaction. The number of values averaged was usually six or seven, and the ±errors were of the order of one per cent. The average rate constant for each run is listed in Table II.

Figure 1 gives a plot of log k against $1/T$ for the hydrolysis of these esters. The activation energies were calculated from the slopes of these lines, and were checked by the method of least squares. These activation energies together with reaction rate constants at 25° are found in Table III. Included in this table are also k_{25} and activation energies for the processes of esterification and saponification. Figures for several unsubstituted esters are given for comparison purposes.

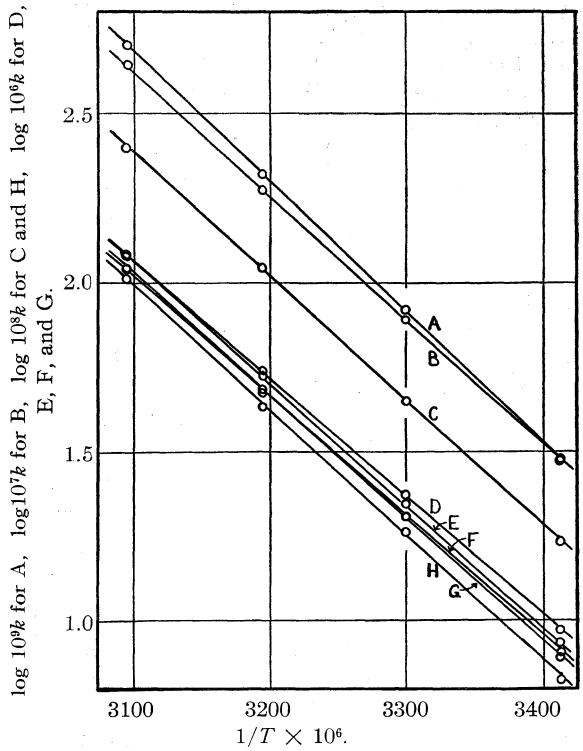

Fig. 1.—Temperature coefficients for acid hydrolysis of phenyl substituted aliphatic esters: A, ethyl diphenylacetate; B, ethyl cyclohexylacetate; C, ethyl hydratropate; D, ethyl phenylacetate; E, ethyl δ-phenylvalerate; F, ethyl hydrocinnamate; G, ethyl γ-phenylbutyrate; H, ethyl phenylethylacetate.

The relative entropies of activation of these acids and esters have been calculated for the processes of esterification, acid hydrolysis and saponification, and are given in Table III. These values were calculated from the equation

$$\Delta S^* - \Delta S_0^* = R \ln A/A_0$$

where $\Delta S^* - \Delta S_0^*$ is the relative entropy of activation and A is the "temperature independent" factor in the Arrhenius equation

$$k = Ae^{-E/RT}$$

The subscript zero refers to ethyl acetate for acid hydrolysis and saponification and to acetic acid for the process of esterification.

Discussion

As seen from an inspection of Table III, the substitution of a phenyl group on the terminal carbon atom of an alkyl chain causes an increase in the reaction rate for the process of saponification, and this is accompanied by the expected decrease in the activation energy. These changes are apparently caused by the fact that the phenyl group, when not a part of a conjugated system, acts as an electron sink, thus drawing electrons away from the carboxyl group, and so facilitating the approach of the hydroxyl group. The magnitude of this effect decreases as the phenyl group is moved farther from the carboxyl group, as would be expected. When, however, substitution of the phenyl group takes place in the alpha position of an ester such as ethyl propionate or butyrate, the reaction rate is decreased, and the activation energy increased. This is evident from inspection of Table III.

This apparent discrepancy in the influence of the introduction of a phenyl group on the velocity of saponification has been explained as being due to the fact that this group not only acts as an electron sink, but also exhibits a rather large steric effect.[5] The former causes an increase in the rate of reaction and a lowering of E. The latter causes a decrease in the reaction rate, and apparently an increase in the activation energy.

The data for acid hydrolysis as given in Table III offer no direct evidence that the phenyl group acts as an electron sink, since its introduction always decreases the reaction velocity. Other data, however, may lead one to expect the opposite result.[12] In fact, the postulated mechanisms for acid and alkaline hydrolysis involve the same intermediate,[13] although the influence of substituents is smaller for the acid catalyzed reaction.[14]

Some idea of the relative magnitude of the inductive effect may be gained from a comparison of the rates of ethyl cyclohexylacetate with those for ethyl phenylacetate. In saponification the activation energy is 15,600 calories per mole for cyclohexylacetate and 14,100 for the phenylacetate. For acid-catalyzed hydrolysis the corresponding values are 16,900 and 16,100. Assuming the steric influence of the phenyl and cyclohexyl groups to be the same, the inductive effect is represented by some 700 calories less influence in the activation energy for acid hydrolysis than for base catalyzed hydrolysis. Since the drop in activation energy caused by introduction of a phenyl group into ethyl acetate is only 600 calories for saponification, one would expect little change in the activation energy for the process of acid hydrolysis. This agrees with the experimental findings as shown in Table III.

This type of reasoning also explains the fact that ethyl diphenylacetate is hydrolyzed about twice as fast as ethyl phenylethylacetate in the

(8) Interpolated from the data in Table II and from those of Smith and Steele, ref. 2.

(9) Calculated from the data of Smith, ref. 6, and of Smith and Reichardt, THIS JOURNAL, **63**, 605 (1941).

(10) From the data of Levenson and Smith, ref. 5.

(11) From the data of Davies and Evans, *J. Chem. Soc.*, 339 (1940). These values were determined using 0.05 *M* solutions of ester and catalyst. Under these conditions the reaction rate is greater by about 5% than when 0.10 *M* concentrations are employed (see Smith and Steele, ref. 2).

TABLE IV

EFFECT OF α-PHENYL SUBSTITUTION ON SAPONIFICATION AND ACID HYDROLYSIS

	Saponification		Acid hydrolysis	
	Δ log k	ΔE	Δ log k	ΔE
Acetate → phenylacetate	+ .1642	− 600	− .4907	− 100
Propionate → hydratropate	− .6460	+ 700	−1.1338	+ 600
Butyrate → phenylethylacetate	− .8409	+1000	−1.2281	+ 700
Phenylacetate → diphenylacetate	−1.2561	+1900	−1.4657	+1600

base-catalyzed reaction, but only half as fast when the acid catalyst is employed. It is also substantiated by noting that in both processes the introduction of a phenyl group into the alpha position causes a much greater effect when another substituent is already present on the same carbon atom. This is shown in Table IV.

Unfortunately, the data for esterification are not sufficiently complete to allow many deductions, but apparently this process is similar to that of acid hydrolysis in that the steric effect due to phenyl substitution always outweighs the inductive influence, even when such substitution takes place on the terminal carbon atom. The fact that phenylacetic, hydrocinnamic and γ-phenylbutyric acids esterify with almost identical rates is perhaps better explained as a fortuitous balance between inductive and steric effects than as caused by ring formation.[6]

Summary

The kinetics of acid catalyzed hydrolysis in 70% acetone has been studied for ethyl phenylacetate, ethyl hydrocinnamate, ethyl γ-phenylbutyrate, ethyl δ-phenylvalerate, ethyl hydratropate, ethyl phenylethylacetate, ethyl diphenylacetate and ethyl cyclohexylacetate.

The introduction of a phenyl group into an aliphatic ester results in a decrease in the reaction rate for all esters studied, even though the phenyl group acts as an electron sink, and should cause an increase in the rate of hydrolysis. The results may be explained on the assumption that the steric effect of the phenyl group always outweighs its inductive effect for this process.

A comparison is made of the effect of phenyl substitution on the processes of acid hydrolysis, saponification and esterification.

The Reduction of Unsaturated Hydrocarbons at the Dropping Mercury Electrode. II. Aromatic Polynuclear Hydrocarbons[1]

BY S. WAWZONEK AND H. A. LAITINEN

Aromatic compounds possessing a high degree of resonance, such as benzene, do not undergo reduction at the dropping mercury electrode. On the other hand, aromatic polynuclear hydrocarbons showing a diminished degree of resonance are reducible. The polarographic reduction of such hydrocarbons is described in the present paper.

Results

The behavior of various aromatic polynuclear hydrocarbons was studied in a 0.175 M tetrabutylammonium iodide, 75% dioxane solution.[1] A summary of the observed half-wave potentials and individual diffusion current constants is given in Table I.

In general, all of the hydrocarbons gave well-defined reduction waves similar to that shown in Fig. 1 for 3-methylcholanthrene. Exceptions to this behavior were treated in the following manner. For compounds (phenanthrene and pyrene) showing two waves of equal height close together such as those shown in Fig. 2 for phenanthrene, the half-wave potentials were calculated by using one-fourth and three-fourths of the total diffusion current. In the table for such cases only the total diffusion current is reported even though two waves were obtained. For compounds (chrysene and 3,4-benzpyrene) which gave indefinite waves such as that shown in Fig. 3 for 3,4-benzpyrene, only the total diffusion current is given. For indene which gave a wave at a potential too negative to be measured, the starting point of the wave is given.

		2.58		10.85		2.22	4.89	
Indene		starting point 2.54						
3-Phenylindene		2.33		4.28		9.12	4.69	
		2.32		8.40		1.823	4.61	
Fluorene		2.65		7.50		1.33	5.65	
Biphenyl		2.70		5.19		0.745	6.96	
Phenanthrene		2.46	2.71	19.9		2.252	8.84	
		2.44	2.67	14.1		1.376	10.25	
9,10-Dihydrophenanthrene		2.62		6.70		0.932	7.18	
Chrysene		....		14.3		1.11	12.88	
Pyrene	2.10	2.46	2.67	2.38	3.89	0.740	3.22	5.25
	2.10	2.47	2.69	4.77	8.26	1.580	3.22	5.59
Anthracene		1.94		4.17	(3.48)	0.933	4.47	
1,2-Benzanthracene		2.03	2.54	6.80	(5.73)	1.66	4.10	4.54
				7.53				
1,2,5,6-Dibenzanthracene		2.07	2.53	3.18	(2.18)	0.773	4.12	7.55
				5.83				
9,10-Dimethyl-1,2-benzanthracene		2.05	2.53	3.62	(2.85)	.875	4.14	4.32
				3.78				
3-Methylcholanthrene		2.11	2.51	4.86	5.44	1.313	3.70	4.15
3,4-Benzpyrene		1.88	....	2.71	4.52	0.966	2.72	4.54

The reduction of anthracene gave a wave of constant diffusion current of 3.48 microamperes which, at more negative potentials, increased to 4.17 microamperes. The larger value is probably the true diffusion current since it is closer to that observed for phenanthrene (5.15 microamperes). A similar phenomenon occurred with the substituted anthracenes. A small wave always preceded the second reduction wave as shown in Fig. 4 for 9,10-dimethyl-1,2-benzanthracene. The figures in parentheses in the table are the lower diffusion current values used in calculating the half-wave potential of the first wave. The figures without parentheses include the small wave.

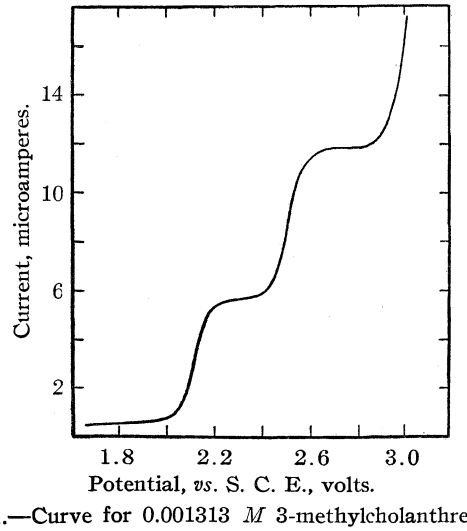

Fig. 1.—Curve for 0.001313 *M* 3-methylcholanthrene in 0.175 *M* $(C_4H_9)_4NI$, 75% dioxane.

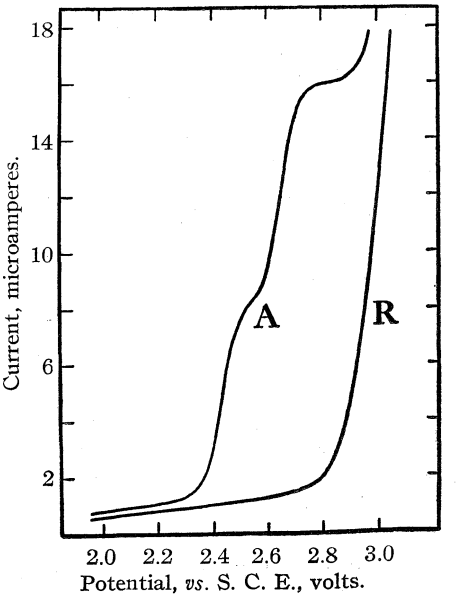

Fig. 2.—Curves in 0.175 *M* $(C_4H_9)_4NI$, 75% dioxane; R, residual current; A, 0.001376 *M* phenanthrene.

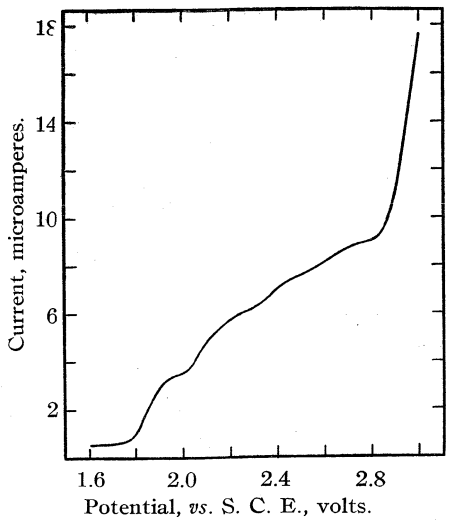

Fig. 3.—Curve for 0.000966 *M* 3,4-benzpyrene in 0.175 *M* $(C_4H_9)_4NI$, 75% dioxane.

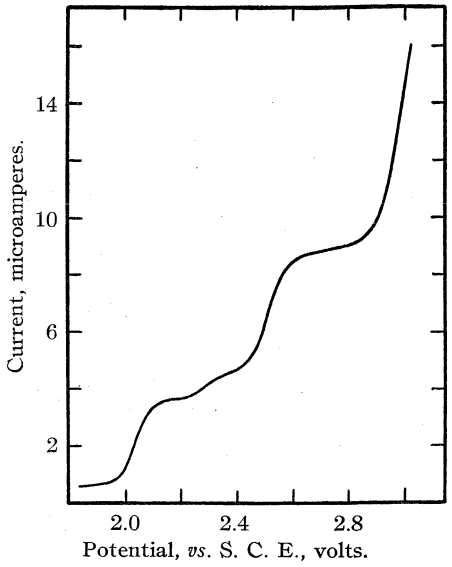

Fig. 4.—Curve for 0.000875 *M* 9,10-dimethyl-1,2-benzanthracene in 0.175 *M* $(C_4H_9)_4NI$, 75% dioxane.

The half-wave potential was found to be independent of the concentration of the hydrocarbons. From this behavior it is assumed that the half-wave potential is independent of the *p*H of the solution, as was the case with the phenyl substituted olefins and acetylenes.[1]

The diffusion current was proportional to the concentration in every case studied. An apparent exception is phenanthrene but in this case two different samples of phenanthrene were used. One sample (diffusion current constant of 10.25) was obtained from Gesellschaft für Teervertung while the other (diffusion current constant of 8.84) was prepared by purifying crude phenanthrene by the method of Bachman.[2] It is evident that the polarographic method offers a possible quantitative procedure for the determination of these hydrocarbons in the absence of more readily reducible substances.

Comparison of the diffusion current constants and of the half-wave potentials for the various hydrocarbons indicates that the reduction resembles the phenomenon of the addition of alkali metals to aromatic polynuclear hydrocarbons or their reduction by alkali metals and alcohol. Polarographic data likewise offer a means of determining the arrangement of the double bonds in the various nuclei.

The reduction of naphthalene involved only two electrons and must take place by a 1,4-mechanism since 1,2-dihydronaphthalene was reducible at a more negative potential. The low diffusion current obtained in the latter case was probably due to the presence of some 1,4-dihydronaphthalene which is not reducible at the dropping mercury electrode. The electroreduction of a double bond conjugated with a phenyl group is apparently not affected by its presence in a ring since the value of 2.57 volts obtained for 1,2-dihydronaphthalene is very close to the value obtained for β-methylstyrene (2.54 volts).[1] Tetralin, the reduction product from 1,2-dihydronaphthalene, was not reducible at the electrode. Acenaphthene was reduced similarly to naphthalene since it gave a wave involving two electrons.

Indene gave a wave at a potential too negative to be evaluated. This behavior is probably due to resonance of the double bond in the five-membered ring. The resonance apparently disappears or is diminished with the introduction of a phenyl group into the ring as it is shown by the more positive value of 2.32 volts obtained for 3-phenylindene. This value would point to the conjugation of the double bond with the phenyl group since the value is approximately equal to the value of 2.27 volts obtained for 1,1-diphenylethylene. Reduction of a double bond in the other position would certainly give a value closer to that of 1,2-dihydronaphthalene or β-methylstyrene. Hydrindene did not reduce at the dropping mercury electrode.

The reduction of biphenyl and fluorene seems to be similar in nature. The course of the reduction is probably through a 1,4-addition like that proposed for the reaction of lithium with biphenyl.[3]

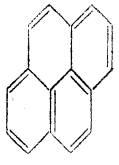
(2) W. E. Bachman, THIS JOURNAL, **57**, 557 (1935).

(3) Schlenk and Bergmann, *Ann.*, **463**, 1–97 (1928).

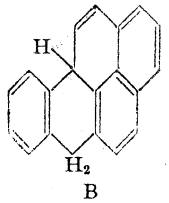
Phenanthrene gave two waves involving two electrons each, with the first wave at 2.44 volts corresponding to the reduction of the 9,10-double bond since 9,10-dihydrophenanthrene reduces at 2.62 volts, a value approximately equal to the 2.67 volts observed for the second wave of phenanthrene. This second reduction wave corresponds to that observed for biphenyl and fluorene, and probably involves a 1,4-reduction in one of the rings similar to the 1,4-addition of lithium to biphenyl observed by Schlenk and Bergmann.[3]

Chrysene gave rather ill-defined waves starting at 2.18 volts with a diffusion current constant of 12.88 microamperes per millimoles per liter. This indicates the introduction of six electrons, two for either the 5,6- or the 11,12-double bond, two for the resulting substituted naphthalene nucleus and two for the resulting substituted dihydrophenanthrene.

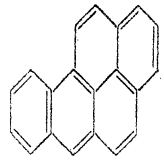
Pyrene gave three waves involving two electrons each. The first wave, at 2.10 volts, corresponds to that observed for stilbene[1] at 2.14 volts and must be due to the reduction of the 1,2-double bond. The remaining two waves at 2.46 and 2.69 volts are identical with the two waves observed for phenanthrene at 2.46 and 2.71 volts, respectively. A structure for pyrene which would fit these facts is shown by formula A and is in agreement with ozonolysis studies carried out with this compound.[4]



A



B



C

Anthracene gave a wave at 1.94 volts involving two electrons and a 1,4-reduction at the 9,10-positions. Substituted anthracenes, such as 1,2-benzanthracene, 1,2,5,6-dibenzanthracene, 9,10-dimethyl-1,2-benzanthracene and 3-methylcholanthrene, which possess carcinogenic properties, were also studied. All showed one half-wave potential value approximately equal to that for anthracene and another of 2.53 volts, which corresponds to the reduction of the resulting naphthalene residue. This latter value is apparently a very characteristic reduction potential for the naphthalene nucleus. For 3,4-benzpyrene the first wave at 1.88 volts, involving two electrons, indicates a reduction similar to that occurring in anthracene. This type of reduction is likewise indicated by a second wave of two electrons, which would necessarily be the reduction of the naphthalene residue in structure B. The total reduction is in agreement with structure C proposed for 3,4-benzpyrene by Cook and Hewett[5] on the basis of absorption spectra.

(4) Vollmann, Becker, Corell and Streeck, *Ann.*, **531**, 1–160 (1937).

Experimental

The conditions and electrode used were exactly the same as described in the first paper of this series.[1]

Materials.—Naphthalene, tetralin, acenaphthene, indene, 3-phenylindene, fluorene, biphenyl, phenanthrene, chrysene and pyrene were obtained from stock and purified before using. Anthracene and all carcinogenic hydrocarbons were obtained from Eastman Kodak Company and used without further purification. 1,2-Dihydronaphthalene,[6] 9,10-dihydrophenanthrene[7] and hydrindene[8] were prepared by appropriate methods given in the literature.

Summary

A polarographic study has been made of the reduction of certain aromatic polynuclear hydrocarbons.

The compounds gave half-wave potentials which were independent of their concentration and characteristic of certain structures. The diffusion current was found to be proportional to the hydrocarbon concentration. The polarographic method has been shown to be useful in the quantitative determination of the hydrocarbons and in determining the arrangement of double bonds in their various rings.

The Apparent Energy of the N–N Bond as Calculated from Heats of Combustion[1]

BY CARL M. ANDERSON AND E. C. GILBERT

Heats of combustion of suitable simple compounds in the gaseous state have offered the most direct approach to the calculation of bond energies,[2] and results recently obtained in this Laboratory on hydrazine[3] have been used thus to calculate the energy of the covalent N–N bond.[2] This calculation has also been made from data on the heat of combustion of phenylhydrazine and methylphenylhydrazine[2,4] giving somewhat different values. The combustion data on phenylhydrazine[5] are very discordant and it was thought that new and accurate data on combustion might give better agreement in the bond energy calculation. Redetermination of the heat of combustion was undertaken and in the meantime measurements on the velocity of dissociation of tetraphenylhydrazine by Cain and Wiselogle[6] indicated to them the possibility that the value for the N–N bond was subject to revision or re-interpretation of the data. Lewis and Lipkin[7] in turn have examined the conclusions of Cain and Wiselogle.

In an effort to provide additional data for the elucidation of this problem the heat of combustion of tetraphenylhydrazine has now been determined. Calculation of bond energies in the ordinary manner is precluded with such a compound since the heats of fusion and vaporization are unknown and presumably unobtainable. Were these available, there remains the question of resonance energy, which for complex molecules is still only a matter of estimate. This is true for instance with phenylhydrazine, which contains an undetermined amount of resonance energy.

An interesting approach is possible however in which the effect of several of these variables can be reduced to a minimum. This may be done by comparing the heat of combustion of structurally similar molecules in pairs. For this purpose the following pairs were chosen and the various heats of combustion determined: (1) tetraphenylhydrazine and diphenylamine (2 moles); (2) phenylhydrazine and aniline; (3) benzamide (2 moles) and dibenzoyl hydrazide; (4) hydrazobenzene and aniline (2 moles). In the last instance the recent combustion data of Swietoslawski and Bobinska on hydrazobenzene were utilized.[8]

Experimental

The Calorimeter.—The calorimeter used was of the adiabatic type and has been described previously.[3,9] It was recalibrated with the use of benzoic acid, Standard Sample No. 39e, Natl. Bur. Standards, and found to have the same heat capacity as reported in the earlier work, *i. e.*, 2607.3 cal. per degree. The precision attainable under optimum conditions with this calorimeter is 0.01–0.02%.

Materials.—The materials used in the combustions were prepared in the following ways. The physical constants given have only a general significance since the calorimetric measurements are much more sensitive to very small amounts of impurities than common criteria of purity.

Aniline.—A single sample, enough for twelve combustions, was prepared from Eastman Kodak Co. white label grade by vacuum distillation from zinc dust in a nitrogen atmosphere, collected over stick sodium hydroxide and redistilled.

Benzamide.—Benzamide was recrystallized from alcohol three times and dried at 60° in a vacuum oven twenty-four hours and over phosphorus pentoxide two days. The sample had a melting point of 130°.

***sym*-Dibenzoylhydrazide.**—A large sample of dibenzoylhydrazide had been previously prepared by Albert Hughes of this Laboratory in 1938. A portion of this was recrystallized from ethanol and ethanol–water, dried in vacuum at 60° twenty-four hours and over phosphorus pentoxide three days. A melting point of 237–238° was found.

Diphenylamine.—Samples of diphenylamine were purified by each of the following methods: (1) recrystallized four to six times by precipitation from ethanol solution by adding water. (2) recrystallized three to four times from high boiling petroleum-ether. (3) the residues from the above procedure were steam distilled and recrystallized once from ethanol–water. The samples were dried over phosphorus pentoxide for two to four days before using them. Each of the samples had a melting point of 53°.

Phenylhydrazine.—Eastman Kodak Co. white label grade of phenylhydrazine was crystallized in a nitrogen atmosphere by cooling with cold water. About one-half of the material was crystallized out and the mother liquor was removed with a filter stick by suction. A given sample was crystallized four to six times before filling the bulbs

(9) Davies and Gilbert, THIS JOURNAL, **63**, 2730 (1941).

The freezing point of each sample was 19.6° for at least the last two crystallizations. Phenylhydrazine purified in this manner retained a faint yellow color and slight odor.

Colorless and odorless samples were obtained by vacuum distillation in a nitrogen atmosphere of 400–500 cc. of the material collecting the middle 100-cc. fraction over stick sodium hydroxide and redistilling. These samples had a freezing point of 19.6° and rapidly turned yellow in contact with air.

Additional amounts of phenylhydrazine were prepared in this Laboratory according to the procedure given by Coleman.[10]

Tetraphenylhydrazine.—Tetraphenylhydrazine was prepared by the oxidation of diphenylamine with potassium permanganate in acetone solution according to the procedure given by Gattermann and Wieland.[11] Samples were recrystallized from benzene by precipitation with ethanol and were well washed with cold ether. These were then dried in the vacuum desiccator over phosphorus pentoxide for twenty-four hours. After standing three to four days the samples were rewashed with cold ether or recrystallized again. Melting points anywhere in the range of 145–175° could be obtained depending upon the rate of heating the melting point bath and the temperature at which the melting point tube was placed in the bath.

Calculations.—All weighings were *in vacuo*. The data are referred to a standard temperature of 25°. The energy unit used is the arbitrary calorie obtained by multiplying the international joule by the factor 4.1833. The technique and precautions were the same as described in the earlier work.[3,9] $-\Delta U_B$, the heat experimentally evolved in the bomb process per gram formula weight was first calculated. From this was obtained $-\Delta U_R$ the decrease in energy for the combustion reaction at the standard state at constant volume, as defined by Washburn.[12] In making this calculation it was assumed that the nitrogen produced in the reaction may be treated as if it were oxygen and the correction equations modified appropriately. $-\Delta H_R$, the heat evolved in the isothermal process in the standard state at constant pressure was also calculated. The 1941 table of atomic weights was used.

Results

The combustion data are shown in Tables I–VI, and collected values for the isothermal heats of combustion in comparison to earlier results in Table VII. Of the substances investigated the latent heat of vaporization at 25° is obtainable for only two, aniline[13] (*ca.* 12,000 cal./mole) and phenylhydrazine[14] (14,690 cal./mole). Utilizing these data and the accurately established heats of formation of water and carbon dioxide,[15] $\Delta H_{298.1}$ for formation of aniline in the gaseous state is

SUMMARY OF THE HEATS OF COMBUSTION MEASURED AND THE VALUES RECORDED IN THE LITERATURE

Substance	Heat of combustion, ΔH_R kcal./mole: Found	reported[b]	Observer
Aniline	− 810.55	− 812.7	Stohmann
		− 811.7	Lemoult
		− 816.7	Swartz
		− 810.48	Huffman[c]
Benzamide	− 848.76	− 847.6	Stohmann and Schmidt
Dibenzoylhydrazide	−1675.5		
Diphenylamine	−1531.9	−1536.2	Stohmann
		−1530.2	Lemoult
Phenylhydrazine	− 871.68	− 875.4	Lemoult
		− 805.4	Petit
Tetraphenylhydrazine	−3048.7		

[b] These values are those reported by Kharasch.[5] [c] Private communication (1942).

found to be +48.91, and for phenylhydrazine +19.25, kcal./mole. From the structures of the two compounds it is seen that the difference $\Delta H = 29.66$ kcal./mole, involves any difference in resonance energies, the formation of an atom of hydrogen and an atom of nitrogen, respectively, from their molecules ($\Delta H = 136.7$ kcal.),[2] the formation of one N–H bond and the formation of one N–N bond. If the approximation used by Pauling is now made for the formation of the N–H bond, *i. e.*, $\Delta H = 83.7$ kcal. (one-third of the energy required to dissociate the ammonia molecule completely in the gaseous state) the apparent energy of formation of the N–N bond becomes $\Delta H = 23.3$ kcal. That the assumption of equality of resonance energy in the two molecules and the equivalence of the 3 N–H bonds in ammonia to each other and to N–H bonds in substituted ammonias is only an approximation is shown by the appreciable lack of agreement between the figure thus obtained for the N–N bond and that derived from combustion data on hydrazine itself ($\Delta H = -20.0$ kcal.).[2]

If the heat of formation of gaseous phenylhydrazine alone is used, assuming a resonance energy of 6 kcal. per mole (the same as aniline[2]) and using Pauling's values for the remaining bonds, the energy of the N–N bond is 23.7 kcal.

The remaining compounds investigated are solids (except for aniline whose heat of fusion is known) and examination of the pairs chosen shows that in each case the difference in the heat of formation lies in the energy of two N–H bonds and one N–N bond. For solids however objection may be made to the simple assumption used previously that the energy of the N–H bond is one-third of the total required to dissociate the gaseous ammonia molecule, although such an assumption serves as a basis to show definite trends in the apparent value of the N–N bond in different compounds. A reasonable compromise can be made however by combining the heat of vaporization and fusion with the gaseous data on ammonia to arrive at an energy for the reaction

$$\text{(N–H) in solid ammonia} \longrightarrow \text{N(g)} + \text{H(g)} \qquad \Delta H = -85.9 \text{ kcal.}$$

By the use of this value qualitative allowance is made for lattice energies, etc. To test the comparative effect of such assumption the fusion and vaporization data for hydrazine[16] were also incorporated with the gaseous data on that compound and calculation made for the N–N bond in solid hydrazine. A value N–N = 22.3 kcal. was thus obtained, compared to 20.0 kcal. from the gaseous data.

Similarly for use with some of the pairs for

(16) Hieber and Woerner, *Z. Elektrochem.*, **40**, 252 (1934).

which liquid data or heats of fusion are available a value of

(N–H) in liquid ammonia ⟶ N(g) + H(g), $\Delta H = -85.4$ kcal.

may be obtained.

A summary of the apparent values of the N–N bond calculated from the various pairs, and using the three assumptions for the N–H bond is shown in Table VIII.

TABLE VIII

CALCULATED ENERGY OF N–N BOND

Compounds compared		Assumption N–H = 85.9 kcal.	Assumption N–H = 83.7 kcal.	Assumption N–H = 85.4 kcal.
Tetraphenylhydrazine Diphenylamine	solids	14.8	(10.5)	..
Dibenzoylhydrazide Benzamide	solids	22.1	(17.7)	..
Hydrazobenzene Aniline	solids	29.4	(25.0)	..
Hydrazobenzene Aniline	liquid	..	..	28.4
Phenylhydrazine Aniline	gas	..	23.3	..
Phenylhydrazine Aniline	liquid	..	..	24.5
Phenylhydrazine Aniline	solids	25.9	..	..
Hydrazine—solid		22.3	..	..
Hydrazine—liquid		..	..	23.3
Hydrazine—gas		..	20.0	..

These values, calculated on any basis, support the contention of Lewis and Lipkin[7] that the apparent strength of the N–N bond is dependent upon the substituents in the molecule. Further work is under way in this Laboratory which it is hoped will throw additional light on this issue. By all calculations the value of the N–N bond in tetraphenylhydrazine thus obtained is considerably less than in any of the other compounds. The values for hydrazobenzene are somewhat out of line. Previous experience with the data of Swietoslawski and Bobinska indicate that their results may be on the low side.[17] Upward revision of their combustion data would reduce the value assigned to the N–N bond.

Grateful acknowledgment is due to the Cyrus M. Warren Fund of the American Academy of Arts and Sciences and the General Research Council of the College for financial assistance which made this work possible.

Summary

1. New data for isothermal heats of combustion of tetraphenylhydrazine and *sym*-dibenzoylhydrazide are reported.

2. Revisions of earlier data for the heat of combustion of aniline, benzamide, diphenylamine and phenylhydrazine are given.

3. Using certain arbitrary assumptions, values are computed for the energy of the N–N bond in tetraphenylhydrazine, *sym*-dibenzoylhydrazide, hydrazobenzene, and phenylhydrazine. The apparent value thus obtained depends on the substituents attached to the nitrogen.

The Heat Capacity of Organic Vapors. III. A Comparison of Flow Calorimeters

BY JAMES B. MONTGOMERY[1] AND THOMAS DE VRIES

The constant-flow calorimeter for measuring the heat capacity of vapors was devised by Callendar and adapted by Swann[2] to measure the specific heat of air. An improved calorimeter was described by Scheel and Heuse.[3] An outstanding example of good design is the calorimeter used by Osborne, *et al.*[4] Typical of the calorimeters used recently for measuring the heat capacity of organic vapors have been those described by Bennewitz and Rossner, De Vries and Collins, and Pitzer.[5]

In this investigation modifications of the flow calorimeter were studied as part of a general program to measure the heat capacity of organic vapors.

Experimental

Flow calorimeters may be arbitrarily classified on the basis of the method used for correcting for heat losses. In

the calorimeters of the first class there is a direct flow of vapor over the first thermometer, the heater, the second thermometer and out of the calorimeter. The heat loss varies inversely with the rate of flow and may be corrected for by extrapolating the data to infinite rate of flow. The calorimeters described by Swann and by Pitzer belong to this class. In the second class, represented by the Scheel and Heuse design, a reversed flow of the vapor returns part of the lost heat to the calorimeter, and the heat loss varies inversely as the square of the rate of flow.

Apparatus.—The calorimeters were placed in a thermostat filled with hydrogenated vegetable oil and regulated to within 0.005°. Electrical measurements were made with a Rubicon, Type B, potentiometer. The vaporizer used in our earlier work[5] was found to have insufficient capacity to permit attainment of equilibrium at high rates of flow. A recycling vaporizer was designed which proved to be satisfactory. It consisted of a "Pyrex" glass boiler of 600-ml. capacity with an exposed twelve-ohm internal chromel wire electrical heater at the bottom and a spray trap at the top (Fig. 1). The vaporizer was supported in a copper hypsometer in which was placed either the same type of liquid as was used in the vaporizer or a liquid having the same boiling point.

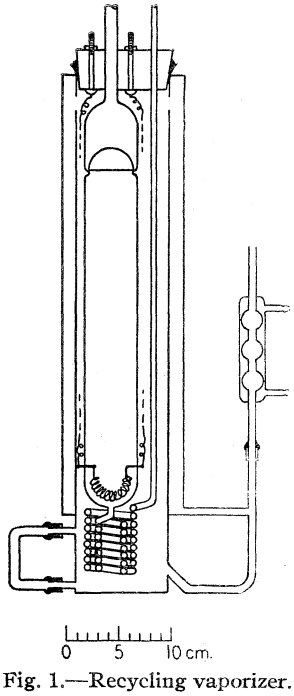

Fig. 1.—Recycling vaporizer.

Electrical heaters in the calorimeters were constructed from chromel wire and supported on glass supports. The current through the heater was computed from the potential drop across a standard resistance of 0.9339 ± 0.0003 ohm in series with the heater, and from the potential across the heater.

In the first two calorimeters platinum resistance thermometers were used. They had a resistance of approximately 60 ohms, and were constructed from no. 40 B. and S. gage platinum wire which was bifilarly wound on mica supports and fused to gold lead out wires (two at each end). The thermometers were annealed to remove strains and were found to give reproducible calibrations at the ice, steam and boiling sulfur points. In the third calorimeter a five-junction copper–constantan thermel of no. 30 gage wire was used. Measurements made with and without a heat block[5] on the outlet end of the thermel proved the value of using the heat block.

The calorimeters were constructed from "Pyrex" glass tubing. Their jackets were silvered, evacuated with a mercury vapor pump while being slowly heated to 500°, cooled to 400°, and sealed off. The cross-sections of the three calorimeters are shown in Fig. 2.

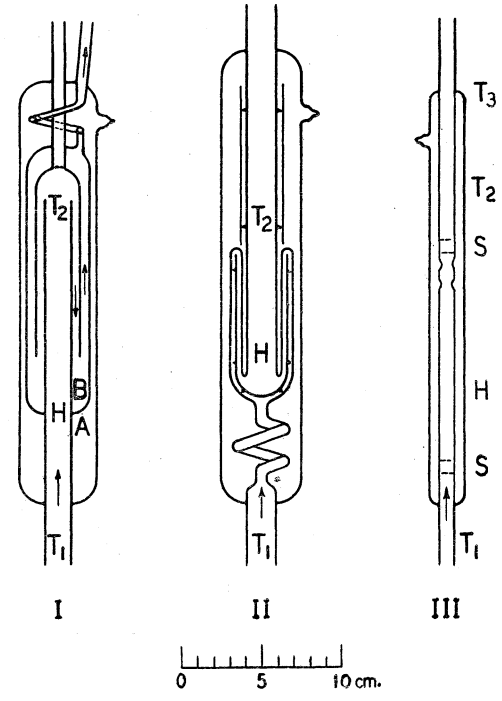

Fig. 2.—Sketch of calorimeters, details not shown.

Results.—The first calorimeter (I) was designed to provide a double layer of heated vapors around the outlet thermometer. Measurements were made upon methyl alcohol vapor at 109°. Steady state conditions were attained slowly because of the large amount of glass which had to be heated. The precision of the experimental points was excellent. The results (see Fig. 3) with the heater exposed to region A were too high because of a direct loss of heat to the surroundings which is only partially corrected for by increasing the rate of flow (F) and extrapolating the data to infinite rate of flow according to the equation, $C_p = H(1 - k/F)/F\Delta T$, which obtains for this type of calorimeter. With the heater further into the calorimeter at position B, the results were about 8% lower than those reported by De Vries and Collins.[5] These low results were explained by assuming that heat from the hot vapors in region B was conducted along the wall of the tube to the entering vapor, thus being used twice.

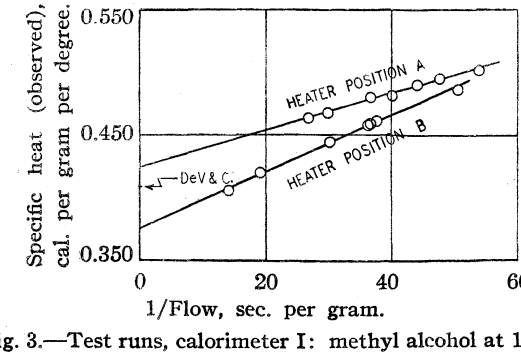

Fig. 3.—Test runs, calorimeter I: methyl alcohol at 109°.

From the results obtained with the first calorimeter it became evident that the Scheel and Heuse modification is

preferable for the arrangement which returns part of the lost heat to the incoming vapor with the result that the heat loss varies inversely as the square of the rate of flow.[5] The second calorimeter (II) was built with a short reverse section to minimize the time required to obtain steady state conditions. Measurements were made with carbon tetrachloride at 107°. The observed specific heats gave a curved line when plotted against $1/F^2$ indicating that the heat loss, which was proportional to $1/F$ in the region around the outlet thermometer (T_2), was becoming appreciable at low rates of flow. A straight line could be obtained even at low rates of flow by plotting the results against $1/F^{1.8}$. Extrapolation to infinite rate of flow gave 0.1417 cal. per gram degree (see Fig. 4). About two hours were required to obtain steady temperatures before weighed samples of the compound were collected for five to twenty minutes.

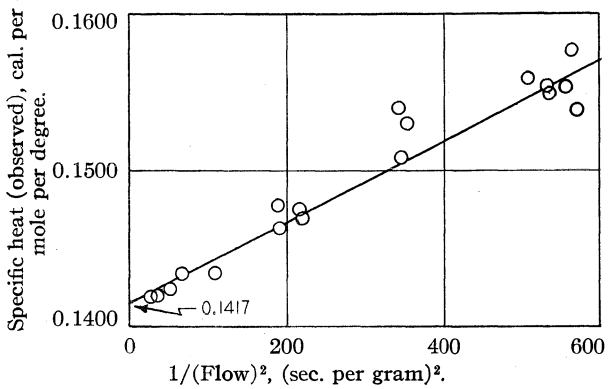

Fig. 4.—Test runs, calorimeter II: carbon tetrachloride at 107°.

A third (III) calorimeter was built in which steady temperatures were obtained in about fifteen minutes. For the first heater arrangement (not shown) the results were about 3% low. It was believed that radiation from the heater direct to the thermel junction at T_2 made ΔT too large. This belief was substantiated by the fact that higher results were obtained when the heat input was held constant and ΔT was decreased at the higher rates of flow.

Another heater arrangement (III in Fig. 2) gave satisfactory results. The method of measurement with either ΔT constant or ΔH constant had no effect on the result. It appeared that the radiation error had been eliminated. In this arrangement the heater, 4 cm. long, was supported on a glass tube, 10.5 cm. long, with two radiation shields (S) of nickel gauze at the upper end. The current carrying leads of no. 26 copper wire were in the vapor region for 5 cm., passed inside the glass tube for one cm. to avoid the radiation shields, then reappeared in the vapor space and passed the thermel junctions at T_2. Just beyond this point the potential leads were attached to the current carrying leads. With this arrangement no heat is lost from the heater without first passing into the vapor. A failure to obtain this condition gives a positive error in the data.

The performance of the third calorimeter was checked by measuring the heat capacity of oxygen at 100°. Compressed oxygen from a tank was used and purified to remove ammonia and water vapor. At atmospheric pressure the value 7.158 cal. per mole degree was found, based upon the use of 4.1833 joules per cal. (see Fig. 5). This value is 0.2% higher than 7.143, calculated from spectroscopic data by Johnston and Walker,[6] and experimentally determined by Henry.[7] The above value includes the correction from the Berthelot equation for the difference between the ideal state of zero pressure and one atmosphere.

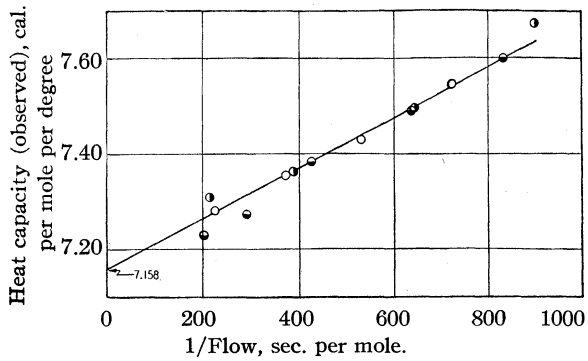

Fig. 5.—Test runs, calorimeter III, oxygen at 100°, ΔT: ○, 2°; ◑, 4°; ◒, 8°.

The heat capacity of carbon tetrachloride was measured at various rates of flow at 107° (Fig. 6). The result 21.82 cal. per mole degree agrees well with 21.80, measured with the second calorimeter of this investigation, and with the value 21.68, measured by Mr. Chas. F. Coleman[8] of this Laboratory using the apparatus of De Vries and Collins.[5] The above value is about 1% lower than 22.05 reported by Pitzer[5] and calculated by Vold[9] from spectroscopic data. But Pitzer's value at 107° was based upon measurements at only two rates of flow and Vold claimed an accuracy of only 3% (5% for C_p calculated to atmospheric pressure). A definite positive error may result from the use of vibrational frequencies determined in liquids, an error which may only be partially compensated by the fact that Vold used the rigid rotator–harmonic oscillator formulas.

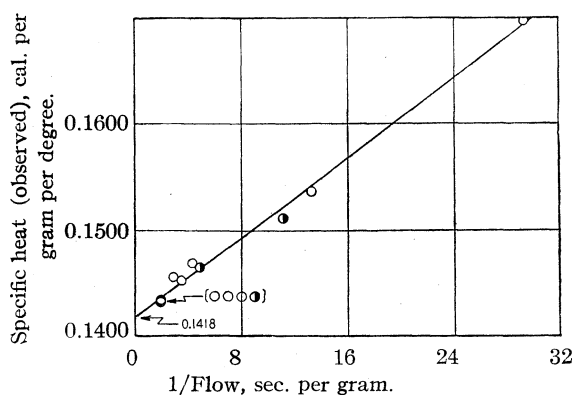

Fig. 6.—Test runs, calorimeter III, carbon tetrachloride at 107°: ○, ΔT constant; ◑, ΔH constant.

This study has indicated that it is possible to construct flow calorimeters in which the results may be precise to

(6) Johnston and Walker, THIS JOURNAL, **55**, 172 (1933).
(7) Henry, *Proc. Roy. Soc.* (London), **A133**, 492 (1931).

(9) Vold, THIS JOURNAL, **57**, 1192 (1935).

within ±0.3%, and to make measurements in which accidental errors are reduced to values within this limit of precision. However, the elimination of constant errors from design and the construction of flow calorimeters which will give accurate measurements of specific heat to better than a few per cent. is much more difficult. Also these results would suggest that some of the high degree of accuracy which has been claimed for published data on heat capacity might be actually a high degree of precision.

Some essentials of a properly designed flow calorimeter include: (a) a minimum rate of heat loss, obtained by reducing the radiating surface to a minimum, by evacuating the jacket space around the calorimeter, and by using properly spaced radiation shields to prevent radiated heat from being used twice; (b) a proper arrangement of the vapor heater and thermometers to eliminate constant errors due to the effect of direct radiation and conduction from the heater; and (c) a construction which uses a minimum volume of material of low heat capacity to reduce the time-lag to temperature changes.

One of the authors (J. B. M.) is grateful to E. I. du Pont de Nemours and Co., Inc., for a fellowship which made this work possible.

Summary

A study was made of flow calorimeters for the determination of the heat capacity of organic vapors. The simpler calorimeter, following the design of Callendar, was preferred.

A recycling vaporizer for producing a constant rate of vapor flow was designed.

The Heat Capacity of Organic Vapors. IV. Benzene, Fluorobenzene, Toluene, Cyclohexane, Methylcyclohexane and Cyclohexane

BY JAMES B. MONTGOMERY[1] AND THOMAS DE VRIES

This paper is a continuation of a program for measuring the heat capacity of organic vapors. The heat capacities of benzene, fluorobenzene, toluene, cyclohexane, methylcyclohexane and cyclohexene vapors have been measured at atmospheric pressure at temperatures from their boiling points to 410°K. With the exception of benzene, little information is available on the heat capacity of these compounds. There are no published data for fluorobenzene and cyclohexene.

Experimental

The heat capacity of the vapor was determined by a flow-calorimeter method, using the modified Callendar direct-flow calorimeter described in the preceding paper of this series.[2] To correct for heat losses in the calorimeter, the observed heat capacities were plotted against the reciprocal of the rate of flow and extrapolated to infinite rate of flow. At each temperature approximately ten determinations were made at different rates of flow. The method of least squares was used to make the extrapolations. The precision of the results is within ± 0.3%.

Purification of Chemicals.—The observed boiling points and refractive indexes of the compounds are compared with reported values in Table I. The compounds were rectified in a twelve plate column, and only the middle fractions with boiling point ranges within 0.1° were used. Several compounds were distilled from a flask before rectification in a column.

TABLE I

PHYSICAL CONSTANTS OF COMPOUNDS

Compound	Boiling point, °C. Obs.	Boiling point, °C. Lit.	Refractive index, $n^{20}D$ Obs.	Refractive index, $n^{20}D$ Lit.
Benzene	80.0	80.09[a]	1.5004	1.5017[b]
Fluorobenzene	84.6	84.85[c]	1.4657	1.4677[b]
Toluene	110.8	110.70[d]	1.4962	1.49675[d]
Cyclohexane	80.6	80.80[e]	1.4262	1.4262[f]
Methylcyclohexane	100.7	100.8[g]	1.4224	1.4230[f]
Cyclohexene	82.8	83.25[h]	1.4465	1.44646[i]

Benzene.—Thiophene-free benzene from the Barrett Company was dried over phosphorus pentoxide, rectified and stored over sodium.

Fluorobenzene.—The fluorobenzene was prepared by the method of Flood.[3] It was dried over calcium chloride, distilled through a Glinsky type column and rectified.

Toluene.—A Merck and Company purified grade of toluene was treated successively with concentrated sulfuric acid, 5% sodium hydroxide solution and water. It was dried with calcium chloride, allowed to stand over mercury

(1) This paper is an abstract from the thesis submitted by J. B. Montgomery in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(2) Montgomery and De Vries, THIS JOURNAL, **64**, 2372 (1942).

(3) Flood, "Org. Syntheses," **13**, 46 (1933).

for ten days, dried over phosphorus pentoxide, rectified and stored over sodium.[4]

Cyclohexane.—An Eastman Kodak Co. practical grade of cyclohexane was treated with nitrating acid to remove benzene, washed, dried over calcium chloride, distilled, rectified and stored over sodium.

Methylcyclohexane.—The methylcyclohexane, obtained from the Paragon Testing Laboratories, was treated with nitrating acid, distilled, dried over sodium, rectified and stored over sodium.

Cyclohexene.—The cyclohexene was prepared by the method of Coleman and Johnstone,[5] dried over calcium chloride and rectified.

Results.—The results are summarized in Table II and in Fig. 1. Data from this investigation are indicated by open circles which are connected by lines to facilitate comparison. All data are reported in terms of the defined calorie equal to 4.1833 Int. joules. The experimental results were corrected for gas imperfections by means of the Berthelot equation. The critical point data for benzene, fluorobenzene, toluene and methylcyclohexane were taken from the literature.[6] The critical temperature for cyclohexene was estimated to be 534°K. The critical pressures of methylcyclohexane and cyclohexene were estimated to be 34.6 and 31.6 atmospheres, respectively. The uncertainty involved in these estimations and calculations is negligible, since the gas imperfection correction is of the order of one per cent.

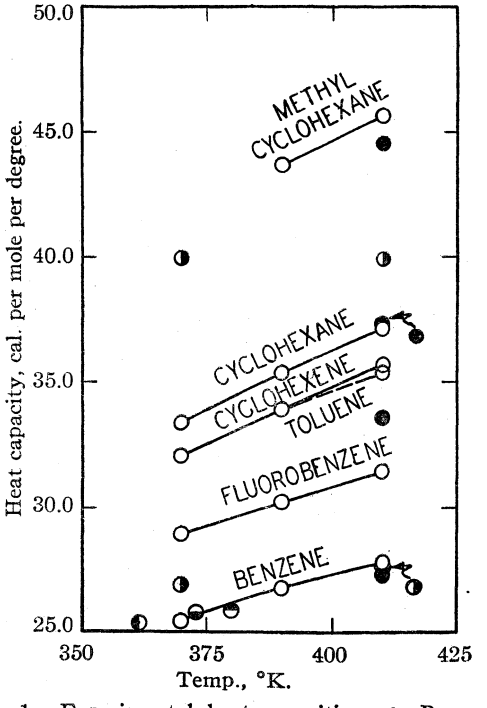

Fig. 1.—Experimental heat capacities: ●, Bennewitz and Rossner (benzene, toluene, cyclohexane, methylcyclohexane); ◑, Jatkar (benzene, cyclohexane); ◐, Dixon and Greenwood; ⊖, Déjardin; ⊖, Wiedemann.

TABLE II

EXPERIMENTAL HEAT CAPACITIES

(Units are cal. per mole per degree C.)

T, °K.	C_p (1 atm.)	C_p^0	C_p^0 (calcd.)	% Diff.
		Benzene		
370	25.43	25.1	24.6	−2.0
390	26.81	26.5	25.9	−2.3
410	27.81	27.6	27.1	−1.8
		Fluorobenzene		
370	28.98	28.6	26.8	−6.3
390	30.24	29.9	28.1	−6.0
410	31.45	31.2	29.4	−5.8
		Toluene		
390	33.93	33.5	31.6	−5.7
410	35.35	35.0	33.2	−5.1
		Cyclohexane		
370	33.41	33.0	34.8	+5.5
390	35.38	35.0	36.5	+4.6

		Cyclohexene		
370	32.08	31.9	30.5	−4.4
390	33.91	33.8	32.1	−5.0
410	35.62	35.5	33.7	−5.1

The results for benzene agree reasonably well with previous work. The result taken from Dixon and Greenwood's[7] measurement of C_p/C_v at 363°K. by a velocity of sound method was 2.5% above the extrapolated curve. Déjardin's result[8] from C_p/C_v at 373°K. was 0.8% above the curve. Wiedemann's[9] average value of 25.9 cal. per mole degree over the temperature range from 308 to 453°K. was 0.6% below the curve. Regnault's[10] average value of 29.3 for the temperature range from 389 to 491°K. falls on a straight-line extrapolation of the experimental curve. Bennewitz and Rossner's[11] value at 410°K., obtained with a flow calorimeter, was 1.6% lower than the measurement in this investigation.

Bennewitz and Rossner also reported the follow-

ing values at 410°: toluene, 33.6 cal. per mole degree; cyclohexane, 37.3; and methylcyclohexane, 44.5. With the exception of cyclohexane, these values are lower than the results found in this investigation. Other investigators have obtained higher results than Bennewitz and Rossner for acetone,[12] heptane and pentane.[13]

Discussion

For the more complex organic molecules, which have not yet yielded to the methods of calculating heat capacity from spectroscopic data, semi-empirical equations for the calculation of heat capacity have great practical importance. An excellent general equation is the one which was proposed by Bennewitz and Rossner[11] and modified by Fugassi and Rudy[14] and by Dobratz.[15] In this equation, the vibrational contribution to heat capacity is calculated by means of the Einstein functions, using valence-bonding frequencies evaluated from Raman spectra and deformation frequencies empirically calculated from experimental data.

(13) Pitzer, THIS JOURNAL, **62**, 1224 (1940); *ibid.*, **63**, 2413 (1941).
(14) Fugassi and Rudy, *Ind. Eng. Chem.*, **30**, 1029 (1938).
(15) Dobratz, *ibid.*, **33**, 759 (1941).

Heat capacities calculated with the modified equation of Dobratz are represented in Table II. The agreement with toluene, fluorobenzene, cyclohexane and cyclohexene is not very satisfactory. In both the aromatic and alicyclic series the calculated results are relatively lower for the compounds in which the ring symmetry has been destroyed by substituted groups. The discrepancy between the experimental and calculated results suggests that the empirically assigned deformation frequencies should be corrected to bring the calculated values into closer agreement with recent experimental data. Further work is in progress on this problem.

One of the authors (J. B. M.) is grateful to E. I. du Pont de Nemours and Co., Inc., for a fellowship which made this work possible.

Summary

Measurements have been reported for the heat capacities of benzene, fluorobenzene, toluene, cyclohexane, methylcyclohexane and cyclohexene vapors at atmospheric pressure from their boiling points to 410°K.

The experimental results have been compared with semi-empirically calculated heat capacities.

The Preparation and Physical Properties of Trimeric Phosphonitrilic Chloride

BY R. STEINMAN, F. B. SCHIRMER, JR., AND L. F. AUDRIETH

The phosphonitrilic chlorides, which may be represented by the empirical formula $PNCl_2$, may be looked upon as the ammono analogs of phosphoryl chloride. Like their aquo analog they are capable of undergoing a wide variety of solvolytic reactions. However, they differ from phosphoryl chloride in their ability to undergo polymerization with formation of compounds of high molecular weight, some of which resemble rubber in appearance and properties. In addition to these highly polymerized forms a series of stable polyhomologs is known ranging from $(PNCl_2)_3$ to $(PNCl_2)_7$.

The preparation of the phosphonitrilic chlorides involves the partial ammonolysis of phosphorus pentachloride. Ammonia,[1] ammonium chloride and ammonobasic mercuric chloride[2] have been employed as ammonolytic agents. However, only ammonium chloride has been used successfully, first by Stokes,[3] who heated mixtures of the reactants in closed tubes under pressure, and later by Schenck and Römer,[4] who employed *s*-tetrachloroethane as a medium for the reaction. Mixtures of the various polyhomologs are always obtained.

It has also been reported by Besson and Rosset[5] that phosphonitrilic chlorides may be obtained by heating together equimolecular quantities of phosphorus pentachloride and ammonium chloride; in other words, neither solvent nor reaction under pressure are necessary. Unfortunately, neither yields nor conditions are specified by

these investigators. A careful study of all three procedures led to choice of the Besson and Rosset method, after the influence of ratio of reactants and of temperature conditions had been determined. The present paper describes the preparation of the phosphonitrilic chlorides, the separation and the purification of the trimer and a study of the vapor pressure of the latter over the temperature range 75.2 to 189.3°.

Experimental

Preparation of the Phosphonitrilic Chlorides.—The equation $PCl_5 + NH_4Cl \longrightarrow PNCl_2 + 4HCl$ indicates that the extent and speed of the reaction can be determined readily by observing the rate of evolution of hydrogen chloride and by weighing the reaction product. All experiments were carried out in 50-cm. test-tubes made from 35 or 50-mm. Pyrex tubing. Intimate mixtures of phosphorus pentachloride, 52.1 g. (0.25 mole), and varying quantities of ammonium chloride (25 to 100 g.) were placed in the bottom of the tube and then covered with a capping of ammonium chloride one to three inches in thickness. The tube was immersed in an oil-bath to such a depth that the ammonium chloride cap was kept largely above the liquid level. The outlet to the reaction tube was connected to a trap containing sulfuric acid.

Heating was continued at bath temperatures varying from 120 to 160° until the evolution of hydrogen chloride had practically ceased. During the course of the reaction considerable amounts of the trimer were observed to sublime and collect in the cooler portions of the reaction vessel. On the basis of a large number of experiments optimum yields of trimer–tetramer fractions are obtained if the bath temperature is kept between 145 and 160°. A heating time of four to six hours is necessary to achieve 90–95% conversion to the phosphonitrilic chlorides.

After completion of the reaction, the residue was extracted with low-boiling petroleum ether (50–70°) which removes quantitatively the trimeric and tetrameric homologs. Evaporation of the solvent yielded mixtures of these corresponding to 38 to 43% of theory based upon the amount of phosphorus pentachloride used. Using the amounts specified above, 11 to 12.5 g. of the trimer–tetramer mixture was obtained consistently.[6]

For preparation of the pure trimer it was necessary to distill fractionally the mixture under reduced pressure to give a trimer-rich fraction (12–14 mm. with a bath temperature of 140°). This product was then recrystallized by solution in a minimum amount of hot 100% acetic acid and subsequent cooling. It was then further purified by repeated fractional sublimation at 100 ± 5° at a pressure of one mm. or less. Products prepared in this manner were used for the determination of the vapor pressure.

Vapor Pressure of Trimeric Phosphonitrilic Chloride.—The apparatus and method employed in the measurement of the vapor pressures of trimeric phosphonitrilic chloride were those previously described by Laubengayer and Schirmer.[7] Two series of measurements using different samples were carried out representing a total of 37 readings whose maximum deviation from calculated values, with one exception, amounted to ±0.5 mm. with an average deviation of 0.2 mm. A plot of these results as a function of log p and $1/T$ gives two straight lines which represent the solid–vapor and the liquid–vapor equilibria, the equations for these lines being

$$\log p = -3978(1/T) + 11.187 \text{ (where } t = 75.2 - 114.9)$$

and

$$\log p = -2880(1/T) + 8.357 \text{ (where } t = 114.9 - 189.3)$$

respectively. The intersection of these curves, the triple point, representing the melting point of the trimer, corresponds to a temperature of 114.9°. This agrees well with the value 114° reported by other investigators.[3,4] The normal boiling point obtained by extrapolation of the liquid–vapor curve to 760 mm. pressure is 252.7° which is somewhat lower than the previously accepted value 256° reported by Stokes[3] in 1897.

The molal heat of vaporization calculated from the slope of the liquid–vapor curve is 13.2 kilocalories; the molal heat of sublimation calculated from the slope of the solid–vapor curve is 18.2 kilocalories; and the molal heat of fusion obtained by difference is 5.0 kilocalories.

Summary

1. A simplified procedure for the preparation of the phosphonitrilic chlorides is described.

2. The trimer has been carefully purified and its vapor pressure determined over the temperature range 75.2 to 189.3°.

URBANA, ILLINOIS RECEIVED JUNE 26, 1942

(6) After the trimer and tetramer have been removed, the higher polyhomologs can then be obtained from the residue by extraction with benzene, carbon tetrachloride or chloroform. Evaporation of these solutions invariably resulted in the formation of thick, viscous oils or rubbery solids. This extraction also removes the unreacted phosphorus pentachloride, and it is the opinion of the authors that the presence of this material causes extensive polymerization to take place.

Partial Molal Volumes of Nickel Sulfate Solutions

BY R. W. GELBACH AND H. M. LOUDERBACK

Densities of nickel sulfate solutions have been determined at 25 ± 0.02°.

Materials, Apparatus, Method.—Mallinckrodt Analytical Reagent nickel sulfate was thrice recrystallized from distilled water. A stock solution was prepared by dissolving the purified salt in redistilled water. The nickel sulfate content was determined by precipitation of the nickel dimethylglyoxime salt from weighed samples of the stock solution. The precipitates were filtered into weighed Gooch crucibles and brought to constant weight at 105°.[1] The accepted value was the average of three analyses in which the maximum deviation was less than 0.08% of error. Molal solutions in low concentrations were prepared by diluting weighed samples of stock solution to volume in calibrated flasks at 25°, then weighing the diluted solutions. In this way both molar and molal concentrations were obtained. The concentrated solutions were made up to volume, then weighed portions were analyzed. A saturated solution was prepared by allowing a warm concentrated nickel sulfate solution to cool to 25°, thus permitting it to come to equilibrium with the solid phase which separated. Weighed samples of the supernatant liquid were analyzed as previously. The solubility was found to be 28.42 g. of (±0.02) nickel sulfate per 100 g. of solution.

For density determinations, Weld precision specific gravity bottles of approximately 25-ml. capacity were used. All weighings were corrected to vacuum. The density given for each concentration is the average of two series of determinations. The maximum deviation between each series is 0.005%.

Apparent molal volumes have been calculated from the equation

$$\phi = \frac{F}{d} - \frac{1000}{md}\,\frac{d - d_0}{d_0} \qquad (1)$$

where ϕ is the apparent molal volume, F the formula weight of nickel sulfate, d_0 the density of water, 0.99707, d the density of the solution and m the molal concentration. Densities and the corresponding values of ϕ are shown in Table I.

(1) Kolthoff and Sandell, "Textbook of Quantitative Inorganic Analysis," The Macmillan Co., New York, N. Y., 1936, p. 684.

TABLE I

Concentration Molar	Concentration Molal	d_4^{25}	ϕ	$\delta\phi$
0.06343	0.06357	1.00758	−10.98	−0.01
.34504	.34537	1.05250	− 5.92	+ .10
.74331	.74465	1.11332	− 1.64	− .24
1.1612	1.1659	1.17592	+ 0.77	+ .07
1.6448	1.6575	1.24685	2.90	+ .06
2.0538	2.0774	1.30646	4.12	+ .09
2.3467	2.3806	1.34889	4.84	+ .01
2.5246	2.5658	1.37460	5.22	− .09

From the data, an equation expressing ϕ as a function of m was found by the method of averages,[2] employing finally the principle of least squares to obtain best values of the coefficients

$$\phi = -14.88 + 15.10m^{1/2} + 1.80m - 2.14m^{3/2} \qquad (2)$$

In column 5 are shown the deviations, $\delta\phi$, of the observed values from those calculated by equation (2).

Redlich[3] has on the basis of the Debye–Hückel theory given as a limiting relationship

$$\phi = \phi_0 + kw^{3/2}c^{1/2} \qquad (3)$$

where $w = {}^1/_2\,\Sigma\nu_i z_i^2$; ν_i is the number of ions of species i and z is the valence. Assuming $k = 1.86$, expressing ϕ as a function of m and applying the equation to nickel sulfate, a bi-bivalent electrolyte, the equation becomes

$$\phi = \phi_0 + 14.88m^{1/2} \qquad (4)$$

The slope, $d\phi/dm^{1/2}$, as m approaches 0, is 15.1 for equation (2) as compared to 14.88 in equation (4). The deviation in slope from that corresponding to $k = 1.86$ is within limits of experimental error, thus further confirming the validity of the limiting equation, (3). The partial molal volume at zero concentration was determined as −14.88 ml. per gram formula weight.

Summary

1. Densities at 25° of nickel sulfate solutions ranging from 0.0634 molar to 2.525 molar (saturated) have been determined.

2. The solubility of nickel sulfate at 25° was determined: 28.42 g. per 100 g. of solution.

3. Nickel sulfate was found to conform to the limiting equation as developed from Debye–Hückel theory.

The Solubility Relations of Mercuric Oxide in Aqueous Solutions of Hydrogen Chloride[1]

BY A. B. GARRETT AND JAMES LEMLEY

This paper presents data on the solubility of mercuric oxide (yellow) and basic mercuric chloride ($2HgO \cdot HgCl_2$) in dilute solutions of hydrochloric acid. The data on the mercuric oxide–hydrochloric acid equilibria are similar to those obtained in a study of the mercuric oxide–nitric acid equilibria[2] which involve the hydrogen ion effect, but these have the additional interest in that they include the reaction with the chloride ion. Hence, the following equilibria are involved in interpreting the mercuric oxide–hydrochloric acid data in the very dilute range.

$$HgO(s) + H_2O \rightleftarrows Hg(OH)_2(aq.) \quad (1)$$

$$HgO(s) + H^+ \rightleftarrows Hg(OH)^+ \quad (2)$$

$$HgO(s) + 2H^+ \rightleftarrows Hg^{++} + H_2O \quad (3)$$

$$HgO(s) + H^+ + Cl^- \rightleftarrows Hg(OH)Cl(aq.) \quad (4)$$

$$HgO(s) + 2H^+ + 2Cl^- \rightleftarrows HgCl_2(aq.) + H_2O \quad (5)$$

$$HgO(s) + 2H^+ + 3Cl^- \rightleftarrows HgCl_3^- + H_2O \quad (6)$$

$$HgO(s) + 2H^+ + Cl^- \rightleftarrows HgCl^+ + H_2O \quad (7)[3]$$

Since the compound $2HgO \cdot HgCl_2$ was identified as the solid phase in the higher concentrations of acid, the following additional reactions are to be considered

$$3HgO(s) + 2H^+ + 2Cl^- \rightleftarrows 2HgO \cdot HgCl_2(s) + H_2O \quad (8)$$

$$2HgO \cdot HgCl_2(s) + H_2O + H^+ + Cl^- \rightleftarrows 3Hg(OH)Cl \quad (9)$$

$$2HgO \cdot HgCl_2(s) + 4H^+ + 4Cl^- \rightleftarrows 3HgCl_2(aq.) + 2H_2O \quad (10)$$

$$2HgO \cdot HgCl_2(s) + 4H^+ + Cl^- \rightleftarrows 3HgCl^+ + 2H_2O \quad (11)$$

$$2HgO \cdot HgCl_2(s) + 4H^+ + 7Cl^- \rightleftarrows 3HgCl_3^- + 2H_2O \quad (12)$$

The preparation of this trimercuric oxychloride is described in this paper. The existence of it is reported in early work.[4]

(1) Original manuscript received April 5, 1940.

(2) Garrett and Howell, THIS JOURNAL, **61**, 1730 (1939).

(3) Other equilibria may be indicated by writing such equations as

$$HgO + Cl^- \rightleftarrows HgOCl^- \quad (a)$$

$$2HgO + 2Cl^- + H_2O \rightleftarrows 2Hg(OH)Cl \quad (b)$$

However, equations (a) and (b) seem very improbable due to the pronounced hydrogen ion effect in this reaction.

(4) See Mellor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry," Longmans and Company, London, 1923, Vol. IV, pages 839–844, for a discussion of the oxychlorides of mercury. Reference is given here to several of the early workers who crystallized $2HgO \cdot HgCl_2$ from a hot solution containing mercuric oxide and mercuric chloride. See Roucher, *Ann. chim. phys.*, [3] **27**, 353 (1849); *Compt. rend.*, **19**, 773 (1844); Thummel, *Arch. Pharm.*, **223**, 919 (1885); **227**, 589 (1889); Schroek, THIS JOURNAL, **29**, 332 (1903); and Droit, *Compt. rend.*, **152**, 960 (1911).

The constants for the equilibria represented by equations (1), (2), and (3) have been evaluated.[2]

Procedure.—The general procedure is identical to that described in earlier work.[2] The hydrochloric acid used was Grasselli C. P. acid. The samples from which the data were obtained for Table II were made by adding the same amount of Baker and Adamson Reagent mercuric oxide (6.000 g.) to each flask to which was then added 200 ml. of the standard hydrochloric acid solution. This procedure was followed in order that we might attempt to observe the progressive change in the solid phase as well as the change in solubility. The samples from which the data were ob-

		5.0×10^{-1}	1480[s]

[s] and [u] indicate approach to equilibrium from the side of saturation and unsaturation, respectively; these symbols are also used in Tables II and III.

tained for Table I were made from Baker and Adamson Reagent mercuric oxide (yellow) which was washed ten times with conductivity water before use.

The Basic Mercuric Chloride, $2HgO \cdot HgCl_2$ (Trimercuric Oxychloride).—The black solid phase in the samples (Table II) containing 0.1 *N* to 0.28 *N* hydrochloric acid was identified by mercury and chloride analysis as conforming to the formula $2HgO \cdot HgCl_2$. Basic mercuric chloride was prepared by adding mercuric oxide to 0.15 *N* solutions of hydrochloric acid, in a slight excess of the amount sufficient to convert the mercuric oxide to the basic salt in accordance with the equation

$$3HgO(s) + 2HCl \rightleftarrows 2HgO \cdot HgCl_2(s) + H_2O \quad (8)$$

The mixture was stirred vigorously, during which time its color turned from a yellow to black; this color change usually occurred within the first two hours. The solution was then decanted and the black solid washed repeatedly with conductivity water containing a small amount of hydrochloric acid. The samples used to obtain the water solubility (Table III) were washed carefully with water before they were made. The mercury analysis of four of these samples analyzed was 85.5%, the chloride analysis was 9.9% (theoretical, Hg 85.4% and Cl 10.06%).

The data are given in Tables I, II and III and are shown grapnically in Figs. 1 and 2. All values are expressed in moles per 1000 g. of water.

TABLE II

SOLUBILITY OF YELLOW MERCURIC OXIDE IN HYDROCHLORIC ACID

200 ml. of standard HCl solution added to each sample containing 6.000 g. of dried reagent HgO.

Moles of HCl/1000 g. H_2O	10^{-4} × moles of HgO/1000 g. of H_2O	*p*H (glass electrode)	Character of solid phase Color	% Hg
0.00100	9.0	5.0	Yellow

.2832	1410		Black	85.4

Theoretical normality of 200 ml. of HCl to change 6.000 g. HgO to $2HgO \cdot HgCl_2$ is 0.0922 *N*. Theoretical % of Hg in $2HgO \cdot HgCl_2$ is 85.4%.

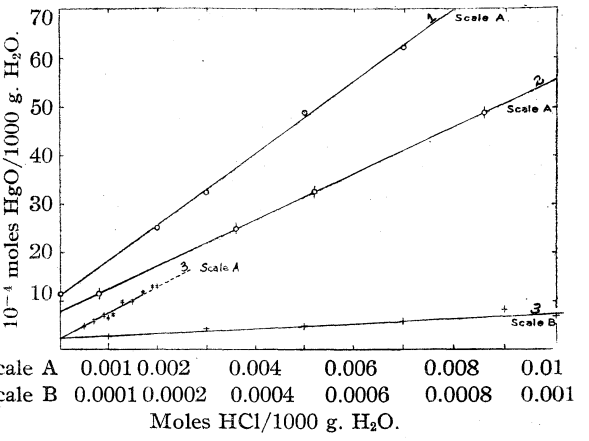

Fig. 1.—Curves 1 and 3, HCl as samples were made up; Curve 2, HCl corrected for HCl added by reaction due to the equation $2HgO \cdot HgCl_2(s) + H_2O = 3HgO + 2HCl$.

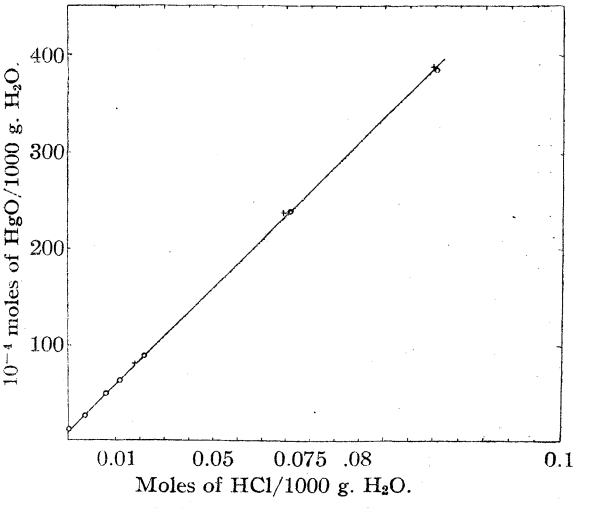

Fig. 2.—+, Table II data corrected for HCl necessary to convert HgO to $2HgO \cdot HgCl_2$; O, Table III data; data corrected for the amount of HCl added due to the reaction $2HgO \cdot HgCl_2(s) + H_2O = 3HgO + 2HCl$.

The data in Table II show a definite change in the solubility which is accompanied by a change in the solid phase from yellow HgO to black $2HgO \cdot HgCl_2$. This indicates that reactions represented by equations (4), (5), (6) and (7) are applicable to the data only below the region of the change; above this region and up to $m_{HCl} = 0.1$ a new solid phase is being formed, equation 8; above $m_{HCl} = 0.1$ a new equilibrium is estab-

lished which may be represented by equations (9), (10), (11), and (12).

The value of the water solubility of this basic chloride ($2HgO \cdot HgCl_2$) is 11.4×10^{-4} (Table III).

Solid phase removed from flasks of samples, reported in Table II, containing HCl varying from 0.12 to 0.28 N; this material was washed with conductivity water previous to making these samples: theoretical % Hg in $2HgO \cdot HgCl_2$, 85.4%; theoretical % Cl in $2HgO \cdot HgCl_2$, 10.1%.

Above $m_{HCl} = 0.1$ Table II only one phase (black) is observed. This phase gave the mercury and chlorine analysis in agreement with the formula $2HgO \cdot HgCl_2$. Further evidence of the identity of this phase is the fact that 200 ml. of $m_{HCl} = 0.0922$ should convert the 6.00 g. of mercuric oxide to $2HgO \cdot HgCl_2$. It is to be observed from the data in Table II that the solid phase becomes homogeneous at approximately 0.1 M hydrochloric acid and the inflection of the solubility curve appears here. Additional evidence is obtained from the data in Table III also shown in Fig. 1. In this experiment samples of $2HgO \cdot HgCl_2$ were prepared by the method described above, and their water and acid solubility determined. These data were then plotted on the same graph (Fig. 1) as is used for the data in Table II. In order to compare these two sets of data the ordinate is moved to the right to $m_{HCl} = 0.0922 + m_{HCl}$ (due to solution of $2HgO \cdot HgCl_2$) which is the point at which all the HgO should be converted to $2HgO \cdot HgCl_2$ and at which the data from Tables II and III should be comparable. The agreement is excellent.

The equilibrium constants, K_4, K_{10}, K_{11} and K_{12}, are difficult to evaluate due primarily to the uncertainty of the value of a_{Cl^-}. Some information can be obtained about the relative distribution of the dissolved mercury among the forms $Hg(OH)Cl$, $HgCl_2$, $HgCl^+$ and $HgCl_3^-$ above the transition point if one makes the safe assumption that the two mercury bearing ions $HgCl^+$ and $HgCl_3^-$ only appear in appreciable concentrations at higher concentrations of mercury. The relative distribution of the dissolved mercury between $Hg(OH)Cl$ and $HgCl_2$ above the transition point is given in Table IV.

TABLE IV

.02	161	3
.04	308	1

$$X = \frac{(S/C) - 0.75}{2.25}$$

The Transition.—No definite statement can be made of the exact value of m_{HCl} at the

transition point. The problem yet to be solved is to determine the equilibrium concentrations of HCl, HgO and 2HgO·HgCl at the triple point.

Summary

The solubilities of mercuric oxide and of basic mercuric chloride, $2HgO \cdot HgCl_2$, have been measured in hydrochloric acid solutions. A break occurs in the solubility relationships due to the formation of a new solid phase ($2HgO \cdot HgCl_2$). This basic mercuric chloride, $2HgO \cdot HgCl_2$, has been prepared and identified; the water solubility is 11.4×10^{-4}. The relative distribution of mercury among several different ion species is indicated.

Adsorption and the Energy Changes[1] at Crystalline Solid Surfaces

BY G. E. BOYD AND H. K. LIVINGSTON[1a]

Theory

Adsorption is accompanied by a change both in the total and in the free surface energy of a surface. The classical relation of J. W. Gibbs[2] for interfaces between fluids has been used extensively and certainly must be regarded as valid when properly applied. The question of the applicability of the theorem to the interface between solids and fluids must be considered, and we are fortunate that Gibbs has discussed the problem in detail in the case in which the solid is anisotropic.

Thus, if the total surface energy, E_{so}; surface entropy, S_{so}; surface densities of chemical species, Γ_i; chemical potentials, μ_i; and temperature, T, are used, it is possible to define a quantity, ζ, for the arbitrarily restricted case of a system of two components by the equation[3]

$$\zeta = E_{so} - TS_{so} - \mu_1\Gamma_1 - \mu_2\Gamma_2 \qquad (1)$$

In Gibbs' words, "The quantity ζ evidently represents the tendency to contraction in that portion of the surface of the fluid which is in contact with the solid. It may be called *the superficial tension of a fluid in contact with a solid.* Its value may be either positive or negative.

"It will be observed for the same solid surface and for the same temperature but for different liquids the values of γ_{sf} (in all cases to which the definition of this quantity is applicable) will differ from those of ζ by a constant, *viz.*, the value of γ_{so} for the solid surface in a vacuum."

Obviously, ζ is defined by

$$\zeta = \gamma_{sf} - \gamma_{so} = -\pi \qquad (2)$$

or, the spreading pressure, π, is equal to the difference between the free surface energy of the clean solid surface (in a vacuum) and the free surface energy when in equilibrium with a chemically dissimilar fluid component (*i. e.*, gas or liquid).

Utilizing Gibbs' general thermodynamic methods, from equation (1), it is possible to obtain for a system consisting of a crystalline adsorbent and one adsorbate

$$d\pi = S_{so}dT + \Gamma_1 d\mu_1 + \Gamma_2 d\mu_2 \qquad (3)$$

If isothermal conditions are maintained, and if the Gibbs plane from which adsorption is reckoned is chosen so that the surface density of adsorbent, Γ_1, is zero, one may write

$$d\pi = \Gamma_2^{(1)} d\mu_2$$

or

$$\Gamma_2^{(1)} = \left(\frac{\partial \pi}{\partial \mu_2}\right)_{T,\,P,\,\mu_1} \qquad (4)$$

For the case in which the fluid contiguous to the solid surface is a gas or a vapor

$$d\mu_2 = RT\, d \ln f_2 \qquad (5)$$

where f_2 is the fugacity, and for vapors at low pressures

$$RT\, d \ln f_2 = RT\, d \ln p_2 \qquad (6)$$

is true with sufficient accuracy, so that equation (4) may be written as

$$d\pi = RT\Gamma_2^{(1)} d \ln p_2 \qquad (7)$$

where p_2 is to be taken as the equilibrium pressure of a gas or vapor above the crystal surface upon which adsorption has occurred.[4]

(2) J. W. Gibbs, "Collected Works," Longmans, Green & Co., New York, N. Y., 1928, p. 314.

(3) It will be noticed that we have taken the liberty of modifying part of Gibbs' original nomenclature in order to bring it into approximate correspondence with present-day usage in chemical thermodynamic literature.

(4) Extensive calculations to establish the correctness of Eqn. (6) for a number of vapors are given in Appendix C of H. K. Livingston, Ph.D. Thesis, University of Chicago, December, 1941.

Evidently, values of p_2 may range from zero to the saturation vapor pressure, p_2^0, of the pure liquid from which the vapor is formed. An integration of equation (7) gives

$$\int_0^{\pi} d\pi = \gamma_{so} - \gamma_{sv} = RT \int_0^{p_2} \Gamma_2^{(1)} \, d \ln p_2 \qquad (8)$$

where γ_{sv} represents the free surface energy of the solid in equilibrium with the vapor of the foreign component 2 at pressure p_2. The quantity $\gamma_{so} - \gamma_{sv}$ may be looked upon as either the two-dimensional spreading pressure of the adsorbed film on the solid surface,[5] or, as the free energy of immersion at constant temperature of a unit surface of clean solid in an infinite amount of vapor at pressure p_2. If the solid be immersed in a saturated vapor, of pressure p_2^0, equation (8) becomes

$$\gamma_{so} - \gamma_{sv^0} = RT \int_0^{p^0} \Gamma_2^{(1)} \, d \ln p_2 \qquad (9)$$

A determination of the important free energy of immersion of a solid in a saturated vapor is possible if the right-hand member of (9) can be integrated. This might be effected if an equation for the adsorption isotherm up to the pressure of the saturated vapor were known (*i. e.*, $\Gamma_2^{(1)}$ as a function of p_2). Recent attempts[6] in this direction have been partially successful, but, for the problem at hand, it was found that a graphical integration of (9) was the least time-consuming.

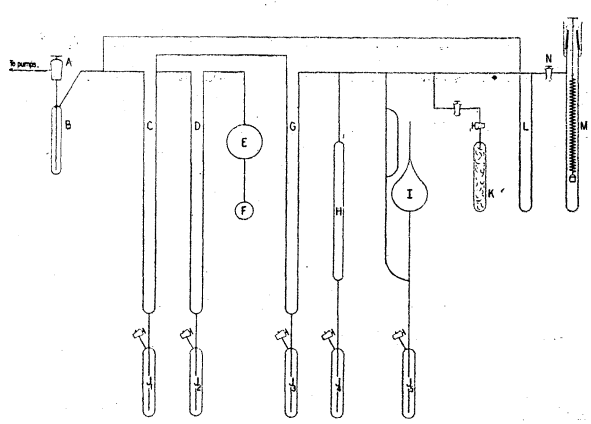

Fig. 1.—Vapor adsorption apparatus showing silica spring and platinum powder bucket, M; manometer, L; charcoal trap, K; McLeod gage, I; vapor compressing chamber, H; cutoffs, G, D and C; vapor pipets, E and F, and trap, B.

Two special points need be made concerning this procedure. From (9) it is evident that at $p_2 \doteq 0$ the integrand approaches negative infinity, whereas, as $p_2 = p_2^0$, experimentally the adsorption, $\Gamma_2^{(1)}$, appears to increase without bound.

The first difficulty may be overcome by observing that

$$RT \int_0^{p_2^0} \Gamma_2^{(1)} \, d \ln p_2 = RT \int_0^{p_2^0} \frac{\Gamma_2^{(1)}}{p_2} \, dp_2 \qquad (10)$$

Since the ratio $\Gamma_2^{(1)}/p_2$ approaches a constant value (Henry's law for surfaces) for the adsorption of gases or vapors at low pressures, the integral may be evaluated at the lower limit. At the upper limit, the value of the integral is obtained by a short extrapolation when suitable methods are used.[7,8]

Experimental

In order to carry out the calculations described in the previous section it is necessary to have accurate adsorption data up to the saturation pressure of the vapor studied. An examination of the volumetric adsorption method as used in these laboratories[9] indicates that it is not a feasible technique to employ at pressures higher than half-saturation. Consequently, in these more recent studies the technique of McBain and Bakr[10] was used in which the amount of material adsorbed, q, is determined directly by the increase in weight of a given mass of crystalline non-porous adsorbent shown by the increased extension of a fine silica spring which supports the adsorbent, as in Fig. 1, M. The method has numerous advantages for this type of work, among which are: it is (1) rapid and accurate; (2) buoyancy corrections are small; and (3) organic vapors may be utilized without difficulty. Isotherms by this method are shown in Figs. 2–5.

It is important to make clear the connection between the adsorption experimentally meas-

(5) The concept that the molecules of a substance adsorbed on a crystal surface exert a two-dimensional spreading pressure was used first by Volmer, (*Z. physik. Chem.*, **115**, 253 (1925)) and arose quite naturally out of the researches on mobile films on solids. In this paper no assumptions are made concerning the physical state of the adsorbed films, but rather a thermodynamic viewpoint is maintained.

(7) See Appendix D of H. K. Livingston, Ph.D. Thesis, University of Chicago, 1941.

(8) Although the ideas presented in this section stem directly from the classic paper of J. W. Gibbs on the "Equilibria of Heterogeneous Substances," the authors wish to acknowledge the stimulation they have received from the very recent publications of Bangham and his co-workers (Bangham and Razouk, *Trans. Faraday Soc.*, **33**, 1459, 1463 (1937); *Proc. Roy. Soc.* (London), **A166**, 572 (1938)). The experimental work from the laboratory at Cairo has dealt so far only with a porous charcoal in which it is likely that the effects of capillary condensation were present.

(10) McBain and Bakr, THIS JOURNAL, **48**, 690 (1926).

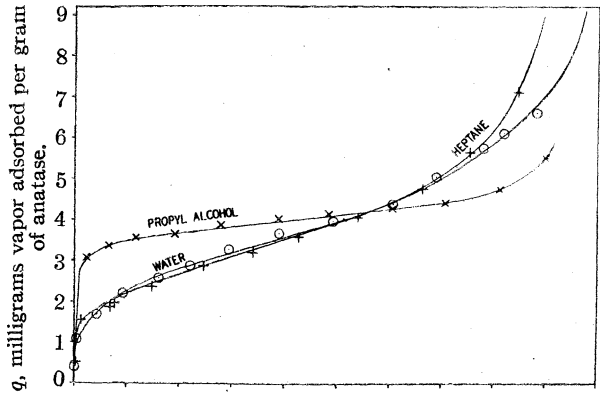

Fig. 2.—Adsorption of water, propyl alcohol and heptane vapors on crystalline, non-porous TiO_2 (anatase).

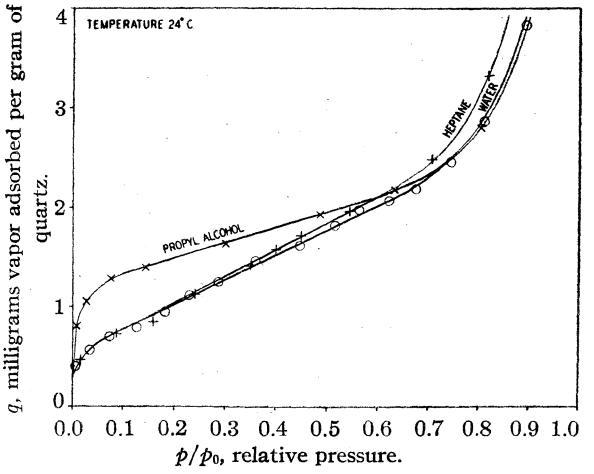

Fig. 3.—Adsorption of water, propyl alcohol and heptane vapors on crystalline SiO_2 (quartz).

ured, expressed in milligrams (or micromoles) adsorbate per gram adsorbent, and the quantity, $\Gamma_2^{(1)}$, of equation (9). This latter adsorption has units of moles of adsorbate per sq. cm. adsorbent, and is defined by Gibbs[2] as, " . . . the surface density of fluid (in our case, vapor) component determined by the excess of matter in the vicinity of the surface over that which would belong to the solid if it were bounded by a vacuum in place of the fluid, and to the fluid, if it extended with a uniform volume-density of matter just up to the surface of the solid . . . . "

Thus, equation (11) serves to define $\Gamma_2^{(1)}$ experimentally

$$\Gamma_2^{(1)} = \frac{q}{M\Sigma} - \frac{\tau}{v_2} \qquad (11)$$

where q is the measured adsorption given in milligrams per gram of adsorbent, M the molecular weight of the vapor, Σ the area in sq. cm. per gram

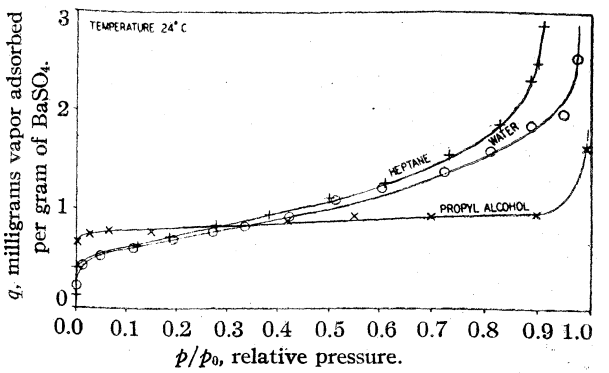

Fig. 4.—Adsorption of water, propyl alcohol and heptane vapors on crystalline $BaSO_4$ (X-ray grade).

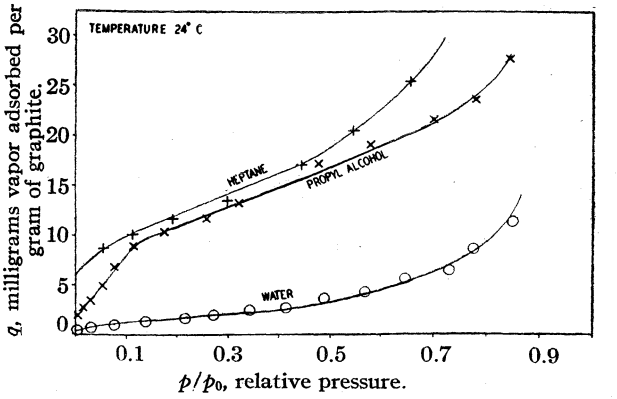

Fig. 5.—Adsorption of water, propyl alcohol and heptane vapors on graphite (Dixon 0708).

of solid, τ the thickness of the surface region, and v_2 is the molal volume of the vapor. Since the vapor behaves as a perfect gas

$$v_2 = RT/p_2 \qquad (12)$$

so that

$$\Gamma_2^{(1)} = \frac{q}{M\Sigma} - \frac{\tau p_2}{RT} \qquad (13)$$

Substituting equation (13) into (9)

$$\gamma_{s_0} - \gamma_{sv_0} = \frac{RT}{M\Sigma}\left[\int_0^{p^0} \frac{q}{p_2}\,dp_2\right] - \left[\int_0^{p_2^0} \tau\,dp_2\right] \qquad (14)$$

A simple numerical computation shows that the term $\int_0^{p^0} \tau dp_2$ makes no significant contribution; therefore

$$\gamma_{s_0} - \gamma_{sv_0} = \frac{RT}{M\Sigma}\int_0^{p_2^0} \frac{q}{p_2}\,dp_2 \qquad (15)$$

If the adsorption isotherm for a vapor on a crystalline non-porous powder is obtained, and if the total area per gram of powder, Σ, is determined, it is possible to calculate the change in the free energy of a clean solid surface upon immersion in a saturated vapor. The surface areas em-

ployed in this calculation were determined by the method of Brunauer, Emmett and Teller.[11]

Table I summarizes the results of the graphical integrations carried out on the data obtained in this work, as well as on selected data from the literature.

The Change of the Free Energy of a Solid Surface upon Immersion in Bulk Liquid.[12]— In order to determine the magnitude of the free energy of immersion of a clean solid surface, $\gamma_{so} - \gamma_{sl}$, in a large amount of bulk liquid, it is necessary to find some relation of this quantity to the magnitude in Table I.

If a drop of liquid is placed upon a freshly cleaved crystal surface, in the absence of any other components, a number of possibilities arise: (1) the droplet will extend over the solid surface until it appears to cover the surface with an extremely thin film of uniform thickness; (2) the droplet flattens under gravity to an equilibrium shape in which an angle of contact is formed between the liquid and the crystal surface now covered with a film which may be monomolecular or of somewhat greater thickness as is shown in Fig. 6.[13]

According to Gibbs[2] the condition for the formation of an equilibrium contact angle is

$$\zeta_{sB} - \zeta_{sA} = \gamma_{AB} \cos \theta_E \qquad (16)$$

where ζ_{AB} and ζ_{sA} are quantities related to the film pressures π_{sB} and π_{sA} and θ_E is the equilibrium contact angle[14]

Since

$$\pi_{sB} = \gamma_{so} - \gamma_{sB} = -\zeta_{sB}$$

and

$$\pi_{sA} = \gamma_{so} - \gamma_{sA} = -\zeta_{sA}$$

equation (16) may be written

$$\pi_{sA} - \pi_{sB} = \gamma_{AB} \cos \theta_E$$

or

$$\gamma_{sB} - \gamma_{sA} = \gamma_{AB} \cos \theta_E$$

If fluid phase B is the saturated vapor and phase A the pure liquid with which the vapor is in equilibrium, then

$$\gamma_{sv^0} - \gamma_{sl} = \gamma_{lv^0} \cos \theta_E \qquad (17)$$

where γ_{sv^0} is the free surface energy for the interface between solid and saturated vapor, γ_{sl} for the solid-bulk liquid interface, and γ_{lv^0} for the bulk liquid and its own saturated vapor.

Equation (17) may be written as

$$(\gamma_{so} - \gamma_{sl}) - (\gamma_{so} - \gamma_{sv^0}) = \gamma_{lv^0} \cos \theta_E \qquad (18)$$

from which the free energy of immersion in bulk liquid may be computed if the quantities ($\gamma_{so} - \gamma_{sv^0}$), γ_{lv^0}, and θ_E are known.

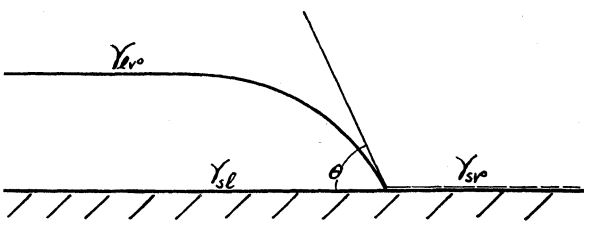

Fig. 6.—Equilibrium contact angle diagram: γ_{lv^0}, surface tension of pure liquid in equilibrium with its saturated vapor; γ_{sl}, interfacial tension between solid and liquid; γ_{sv^0}, surface free energy (or tension) of film covered solid in equilibrium with the saturated vapor of the pure bulk liquid.

In the special case in which $\theta_E = 0$, equation (18) assumes the form

$$(\gamma_{so} - \gamma_{sl}) - (\gamma_{so} - \gamma_{sv^0}) = \gamma_{lv^0} \qquad (19)$$

An examination of the relatively limited amount of reliable contact angle data[15-20] indicates that (a) clean polar solid surfaces are completely wet

(11) Brunauer, Emmett and Teller, THIS JOURNAL, **60,** 309 (1938).

(12) The material in the following section was given on September 24, 1941, in a paper read by G. E. B. at the Symposium on Surface Chemistry in celebration of the Fiftieth Anniversary of the University of Chicago under the title: Some Aspects of the Properties of Solid Surfaces. Subsequently, Professor W. D. Harkins has incorporated a portion of the data presented (Table II) and some of the conclusions in a recent publication, W. D. Harkins and H. K. Livingston, *J. Chem. Phys.*, **10,** 341 (1942).

(13) In his pioneering researches on this subject W. B. Hardy [*Phil. Mag.*, **38,** 49 (1919); Institut International de Chimie Solvay, Brussels (1925)] has described the diverse phenomena involved in the spreading and lens formation by liquids on clean solid surfaces. It is of interest that he remarks that mechanism (1) never occurs for a pure liquid and that the process whereby a film is built in (2) involves a transfer of molecules of liquid through the vapor phase from the lens to the solid (*i. e.*, "vapor spreading").

(14) This is the equilibrium value theoretically assumed by the angle between the solid and liquid surfaces when movement of the liquid over the solid surface is such as to alter this angle; *cf.* C. G. Sumner, "Wetting and Detergency," Chemical Publishing Co., New York, N. Y., 1937, p. 15.

(17) Hunten and Maass, *ibid.*, **51,** 156 (1929).

(18) Carver and Hovorka, *ibid.*, **47,** 1325 (1925).

(19) Bartell, Culbertson and Miller, *J. Phys. Chem.*, **40,** 881 (1936).

(20) Bartell and Zuidema, THIS JOURNAL, **58,** 1449 (1936).

(*i. e.*, $\theta_E = 0$) by water and by polar and non-polar organic liquids,[21] (b) that non-polar liquids wet non-polar solids; but that generally, (c) polar liquids show finite angles with non-polar solids.[22]

The values of the free energy change upon immersion in bulk liquid, $\gamma_{so} - \gamma_{sl}$, calculated using (19) for the polar solids given in Table I are given in Table II. A comparison with the values for a non-polar solid, graphite, is included. In this case the free energy change was calculated from (18) using the measured contact angle of 85.7° with water taken from the work of Fowkes.[23]

The Work of Adhesion of a Liquid to a Solid. The Spreading of a Liquid over a Crystal Surface.—The work of adhesion[24] of a pure liquid to a clean solid surface is given by equation (20)

$$W_a = \gamma_{so} + \gamma_{lv^0} - \gamma_{sl} \qquad (20)$$

and this quantity may be calculated from the previous value of the free energy of immersion in bulk liquid. These values are shown in Table II.

An important consequence of a knowledge of the free energy of immersion in bulk liquid, $\gamma_{so} - \gamma_{sl}$, is that a measure of the tendency of a bulk liquid to spread over an initially clean crystalline surface can be obtained. Although the spreading of liquids on clean crystalline surfaces bears an analogy to the spreading of immiscible liquids on water or mercury, a special consideration of the coefficients of spreading must be given in the light of the fundamental differences in mechanism in the two cases.[25]

For the spreading of a liquid as a *duplex* film over a solid surface, the initial spreading coefficient, $S_{lv^0/so}$, may be defined by equation (21)

$$S_{lv^0/so} = \gamma_{so} - \gamma_{sl} - \gamma_{lv^0} \qquad (21)$$

and the final spreading coefficient, S_{lv^0/sv^0}, by equation (22)

$$S_{lv^0/sv^0} = \gamma_{sv^0} - \gamma_{sl} - \gamma_{lv^0} \qquad (22)$$

Combination of equations (22) and (17) yields

$$S_{lv^0/sv^0} = \gamma_{lv^0}(\cos\theta_E - 1) \qquad (23)$$

which is a useful form for the purpose of calculation of the latter coefficient.

(21) However, mercury, a non-polar liquid, shows a large contact angle on glass, a polar solid. Published values of θ_E range from 128 to 148°, since effects of roughness and contamination of the solid or liquid surface all combine to cause angles greater than 90° to be too large; the value of 128° mgy be the more reliable.

(22) This generalization is again not without exception as has been shown by the work of Bartell and Zuidema (ref. 20) where zero angles for butyl acetate and amyl alcohol on talc are reported.

[a] Surface tensions of pure liquids and mercury were taken from "International Critical Tables," **4**, 436 (1928). [b] *Cf.* Bartell, Case and Brown, THIS JOURNAL, **55**, 2769 (1933).

However, equations (21) and (22) refer to the tendency of the film of liquid to spread over the solid surface without change of the angle between solid and liquid at the line of contact, whereas θ_E of equation (23) refers to equilibrium conditions. Now this restriction may be satisfied if in spreading the movement of the liquid over the crystal surface is made to take place infinitely slowly, for then the contact angle would theoretically achieve its equilibrium value. Under these circumstances evaporation from the liquid and condensation on the crystal (*i. e.*, Hardy's secondary spreading) may be the actual physical process whereby the solid is covered. The final result at equilibrium in either case will be that the crystal face is covered with an exceedingly thin film, which is duplex if $\theta_E = 0$ and non-duplex for $\theta_E > 0$.

Equation (23) shows us that if $\theta_E = 0$, the final spreading coefficient vanishes or, that the free surface energy of the solid in equilibrium with a saturated vapor, γ_{sv^0}, is equal to the sum for the surface tension of the bulk liquid against its own vapor, γ_{lv^0} and the interfacial tension between

solid and liquid, γ_{sl}. This equality can be taken as the definition of a duplex film on a solid surface. Values for the initial and final spreading coefficients are included in Table II. Also it is instructive to note that combination of equations (19) and (21) gives

$$S_{lv^0/so} = \gamma_{so} - \gamma_{sv^0} \qquad (24)$$

or, if a liquid forms a zero contact angle with a solid, the initial spreading coefficient of that liquid on the solid surface has the same value as the free energy change upon immersion in the saturated vapor of that liquid.

Energy Changes for Solids Showing Finite Contact Angles.—Inspection of equation (23) shows that S_{lv^0/sv^0} cannot be positive for finite values of θ_E. In such cases the final spreading coefficient is more appropriately a "recession coefficient," and measures the tendency of a *duplex* film, produced by some means over the surface, to contract. However, this does not mean that the withdrawal of the duplex film will denude the solid of molecules of the liquid substance. In fact, some evidence can be obtained that a non-polar crystalline surface is actually partially covered with a monolayer when a drop of liquid showing a finite contact angle rests upon another part of the surface.

The work of adhesion defined by equation (20) gives the amount of energy necessary to destroy one sq. cm. of liquid–solid interface and to form a unit area of liquid and of clean solid surface. However, since it is physically impossible to separate a solid and a liquid without leaving the solid covered with at least a monolayer in equilibrium with the vapor of the bulk liquid, it is convenient to define the work for such a process, W_a', shown in equation (25)

$$W_a' = \gamma_{sv^0} + \gamma_{lv^0} - \gamma_{sl} \qquad (25)$$

Substitution of (25) into (17) gives the work of separation, W_a', as

$$W_a = \gamma_{lv^0}(1 + \cos\theta_E) \qquad (26)$$

It is evident also that

$$W_a - W_a' = \gamma_{so} - \gamma_{sv^0} = S_{lv^0/so} \qquad (27)$$

Table III gives a summary of values for a number of liquids on a few hydrophobic solids compared with a value of mercury on glass.

TABLE III

ENERGY RELATIONS WITH SOLIDS SHOWING FINITE CONTACT ANGLES

A deduction consistent with the data of Table III is that in separating bulk water from a non-polar solid, since the amount of work, W_a', is considerably less than the work of cohesion, W_c, of water, the film left on the solid does not possess the properties of a liquid. It is possible that this film is even somewhat less than a complete monolayer.

Summary

1. The determination of the fundamentally important free energy change upon immersion in a saturated vapor for the non-porous crystalline solids, TiO_2 (anatase), SiO_2 (quartz), $BaSO_4$, SnO_2 and graphite has been made. This was accomplished through the graphical integration of vapor adsorption data utilizing the Gibbs adsorption relation.

2. The free surface energy change upon immersion in bulk liquid was obtained for these solid surfaces from the data of (1) combined with the correct equilibrium contact angle equation.

3. The data of (2) were employed to obtain the work of adhesion of a liquid to a solid surface, and to determine values of the changes in free energy associated with the spreading of a liquid as a duplex film over a crystal face.

4. An examination of the free energy changes for solids and liquids where the equilibrium contact angle is greater than zero indicates that, although a duplex film cannot exist, a monolayer may cover the solid surface.

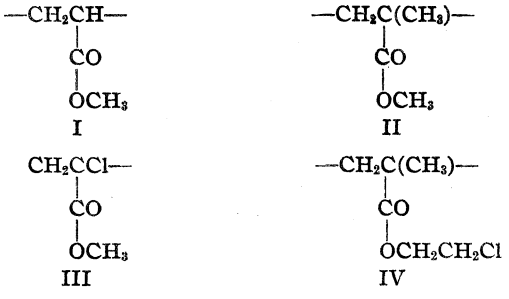
Electrical Properties of Solids. XIII. Polymethyl Acrylate, Polymethyl Methacrylate, Polymethyl-α-chloracrylate and Polychloroethyl Methacrylate[1]

BY DARWIN J. MEAD AND RAYMOND M. FUOSS

1. **Introduction.**—In a recent paper,[2] we presented some measurements on several high polymers in which the polar groups were attached to chain carbons by flexible bonds. In this paper, we present data covering the following four systems: I, polymethyl acrylate; II, polymethyl methacrylate; III, polymethyl-α-chloracrylate and IV, polychloroethyl methacrylate.



In these, the polar carbonyl group is attached to a chain carbon, and then a second polar group is attached to the carbonyl. In addition, two of them contain C–Cl dipoles. These compounds are the first of a series of polymers of the general type $(—CH_2·CXY—)_n$ which we planned to investigate.

Polymethyl acrylate is an isomer of polyvinyl acetate. The reversal of position of the —CO·O— group with respect to the chain produces several distinct changes in the electrical properties. The static dielectric constant of polymethyl acrylate is lower than that of polyvinyl acetate at a given temperature, and the peak loss factor is much lower. The distribution of relaxation times[3] is wider for the acrylate, because the highly polar carbonyl group is attached to the chain carbon, and only the weaker methoxy group is relatively free from the restrictions of motion imposed by the chain configurations.

Substituting a methyl group for a chain hydrogen of I gives II ("Lucite"), polymethyl methacrylate, which is markedly different in its electrical behavior from the simple acrylate. Apparently the methyl group on the same carbon which carries the polar group stiffens the chain so that free rotation[4] is very much reduced. Consequently we find here a low static dielectric constant and a very broad distribution of relaxation times. Furthermore, the low temperature maximum in loss factor which has appeared for the other polar polymers which we have investigated fails to appear. Replacing the ester methyl group by a chloroethyl group again raises the dielectric constant, as expected. The chloracrylate is quite similar to the methacrylate, when allowance is made for the dielectric contribution of the halogen. Like Lucite, it also does not have a secondary low temperature maximum in loss factor, which confirms the idea that steric hindrance due to two groups on a chain carbon prevents crystallization.

2. **Experimental Details.**—Cells, electrical apparatus and general procedure were much the same as those used in previous papers of this series.

Polymethyl acrylate was otained from a commercial sample. It was freed from monomer and some material of low molecular weight by dissolving in acetone (17 g. to 800 cc.) and precipitating by adding an excess of cold methyl alcohol slowly to the chilled acetone solution. The original polymer was rather soft and the precipitate coagulated, instead of remaining flocculent. It was vacuum dried and stored over phosphorus pentoxide in an evacuated desiccator for a week before use. Discs were made by pressing for five minutes in a closed mold at 145°. Aquadag electrodes were painted on the discs, after which they were dried in a desiccator over phosphorus pentoxide. The index of refraction, measured on a Benford refractometer,[5] was 1.48.

The viscosities at 25° in cyclohexanone were measured for solutions containing 0.0288, 0.0528 and 0.0784 monomoles per liter of polymethyl acrylate. The measurements at each concentration were made at a series of pressures, and extrapolated to zero pressure.[6] The pressure dependence was about four times as large as for polyvinyl chloride. The three data give a straight line when $\lambda = (\ln \eta_r)/c$, the equivalent viscosity, is plotted against concentration. The corresponding equation is

$$\lambda = 12.38\ (1 - 1.92\ c) \qquad (1)$$

No estimate of molecular weight can be made because no absolute determination for polymethyl acrylate is available.

Polymethyl methacrylate was obtained in powder form by pouring a dilute (25 g./1300 cc.) dioxane solution of a commercial polymer into water. After digesting to degelatinize the precipitate, it was thoroughly washed with water and vacuum dried. Discs for measurements were hot pressed, five minutes at 170°. Aquadag would not wet the polymer satisfactorily, so thin tin-foil electrodes[7] rubbed on with a little vaseline were used to eliminate the air film. The index of refraction was 1.47.

Several plasticized samples were made, by dissolving diphenylmethane in petroleum ether and mixing the solution with the powdered polymer.[8] After evaporation of the ether, discs were hot pressed: five minutes at 155° for the 20% sample, and five minutes at 150° for the 30% sample. The indices of refraction were 1.53 and 1.68.

Viscosities of solutions of the polymethyl methacrylate in cyclohexanone at 25° were determined. Concentrations were 0.0232, 0.0502 and 0.0760 monomole per liter; the data, after extrapolation to zero pressure, gave a straight line when λ was plotted against c

$$\lambda = 5.29(1 - 0.44\,c) \qquad (2)$$

Although the methyl methacrylate probably has a higher molecular weight than the acrylate, the constant λ_0 is smaller for the former; this may mean that the methyl groups on the chain carbon inhibit curling of the chain in the methacrylate.

Polymethyl-α-chloracrylate was used without any fractionation. A piece of resin was crushed cold, and then hot pressed for five minutes at 155°, to form a test disc. The d. c. conductance was rather high, either due to pyrolysis or to impurities in the sample. The conductance, however, was not high enough to interfere with the low temperature measurements, which were the main point of interest for this polymer.

Chloroethyl methacrylate was prepared by ester interchange between methyl acrylate and ethylene chlorohydrin: 200 g. (2 moles) of monomethyl methacrylate, 241 g. (3 moles) of ethylene chlorohydrin, 6 g. of concd. sulfuric acid in 40 cc. of water and 4 g. of pyrogallol were refluxed for two hours, and then distillation of methyl alcohol was started. After the expected amount of alcohol was removed, the contents of the flask were washed several times with water containing 2.5% pyrogallol (to inhibit polymerization), in order to remove sulfuric acid and excess chlorohydrin, and then the chloroethyl methacrylate was distilled; it came over at 78° at about 18 mm. The normal boiling point was found to be 170°, by the usual micro-method. (By using the micro-method, a boiling point determination could be made before appreciable polymerization took place.) The ester was then polymerized by heating for five days at 40–45°. A hard, transparent solid was obtained. Chlorine analyses gave 20.87, 20.80% Cl, as compared with 23.8% theoretical. Apparently, some hydrogen chloride split out during the heating, giving a small amount of vinyl methacrylate. This was confirmed by the behavior of the polymer toward solvents: it swelled in ketones and ethylene chloride, but would not dissolve. Vinyl methacrylate is a bifunctional polymerant, and hence could give cross bonds in the final product, which would account for the insolublity. For electrical measurements, discs were pressed (ten minutes at 150°) from a coarse powder made by crushing a piece of the polymer. The samples were not quite smooth, so they were polished flat before painting on the aquadag electrodes. The index of refraction was 1.51.

The results for several frequencies in the dispersion range for the polymers are shown in Figs. 1, 2, and 3. A definite similarity between the behavior of polymethyl acrylate (I) and that of its isomer, polyvinyl acetate (PViAc),[10] will be noticed, as well as some marked differences. Both show a dispersion and absorption which is describable in terms of a distribution of relaxation times, as indicated by the fact that the maximum loss

(9) For a copy of these tables, order Document 1642 from the American Documentation Institute, Offices of Science Service, 2101 Constitution Ave., Washington, D. C., remitting 25 cents for microfilm or 60 cents for photocopies readable without optical aid. The tables give dielectric constants and loss factors for the following: Table S-I, polymethyl acrylate at 60, 600, 6000 cps. 0 to −70°; S-II, polymethyl acrylate at 60, 120, 240, 480, 1000, 2000, 4000 and 8000 cps., 5 to 100°; S-III, polymethyl methacrylate at 1000 cps., −20 to −70° and at 60, 600 and 6000 cps., 40 to 90°; S-IV, polymethyl methacrylate–diphenylmethane, 80:20 at 60–8000 cps., 20 to 90°; S-V, polymethyl methacrylate–diphenylmethane, 70:30 at 60–8000 cps., 20 to 70°; S-VI, polychloroethyl methacrylate at 60, 600 and 6000 cps., −70 to +100°; and S-VII, polychloroethyl methacrylate at 60–8000 cps. and −73°.

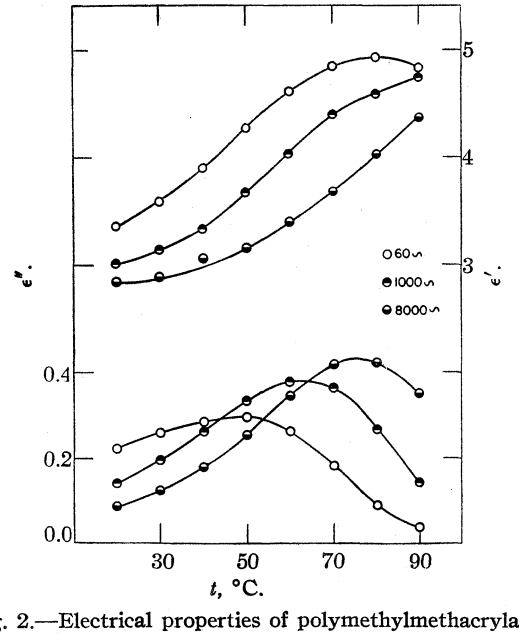

Fig. 2.—Electrical properties of polymethylmethacrylate–diphenylmethane, 80:20.

factor is considerably less than half the difference between the square of the index of refraction and the static dielectric constant.[11] For I, the ratio $2\epsilon''_m/(\epsilon_0 - \epsilon_\infty) = 0.245$ while for PViAc, it is 0.536, nearly twice as large. (These figures are calculated from the 60 cycle data; $\epsilon'' = 0.645$ at 27° for I and 1.78 at 57° for PViAc. The static dielectric constants were determined by extrapolating the asymptotic envelopes of the corresponding $\epsilon' - T$ curves to the temperatures of the

(11) Fuoss and Kirkwood, THIS JOURNAL, 63, 385 (1941).

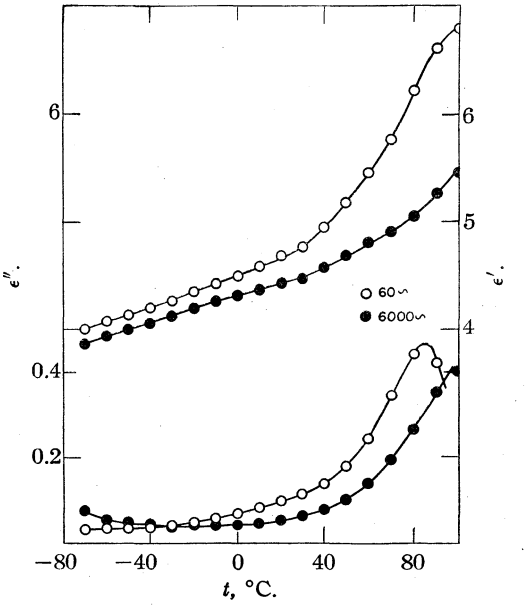

Fig. 3.—Electrical properties of polychloroethylmethacrylate.

loss factor maxima.[2]) For a system describable by a single relaxation time, this ratio is unity, of course. It is interesting to note that the spatial reversal of the —CO·O— ester group from PViAc to I broadens the distribution considerably; in the former, the strongly polar carbonyl is attached to the chain by a flexible oxygen hinge and hence is relatively free to move, while in the latter it is directly attached to the chain carbon (like the halogen in PViCl) and its orientation is controlled by the configurations of the polymeric chain. The moment per monomer unit[11] of polymethyl acrylate is 2.0×10^{-18}, as compared with 2.3×10^{-18} for polyvinyl acetate.

The mechanical properties of polymethyl acrylate are also quite different from those of polyvinyl acetate. The former was soft and flexible at room temperatures, while both Gelva 15 and 60 were hard. The corresponding limiting viscosities in cyclohexanone were: I, 12.38; Gelva 15, 4.25 and Gelva 60, 9.25. If we assume that the loss factor maximum at a given frequency comes at lower temperatures for compounds of lower molecular weight,[12] then the acrylate had the lower molecular weight, because its 60-cycle maximum is at 27°, while those for the Gelvas are at nearly 60°. If it is argued, however, that the acrylate is soft, because it has a low molecular weight, then it must have a very much larger Staudinger constant than the acetate; ultracentrifuge or os-

(12) Fuoss, *ibid.*, 63, 2401 (1941).

mometer data on these compounds would be very valuable aids in clearing up this point.

The only structural difference between the acrylate and methacrylate (aside from differences in molecular weight and distribution) is that, in the latter, the hydrogen atom on the carbon carrying the polar group has been replaced by a methyl group. This substitution has a far-reaching effect on the properties of the polymer. The 60-cycle loss factor maximum is shifted up to 50° from 27°, which indicates a very considerable increase in internal viscosity. At the same time, the static dielectric constant is reduced from 7+ to 5+, showing that internal rotations are very much hindered, even at low frequencies.

The most striking difference between polymethyl methacrylate and the other polymers so far studied, however, appears in the low temperature properties. Instead of showing a secondary loss factor maximum at low temperatures, polymethyl methacrylate has a single absorption peak in the high temperature range, from which it drops uniformly with decreasing temperature.

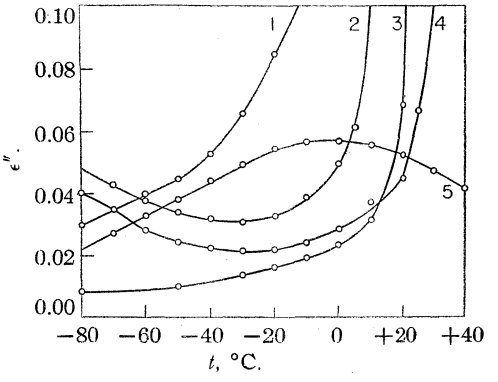

Fig. 4.—Comparison of polymers at low temperatures: 1, *p*-methyl-methacrylate; 2, *p*-methyl acrylate; 3, 20% plasticized *p*-vinyl chloride; 4, *p*-vinyl chloroacetate; 5, *p*-vinyl chloride.

As is shown in Fig. 4, the shape of the curve resembles most closely that of a plasticized polymer, which contains enough plasticizer to eliminate the low temperature maximum. It is not likely that polymethyl methacrylate exhibits a secondary maximum at temperatures below −70°, the lower limit of our experimental range, because the Cole plots[13] are symmetrical and, as was shown in the case of polyvinyl chloride and acetate, they are necessarily unsymmetrical when a low temperature maximum appears. Data for polymethyl methacrylate in the dispersion range are given in Table II. A circular arc through these points extrapolates at $\epsilon'' = 0$ ($f = \infty$) very closely to 2.16, the square of the index of refraction, n. In all cases where a low temperature maximum appeared, a circular arc through the $\epsilon' - \epsilon''$ points in the dispersion range terminated at a point on the ϵ'-axis much larger than n^2.

TABLE II

ELECTRICAL PROPERTIES OF POLYMETHYL METHACRYLATE: DISPERSION CURVES

	t = 60°		t = 70°		t = 80°	
f	ϵ'	ϵ''	ϵ'	ϵ''	ϵ'	ϵ''
60	4.16	0.282	4.36	0.252	4.56	0.216
120	4.03	.305	4.24	.289	4.46	.259
240	3.88	.311	4.09	.316	4.33	.294
480	3.72	.309	3.93	.330	4.18	.333
1 kc.	3.55	.297	3.75	.335	4.00	.348
2	3.42	.258	3.58	.318	3.80	.358
4	3.28	.227	3.42	.291	3.62	.343
8	3.17	.207	3.26	.255	3.43	.311

It has been argued[2] that the secondary maximum was characteristic of a polymer which was largely crystalline, while the high temperature maximum was due to dipole orientation in the liquid-like disordered or amorphous state. If this hypothesis is correct, then we assume that the methyl groups on the chain carbon interfere with close packing of the polymeric chains, and thus prevent crystallization, much as does the addition of a plasticizer of low molecular weight to a polymer of the $(—CH_2·CHX—)_n$ type. The addition of plasticizer[9] to polymethyl methacrylate affects the electrical properties in the expected way: it shifts the loss factor peak for a given frequency to lower temperatures.

Polymethyl-α-chloracrylate resembles polymethyl methacrylate in its mechanical and electrical properties. Data through the dispersion range were not obtained, on account of difficulties due to warping, and to the high d. c. conductance ($\kappa_0 = 0.078 \times 10^{-10}$ at 90°). Enough of the curve was obtained, however, to show that the 60-cycle maximum in absorption comes at about 90°, and an estimate of 9.2 as the lower limit for the static dielectric constant at 90° can be made. The chlorine atom on the chain raises the dielectric constant by about the expected amount, and, like the methyl group in Lucite, gives a uniformly decreasing loss factor with decreasing temperature (Table I).

Polychloroethyl methacrylate (IV) has a higher static dielectric constant than II, on account of the halogen, and the relatively free rotation of the

(13) Cole and Cole, *J. Chem. Phys.*, **9**, 341 (1941).

latter at the end of the —$CH_2 \cdot CH_2Cl$ group. It is, however, much lower than the static dielectric constant of polyvinyl chloroacetate,[2] although it contains the same kind and number of polar groups. Two reasons for this difference may be advanced: (1) the methyl group in IV inhibits the rotation of the polar ester group, as shown by the comparison of I and II, and (2) the carbonyl group is attached directly to the chain, instead of through an oxygen. There is also a possibility that the side-chain carrying the chlorine is long enough to permit some intramolecular association of dipoles, which reduces the polarization much as intermolecular dipole interaction decreases the polarization of ordinary polar liquids.

A detailed discussion of IV is not possible, because the chlorine analysis and the insolubility suggest that it is somewhat cross-linked, instead of being a simple linear polymer. Other preparations, made under milder conditions, gave higher chlorine analyses, but the polymers were also insoluble in solvents which might be expected to dissolve polymers of the structure IV. However, only a few hundredths of a per cent. of bifunctional polymerant is enough to produce an insoluble polymer. It will be noted that IV, in contradistinction to II, shows the presence of a secondary maximum at low temperatures. Probably the replacement of a methyl hydrogen of II by the —CH_2Cl group changes the spatial relationships so that crystallization becomes possible again; this is indicated by some simple experiments with models. But considerable work remains to be done on the $(—CH_2 \cdot CXY)_n$ polymers before a detailed correlation between structure and mechanical and electrical properties can be made.

Summary

1. The dielectric constants and loss factors of polymethyl acrylate, polymethyl methacrylate (alone and plasticized with 20 and 30% diphenylmethane), polymethyl-α-chloracrylate and polychloroethyl methacrylate at temperatures in the range −70° to +100° and at frequencies from 60 to 8000 cycles have been determined.

2. The preparation of chloroethyl methacrylate (b. p. 170°) is described.

3. Some preliminary results on a correlation between structure and electrical properties for polymers of the type $(—CH_2 \cdot CXY—)_n$ are given.

The Hydration of β-Lactoglobulin Crystals*

BY THOMAS L. MCMEEKIN AND ROBERT C. WARNER

Knowledge of the composition of protein crystals is of importance in the interpretation of solubility, precipitation and X-ray data on proteins.

Several methods have been utilized in calculating hydration of protein crystals. Sørensen and Høyrup[1] developed the "Method of Proportionality" for evaluating the water content of protein crystals. Adair and Adair[2] applied density determinations to the measurement of hydration. A further method was devised by Crowfoot and Riley,[3] which is based on X-ray measurements of wet and dry crystals. The present report deals with the direct measurement of hydration by the loss in weight of a single protein crystal as well as hydration deduced from density determinations.

β-Lactoglobulin crystals as described by Palmer[4] are particularly valuable for direct study of hydration, since the crystals are quite large and may be prepared in the absence of salt or in the presence of high concentrations of salt.

Materials and Methods

β-Lactoglobulin was prepared from skim milk by the method of Palmer.[4] After several recrystallizations by dialysis, a further crystallization was made by adding concentrated ammonium sulfate solution to the protein solution through a rotating cellophane membrane. When the concentration of ammonium sulfate reached 2.66 molar, needle-shaped crystals appeared. The crystals were separated from the supernatant liquid and dissolved in a small volume of water. Salt was then removed by dia-

(4) Palmer, *J. Biol. Chem.*, **104**, 359 (1934).

lyzing for two days against distilled water in the presence of toluene. The solution contained 3% protein and had a *p*H of 5.2. This solution, with a small amount of toluene, was stored at 4° in a closed Erlenmeyer flask. After several weeks large crystals of β-lactoglobulin appeared. Both tabular and plate crystals were present; however, only the stable tabular crystals were used in obtaining the reported measurements. Many of the crystals were from 2 to 3 mm. in length and about 1 mm. in each of the other dimensions. The nitrogen content of a single oven-dried crystal was found to be 15.7% in good agreement with Palmer's[5] most recent value of 15.6%.

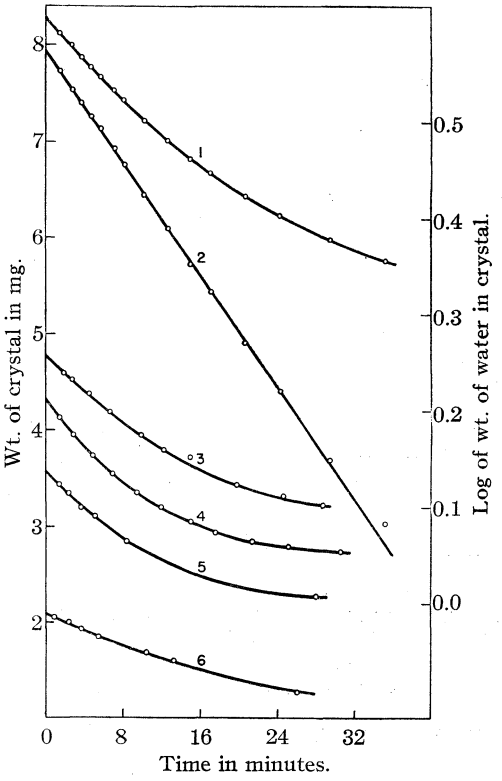

Fig. 1.—Rate of loss of water by β-lactoglobulin crystals at room temperature: Curves 1, 4 and 5, crystals from salt free solution; Curve 3, crystal from ammonium sulfate solution; Curve 6, crystal of $Na_2SO_4 \cdot 10H_2O$; Curve 2, plot of logarithm of weight of water in the crystal shown in Curve 1.

Hydration of the protein crystal was determined by weighing the wiped crystal on a rapid-weighing spring balance sensitive to 0.01 mg. The loss in weight by the crystal from the moment of its removal from the mother liquor until it reached the equilibrium weight obtained after drying in a vacuum oven at 80°, or over phosphorus pentoxide at room temperature was considered to be the water of hydration. The loss in weight with time was plotted (Fig. 1) and the weight of the crystal at zero time was determined by extrapolation. The adhering mother liquor was removed by placing the crystal between the smooth sides of two small pieces of absorbent cotton flannel. This operation required about thirty seconds. The drying crystal was kept on a removable weighing pan during the entire drying and weighing operation. The effectiveness of the method of removing the adhering mother liquor was demonstrated on crystals of ammonium sulfate, sodium sulfate decahydrate and copper sulfate pentahydrate. The crystals of ammonium sulfate or copper sulfate did not lose weight in air after being wiped with the cloth as described. The copper sulfate crystal lost 29.1% of its weight in a vacuum oven at 80°. The theoretical loss in weight is 28.8% when four molecules of water are removed. The amount of water in the hydrated sodium sulfate crystals was found by this method to be: (a) 55.8%, and (b) 57.2%. The theoretical value for 10 molecules of water is 55.9%. While it seems probable that a small amount of mother liquor would adhere to the crystal, these results on crystals with and without water of crystallization indicate that the amount of mother liquor adhering to the crystal is small and within the experimental error of other measurements involved.

The amount of protein in the β-lactoglobulin crystal was determined from the dry weight in vacuum at 80°, or in vacuum over phosphorus pentoxide at room temperature. In the case of the experiments with added ammonium sulfate, the weight of ammonium sulfate was deducted from the total dry weight to give the weight of the protein. Ammonium sulfate was determined by direct nesslerization in a volume of 50 ml. The presence of the protein during the development of the color with ammonia and Nessler reagent caused a small increase in the color, amounting to 3.5%. Correction for this effect has been applied to the measurements.

Densities were determined in mixtures of bromobenzene and xylene and, in some cases, in solutions of saturated ammonium sulfate containing added sodium sulfate or in solutions of sucrose. The crystals were removed from the mother liquor on the end of a thin strip of paper, pressed against a piece of cotton flannel and then placed in a test-tube containing the flotation medium in a water-bath at 25°. The composition of the solutions was adjusted so that the crystals just sank in one solution and just floated in another. The densities of the two solutions, referred to water at 4°, were then determined pycnometrically at 25°. The density of the crystal was taken as the mean of the two values.

Hydration of β-Lactoglobulin at *p*H 5.2 in the Absence of Salt.—The loss of water by single protein crystals at room temperature and at 80° *in vacuo* was determined. The amount of water present in the crystal was independent of the temperature at which the crystal had been stored. Thus, the amount of water in a crystal kept at 4° was the same as that of a similar crystal stored at 25°. The results of the measurements on the rate of evaporation at room temperature and total amount of water present in β-lactoglobulin crystals are shown in Fig. 1 and Table I. The average values of 0.66 g. of water per g. of air-dried protein and 0.84 g. of water per g. of vacuum-dried protein are of the same order as the value of 0.54 g. of water per g. of air-dried protein calculated from the data of Crowfoot.[6] The rate of evaporation follows a first-order equation, the rate of loss of water being proportional

to the amount of water remaining. This is shown by Curve 2 in Fig. 1, in which the logarithm of the weight of water in the crystal is plotted as a function of time. A straight line is obtained up to the point at which about 70% of the water has been lost. Beyond this the rate falls below that calculated from a first-order equation. It might be inferred from this calculation that the vapor pressure of water in the crystal does not change while most of the water is being lost. The first-order constant obtained for the rate of loss of water increases as the size of the crystal is decreased, presumably because of the increase in surface per volume ratio. Ferry and Oncley[7] analyzed dielectric dispersion curves of β-lactoglobulin solutions and compared the results with those obtained from ultracentrifuge, diffusion and viscosity measurements. The data are interpreted in terms of an elongated ellipsoidal molecule and hydration of 0.3 g. of water per g. of protein. Since their measurements were made on solutions, it is not necessarily to be expected that such hydration would be the same as that of the crystal.

Hydration of β-Lactoglobulin in the Presence of Concentrated Ammonium Sulfate Solutions.—β-Lactoglobulin crystals freed from adhering solution were placed into 28.9, 30.2 and 31.6% by weight solutions of ammonium sulfate. All of the crystals floated at first and later sank to the bottom, the time of sinking increasing with increase in concentration of salt. The crystals and salt solutions were allowed to equilibrate for two days at 25° and then the crystals were removed and their surfaces freed from adhering liquid. The amounts of water and ammonium sulfate in the crystal were determined as previously described. The results are recorded in Table II.

The amount of water associated with 1 g. of protein remained unchanged when the salt-free crystals were placed in concentrated salt solutions. However, ammonium sulfate diffused into the crystal and, on the assumption that ammonium sulfate goes into the water of the protein crystal rather than becoming attached to the protein, the concentration of salt in the water of the protein crystal

amounts to about 82% of the salt concentration in the surrounding liquid. This finding is confirmed by density determinations as recorded in the next section.

Direct measurements were made of the length and width of a crystal by means of a micrometer at low magnification before and after placing it in the concentrated salt solution. No change in crystal dimensions was noted. However, the method was sensitive to only about 2% and the calculated increase in the linear dimensions of the crystal due to the presence of ammonium sulfate would be about 2%, assuming that the partial specific volumes of the constituents remain unchanged in the presence of salt. The protein crystals break more easily in the presence of salt than in its absence. This may be an indication of an increase in volume of the protein crystal due to the added salt.

When a β-lactoglobulin crystal, in equilibrium with a 30.2% by weight solution of ammonium sulfate of *p*H 5.2, was heated in boiling water for thirty minutes, the crystal became opalescent and insoluble in water without obvious loss of form. The heat-coagulated crystal contained less water than the uncoagulated crystal, the water content being 0.53 g. per g. of protein. However, the salt concentration calculated on the basis of the water present in the coagulated crystal was found to be the same as in the uncoagulated crystal. When the method of proportionality is applied to the data obtained on the heat-coagulated β-lactoglobulin crystal, a value of 0.15 g. of water per g. of protein is obtained. Adair and Adair[2] obtained values of 0.17 to 0.19 for coagulated egg albumin by means of the method of proportionality.

Density of β-Lactoglobulin Crystals.—The data obtained on density determinations are recorded in Table III. The "density difference" given in the table is the difference between the densities of the solutions of higher and of lower density than the crystal.

The wet crystals were found to increase gradually in density after immersion in the bromobenzene–xylene mixture. There was essentially no change for about five minutes and the densities recorded are based on the initial behavior of the crystals on being placed in the solutions. Since this behavior was independent of the size of the crystal over a range of more than tenfold in weight, it is improbable that the results are appreciably influenced by occlusion of air or other possible surface effects. When the wet crystals had stood for as long as twenty-four hours in

TABLE III

DENSITY DETERMINATIONS ON β-LACTOGLOBULIN CRYSTALS

Preparation	Flotation medium	Density	Density difference
Wet crystals	BBX[a]	1.146	0.004
Dry crystals	BBX	1.260	.003
Wet crystals after standing 24 hrs. in BBX[a]	BBX	1.260	.001
Crystals equilibrated with 30.2% $(NH_4)_2SO_4$	BBX	1.214	.005
Wet crystals	Satd. $(NH_4)_2SO_4$ + Na_2SO_4	1.240	.007
Wet crystals	Sucrose	1.256	.008

[a] BBX refers to mixtures of bromobenzene and xylene.

the flotation medium, their density had increased so that it was precisely equal to that of the dry ones. The water in the crystal had thus evidently been removed, leaving only the anhydrous protein. Crystals which were dried over phosphorus pentoxide did not change in density following immersion and were not influenced by placing the system in a vacuum.

The density of 1.260 for the anhydrous crystal is in good agreement with determinations on other dry proteins. The specific volume of 0.794 for the crystal is thus much higher than the partial specific volume of 0.751 determined in dilute solution.[8] Cohn[9] has pointed out that this difference cannot be accounted for by electrostriction of the solvent as is the case with amino acids.

The density of 1.146 found for the wet crystals is lower than any density previously reported for protein crystals. It is, however, consistent with the high fraction of water found in the crystal. Using the partial specific volume of lactoglobulin $v_p = 0.751$ determined by Pedersen,[8] and assuming that of water to be $v_{H_2O} = 1$, the specific volume of the crystal, $\bar{v}$, can be calculated from the formula $\bar{v} = v_p X_p + v_{H_2O} X_{H_2O}$, where X_p = fraction of protein = 0.54, and X_{H_2O} = fraction of water = 0.46. The density $(1/\bar{v})$ is found to be 1.155. The partial specific volumes of proteins have been found in general to be independent of concentration over a range up to 10 or 15% protein. It is probable that this constancy does not extend to a system which has the composition of the crystals and that v_p is higher than the value assumed above (and v_{H_2O} consequently lower). Any change of this sort would tend to give a better agreement with the observed value.

The higher values reported in the literature for the density of wet protein crystals have all been obtained in aqueous media. In view of the results reported above on the salt content of crystals in ammonium sulfate solution which demonstrate the ease with which salt exchange takes place with the environment, it can be concluded that the density of a protein crystal in equilibrium with its mother liquor cannot be determined by immersion in an aqueous medium of different composition. This is well shown by the density determinations in aqueous media given in Table III. The crystals which had a density of 1 146 in bromobenzene–xylene increased to 1.240 in $(NH_4)_2SO_4$ + Na_2SO_4 and to 1.256 in sucrose because of the diffusion of salt or sugar into the water in the crystal. The difference between the densities in the two aqueous media is similar to that found by Adair and Adair[2] and is evidently due to a difference in the distribution of salt and sugar between the inside and the outside of the crystal. The fact that the observed density in the sugar solution approaches the value for the density of the anhydrous protein indicates that the distribution must be nearly equal in this case.

The density of crystals equilibrated with 30.2% ammonium sulfate was determined in bromobenzene–xylene to be 1.214. The analytical results on such crystals (Table II) show the concentration of ammonium sulfate in the water of the crystal to be 24.4% and the composition of the crystal to be 48.7% protein and 51.3% salt solution. The ammonium sulfate solution in the crystal would have a specific volume of 0.877. From these data and the assumption that the partial specific volume of the β-lactoglobulin is 0.751, the density of the crystal can be calculated to be 1.225 by the method used above for the salt-free solution. The error in the calculation is probably referable to the value assumed for the partial specific volume of the protein.

The use of organic solvents for density determinations on wet crystals has been criticized because of the possibility of irreversible changes caused by the solvents. We have found that crystals which have stood for several days in the bromobenzene–xylene are completely soluble in dilute salt solutions, indicating the absence of denaturation. Any error incurred by the use of such solvents is certainly less than that inherent in the use of salt solutions which yield densities bearing little relation to the density of the crystal in its mother liquor.

Discussion

The hydration of proteins as determined by the "method of proportionality" of Sørensen and Høyrup[1] involves the determination of the nitrogen factor (x) as calculated from the equation $x = 100/P_b[1 - a_b/a_f]$ where a_f is weight per cent. of ammonia nitrogen in the filtrate, a_b is weight per cent. of ammonia nitrogen in the crystal and adhering mother liquor, and P_b is weight per cent. of protein nitrogen in the crystal. The hydration value is obtained by comparing the nitrogen factor of the wet crystals with the nitrogen factor of the anhydrous salt-free protein. Adair and Adair[2] have derived a formula to give the same information from density determinations as is obtained by the "method of proportionality" from analytical data.

Sørensen and Høyrup[1] found the nitrogen factor (x) to be independent of the concentration of salt in the presence of varying concentrations of ammonium sulfate. They considered this to be evidence that salt did not go into the crystal. Table IV shows the results obtained when our data are calculated by means of the proportionality formula.

The nitrogen factor here is found to be independent of the concentration of salt. Direct analysis of these identical crystals shows a con-

centration of salt in the crystal which is apparently a constant ratio of the concentration of salt in the surrounding liquid. If the total water in the crystal and the ratio of the concentration of salt inside the crystal to that outside are independent of the salt concentration, it follows that the nitrogen factor (x) will show a variation of about 0.5% for the salt concentration range used in our experiments. Thus the constancy of the nitrogen factor is not a measure of the freedom of the crystal from salt, and the value of this factor is not related to the total amount of water associated with the protein crystal. This view, that the salt penetrates the protein crystal and that the concentration of the salt in the crystal is about 82% of the salt concentration in the surrounding liquid, independently of the concentration, is strengthened by the results of Chick and Martin[10] on egg albumin in ammonium sulfate solutions. Chick and Martin found that the water in pressed crystalline egg albumin contained less salt than the filtrate. In three experiments the salt present in the pressed crystals amounted to 17.6, 22.1 and 22.4% by weight of ammonium sulfate, while the corresponding filtrates contained 26.9, 27.2 and 28.1% by weight of ammonium sulfate. The percentage ratio of salt inside of the crystals to that of the filtrate is 65.4, 81.2 and 80.0 which compares with our value of 82.3% for β-lactoglobulin.

The finding that ammonium sulfate diffuses into the protein to the extent of 82% of the outside concentration on the basis of water of crystallization may be considered to indicate that the water of crystallization is bound in two different ways, as is the case of water in copper sulfate crystals.[11] The present measurements do not furnish evidence of the distribution of salt in the crystal, although in the calculation of a numerical value for the ratio of the concentration of salt in the crystal to the outside salt concentration, the assumption is tacitly made that the salt is equally distributed in the water of the crystal. Following the formula of Sørensen and Høyrup,[1] the water of hydration for β-lactoglobulin may be calculated as $(7.70-6.41)/6.41 = 0.20$ g. of water per g. of protein, in contrast to the direct experimental finding of 0.83 g. of water per g. of protein.

Adair and Adair's[2] formula may be applied to the experiment in 30.2% ammonium sulfate for which density determinations on the crystals were made. Their formula requires the density of the crystal to be equal to that of the salt solution in which it is suspended and hence it is not directly applicable to the case considered above. However, by the use of the additional analytical data available, a value for the water of hydration of 0.294 g. water per g. of protein can be calculated by their method as compared with the above value of 0.20 g. The application of the method of proportionality to β-lactoglobulin in very dilute salt solutions led M. Sørensen and Palmer[5] to conclude that β-lactoglobulin does not contain "surplus water but, on the contrary, surplus ammonia or ammonium chloride."

Density determinations on protein crystals have been made in connection with X-ray measurements. Crowfoot and Riley[3] thus report values for β-lactoglobulin of 1.257 for the wet crystal in sugar solutions and 1.27 for the dry crystal in organic solvents. These values are in agreement with those found here under similar experimental conditions. Crowfoot realized that the value for the wet crystal was an upper limit, but nevertheless discarded the value for the dry crystal because it was so close to that for the wet crystal. She assumed 1.31 (dry density of insulin) in making her calculations when it was the wet density that was in error. A recalculation from the data of Crowfoot[6] using the density 1.146 for the wet β-lactoglobulin crystal gives a value for the wet molecular weight of 61,100 and on a dry basis (46% water) a value of 33,000.

The molecular weight for an air-dried crystal calculated from the data of Crowfoot,[6] using a density of 1.26, is 39,700. The data in Table I show that our air-dried crystals contained 9.78% water. Applying this correction, an anhydrous molecular weight of 35,800 is obtained.

(10) Chick and Martin, *Biochem. J.*, **7**, 392 (1913), and correction on page 548 of the same volume.

(11) Beevers and Lipson, *Proc. Roy. Soc.* (London), **A146**, 570 (1934).

Crowfoot[6] also has given the dimensions of the unit cell in wet and in air-dried β-lactoglobulin crystals, and the following shrinkages on drying can be calculated for the various dimensions: $a = 11.1\%$, $b = 6.7\%$, and $c = 28.6\%$. In order to correlate the unit cell shrinkage with the macroscopic behavior of the crystal, we have observed the change in dimensions of the crystal on drying in the air in a low power microscope with a micrometer eyepiece. The shrinkages observed in two experiments were: length, 8.5% and 9.9%; height, 6.8% and 7.8%; width, 29.5% and 26.4%. These changes are of the same order as those in the unit cell. The shrinkage of the crystal was also measured in a mixture of bromobenzene–xylene over a period of twenty-four hours. The change in dimensions observed was 9.8% and 31.5% in the length and width, respectively. This confirms the conclusions from density determinations that a dehydrated crystal is obtained after contact with bromobenzene–xylene for twenty-four hours. It also indicates that the water in the crystal is not replaced by the organic liquid. In order to check this point a crystal which had been dehydrated in xylene was wiped and weighed by the technique used previously. There was no change in weight after putting the crystal on the balance or after placing the crystal in an oven at 105°. These measurements, together with the consideration that the densities of vacuum-dried crystals and crystals which stood in bromobenzene–xylene are the same, indicate that in the dry crystal there is no space occupied by air.

The dehydrated crystals obtained with bromobenzene–xylene had good form and a high degree of birefringence as compared with the air-dried crystal. This technique might be used with advantage to obtain completely dehydrated crystals for X-ray examination. In any such application xylene alone should be used as the dehydrating agent because of the tendency of the crystal to become discolored after long standing in the presence of bromobenzene.

It seems likely that previous estimates of the water of hydration of protein crystals are entirely too small, because of the effect of diffusion of salt into the crystals. It may be calculated that the cell shrinkage reported by Crowfoot[6] for crystalline hemoglobin amounting to 46.6% would lead to a hydration value nearer to 0.9 g. of water per g. of protein than the value of 0.18 to 0.30 g. calculated by Adair and Adair.[2,12]

Summary

1. β-Lactoglobulin crystals were found to contain 0.83 g. of water for each g. of anhydrous protein over a wide range of temperature in the absence of salt or in the presence of high concentrations of ammonium sulfate.

2. Ammonium sulfate diffuses rapidly into the β-lactoglobulin crystal; however, the concentration of ammonium sulfate on the inside of the crystal reaches only 82.3% of the salt concentration in the surrounding liquid.

3. The density of wet β-lactoglobulin crystals was measured in organic liquids and was found to be 1.146. This value is consistent with the high water content of the crystal. Values for the density of β-lactoglobulin crystals under various conditions are reported. It is shown that the method of measuring the density of wet crystals in aqueous media is subject to large errors.

PHILADELPHIA, PA. RECEIVED JULY 3, 1942

(12) Since the preparation of this paper, Bailey (*Trans. Faraday Soc.*, **38**, 186 (1942)), has reported that crystalline edestin contains about 0.67 g. of water per g. of protein.

Macromolecular Disorder in Linear Polyamides. Relation of Structure to Physical Properties of Copolyamides

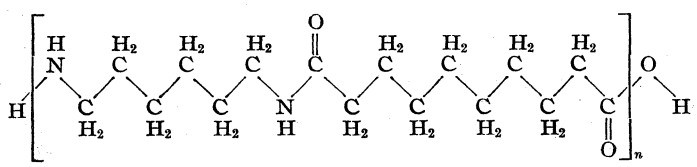
BY W. O. BAKER AND C. S. FULLER

Macromolecular solids are supposed to gain especial strength and continuity because the primary valence bonds of a single chain extend for hundreds of Ångström units and it thus reacts with the force fields of numerous other polymer molecules. Also, the ends of adjacent chain molecules in a given cell are presumed not to be coplanar. Rather, the chains overlap,[1] and thus planes along which ordinary molecular solids are easily sheared and ruptured are actually absent in the polymers. It is desirable to investigate what general chain arrangements (such as dipole association) are characteristic of these especial physical properties of polymer solids.

The present report includes the results of X-ray diffraction and elastic modulus measurements on several linear polyamides.[2] Simple relations between the mechanical properties of the molecular solids, and the atomic constitution and relative positions of the long chains have been found.

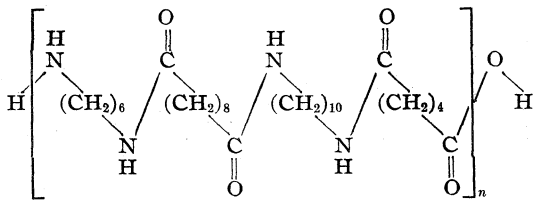
Experimental

Materials.—The linear polyamides studied are obtained from the controlled reaction of dibasic acids and diamines.[3] For the aliphatic series, a single dibasic acid and a single diamine yield a simple linear polyamide which is described by two numbers: the first, the number of C atoms in the diamine chain; the second, the number in the acid chain. Thus, polyhexamethylene adipamide, from hexamethylenediamine (1,6-diamino-hexane) and adipic acid, is a 6–6 polyamide, polyhexamethylene sebacamide is a 6–10 of the typical formula



Various diamines and various dibasic acids may react together to form copolyamides, as shown by Carothers' work.[4] These contain the base units presumably randomly distributed (see a later discussion) along the chain, but always in the sequence dibasic acid–diamine–dibasic acid–, etc. The randomness varies with the relative amounts of different diamines and/or different acids.

A representative copolyamide chain containing 50–50 proportions of the 6–6 and 10–10 base units is



For convenience in describing the copolyamide series studied here, each composition has been considered to arise from the random mixture of the components of simple polyamides which have also been studied. No polymers containing more than two different diamines and two different dibasic acids are discussed below, so that the compositions of the series are recorded as the molar percentage of one pair (giving one simple polyamide), say 6–6, in another, say 6–10. Such grouping of constituents does not, of course, imply that order in the reaction products.

The polymers were obtained either commercially or according to the published procedures. The intermediates were carefully purified and each polymer represents a well-characterized compound containing a statistical distribution of chain lengths. All polymers were of weight average molecular weight, M_w, greater than 10,000, as estimated from viscosities.

X-Ray diffraction patterns were obtained for both unoriented and cold drawn[2] polyamides. The latter were highly oriented fibers; both types of samples were first studied quenched from the melt, and then annealed to states of maximum crystallinity.[5,6] The determinations of Young's modulus and moisture sorption were made on sheets molded in a nitrogen atmosphere between plane plates and uniformly annealed. Each was 3 × 2 cm. and 0.051 cm. thick. These specimens were conditioned or dried over phosphorus pentoxide before measurement.

X-Ray Methods.—Copper characteristic radiation, nickel filtered and carefully collimated, was directed through rigidly mounted samples onto a cassette containing the film. Each oriented sample employed for estimation of the repeating distance, I, along the fiber axis was dusted with finely ground and screened sodium chloride, whose Debye–Scherrer rings superposed on the fiber pattern served as a primary standard for the distance determinations on each photograph. The fibers were flat, and of approximately 18-mil thickness; the salt was always dusted on both sides. Repeated exposures of each composition facilitated selection of an exposure time giving the optimum intensity of the features measured. This was essential for the copolyamides possessing the middle concen-

trations of components, since their "identity period" spots were relatively diffuse. The X-ray negatives were measured on an improved light box of the type described by Klug.[7]

All of the I, Å. values reported were obtained on separately repeated photographs with a precision of ±0.3 Å.

Elastic Modulus.—Young's modulus was computed from the elastic indentation of a spherical quartz segment in a plane panel of the polymer. For such a penetration

$$E = c\frac{L}{d^{3/2}D^{1/2}} \qquad (1)$$

where E is Young's modulus in dynes per sq. cm., c is a constant, L is the load on the sphere, in grams, D is its diameter, in cm., and d is the depth (cm.) to which the sphere sinks below the surface under the weight.[8,9] This depth was read five seconds after application of the load. The latter was chosen so that only elastic and no permanent deformation occurred, except for a few of the softest compositions. For the latter, E is modified by a plasticity factor (yield point), but it still characterizes the polymer.

The measuring apparatus is essentially a Pfund hardness tester. A heavy steel lever with the fulcrum at one end contains the quartz spherical segment in the center and a platform for the load weights on the other end. The quartz segment is ground on the end of a quartz cylinder. Coaxially with this cylinder and above the lever is mounted a microscope fitted with a Leitz ocular micrometer. Since the refractive index of the quartz–polymer interface differs from that of the quartz–air interface, the intersection of the plane of the surface of the test material with the periphery of the quartz segment produces a dark disc in the microscope field. The diameter of this highly magnified disc is measured with the micrometer. The radius of the sphere corresponding to the quartz section, $D/2$, is 3.24 mm. When r is the radius of the dark disc, the depth of impression, d, is given by

$$d = 0.324 - \sqrt{(0.324)^2 - r^2} \qquad (2)$$

Numerous readings were obtained and averaged for each dried sample, at 25 ± 2°.

Moisture Sorption.—Samples of equal dimensions were dried to equilibrium over phosphorus pentoxide, in glass-stoppered weighing bottles, weighed and reweighed after equilibration at 100% R. H. in water at 25.0 ± 0.5°.

Results and Discussion

Crystalline Nature of Linear Polymers.—The molecules of *n*-paraffins and their derivatives have been shown to lie in the crystal as extended chains whose terminal groups formed planes in some cases perpendicular and in others oblique to the long chain axes.[10,11,12] Linear polymers such as polyoxymethylenes, polyesters and polyamides likewise possess chains, and a series of studies has indicated analogous structures except that the repeating polar groups of the polymers replace the terminal groups of the monomers in generating the characteristic planes recurring along the chain axes.[1,13,14,15] However, other investigations[5,6] have emphasized sharp differences, and especially imperfections, in the crystalline state of macromolecules compared to ordinary molecular crystals. The molecules are of non-uniform size; the chains comprise a distribution of lengths clustering about an average value.[16] Also, they presumably do not lie like extended rods for their whole length in the polycrystalline solid but are highly kinked.[17,18] The crystalline content profoundly affects the physical properties of the solid polymers and can be readily varied by thermal treatment: quenching produces minimum and annealing maximum crystallinity.

Amid the complexity, striking generalities about these polymer solids appear. The polar groups which repeat along the chains always associate strongly to form dipole layers. The interaction in these layers and their concentration per unit volume govern the internal energy, melting point and strength of the solids. Such interaction is especially significant in the polyamides, where, as in the proteins, both ordinary dipole attraction and also hydrogen bonding obtain. Laterally, the chains pack somewhat similarly in all of the compounds, although even the lateral packing is a function of the structure of the polar layers. (Also, the chains do not necessarily assume planar zigzag configurations.) We shall thus regard the dipole layers, distributed through the polycrystalline mass as though imbedded in a paraffin chain matrix, as the critical factors in the solid structure. In the studies below, (1) the separation of these planes has been varied by varying the number of methylene group "spacers" in the base units of the simple polyamides. The (2) population of polar groups in the average planes has been varied by copolymerization, for, in adjacent chain sections containing mixed base units, if the polar groups coincide at one point, they will often fail to do so further along the same chains, because of unequal methylene group spacing. This factor is represented to scale in Fig. 1, for the 50% composition of the 6–6:6–10 copolyamide. The circles indicate the polar groups

along the chains. Thus, fewer of them can inhabit the average planes, and, also, the displaced polar units are, in general, surrounded by hydrocarbon groups. They are effectively sheathed from contributiing to the dipole interaction. The copolymerization also alters the apparent average plane separation (in addition to the plane population) in striking and still unexplained fashion. Finally, (3) the order in the dipole planes has been modified by both changes in population (whereby hydrocarbon chains occupy defect sites in the layers) and by quenching (whereby the groups are turned out of the most stable positions in the layers[5]).

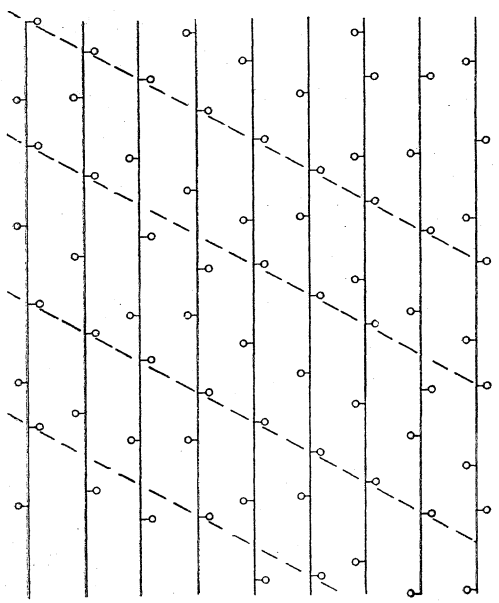

Fig. 1.—Formation of polar layers in 50% 6-6 and 50% 6-10 copolyamide (schematic).

Spacing of Dipole Layers.—Either layer-line or meridian reflections[19,20] on the fiber diagrams yielded several orders of the identity period, I. This we associate with the separation of successive planes of polar groups tilted or normal, as the case may be, to the chain axes. Less directly, I represents the identity period within the molecules. A possible formation of these layers in the 6–6 polyamide is represented schematically in Fig. 2. Actually, disorder may occur in this idealized arrangement. For instance, a polar linkage in a given chain is formed by an A–D (acid–diamine) union. The associated linkage in an adjacent chain may result (in the same direction along the

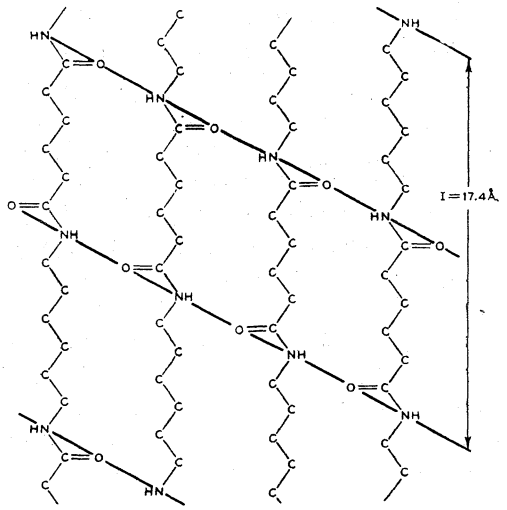

Fig. 2.—Layer structure resulting from association of polar groups in polyhexamethylene adipamide (schematic).

chain axis as above) from a D–A union. This phenomenon leads to a displacement of certain succeeding polar groups along the chains, and thus causes disorder in the system. This condition can be seen by turning one of the chains in Fig. 2 end-for-end about a C=O axis. Such "chain inversion" in adjacent segments in the solid must be considered in the structures of all polymers of the types considered here.

Figure 3 relates the structural property, I, to a thermodynamic quality, the melting point, of simple polyamides. The triangles are the spacings calculated for a plane, zigzag chain containing no kinks or bends between the diffracting planes. The best interatomic distances were used.[21]

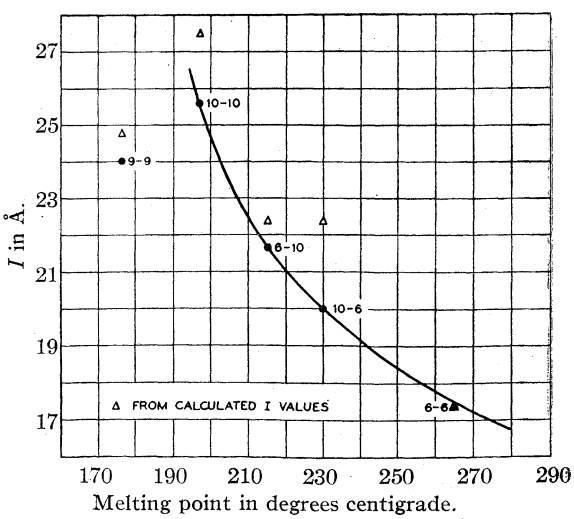

Fig. 3.—Relation of interplanar spacing, I, to melting points of linear polyamides.

(21) Astbury, *Chem. and Ind.*, **60**, 491 (1941).

Only for polyhexamethylene adipamide (6–6) do the calculated agree with the observed values. The observed spacings in the other polyamides are, although carefully checked, always short. It appears that chain tilting or twisting *between* the planes defining the period I may occur. Figure 3 gives independent evidence of diminished plane separation and attendant closer packing. The observed points, except those of polynonamethylene azelamide (9–9), lie on a smooth curve; the calculated points cannot be thus connected. The greater the I, the lower the melting point, because the fewer the polar groups per unit volume to contribute to the mol cohesion. But, the comparison of polyhexamethylene sebacamide (6–10) with polydecamethylene adipamide (10–6) and of 9–9 with the rest of the series emphasizes further significance of the separation. When the dipole planes are oblique to the chain axes, the chains are "tilted" and pack more closely than when the chains are vertical and the planes perpendicular; the lattice energy is higher. This was strikingly demonstrated for the paraffin derivatives.[12,22,23,24] From the X-ray results for 9–9, its chain sections are essentially in the perpendicular form; a low melting point is implied. If its chains were in the form of the other polyamides, it should melt at 202°; a 27° lower value is found, 175°. Further, 6–10 and 10–6 have the same calculated I, their chains are in the tilted form, and if they had the same sort of interplanar modification to explain the shortened observed I, they should melt at the same temperature. However, 10–6 exhibits a markedly reduced I, closer packing is expected, and the observed melting point is 15° higher than for 6–10. The association

of the lattice energy with the spacing between dipole layers and their concentration per unit volume is thus established. The vertical form of the odd-membered (9–9) polyamide chains has been proposed to result from the alternating directions of the interchain dipole association, as generally found for polymers formed from odd-membered base units,[25] in addition to the favorable hydrogen bonding of the vertical form.

Mechanical Mixture Patterns.—We proceed next to consider the effect on I and on the solid state properties of mechanical mixtures of two simple polyamides. Can the effective spacings in the lattice be thus altered? The molar proportions indicated in Fig. 4 of 6–6 and 6–10 were fused and thoroughly mixed under hydrogen at 280°. Fibers were drawn, and the patterns of both polymers appeared on each photograph obtained. These are illustrated in Fig. 5C. However, the component present in 25% amount gave features too weak to measure well, and these points have been omitted from the graph. While there appears to be some systematic decrease of I with increase in added polymer, the respective contributions to the structure are relatively independent. Similarly, the crystallization appears to be separate, although the melting points of the mixtures lie surprisingly near the figures for the higher melting component, 6–6. The mechanical and structural effects of mechanical mixture are slight. Interestingly, although the two polymers differ by only four carbon atoms in the acid chains, mixed crystal formation was undetected. The same result arose for mixtures of polyesters[26] and also of ten- and twelve-membered polyoxymethylenes[13]; the individual patterns (from the end-group planes) persisted. When, however, the polyoxymethylene chains were very long and of a distribution of lengths, a single pattern was found, involving repeating distances within the chains. We show below that when a mixture of base units in the solid is effected by co-reaction rather than mechanical mixture of chains, a single pattern with an "identity period" depending on composition is obtained.

Copolyamide Patterns.—The curve for the copolyamide 6–6 :6–10 in Fig. 6 (the data for all of the series are in Table I) resembles Fig. 4 but the diagrams of the former showed always but one set of I spacings, in contrast to the mechanical mix-

tures. The copolyamide structure exhibits a rapid change in the neighborhood of 50%, and here, also, the diffuse scattering is greatest and the population of the scattering planes least. The melting point is near the minimum and the polymer is softest, with greatest molecular disorder. The concentration variation of I in the similar system containing the components of 6–6:10–6

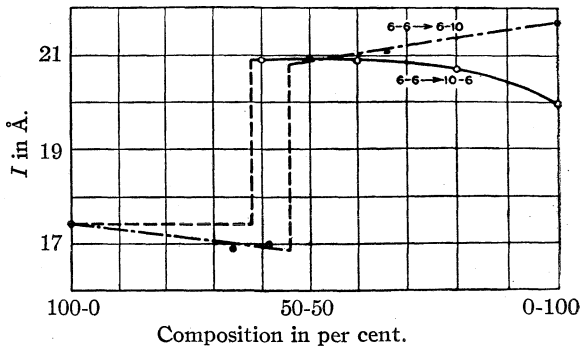

Fig. 6.—Variation of the spacing I with composition of copolyamides: hollow circles, 6-6:10-6; filled circles, 6-6:6-10.

also has a rapid change in the 50% region, but here the altered structure of the 10–6, remarked above, is evident as a down slope of the I curve on the 10–6 side. In both the 6–6:6–10 and 6–6:10–6 series, and the 6–10:10–10 and 10–6:10–10 subsequently discussed, the introduction of a single new acid or single new diamine so that it just exceeds in molar concentration the other acid or other diamine, respectively, causes the sharp change in spacing. That is, keeping the diamine constant and changing the relative concentration of the dibasic acids, or keeping the acid constant and changing the diamines, causes this characteristic sharp shift of I around 50%.

When the constituent units are made longer, but when still only an acid or a diamine, not both, is varied, the phenomena of Fig. 7 result. For the system 6–10:10–10, the "transition" range is broadened. The concentration of the dipole layers per unit volume is decreased, compared to the earlier series, and there is enhanced opportunity for defects in their population, *i. e.*, there is more hydrocarbon matter in which a polar linkage may become isolated. Some illustrative patterns from this series are shown in Fig. 8. The 55–45 (8C) copolymer exhibits the characteristically diffuse reflections corresponding to the layer line spots of the ordered structures. Throughout the series, normal equatorial features can be obtained, in support of the concept that the lateral packing is essentially constant despite changes in the dipole layer spacing. The data for 10–6:10–10 really only define the 10–10 side of the curve in Fig. 7, but have a pronounced maximum in I when about 70% 10–10 is introduced. This may occur partly because the peculiar 10–6 structure perturbs and lessens the factors causing the generally shortened I.

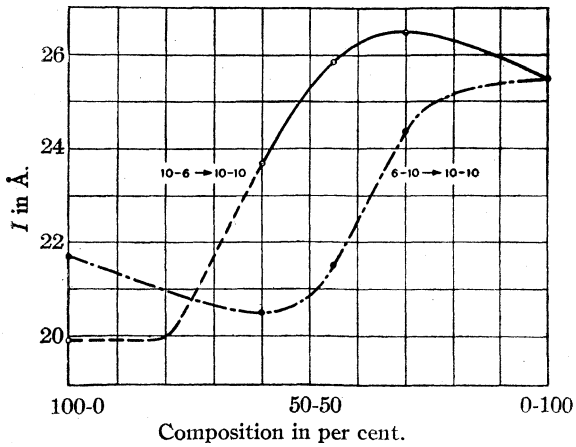

Fig. 7.—Variation of the spacing I with composition of copolyamides: hollow circles, 10-6:10-10, filled circles, 6-10:10-10.

Figure 9 represents the behavior of series in which two dibasic acids and two diamines occur as variables. All of the base units are of different lengths; there is increased scrambling, and the change in I occurs over a very broad concentration range. For 6-6:10-10, addition of the longer components first depresses the I values, then a steep and broad increase leads to a maximum from which still further addition of longer units again decreases I to the figure for pure 10-10. The crystallinity, melting point and elastic modulus are persistently low through the 20 to 80% range. The large and rapid change in the average interplanar spacing is accompanied by much defection in the layers.

The 6-6:9-9 data reflect a new variable of structure. As noted before, the dipole planes of polynonamethylene azelamide (9-9) are essentially vertical to the chain axes, whereas those of 6-6 are tilted. Thus, different features as well as different distances appear on the photographs. At high concentrations of either (arbitrary) pair of components, the patterns of the other are invisible, but at intermediate proportions, features suggestive of both patterns appear and yield the same d values. Thus, each structure is modified quantitatively by components leading to the presence of the other. Figures 10A and 10D illustrate the different structures of 6-6 and 9-9 whereas 10B represents qualitatively the 6-6 structure. However, the 50% composition is dominated by the 9-9 form. The contrast in sharpness of the 50% and 100% 9-9 meridian spots again emphasizes the disorder in the copolyamides.

Figure 11 provides independent evidence for previous interpretations. The components plotted there, 6-10 and 10-6, have the same calculated I. Thus, various molar percentages of the pairs should result in constant identity periods. Of course, this is affected by the shortening found in pure 10-6, but, further, a maximum in I occurs near the usual 50% transition region. It is again as though in the region of maximum scrambling of polar groups, where there are most defects in plane population, the additive scattering produces a concentration on the film corresponding to an increased average plane separation. That is, planes capable of producing the I features occur with diminished frequency throughout the crystals because beginning with one plane, additional progression (than normal) is needed to find enough polar groups organized together to form another.

Equivalently, a large I may result from irregularities in a given long molecule, such as periodic twisting. This is adjunctive to the decreased plane population and enhanced amorphous content already noted for the middle concentrations. A statistical analysis would be required for proof of the preceding hypothesis.

Salt pairs reacted in the formation of the present polyamides,[3] *i. e.*, the salt of the organic base (diamine) and acid was used for a given polymer. If the components react randomly, independent of this salt grouping (which is reflected in the symbols 6–10:10–6, etc.), the 50% concentration in the 6–6:10–10 and 6–10:10–6 series should be the same. Accordingly, equal melting points are found and the I values agree, as seen from Table I.

None of the copolyamide series follows the linear change of I with composition calculated by simple weighted averaging of the constituent units. Thus, they do not follow Vegard's rule for ordinary mixed crystal formation. This rule was approximately observed for the single spacings from mixtures of *n*-fatty acids, by Ott and Slagle.[27] The intrachain nature of the polyamide mixture causes the new behavior.

Quenching of all the copolyamides caused extensive lateral disorder of the chains, including the groups in the dipole layers. This was inferred from the large background scattering and blurring of features, and especially from the characteristic[5] replacement of the two side spacings (4.40 and 3.70 Å.) occurring in the highly crystalline state by a single spacing (4.18 Å.). This indicates that the chains are turned in all directions about their long axes. Annealing (at 20 to 50° below the melting points, in general) was found in all cases to cause rotation of segments in the solid state into the ordered, crystalline array, and a marked hardening of all samples. The temperature (thermal energy) necessary for annealing was in all cases, however, less the greater the dipole layer separation, and the larger the number of defects introduced into the layers by copolymerization. Annealing of the fiber samples always effected a sharpening of the I features as well as resolution of the equatorial spots. Typical examples of these changes appear in Fig. 12, where quenched fiber patterns are compared with those produced by annealing in the solid state. This annealing was evidently effected without loss of orientation since the drawn fibers were annealed and not redrawn.

(27) Ott and Slagle, *J. Phys. Chem.*, **37**, 257 (1933).

Incidentally, when certain of the oriented copolyamides were annealed, especially near the 50% compositions, spontaneous elongation, as observed on cooling stretched rubber, occurred on cooling. This indicates again a partial content of amorphous, kinked chains[5] which straighten as they crystallize.

Elastic Properties.—The graph of Young's modulus in Fig. 13 shows the composition dependence and the abrupt change at 50% of the 6–6:6–10 copolyamide. The diffraction results predict such behavior in support of the concept that the separation, order and population of the dipole layers dominate the internal energy. If the E values reflect the force necessary to displace the chain sections from their equilibrium positions, such motion is markedly easiest when disorder is greatest. We regard the 50% composition as representing the minimum of both crystalline content and order in the crystallites. The elastic modulus can thus be interpreted by structural knowledge of the dipole layers.

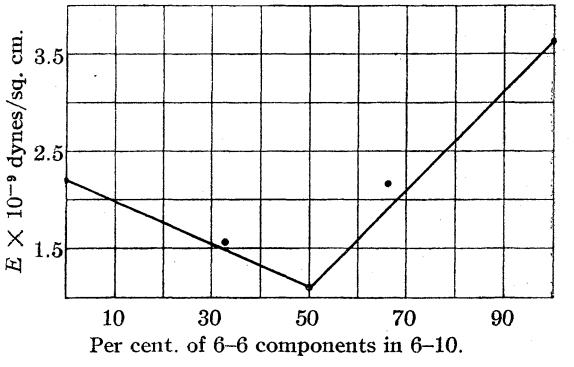

Fig. 13.—Dependence of Young's modulus, E, on composition of the copolyamide 6-6 :6-10.

The dependence of E on composition in the 6–6:10–10 series of Fig. 14 differs from Fig. 13, again in agreement with the X-ray results. The minimum for E is shallow and broad, corresponding to the relatively continuous I variation through the system. Traced from the 6–6 side, E in Fig. 14 falls off on addition of 10–10 components considerably more steeply than in Fig. 13, from addition of 6–10 components, in which only one new unit, the 10 acid, is introduced. The I values follow, respectively, a similar course. The triangle in Fig. 14 was obtained for a sample of relatively short chain-length in which crystallization was more complete than in the high polymers. The higher E shows the importance of crystallite formation as well as copolymeriza-

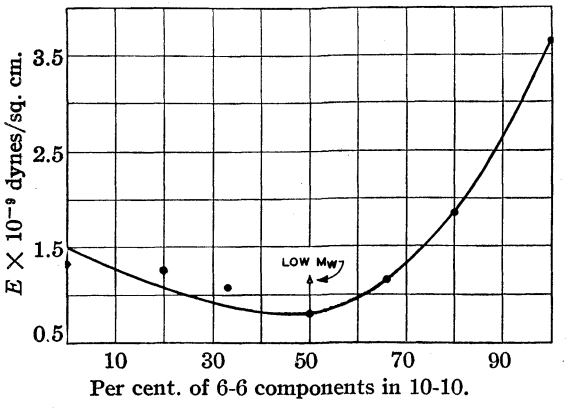

Fig. 14.—Dependence of Young's modulus, E, on composition of the copolyamide 6-6:10-10.

tion in the solids' properties. On the other hand, the significance of the latter factor is repeatedly evident; a new example appears from comparison of the pure 6–10 and the 33% 6–10 polymers of the 6–6:6–10 series in the plot of Fig. 15. These have the same E and virtually the same melting points. Although the disorder is greater in the 33% compound than in the 100%, the former's crystallites contain so many more polar groups because of the 6–6 content that the lattice energies of the two are nearly equal. The maximum disorder in the 50% composition causes it to fall off the line in Fig. 15. Its crystallite content is so sharply reduced compared to the rest of the series that E is reduced beyond the value proportional to the melting point of the remaining crystalline regions.

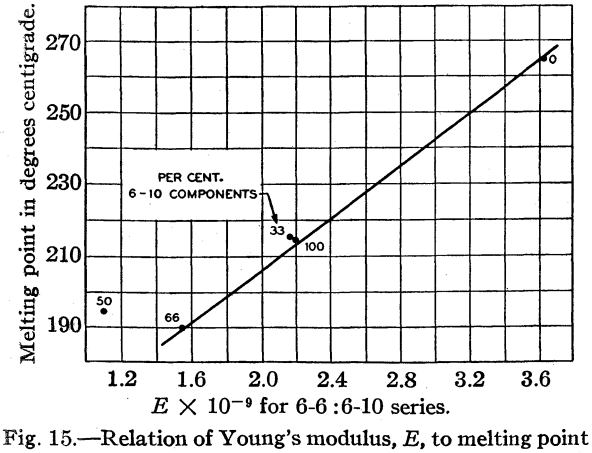

Fig. 15.—Relation of Young's modulus, E, to melting point in 6-6:6-10 series.

Moisture Sorption.—The polar groups in polymers provide loci of water sorption; only minute amounts of moisture are taken up by non-polar solids like polystyrene or polyethylene. Hence, the preceding ideas of dipole layer population may be further tested by sorption measurements. The greater the concentration of polar groups in the simple polyamides, the higher their sorption; this is the chief factor also in the copolyamides and appears for both types in Figs. 16 and 17. Both series show inflection of the sorption

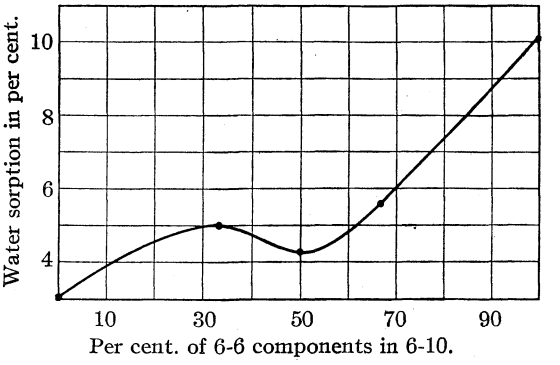

Fig. 16.—Relation of water sorption at 100% R. H. and 25° to composition of the copolyamide 6-6:6-10.

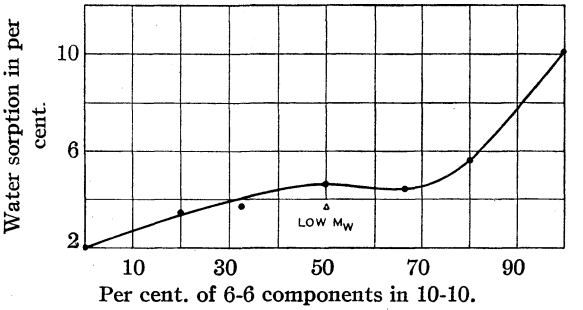

Fig. 17.—Relation of water sorption at 100% R. H. and 25° to composition of the copolyamide 6-6:10-10.

curves in the middle regions of concentration, in accord with the X-ray and elastic modulus determinations. When defects are introduced in the layers by copolymerization, the displaced polar groups are uncompensated by association with other dipoles and can bond with water. This presumably causes the maxima in Figs. 16 and 17. However, the exact significance of the maxima's positions is obscured because the "freed" polar linkages occur immersed in paraffin surroundings (from the methylene portions of the chains). This is a hydrophobic environment, so the water content is not affected as sensitively by disorder as the other properties studied. However, such qualities of technical importance as moisture sorption have not previously shown this direct connection with molecular structure in polymer materials.

A large portion of the water sorption is sup-

posed to be in non-crystalline regions of the polymers. Furthermore, the total polar group concentration changes gradually and continuously in a given series. Hence, the percentage taken up should not be so sensitive a function of composition as I, the spacing in the crystallites. This is confirmed by the data of Table I or by comparison of Figs. 16 and 17.

Acknowledgment.—We are grateful to Dr. B. S. Biggs and Mr. R. H. Erickson, who prepared many of the polymers, especially to Mr. N. R. Pape, who gave valuable assistance in the X-ray studies, and to Mr. J. H. Heiss, Jr., for the determinations of Young's modulus and moisture sorption.

Summary

Thirty-one linear polyamides and copolyamides of varying crystal structures and concentrations of polar linkages along the chains have been studied as fibers and as polycrystalline sections by X-ray diffraction. Also, the elastic modulus and moisture sorption were determined on typical samples of the polymers.

The series represents a range of solid polymers from soft to porcelain-like in properties, with several-fold variation in Young's modulus. The polar linkages which join the paraffin sections of the base units together in the long chains associate in adjacent macromolecules to form hydrogen-bonded dipole layers. This interaction is supposed to govern the physical properties of the solids. By this concept it was possible to interpret systematically the melting points, hardness, elastic modulus and moisture sorption of the solids in terms of the concentration, separation, population and perfection of the dipole layers. Disorder introduced by copolymerization in which dipoles were shifted randomly along the chains altered the average dipole layer separations and also replaced polar groups in the layers by hydrocarbon chain sections. Such disorder caused marked softening of the solids. It likewise caused the X-ray identity periods along the chains to vary with composition of the copolyamides in a novel fashion. Periods were found in the copolymers both larger and smaller than those which arise from any simple polyamides made from the same base units.

Macromolecular solids containing some crystalline regularity may apparently be treated as defect systems in which, nevertheless, relatively simple factors such as the position and organization of interacting polar groups govern physical properties.

Crystalline Aliphatic Esters of Vitamin A[1]

BY JAMES G. BAXTER AND CHARLES D. ROBESON

This Laboratory is engaged in the preparation of the pure growth promoting factors in fish liver oils. As part of this program three crystalline aliphatic esters of vitamin A have been prepared: vitamin A acetate, vitamin A palmitate, and divitamin A succinate. Since in fish liver oils vitamin A is esterified with aliphatic acids, such as palmitic,[2] these crystalline esters are suitable for the study of vitamin A as it occurs naturally. Vitamin A β-naphthoate, a previously prepared crystalline ester,[3] was also made to compare it with the aliphatic esters. It had the undesirable property that the aromatic nucleus contributed extraneous absorption at 328 mμ.

This paper is concerned with these properties of the esters: (a) their resistance to atmospheric oxidation, (b) their extinction coefficients at 328 mμ and of their antimony trichloride blue colors at 620 mμ, (c) their biological potency compared with that of crystalline vitamin A. Part (c) is a preliminary report of bioassays made by Dr. P. L. Harris of this Laboratory.

The esters were made by esterifying crystalline vitamin A[4] with the appropriate acid halide. The yields of ester were sharply reduced when potent vitamin A concentrates ($E^{1\%}_{1\ cm.}$ 328 mμ = 1200 or greater) were esterified instead of crystalline vitamin A.

Resistance to Atmospheric Oxidation.—In crystalline form, vitamin A acetate was the most stable of the esters prepared. The stability test consisted of exposing thin layers of the crystals to air at 5° in darkness. The percentage decomposition at various times was determined by the percentage drop in the extinction coefficient at 328 mμ (Table I).

TABLE I

RELATIVE RESISTANCE OF CRYSTALLINE VITAMIN A ESTERS TO ATMOSPHERIC OXIDATION AT 5°

	% of initial $E^{1\%}_{1\,cm.}$ (328 mμ) value after weeks			
Vitamin A	1	2	7	16
Acetate			97	88
β-Naphthoate			95	40
Palmitate	89	73		
Succinate	84	68		

The superior stability of vitamin A acetate may be partly due to the crystal size (Fig. 1).[5] The large prisms expose a smaller area to the action of air, per unit amount of vitamin A, than do the smaller prismatic crystals of di-vitamin A succinate or the plate-like crystals of vitamin A palmitate and vitamin A β-naphthoate (Fig. 2, 3, 4). The excellent stability of vitamin A β-naphthoate cannot be attributed to the size of its crystals. Possibly they have less tendency to adsorb air than vitamin A palmitate and succinate.

All the esters could be stored in evacuated, sealed glass tubes at −35° for long periods of time without change in the extinction coefficient. Thus, the extinction coefficient of vitamin A palmitate at 328 mμ was unchanged after nine months of storage under these conditions. The tubes were evacuated with a high vacuum condensation pump for four hours before they were sealed off. This removed most of the air adsorbed on the surface of the crystals.

Extinction Coefficients at 328 and 620 mμ.—The extinction coefficients of the esters at 328 mμ, in ethyl alcohol, are given in Table 2A.[6] The extinction coefficient of the vitamin A obtained by saponifying the esters is also compared with the equivalent extinction coefficient of vitamin A calculated from the coefficients of the esters. It appears that the equivalent absorption of vitamin A at 328 mμ is slightly depressed in the fatty acid esters. A marked depression in the equivalent absorption of vitamin A was observed in di-vitamin A succinate and a smaller one was observed in vitamin A β-naphthoate.

The extinction coefficient and melting point obtained for vitamin A β-naphthoate ($E^{1\%}_{1\,cm.}$ 328 mμ = 1090, m. p. 74–75°) were lower than the values reported by Mead ($E^{1\%}_{1\,cm.}$ 328 mμ = 1180, m. p. 78°).[3] Our value for the melting point agreed more closely with the value of 76° determined by Hamano. However, through the kindness of Dr. Mead we were able to examine a sample of his vitamin A β-naphthoate. We found an $E^{1\%}_{1\,cm.}$ (328 mμ) value of 1000 and a melting point of 74–75°. Hence, the β-naphthoate crystals made in the two laboratories appear to be equally pure. Probably the values of the constants were not the same because the experimental technique was different.

The extinction coefficients at 620 mμ of the antimony trichloride blue colors of the esters are given in Table 2B.[7] The equivalent extinc-

[a] Amber glassware was used during saponification and ether extraction to prevent decomposition of vitamin A by light. The estimations were kindly done by H. Rawlings of this Laboratory. [b] In calculating this from $E^{1\%}_{1\,cm.}$ (328 mμ) for vitamin A β-naphthoate, a correction was needed for the absorption of the naphthoate radical at 328 mμ. The correction used was the molecular extinction coefficient of ethyl β-naphthoate at 328 mμ. This we found to be 1058.

(5) Photomicrographs, Figs. 1, 2, 3, 4, courtesy of Mr. R. P. Loveland, Eastman Kodak Company, Research Laboratories.

(6) Spectrographic measurements were made with a Hilger quartz spectrograph, model E-498, with a Spekker ultraviolet photometer. The light source was a tungsten-steel spark.

(7) We are indebted to Mr. E. Richardson, Eastman Kodak Company, Research Laboratories for measuring the absorption spectra. A Hardy recording visual spectrophotometer was used.

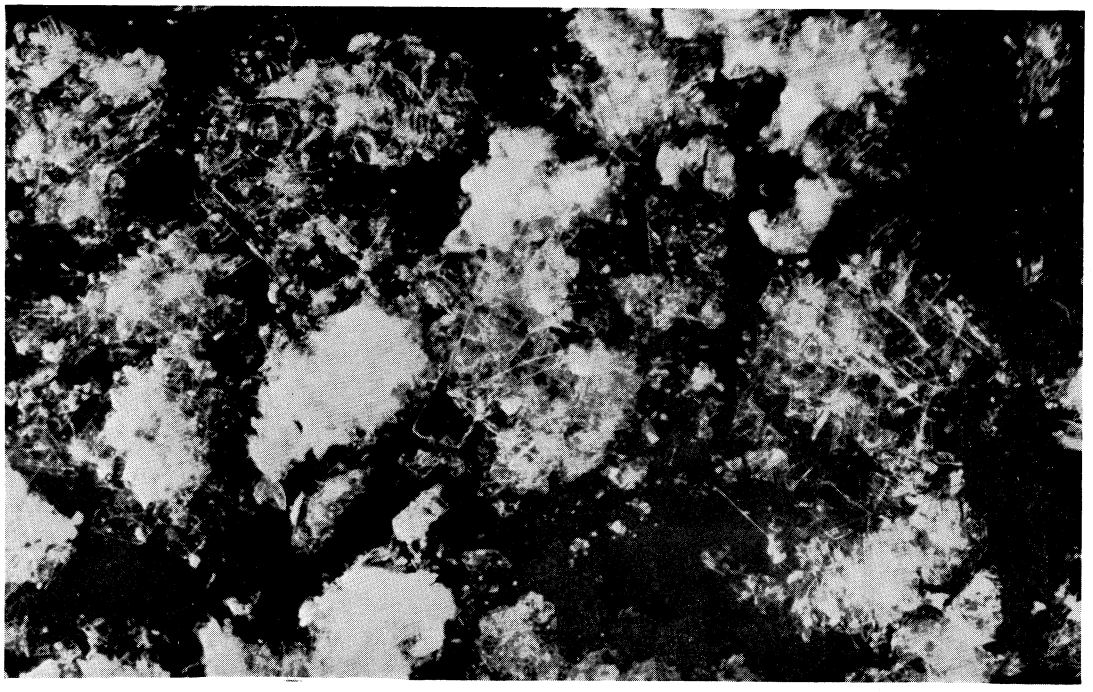

Fig. 4.—Vitamin A β-naphthoate, 24×.

tion coefficients of vitamin A calculated from the extinction coefficients of the esters are also reported. On an equivalent basis vitamin A acetate had a greater $E^{1\%}_{1\,cm.}$ (620 mμ) value than the other vitamin A esters prepared. The equivalent extinction coefficient of the acetate at 620 mμ was also greater than that of free vitamin A.

The method used to determine the $E^{1\%}_{1\,cm.}$ (620 mμ) values has been described.[4]

Biological Potency.—The crystalline aliphatic esters of vitamin A had substantially the same equivalent biological potency as crystalline vitamin A (Table III). The conversion factors of the esters (biological potency/$E^{1\%}_{1\,cm.}$ 328 mμ) were also substantially the same as that of vitamin A. The high conversion factor of di-vitamin A succinate was partly due to the low equivalent extinction coefficient of vitamin A in this ester. The factor for vitamin A β-naphthoate was significantly higher than that of the aliphatic esters. The reason for this is not yet clear.

This finding that certain aliphatic esters of vitamin A have the same equivalent biological potency as vitamin A agrees with the work of Braude, *et al.*[8] These workers found that a natural vitamin A ester concentrate prepared by the molecular distillation of a fish liver oil had the same conversion factor as a vitamin A concentrate prepared by the molecular distillation of a saponified fish liver oil. However, the conversion factor of the vitamin A esters in undistilled fish liver oils has usually been greater than that of the free vitamin A prepared from the oils by saponification.[9] This difference was probably due to the presence of impurities in the oils which absorbed at 328 mμ but which had lower biological potencies than vitamin A. Baxter and Robeson[4] and Braude, *et al.*,[8] review what is known of these substances.

At present it is difficult to compare conversion factors measured in different laboratories because the bioassay procedures are not sufficiently uniform. These procedures may not give the same potency for a pure vitamin A compound. Thus, the biological potency of vitamin A β-naphthoate determined in this Laboratory (four assays gave a mean of 3,440,000 U. S. P. XI units per g.) was over 50% higher than the value found by Underhill and Coward (2,225,000 I. U. per g.).[10] It is in establishing such uniform bioassay procedures in different laboratories that we believe the new crystalline esters should be most useful.

TABLE III

COMPARISON OF BIOLOGICAL POTENCY OF VITAMIN A ESTERS AND VITAMIN A

Vitamin A	No. assays	Total no. of rats	Mean biological potency (U. S. P. XI units/g. × 10^{-6})	Equiv. biological potency of vitamin A (U. S. P. XI units/g. × 10^{-6})	Conversion factor: biological potency / $E^{1\%}_{1\,cm.}$ (328 mμ)
Acetate	9	90	3.52	4.04 ± 0.23	2350 ± 133
Palmitate	8	80	2.31	4.23 ± .31	2520 ± 183
Succinate	1	24	3.14	3.59	2630

Alcohol	8	160	4.30[4]	4.30 ± .39	2460 ± 227

The biological potencies assigned to the vitamin A esters in this paper are provisional values which may be changed slightly in the forthcoming paper by Harris in which the assays are described in detail. H. J. Cannon of the Laboratory of Vitamin Technology, Chicago, independently performed biological assays on solutions of the crystalline compounds (except di-vitamin A succinate) in refined cottonseed oil. These solutions were identified only by code numbers. The biological potencies calculated from his results lay, in each case, within the standard deviations found by Harris.

Experimental

Vitamin A Acetate.—Crystalline vitamin A (4.5 g., 0.016 mole) was dissolved in a mixture of ethylene chloride (25 cc.) and pyridine (5 cc.) and cooled to 10°. A solution of acetyl chloride (1.4 g., 0.018 mole) in ethylene chloride (25 cc.) was slowly added. After standing for two hours at room temperature, protected from light, the mixture was poured into 0.5 *N* aqueous sulfuric acid and extracted with ether. The extract was successively washed with 0.5 *N* sulfuric acid, water, 10% potassium carbonate solution, and water. After distillation of ether under reduced pressure, the residue (5.0 g.) was crystallized from methyl alcohol (50 cc.) at 5°. Recrystallization gave pale yellow prismatic crystals of vitamin A acetate which were filtered and dried under suction in a funnel of the type previously described.[4] The yield was 75% of the theoretical. The acetate melted at 57–58° and had an elimination maximum of 132.5° from petroleum constant yield oil compared with 121° for the standard reference dye, Celanthrene Red.

Anal. Calcd. for $C_{22}H_{32}O_2$: C, 80.48; H, 9.76. Found: C, 80.34; H, 9.86.

Vitamin A Palmitate.—Vitamin A (3.5 g., 0.012 mole) was dissolved in a mixture of ethylene chloride (35 cc.) and pyridine (5.0 cc.) and cooled to −15°. Palmityl chloride (3.7 g., 0.013 mole) was added slowly with shaking. After standing for three hours at room temperature, the reaction mixture was extracted as for vita-

min A acetate, except that after the carbonate washes the ether solution was washed three times with 0.5 *N* sodium hydroxide. After removal of ether the palmitate was obtained as a yellow oil (6.02 g.). This oil was dissolved in petroleum ether (100 cc., b. p. 30–65°) and extracted five times with 83% ethyl alcohol to remove unesterified vitamin A. The recovered palmitate (5.1 g., $E^{1\%}_{1\ cm.}$ 328 mμ = 861) still contained traces of palmitic acid (acid value = 5). This was removed by crystallization from propylene oxide (165 cc.) at −30° for two hours. The acid was filtered (0.19 g.) and the filtrate was cooled slowly, by lagging to −30°. In eighteen hours vitamin A palmitate crystallized as thin yellow plates which were filtered and dried under vacuum. The yield (3.1 g.) was 48% of the theoretical. After recrystallization from propylene oxide the palmitate had m. p. 27–28°. Its elimination maximum from glyceride constant yield oil was 213° (Celanthrene Red 126°).

Anal. Calcd. for $C_{36}H_{60}O_2$: C, 82.45; H, 11.45. Found: C, 82.11; H, 11.52.

The preparation of crystalline vitamin A palmitate was troublesome because the ester frequently separated in amorphous form. This form appeared to be more soluble in propylene oxide than the crystals and separated from solution more slowly. Decomposition of vitamin A during esterification did not cause the formation of amorphous palmitate. It separated frequently from crude preparations with high $E^{1\%}_{1\ cm.}$ (328 mμ) values.

To prevent the formation of amorphous palmitate certain changes in the preparative method were made. Pyridine was replaced by quinoline; ethylene chloride was replaced by chloroform. The esterification was performed in a system from which oxygen was rigorously excluded. The solutions were both rapidly cooled and slowly cooled during the crystallization step. However, these changes were ineffective.

It was then thought that the amorphous ester might be a geometrical isomer of the crystalline ester. Therefore, catalysts known to isomerize carotenoids were employed. Solutions of the amorphous ester in propylene oxide were treated with traces of iodine and organic bases. The solutions were exposed to sunlight. Unsuccessful attempts were then made to crystallize the ester samples. At present the experimental conditions necessary to ensure the preparation of crystalline palmitate are not known.

Di-vitamin A Succinate.—Vitamin A (2 g., 0.007 mole) was dissolved in a mixture of ethylene chloride (10 cc.) and pyridine (2 cc.) and cooled to 0°. A solution of succinyl chloride (0.55 g., 0.0035 mole) in ethylene chloride (10 cc.) was slowly added, with shaking, and the mixture was allowed to stand one hour at room temperature. The extraction was performed as for vitamin A acetate.

The crude product, a red oil (2.4 g.) was crystallized from ethyl formate (10 cc.), then recrystallized from ethyl formate (15 cc.), at −35°. The crystals were yellow prisms, m. p. 76–77°. The yield was 46% of the theoretical. The elimination maximum was above 250° from glyceride constant yield oil.

Anal. Calcd. for $C_{44}H_{62}O_4$: C, 80.73; H. 9.48. Found: C, 80.26; H, 9.50.

Vitamin A β-Naphthoate.—This was obtained by a procedure which gave a better yield than that reported by Mead.[8] Vitamin A (4.5 g., 0.016 mole) was dissolved in ethylene dichloride (25 cc.) and pyridine (5 cc.). β-Naphthoyl chloride (m. p. 51–52°, 3 g., 0.016 mole) in ethylene dichloride (25 cc.) was added at 25° and the mixture was allowed to stand for four hours at room temperature. The ester was extracted as for vitamin A palmitate. It consisted of a viscous yellow oil (7 g.). This was crystallized from absolute ethyl alcohol (150 cc.) at 5° (yield 58% of theoretical). The ester consisted of delicate, yellow plates which melted at 73–74°. After one recrystallization the m. p. was 74–75°. Repeated crystallizations did not raise the m. p. further.

Anal. Calcd. for $C_{31}H_{36}O_2$: C, 84.53; H, 8.18. Found: C, 84.90; H, 8.13.

Summary

1. Three crystalline esters of vitamin A have been prepared by the esterification of crystalline vitamin A. These esters are: vitamin A acetate, vitamin A palmitate, and di-vitamin A succinate.

2. The extinction coefficients of the esters at 328 mμ and of the antimony trichloride blue colors at 620 mμ have been determined.

3. The biological potency of the esters, adjusted for differences in the molecular weights, was the same as that of crystalline vitamin A.

4. Vitamin A acetate was the most resistant of the crystalline preparations to atmospheric oxidation. It appears to be the most stable crystalline ester of vitamin A yet prepared.

Crystalline Vitamin A[1]

BY JAMES G. BAXTER AND CHARLES D. ROBESON

The Holmes and Corbet Crystals

Holmes and Corbet[2] crystallized the vitamin A in ishinagi liver oil from methyl alcohol as yellow needles, melting at 7.5–8°. The authors[3] crystallized the vitamin A in ling cod and other fish liver oils from ethyl formate as yellow prisms, melting at 63–64° (hereafter called 64° crystals) (Fig. 1). Because the Holmes and Corbet crystals had different properties from ours we have prepared and examined specimens of the crystals melting at 7° (hereafter called 7° crystals).[4] This examination indicated that the 7° crystals are not pure vitamin A, but contain methyl alcohol. Crystalline vitamin A melts at 64°. The evidence for these conclusions and certain properties of crystalline vitamin A are given in this paper.

The 7° crystals were prepared from the liver oil of the California jewfish (*Stereolepis gigas*). This oil is similar to the liver oil of the Japanese ishinagi (*Stereolepis ishinagi*), used by Holmes and Corbet. The method of isolation was similar to that of Holmes and Corbet except that the vitamin A esters were concentrated by molecular distillation of the fish liver oil prior to saponification and crystallization from methyl alcohol.

The moist crystals were dried at a temperature gradually rising from −30 to −5° in a system continuously evacuated by a high vacuum condensation pump (limiting vacuum = 0.001 mm.). The rate of drying was determined by measuring the vapor pressure in the system with a Pirani type gage. The pressure decreased steadily during six hours to a value of 0.008 mm., then remained substantially constant for sixteen hours at −5°. The crystals were then examined. They were needle-like in structure (Fig. 2), resembling those of Holmes and Corbet, but melted less sharply at 7–10°.

The following observations were made:

(1) The 7° crystals retained methyl alcohol. This was determined by drying a sample in a stream of nitrogen at 50° and finding the loss in weight. The percentage of alcohol found (10%) corresponded to one mole of methyl alcohol per mole of vitamin A. Since, however, the samples used in the determination were small, this percentage was considered to be only approximate. The 64° crystals lost no weight when they were similarly dried.

(2) The 64 and 7° crystals were interconvertible. When the 7° crystals were cooled in ethyl formate solution, 64° crystals separated. When a solution of the 64° crystals in methyl alcohol was cooled 7° crystals were deposited.

(3) The 64 and 7° crystals gave the same crystalline vitamin A acetate (m. p. 57–58°) and β-naphthoate (m. p. 74–75°). Also, the extinction coefficient of the 7° crystals ($E^{1\%}_{1cm.}$ 328 mμ = 1720, corrected for methyl alcohol present) was nearly the same as that of the 64° crystals ($E^{1\%}_{1cm.}$ 328 mμ = 1750).

It was concluded from these data that the 64° crystals represent crystalline vitamin A. The 7° crystals, which appeared to be similar to those made by Holmes and Corbet, were vitamin A containing methyl alcohol.

Evidence was noted indicating that the methyl alcohol in the 7° crystals was not merely entrained: (1) Most of the alcohol in the moist 7° crystals, as previously mentioned, was removed readily under high vacuum but the last 10% could not be removed in this way. (2) The 7° crystals had a different crystalline structure than crystalline vitamin A (when the latter was crystallized from methyl alcohol) and they separated from solution more rapidly and in greater yield (see next section). (3) Specimens of the 7° crystals prepared independently by Holmes and Corbet,[2] by Mead[5] and by us melted at substantially the same temperature, and hence probably contained similar quantities of methyl alcohol, although they were crystallized and dried by different procedures. It seems improbable that this would have occurred if the methyl alcohol had merely been held by entrainment.

The question as to whether the 7° crystals represent a true molecular compound containing

fixed proportions of vitamin A and methyl alcohol was not examined.

Crystallization of Vitamin A.—In the further study of the affinity of vitamin A for various solvents, a rich concentrate ($E^{1\%}_{1cm.}$ 328 mμ = 1550) was crystallized from methyl alcohol, ethyl formate, petroleum ether (b. p. 30–65°), and propylene oxide, at temperatures of approximately −35 and −70°. The solutions were usually seeded to prevent supersaturation and were allowed to crystallize for as long as two weeks, in certain cases, to attain equilibrium. The nature of the crystals formed and the yields obtained are shown in Table I.

These experiments indicated that vitamin A has an affinity for ethyl formate as well as for methyl alcohol. In the table the notations "vitamin A (MeOH)" and "vitamin A (Et Form.)" mean that the designated crystals contained methyl alcohol and ethyl formate which could not be removed completely under high vacuum without melting the crystals. The notation does not imply that a molecular compound existed nor that a molecular proportion of solvent was retained by the crystals.

Vitamin A (MeOH) separated in Crystallizations (Crystns.) 2 and 3, *i. e.*, when a 20% solution of a vitamin A concentrate in methyl alcohol was cooled to −35° and seeded with vitamin A (MeOH) crystals, or cooled to −70° without seeding. In Crystn. 1, vitamin A separated. Thus, either vitamin A or vitamin A (MeOH) could be crystallized from methyl alcohol.

Vitamin A (Et Form.) crystallized from ethyl formate at −70° (Crystn. 6) unless the solution was cooled gradually to −70° in the presence of vitamin A crystals. Then vitamin A crystallized (Crystn. 5). Only vitamin A could be crystallized from ethyl formate at −35° (Crystn. 4).

Since vitamin A (Et Form.), like vitamin A (MeOH), separated from solution more rapidly than vitamin A, concentrates from distilled and saponified fish liver oils were first crystallized in this form at −70° to remove the bulk of the impurities in the non-saponifiable matter. Vitamin A was then obtained by recrystallizing the concentrate from ethyl formate at −35°.

Vitamin A (Et Form.) was only briefly examined. Even after filtration under pressure the preparations contained as much as 80% adsorbed and entrained ethyl formate. After fifteen hours of continuous evacuation at −35° (final vapor pressure = 0.009 mm.) one sample melted at −4 to 2° and contained 12% ethyl formate. Another preparation contained 10% ethyl formate and melted at 7–10°. The percentages are again only approximate.

Solvent-free vitamin A crystallized from propylene oxide or petroleum ether (Crystns. 7–10). Thus, it appears that only the more polar solvents have an affinity for vitamin A. The hydroxyl group of the vitamin is evidently responsible for this property because esters of vitamin A, such as the acetate, crystallized from methyl alcohol or ethyl formate without solvent of crystallization.

Properties of Crystalline Vitamin A

Extinction Coefficient at 328 mμ and 622 mμ.—Nine recent preparations of crystalline vitamin A have had an average extinction coefficient at the absorption maximum of 1750 ± 21 in absolute ethyl alcohol[6] (unless otherwise stated all extinction coefficients reported in this paper were determined in this solvent). One of these preparations had an extinction coefficient at the absorption maximum of 1780 (average of 3 determinations) (Fig. 3). Dr. F. P. Zscheile and R. L. Henry of Purdue University kindly assayed this latter preparation and also obtained the value 1780 at the maximum. They have recently reported spectrographic data for other preparations of crystalline vitamin A.[7]

The spectrographic measurements did not support the value of $E^{1\%}_{1cm.}$ 325 mμ = 1880 for pure vitamin A, suggested as the probable value by Morton.[8]

The position of the absorption maximum of vitamin A varied from 326–328 mμ in ethyl alcohol with our instrument. Zscheile and Henry, using an instrument capable of greater precision, found the maximum in ethyl alcohol to be at 324 mμ. Thus, the wave length now assigned to the vitamin A maximum (328 mμ) may be incorrect. It has, however, seemed advisable to determine the extinction coefficients reported in this paper at the absorption maximum and to report them as at 328 mμ unless the maximum lay outside the range 326–328 mμ.

In petroleum ether (b. p. 30–65°) and ethyl formate the average extinction coefficients of vitamin A at 328 mμ were 1760 and 1715, respectively. These values were not considered significantly different from that in ethyl alcohol. In cyclohexane and chloroform the extinction coefficients were 1550 and 1260 at 328 mμ and 333 mμ, respectively. These values seemed to be significantly lower than the value in ethyl alcohol.

We believe that certain solvents such as cyclohexane are able to repress the absorption of vitamin A. The suggestion of Adamson and Evers[9] that the extinction coefficient of vitamin A is higher in ethyl alcohol than in cyclohexane because complex formation occurs in the former does not seem probable in view of the high extinction coefficient of vitamin A in petroleum ether.

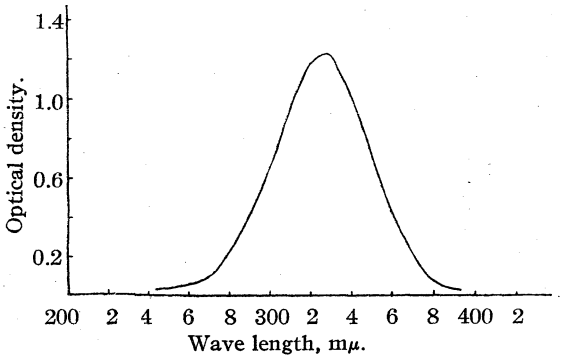

Fig. 3.—Spectrophotometric curve of crystalline vitamin A in ethyl alcohol ($E_1^{1\%}_{cm.}$ 328 mμ = 1780).

The extinction coefficient of solutions of vitamin A in ethyl alcohol was unchanged after two days of storage in amber bottles at room temperature. Thus, we were unable to confirm the observation of Darby, quoted by Holmes and Corbet,[2] that the extinction coefficient of highly purified vitamin A preparations rapidly decreases in ethyl alcohol solution. The solutions in ethyl alcohol were stable also to radiation from the spark used with the spectrograph even when exposures of 160 sec., four times the normal exposure, were given. Zscheile and Henry reported a similar finding.[7] However, the extinction coefficient of solutions of vitamin A in cyclohexane and chloroform did decrease from 2 to 6% during storage for twenty-four hours at room temperature.

The extinction coefficient of the antimony trichloride blue color of vitamin A at 622 mμ was 4800. This is the average of five determinations on vitamin A with $E^{1\%}_{1cm.}$ 328 mμ = 1750 and agrees well with the value 4700 previously reported[3] from measurements on other vitamin A preparations. In a typical determination 1 cc. of a vitamin A solution in chloroform (0.001576 g./100 cc.) was treated with 10 cc. of a chloroform solution of antimony trichloride (saturated at 20°). The percentage transmission at 622 mμ of the transitory blue color was measured within three seconds with a Hardy recording spectrophotometer.[10]

From our work the value $E^{1\%}_{1cm.}$ 617 mμ = 6000, suggested as being probable by Morton,[8] appears to be too high.

(6) Mr. G. Wait and assistants of this Laboratory made the spectrographic measurements using a Hilger quartz spectrograph, model E-498, with a Spekker ultraviolet photometer. The light source was a tungsten–steel spark.

(10) We are indebted to Mr. E. Richardson, Eastman Kodak Company Research Laboratories, for measuring the absorption spectra.

The "L" Value.—Vitamin A can be assayed rapidly by measuring the intensity of its antimony trichloride blue color with certain photoelectric colorimeters, such as the Evelyn. This instrument uses sharply filtered rather than monochromatic light. Therefore, the results are expressed in terms of a quantity L rather than E. L is analogous to E, the extinction, and the L value ($L^{1\%}_{1cm.}$ 622 mμ) is analogous to $E^{1\%}_{1cm.}$ 622 mμ. Dann and Evelyn[11] found that L was proportional to the vitamin A concentration for galvanometer readings (G) between 20 and 70. Thus, in this range the L value was nearly constant. Koehn and Sherman,[12] however, found that L was not proportional to the vitamin A concentration over this range and the L value was consequently not constant. In these experiments pure vitamin A was not used. Both groups of workers used the non-saponifiable matter from fish liver oils, possibly containing oxidized vitamin A.

The relation between L and the vitamin A concentration is of practical as well as theoretical interest. For this reason the L value of crystalline vitamin A was measured at concentrations corresponding to galvanometer readings from 20–70 (Table IIa). The L value of crystalline vitamin A acetate was measured in the same way to determine the effect of esterification on the L value of vitamin A (Table IIb).

3.26	59^2	3635
4.89	46^2	3565
5.22	44^2	3540
6.52	36^0	3575
8.15	28^2	3510
9.78	22^3	3455
11.41	17^3	3455
13.04	14^2	3375

The procedure was similar to that of Dann and Evelyn. Samples of vitamin A (0.0433 g.) and vitamin A acetate (0.0815 g.) were dissolved in chloroform (50 cc.) to prepare stock solutions. From 1–9 cc. of these stock solutions were further diluted to give solutions with the desired vitamin A concentration. Portions of these solutions (1 cc.) were treated with 10 cc. of a solution of antimony trichloride in chloroform, saturated at 20°. Duplicate readings were taken at each dilution (maximum deviation = 1 (G) unit) and the values of G were averaged.

A linear relation did not exist between L and the concentration of vitamin A or vitamin A acetate for galvanometer readings between 20 and 70. A nearly linear relation did exist between G = 30–70. In this range vitamin A ($E^{1\%}_{1cm.}$ 328 mμ = 1740) had an average L value of 3865 ± 39. Vitamin A acetate ($E^{1\%}_{1cm.}$ 328 mμ = 1470) had an average L value of 3570 ± 40.

From the standard deviations it was calculated that 21 out of 22 observations of the L value of vitamin A or vitamin A acetate would lie within ± 2.2% of the average value, for galvanometer readings taken between G = 30–70. This error was doubled if the range G = 20–70 was used.

Our purest vitamin A ($E^{1\%}_{1cm.}$ 328 mμ = 1780) had an L value of 3990. The equivalent L value of vitamin A calculated from the L value of vitamin A acetate was 4090. It thus appears that the L value of vitamin A is about 4000 and that the blue color of one ester of vitamin A had a greater equivalent absorption than vitamin A itself.

The following relations were determined between the extinction coefficients of vitamin A ($E^{1\%}_{1cm.}$ 328 mμ = 1740) and vitamin A acetate ($E^{1\%}_{1cm.}$ 328 mμ = 1470) and the average L values

Vitamin A: $E^{1\%}_{1cm.}$ 328 mμ = L value × (0.45 ± 0.005).

Vitamin A acetate: $E^{1\%}_{1cm.}$ 328 mμ = L value × (0.41 ± 0.005)

The value for the conversion factor of vitamin A lies between the value of 0.41 ± 0.05 reported by Dann and Evelyn and the value 0.50 ± 0.01 reported by McFarland and Sutherland.[13]

Other Physical and Chemical Constants.—The *molecular weight* of vitamin A, determined

(11) Dann and Evelyn, *Biochem. J.*, **32**, 1008 (1938).

(12) Koehn and Sherman, *J. Biol. Chem.*, **132**, 527 (1940).

(13) McFarland and Sutherland, *Can. J. Research*, **16**, 421 (1938).

by a micro modification of the Menzies–Wright ebullioscopic method in ethyl alcohol, was 263.[14] The calculated value for $C_{20}H_{30}O$ was 286. The *index of refraction* was $n^{22}D$ 1.6410. In this determination the refractive indices of 20–70% solutions of vitamin A in refined mineral oil were measured with an Abbe refractometer. These indices when plotted against the vitamin A concentration gave a straight line which could be accurately extrapolated to 100% vitamin A. The *acetyl value*, determined by the method of West, Hoaglund and Curtis,[15] was 149. The calculated value was 150 mg. CH_3CO per gram. The *iodine value* determined by the method of von Mikusch and Frazier[16] was 390. The theoretical value was 444. A 500% excess of 0.4 *N* Hanus solution was used for a reaction period of three hours at 0°.[17] The *elimination maximum* was 125°, one degree below that of the reference dye, Celanthrene Red, added to the solution before distillation. Glyceride constant yield oil was used.[18]

Biological Potency

Crystalline vitamin A was found to have a provisional biological potency of 4,300,000 U. S. P. XI units per gram. This value is about 30% higher than that suggested as being probable by Morton.[8] The factor for converting the average extinction coefficient at 328 mμ of the preparations bioassayed to U. S. P. XI units was 2460.

This conversion factor of 2460 is higher than the value of 2000 widely accepted as the conversion factor of vitamin A in fish liver oils. If confirmed, it means that fish liver oils contain substances (or a substance) absorbing at 328 mμ which are either biologically less active than crystalline vitamin A or are biologically inactive.

Baxter, *et al.*,[19] have reported evidence tending to show that these substances may have vitamin A activity. However, we have not been successful in separating them from vitamin A by chromatographic adsorption. Robinson[20] has suggested that these substances absorbing at 328 mμ are oxidized vitamin A which has no biological activity. His experimental results, however, do not appear to establish this explanation. A significant discrepancy did not appear between spectrographic and biological assays made on his oxidized vitamin A preparations until the 328 mμ band of vitamin A had been badly deformed and shifted toward the ultraviolet.

The value of 4,300,000 U. S. P. XI units per gram for crystalline vitamin A was obtained as the average of eight biological assays (a total of 160 rats used) made by Dr. P. L. Harris of this Laboratory. They will be reported in detail elsewhere. Vitamin A was also assayed by H. J. Cannon of the Laboratory of Vitamin Technology, Chicago. From his results an average biological potency of 4,700,000 U. S. P. XI units per gram was calculated. For the 7° crystals Harris found a biological potency of 3,900,000 U. S. P. XI units per gram, corrected for the methyl alcohol present. Only two assays were performed, however, so the biological potency was not established as accurately as for vitamin A itself.

Experimental

Preparation of Crystalline Vitamin A

A. Distillation of Fish Liver Oils.—Cryst. vitamin A was prepared from shark liver ($E^{1\%}_{1cm.}$ 328 mμ = 100), ling cod liver ($E^{1\%}_{1cm.}$ 328 mμ = 129), California jewfish liver ($E^{1\%}_{1cm.}$ 328 mμ = 317) and halibut viscera ($E^{1\%}_{1cm.}$ 328 mμ = 72), oils.

A cyclic molecular still, similar to that described by Hickman[18] was used. The vitamin A esters distilled from 180–220° at a pressure of 0.003 mm. The distillates were light yellow oils without fishy taste or odor. Fractions with an extinction coefficient at 328 mμ of 400 or greater were combined for saponification. From 50–70% of the initial vitamin A was obtained at this potency.

B. Saponification.—A vitamin A ester concentrate (67 g., $E^{1\%}_{1cm.}$ 328 mμ = 539) from distilled ling cod liver oil was saturated with nitrogen by bubbling commercial gas through it for ten minutes. Then 190 cc. of 2 *N* alcoholic potassium hydroxide, similarly saturated with nitrogen, was added. Saponification was effected by refluxing the mixture for thirty minutes in an atmosphere of nitrogen. The mixture was then diluted with freshly boiled and cooled water and extracted with reagent grade ethyl ether. The extract was washed with 10% aqueous potassium carbonate, with water, and dried. The ether was distilled under reduced pressure.

The free vitamin A concentrate (28.6 g., $E^{1\%}_{1cm.}$ 328 mμ = 1260) was a red viscous oil which could be directly crystallized from ethyl formate. However, vitamin A of greater purity was obtained by first distilling the saponified concentrate.

C. Redistillation.—The saponified concentrate from (B) was dissolved in two volumes of corn oil residue and

(14) We wish to thank Dr. L. T. Hallett, Eastman Kodak Company Research Laboratories, for the microanalysis.

(20) Robinson, *Biochem. J.*, **32**, 807 (1938).

distilled in a cyclic molecular still. Fractions were taken at 10°-intervals from 90–160° with two cycles at each temperature. Vitamin A distilled principally from 105–135° as an odorless, orange oil. The distillate was viscous and the condenser wall had to be warmed to cause the distillate to flow into the receiver. Fractions with an extinction coefficient of 1400 or greater were combined for crystallization (17.5 g., $E^{1\%}_{1cm.}$ 328 mμ = 1440).

D. Crystallization of Vitamin A (Ethyl Formate).—The vitamin A concentrate from (C) was dissolved in ethyl formate (70 cc.), cooled to −35° for eighteen hours, seeded with cholesterol and then cooled to −55° for eight hours. The solids which separated (1.1 g.) were filtered in a Büchner funnel cooled with dry-ice. The filtrate deposited no solids when cooled at −70° for eighteen hours so the flask was scratched at intervals to promote crystallization. In three hours crystallization began and was complete in three days. The crystals were filtered and washed in a modified Büchner funnel, cooled with dry-ice (see Filtration and Drying). Much entrained solvent was pressed out with dental dam. After distillation of ethyl formate under reduced pressure a vitamin A concentrate was obtained (9.2 g., $E^{1\%}_{1cm.}$ 328 mμ = 1670).

E. Crystalline Vitamin A.—The vitamin A concentrate from (D) was dissolved in ethyl formate (40 cc.) and stored at −35° for eighteen hours during which time the flask was repeatedly scratched. Vitamin A began to separate in large prismatic crystals during this period and crystallization was allowed to continue for an additional twenty-four hours. The crystals were filtered in the modified Büchner funnel and dried.

The first crop of crystals weighed 1.67 g. By concentrating the filtrate and seeding it at −35° an additional 1.06 g. was obtained. The yield was further increased by 1.32 g. by cooling the filtrate from the second crop to −70° for five days and recrystallizing the vitamin A at −35°. The average $E^{1\%}_{1cm.}$ 328 mμ value of the three crops of crystals was 1720. Thus, the yield of crystalline vitamin A was approximately 15% of that present in the fish liver oil. After two crystallizations from ethyl formate vitamin A melted at 63–64° and had $E^{1\%}_{1cm.}$ 328 mμ = 1750.

Anal. Calcd. for $C_{20}H_{30}O$: C, 83.84; H, 10.56. Found: C, 83.90, 83.70; H, 10.30, 10.40.[14]

An alternative crystallization procedure gave an over-all yield of 25%. The solution of (D) in ethyl formate (40 cc.) was crystallized at −35, −55, and finally at −70°. The crystals were not filtered until crystallization was completed at −70°. Under these conditions vitamin A and not vitamin A (ethyl formate) separated. The extinction coefficient of the crystals at 328 mμ was 1710 but more small crystals with inferior keeping quality were present than when the other procedure was used.

Vitamin A was sealed in glass ampoules, under vacuum, and stored at −35°. Under these conditions the extinction coefficient and the biological potency were unchanged after four to six months.

Filtration and Drying.—A modified Büchner funnel was constructed to filter vitamin A under nitrogen pressure. A circular steel ring, 0.5″ wide, was provided for the mouth of the funnel (75 mm. inside diameter). This was held in place by tie rods connected to a similar steel ring fitted to the throat of the funnel. A steel cover was provided with a hose connection to admit nitrogen. A pressure-tight union between ring and cover was obtained with a rubber gasket and six bolts attached to the periphery of the metal ring. These bolts fitted through holes in the cover. Excess solvent in the crystals was removed by pressure from a piece of dental dam fitted between gasket and cover. The funnel was cooled by a removable insulated jacket filled with dry-ice.

To dry the crystals the cover was tightened and the funnel was evacuated by connecting its outlet to an oil pump. Evacuation for fifteen to twenty hours at a temperature gradually rising from −60 to 5° was usually necessary. Filtrations and drying were done in a cold room at 5°.

Refrigeration.—Three temperatures were used most frequently, −35, −55, and −70°. An ice-cream cooling cabinet maintained a temperature of −35° ± 5°. A wooden box insulated with cork, and cooled with dry-ice served to keep a temperature near −55°. Vessels were cooled to −70 ± 10° by packing them in powdered dry-ice and storing them in the insulated cabinet.

Solvents.—Eastman Kodak Co. ethyl formate was filtered through anhydrous potassium carbonate to remove formic acid and was then fractionally distilled. Solvents such as propylene oxide, petroleum ether (b. p. 30–65°), and methyl alcohol were Eastman grade and were used without further purification.

Summary

Crystalline vitamin A has been isolated from shark liver, ling cod liver, California jewfish liver and halibut viscera oils as yellow prisms, melting at 63–64°. Evidence was obtained indicating that the crystalline vitamin A of Holmes and Corbet (m. p. 7.5–8°) contained methyl alcohol.

Crystalline vitamin A had a provisional biological potency of 4,300,000 U. S. P. XI units per gram. Its conversion factor, 2460, was higher than the conversion factor of vitamin A in fish liver oils.

The extinction coefficient of crystalline vitamin A at 328 mμ was 1780. The extinction coefficient of the vitamin A antimony trichloride blue color at 622 mμ was 4800. The L value ($L^{1\%}_{1cm.}$ 622 mμ), measured with an Evelyn photoelectric colorimeter, was 3990. L was a nearly linear function of the vitamin A concentration for galvanometer readings (G) between 30 and 70.

The molecular weight, the elimination maximum, the index of refraction, the acetyl value, and the iodine value of crystalline vitamin A were determined. These confirmed the formula for vitamin A proposed by Karrer.

The Nitration of Lepidine and 2-Chlorolepidine

BY STANLEY E. KRAHLER[1] AND ALFRED BURGER

In the course of an investigation of quinoline derivatives of potential antimalarial activity, certain aminolepidines were prepared from the corresponding nitro compounds.[2] It was found that the nitration of 2-chlorolepidine yielded two isomeric mono nitro derivatives in a ratio of 1:6. The isomer formed in smaller amount was identified as 6-nitro-2-chlorolepidine, while the major reaction product was postulated to be 5-nitro-2-chlorolepidine. The 8-position was ruled out for the nitro group because the chloro-2-hydroxy- and chloro-2-chlorolepidine prepared from our nitro product differed from the 8-chloro-2-hydroxy- and the 2,8-dichlorolepidine, respectively, as reported by Kermack and Muir.[3] The data furnished by the British authors did not seem to call for re-investigation since their preparation of 8-chloro-2-hydroxylepidine from *o*-chloroacetoacetanilide, and the melting point of their product, had been confirmed by Monti and Cirelli.[4]

Shortly after the publication of our experiments, Johnson and Hamilton[5] reported that the compound obtained by cyclization of *o*-chloroacetoacetanilide could also be prepared from the major nitration product of 2-chlorolepidine. The melting point of their product checked that of the compound which we had regarded as 5-chloro-2-hydroxylepidine. Likewise, the melting point of the 2,8-dichlorolepidine of Johnson and Hamilton did not agree with that observed by Kermack and Muir for their dichloro compound, but with that of the substance to which we had assigned the structure of 2,5-dichlorolepidine.

In the nitration of lepidine the nitro group enters position 8 since the corresponding aminolepidine can be derived from 8-nitro-2-chlorolepidine by reduction.[5a]

We repeated Johnson and Hamilton's ring closure using commercial *o*-chloroacetoacetanilide, and corroborated the results of these authors. A mixture melting point of the 8-chloro-2-hydroxylepidine obtained by this procedure exhibited no depression with a sample of our chloro-2-hydroxylepidine, and thereby established the structure of our nitro derivative as 8-nitro-2-chlorolepidine.

The position of the nitro group has now been confirmed by degradation to a well-known nitroquinoline. For this purpose, 8-nitrolepidine was converted to 8-nitroquinoline-4-aldehyde by the method of Koenigs,[6] and the aldehyde was oxidized to 8-nitrocinchoninic acid. This acid was decarboxylated to 8-nitroquinoline, which was identified by mixture melting point with a sample prepared from *o*-nitroaniline by the Skraup synthesis. Moreover, 5-nitrocinchoninic acid prepared by nitration of cinchoninic acid[7] depressed the melting point of our 8-nitroquinoline-4-carboxylic acid.

It seemed probable that Kermack and Muir, and Monti and Cirelli, had obtained the isomeric 8-chloro-4-hydroxyquinaldine in their ring closures. A support was given to this assumption by recent studies of Jacini,[8] who showed that in the preparation of acetoacetanilide derivatives by the method of Fierz-David and Ziegler,[9] elimination of one molecule of water rather than of ethanol may occur with the formation of ethyl β-arylaminocrotonates. This method had been used by Monti in the synthesis of compounds interpreted by her as 2-hydroxylepidine derivatives.

8-Chloro-4-hydroxyquinaldine as described by Hughes and Lions[10] melts at 220°. We repeated the synthesis of these investigators, and obtained a compound melting at 229–230°. Chlorination of this derivative yielded 4,8-dichloroquinaldine; the structure of this compound was proved by degradation to quinaldine. The dichloro derivative reacted with piperidine to furnish 8-chloro-4-piperidinoquinaldine; with sodium methoxide it yielded 8-chloro-4-methoxyquinaldine. The melting points of these compounds are listed in the following table and compared with those of the supposedly isomeric lepidine derivatives of Kermack and Muir.

Only 2-hydroxylepidine could be isolated from the reaction mixture when 2-chlorolepidine was oxidized with selenium dioxide. Bromination of 2-chlorolepidine yielded small amounts of 4-(dibromomethyl)-2-hydroxylepidine; this compound could not be hydrolyzed to 2-hydroxyquinoline-4-aldehyde.

In an experiment designed to synthesize 2-lepidylmalonic acid, sodium diethyl malonate was condensed with 2-chlorolepidine in carefully dried ethanol solution. The reaction product was found to be 2-ethoxylepidine instead; sodium ethoxide had competed with sodium diethylmalonate in the condensation.

Experimental

8-Nitroquinoline-4-aldehyde.—Several attempts were made to oxidize 8-nitrolepidine to the aldehyde with selenium dioxide according to the direction of Johnson and Hamilton,[5a] but more reproducible results were obtained by the method of Koenigs.[6] Bromination of 8-nitrolepidine gave 8-nitro-4-(dibromomethyl)-quinoline in 89% yield, m. p. 111.5–112.5°. The hydrolysis of the dibromomethyl group was effected by dissolving equal parts of the compound and of silver nitrate in five parts of 60% acetic acid and heating the mixture on a steam-bath for four hours. A small amount of hydrochloric acid was added to complete the precipitation of silver halides. The solution was filtered, made alkaline with solid sodium carbonate, and the precipitated aldehyde was isolated. The yield of crude colorless product of m. p. 163–173° was 97%; the compound could be used in the following oxidation without further purification.

8-Nitroquinoline-4-carboxylic Acid.—One and seven-tenths grams of the crude aldehyde, dissolved in 50 cc. of acetone, was oxidized by dropwise addition of 17.75 cc. of a 5% potassium permanganate solution at 40°. The precipitated manganese dioxide was brought into solution by adding some water saturated with sulfur dioxide, the acetone boiled off, and the volume of the solution maintained constant by dilution with water. 8-Nitrocinchoninic acid crystallized as glittering yellow needles, m. p. 253–254° (dec.). The yield was 1.3 g. (71%).

Anal. Calcd. for $C_{10}H_6N_2O_4$: N, 12.84. Found: N, 12.55.

8-Nitroquinoline.—Three-tenths gram of 8-nitrocinchoninic acid, mixed with an equal amount of copper bronze, was heated gently at 100 mm. pressure until the rapid decarboxylation had subsided. The reaction product was distilled out under 20 mm. pressure, and the oily distillate crystallized on cooling. Sublimation at 70° and 2 mm. yielded yellow crystals, m. p. 86–89°. A mixture melting point with an authentic sample of 8-nitroquinoline (m. p. 88–90°) showed no depression.

Attempted Preparation of 2-Chloroquinoline-4-aldehyde.—To a boiling solution of 2.2 g. of 2-chlorolepidine and 4.4 g. of anhydrous sodium acetate in 35 cc. of glacial acetic acid was added a solution of 4.2 g. of bromine in 20 cc. of glacial acetic acid. Decolorization occurred after thirty minutes of boiling. The solution was cooled, poured into ice-water, and the precipitated solid extracted four times with ether. The insoluble material was recrystallized from boiling ethanol. The almost colorless needles melted at 307–308° (dec.), the yield was 0.5 g. (12%). The compound proved to be 4-(**dibromomethyl**)-**2-hydroxyquinoline.**

Anal. Calcd. for $C_{10}H_7Br_2NO$: C, 37.86; H, 2.23. Found: C, 38.06; H, 2.65.

Hydrolysis to 2-hydroxyquinoline-4-aldehyde was unsuccessful. This is in accord with the observation[5a] that 2-hydroxy-4-(bromomethyl)-quinoline resists hydrolysis when refluxed with 80% acetic acid.

The oily residue from the combined ether extracts of the high-melting 2-hydroxy-4-(dibromomethyl)-quinoline was hydrolyzed with silver nitrate in acetic acid solution. The oily reaction product gave a pronounced aldehyde test but did not crystallize and yielded no crystalline derivatives.

8-Chloro-4-hydroxyquinaldine.—Ten grams of *o*-chloroaniline was dissolved in 10 g. of ethyl acetoacetate, one drop of 17% hydrochloric acid was added, and the mixture was allowed to stand over sulfuric acid in an evacuated desiccator for twenty-four hours. The oily yellow ethyl β-(*o*-chlorophenyl)-aminocrotonate was dropped with stirring into 100 cc. of dry paraffin oil preheated to 240°. When all the ester had been added, the temperature was maintained at 240° for five minutes. The clear yellow solution was allowed to cool; crystallization set in at 150°. The mixture was diluted with ligroin, the product was filtered and recrystallized from dilute ethanol. The colorless crystals melted at 229–230°; the yield was 4.4 g. (29%).

Anal. Calcd. for $C_{10}H_8ClNO$: C, 62.03; H, 4.17. Found: C, 62.10; H, 4.79.

4,8-Dichloroquinaldine.—A mixture of 1.4 g. of 8-chloro-4-hydroxyquinaldine and 5 cc. of phosphorus oxychloride was heated on a steam-bath until all the material had gone into solution. This chlorination proceeded more rapidly than the corresponding reaction with 2-hydroxylepidine. The mixture was poured into ice-water and made ammoniacal. An oily precipitate appeared, and solidified on scratching. Recrystallization from dilute methanol, and sublimation at 70° and 2 mm. yielded 1.3 g. (85%) of colorless needles, m. p. 87–88°.

Anal. Calcd. for $C_{10}H_7Cl_2N$: C, 56.63; H, 3.33. Found: C, 56.62; H, 4.30.

One-half gram of the dichloro compound was mixed with 3 g. of zinc dust, and heated slowly in a small distilling flask. A few drops of a clear oil distilled from the mixture. The picrate, prepared from the distillate and recrystallized from boiling ethanol, appeared as yellow needles, m. p. 188–190° (dec.). A mixture melting point with quinaldine picrate (m. p. 192–194°) showed no depression.

8-Chloro-4-piperidinoquinaldine.—A mixture of 0.6 g. of 4,8-dichloroquinaldine and 5 cc. of piperidine was re-

fluxed for four hours, poured into water, the precipitated piperidino derivative was filtered and recrystallized three times from dilute methanol. The compound appeared as lustrous colorless plates; m. p. 124–125°.

Anal. Calcd. for $C_{15}H_{17}ClN_2$: C, 69.09; H, 6.57. Found: C, 69.26; H, 7.41.[11]

The **picrate** crystallized from ethanol as yellow needles, m. p. 161–163°.

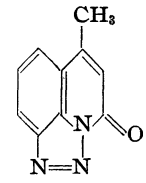
8-Chloro-4-methoxyquinaldine.—A solution of 0.043 g. of sodium in 2 cc. of methanol was added to a solution of 0.4 g. of 4,8-dichloroquinaldine in 30 cc. of methanol, and the mixture was refluxed for twelve hours. The reaction product was precipitated as an almost colorless solid by dilution with water, and purified by fractional sublimation at 90° and 3 mm. The small colorless plates melted at 122–124°.

Anal. Calcd. for $C_{11}H_{10}ClNO$: C, 63.62; H, 4.85. Found: C, 64.30; H, 5.39.

2-Chlorolepidine and Sodium Diethyl Malonate.—A solution of 9 g. of diethyl malonate in 10 cc. of absolute ethanol was refluxed with a solution of 1.3 g. of sodium in 30 cc. of absolute ethanol for five minutes; 10 g. of 2-chlorolepidine in 10 cc. of absolute ethanol was added, and the mixture boiled for fifty hours. The separated sodium chloride was filtered, 7.6 g. of potassium hydroxide was added, and the alkaline mixture refluxed for four hours to complete hydrolysis of the ester. Neutralization with dilute acetic acid precipitated an oil which crystallized on cooling. It was recrystallized from dilute alcohol and appeared as colorless needles, m. p. 49–50°. Analysis showed it to be 2-ethoxylepidine.[12]

Anal. Calcd. for $C_{12}H_{13}NO$: C, 76.97; H, 7.00. Found: C, 76.33; H, 6.91.

2-Oxo-4-methylquinoline-1,8-diazoimide.—The method of preparation of this diazoimide which we had interpreted[2] as 5-hydroxy-3-pyrido-[4,3,2-*de*]-cinnoline, has now been improved. A hot solution of 8-amino-2-hydroxylepidine



in 21 cc. of 10% hydrochloric acid was cooled, and the suspension of the finely divided hydrochloride was diazotized with sodium nitrite solution. The diazoimide separated as a brown amorphous precipitate. It was filtered, suspended in hot water, and the mixture heated on a steam-bath for one hour. The tan solid was filtered; the yield was 1.0 g. (47.5%); m. p. 236–237.5° (dec.).

The diazoimide could be recrystallized from boiling ethanol without decomposition, in contrast to other diazoimides (aryl azides)[13] which decompose under these conditions with the loss of one molecule of nitrogen. However, when our diazoimide was boiled in ethanol solution with "darco" a strong odor of acetaldehyde was noted, and 2-hydroxylepidine crystallized on dilution with water. It was identified by a melting point and a mixture melting point with an authentic sample.

Summary

1. The structure of the lepidine derivatives substituted in position 8 prepared by Johnson and Hamilton has been confirmed. These compounds are identical with those previously interpreted by us as the isomeric 5-substituted derivatives of lepidine.

2. The compound described by us as 5-hydroxy-3-pyrido-[4,3,2-*de*]-cinnoline is therefore 2-oxo-4-methylquinoline-1,8-diazoimide.

3. The 8-chloro derivatives of lepidine reported by Kermack and Muir apparently are 8-chloro derivatives of quinaldine.

(11) The values for hydrogen for our quinaldine derivatives ran high due to weather conditions. The daily test microanalyses of known compounds showed the same tendency.

The Synthesis of Phenolic Glycosides

BY THOMAS H. BEMBRY AND GARFIELD POWELL[1]

In the course of work in this Laboratory on derivatives of tetrahydrocannabinol, we had occasion to attempt the preparation of the glucoside. The method of Helferich and Schmitz-Hillebrecht,[2] employing zinc chloride or *p*-toluenesulfonic acid as catalyst in a fused mixture of phenol and sugar pentaacetate, was first used. It was not possible in the case of the difficultly accessible phenol, tetrahydrocannabinol, to use the large excess ordinarily employed in this procedure, and poor results were obtained when equimolar quantities of the reactants were used.

On the other hand, we found that tetrahydrocannabinol and a number of other phenols condense smoothly with fully acetylated sugars in benzene solution in the presence of moist phosphorus oxychloride, giving high yields of acetyl-

(1) We are indebted to Smith, Kline and French Laboratories, and one of us (T. H. B.) to the Julius Rosenwald Fund for generous grants to support this work.

(2) Helferich and Schmitz-Hillebrecht, *Ber.*, **66**, 378 (1933).

ated β-glycosides based on the amount of phenol used. We believe that this method gives distinct promise of general usefulness for the preparation of the phenolic glycosides.

The present work describes the application of the method to the preparation of the glycosides of a number of representative phenols, using various fully acetylated sugars. The preparation of the glucoside of tetrahydrocannabinol will be described elsewhere.

Experimental

Pure phosphorus oxychloride appeared to be unsatisfactory as a catalyst, and we used as a standard a reagent made by the addition of 1% by volume of distilled water to a redistilled analytical reagent grade of the material.

Procedure

A solution of phenol (1 mole), the fully acetylated sugar (1 mole), and the phosphorus oxychloride reagent (1/3 mole) in dry benzene was heated under reflux for three hours. After cooling, the reaction mixture was shaken with ice water, and the benzene layer was separated, washed with dilute sodium hydroxide solution, then with water, and then dried over calcium chloride. After evaporation of the solvent under reduced pressure, the residue was crystallized from an appropriate solvent, usually 95% ethanol.

In this way we prepared tetraacetyl-phenol-β-*d*-glucoside[2,3] (44%), m. p. 125–126° (cor.), $[\alpha]^{26}D$ −23° ($CHCl_3$), from phenol and β-pentaacetyl glucose; tetraacetyl-phenol-β-*d*-galactoside[2,4] (44%), m. p. 123–124° (cor.), $[\alpha]^{21}D$ −26° (C_6H_6), from phenol and β-pentaacetylgalactose; triacetylphenol-β-*d*-xyloside[2] (57%), m. p. 147–148° (cor.), $[\alpha]^{22}D$ −52° ($CHCl_3$), from phenol and tetraacetylxylose; tetraacetyl-α-naphthol-β-*d*-glucoside[3,5] (58%), m. p. 178–179° (cor.), $[\alpha]^{22}D$ −72° ($CHCl_3$), from α-naphthol and β-pentaacetyl glucose; and the new tetraacetyl-(*o*-hydroxydiphenyl)-β-*d*-glucoside[6] (35%), long white needles form 95% ethanol, m. p. 155–156° (cor.), $[\alpha]^{22}D$ −56° ($CHCl_3$), from *o*-hydroxydiphenyl and β-pentaacetylglucose.

Anal.[7] Calcd. for $C_{26}H_{28}O_{10}$: C, 62.40; H, 5.60. Found: C, 62.56; H, 5.59.

The latter derivative was deacetylated by the method of Zemplén[8] to give *o*-diphenyl-β-*d*-glucoside (90%) as shining needles from water, m. p. 76–77° (cor.), $[\alpha]^{25}D$ −42° (EtOH).

Anal.[7] Calcd. for $C_{18}H_{20}O_6$: C, 65.06; H, 6.02. Found: C, 64.81; H, 6.07.

For the preparation of tetraacetyl-phenol-β-*d*-fructoside,[2] m. p. 129–130° (cor.), $[\alpha]^{22}D$ −147° ($CHCl_3$), it was found that the reaction mixture darkened less and a somewhat better yield (33%) was obtained if (1) the benzene solution of the reactants was allowed to stand at room temperature for twenty-four hours, rather than being heated under reflux for three hours as in the general procedure, and (2) the benzene extract was washed with bicarbonate rather than sodium hydroxide.

As a further check on the identity of the known glycosides, quantitative carbon–hydrogen determinations were run[7] on all samples; satisfactory agreement with theory was obtained in each case.

Summary

A method for the condensation of phenols with the fully acetylated sugars in the presence of phosphorus oxychloride in benzene solution to form glycosides of phenols has been described. The physical constants of *o*-diphenyl-β-*d*-glucoside are reported.

Friedel–Crafts Acylations of Some Sterically Hindered Alkylbenzenes

BY G. F. HENNION AND S. F. DEC. MCLEESE[1]

Introduction

The Friedel–Crafts ketone synthesis has been applied to but few *s*-alkylbenzenes; there are no reports of such reactions with *p*-di-*s*-alkyl derivatives. Since the latter are sterically hindered with respect to the available ortho positions, have tertiary hydrogen in the side chains, which also are susceptible to rearrangement, migration and displacement in the presence of aluminum chloride, it was thought of interest to study the course of their reactions with acetyl and benzoyl chlorides. A variety of these hydrocarbons was available from previous investigations.[2]

We were especially interested in the possibility of acylating within the side chains since these contain labile hydrogen which might react in preference to hindered hydrogen of the ring. This was not observed, however, and it appears now that 1,4-di-*s*-alkylbenzenes substitute normally in the 2-position. Mono-*s*-alkylbenzenes react in the 4-position as expected. Reactions of *t*-butylbenzene, *p*-*s*-butyltoluene and *p*-di-*t*-butylbenzene were studied also to permit comparisons of the products with those obtained from the other hydrocarbons. An anomalous reaction was observed only with *p*-di-*t*-butylbenzene, which lost one butyl group, giving *p*-*t*-butylacetophenone in 72% yield.

In order to establish structures for the various ketones, it was necessary to oxidize them to known or identifiable benzene-carboxylic acids. With sodium dichromate–sulfuric acid–acetic acid mixture the alkyl and dialkylacetophenones gave terephthalic acid. Oxidation of dialkylacetophenones with dilute nitric acid yielded the corresponding 4-alkylisophthalic acids, thus proving that the previous dichromate oxidations had completely removed the acetyl group in each case. Nitric acid converted *p*-*s*-alkylacetophenones to *p*-*s*-alkylbenzoic acids. In further confirmation of the assigned structures, 2,5-di-*s*-butylacetophenone was degraded to trimellitic acid by oxidation with chromic acid followed by heating with nitric acid in a sealed tube. The *p*-alkylbenzophenones and 2,5-dialkylbenzophenones were readily converted to *p*-benzoylbenzoic acid and benzoylterephthalic acid, respectively.

The non-identity of *p*-*s*-butylacetophenone and the *p*-*t*-compound, coupled with the established identity of *p*-*s*-butylbenzoic acid with an authentic sample, serves to show that the *s*-alkyl groups are not altered in structure under the conditions of the experiments.

The various ketones are described in Table I and some of the oxidation products in Table II. These list the new compounds only. It is to be noted (Table I) that there is considerable exaltation in the molecular refractions, characteristic of compounds of this type.

Experimental

Acetophenones.—These were prepared in 0.2- to 0.8-mole quantities after the manner described in "Organic

(1) Present address, Webster College, St. Louis, Mo.

(2) Hennion, *et al.*, THIS JOURNAL, **62**, 1145 (1940); **63**, 2603 (1941).

Syntheses."[3] The monoalkylbenzenes reacted even at −10°; with the dialkylbenzenes it was necessary to heat to the reflux temperature of carbon disulfide for several hours. Products were fractionated through a 40-cm. column to constant n_D. *p*-*t*-Butylacetophenone from *t*-butylbenzene had b. p. 133–134° (11 mm.); $n^{20}D$ 1.5199; d^{20} 0.9642; from *p*-di-*t*-butylbenzene, b. p. 134° (11 mm.); $n^{20}D$ 1.5195; d^{20} 0.9635. The two semicarbazones had identical m. p. and mixed m. p., 220–221° (uncor.).

Benzophenones.—The method of Gattermann and Wieland[4] was used. Products are semi-viscous, slightly yellow liquids. They were distilled twice from glass wool in a low side-arm Claisen flask, followed by fractionation by means of a horizontal flask molecular still.[5]

Oxidations with Dichromate.—Two-gram samples of alkyl- and dialkylacetophenones were heated at 65–75° with 32 g. of sodium dichromate in 60 cc. of acetic acid containing 44 g. of sulfuric acid. After diluting with water and standing overnight, the terephthalic acid was filtered, washed and dried. Neutralization equivalent, calcd., 83; obs. 83.5. Dimethyl ester, m. p. and mixed m. p., 139–140°.

Oxidation of Monoalkylacetophenones with Nitric Acid.—A 6-g. sample was refluxed with 600 cc. of dilute nitric acid (d. 1.09) for from eight to forty-eight hours. Terephthalic acid was removed from the hot solution and the *p*-*s*-alkylbenzoic acid allowed to crystallize.[6] The latter was purified by heating for four hours in 15 cc. of acetic acid containing 4 g. of tin and 1 g. of zinc dust and a little hydrochloric acid, to remove nitrated impurities. Several crystallizations from dilute alcohol then gave pure products.

Oxidation of Dialkylacetophenones with Nitric Acid.—Six-gram samples were boiled with 600 cc. of nitric acid (d. 1.09) for several days and the products purified as described above.

Trimellitic Acid.—An 11.6-g. sample of di-*s*-butylacetophenone was oxidized with 75 g. of chromic acid (added in 1-g. portions over a period of thirty-five hours) in 170 g. of acetic acid. The solution was poured into ice-water and extracted three times with ether. The extract was distilled, yielding a solid residue which could not be purified. Two grams of this material was heated with 10 cc. of 1:2 nitric acid in a sealed tube for twenty-four hours. After the terephthalic acid was separated, trimellitic acid crystallized on cooling. It is very soluble in water; neutralization equivalent, calcd., 70; obs., 76.

Oxidation of Benzophenones.—When boiled with dilute nitric acid, *p*-*s*-butyl- and *p*-*s*-amylbenzophenone gave *p*-benzoylbenzoic acid, m. p. and mixed m. p. 192–193° (cor.). The *s*-octyl and *s*-dodecyl derivatives were not appreciably affected in this manner. Oxidation of 3-g. samples was accomplished by heating for sixteen hours with 20 g. of potassium dichromate in 90 g. of water containing 30 g. of sulfuric acid. 2,5-Di-*s*-butylbenzophenone was oxidized with dichromate–sulfuric acid–acetic acid mixture at 40°: benzoylterephthalic acid, m. p. 283° (cor.); neutralization equivalent, calcd., 135; obs., 137.

Ketone Derivatives.—Monoalkylacetophenones yielded semicarbazones in the usual manner. Prolonged heating was required to derivatize the dialkyl compounds. The new acetophenone semicarbazones with their melting points are: *p*-*s*-butyl, 190–191°; *p*-*s*-amyl, 173–174°; *p*-*s*-octyl, 144–145°; 2-methyl-5-*s*-butyl, 114–115°; 2,5-di-*s*-butyl, 160–161°; 2,5-di-*s*-amyl, 149–150°. Semicarbazones could not be obtained from the benzophenones.

Summary

1. *s*-Alkyl and *p*-di-*s*-alkylbenzenes react with acetyl and benzoyl chlorides in the presence of aluminum chloride without disturbance of the alkyl groups.

2. When *p*-di-*t*-butylbenzene reacted with acetyl chloride one *t*-butyl group was displaced by acetyl.

3. Structures of the various ketones were proved by oxidation.

4. A number of new substituted acetophenones, benzophenones and benzene carboxylic acids are reported and described.

The Preparation and Alkylation of 1,4-Dimesityl-3-methyl-1,2,4-butanetrione Enol

BY ROBERT E. LUTZ AND DANIEL H. TERRY[1]

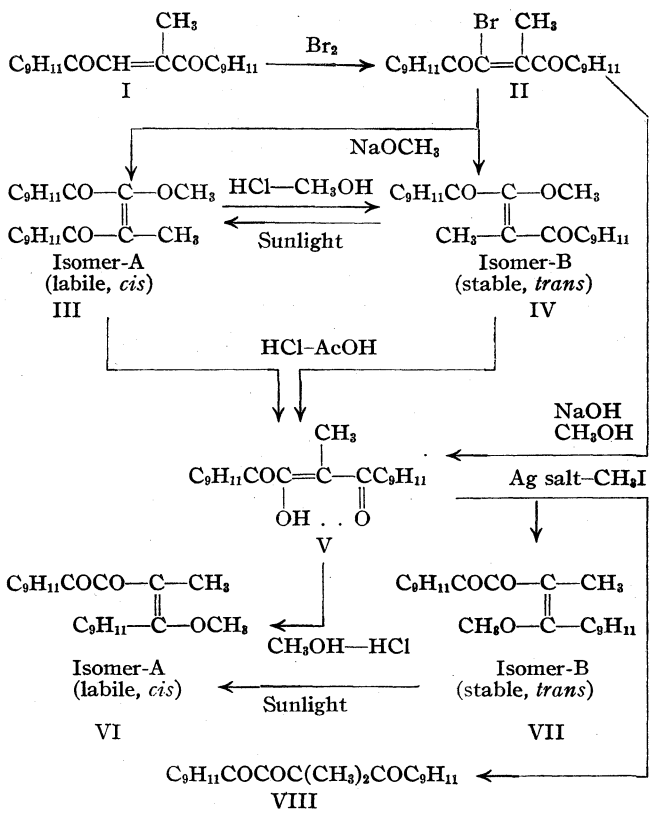
The substitution of halogen, alkyl, phenyl or benzoyl on the 3-carbon of 1,4-diphenyl-1,2,4-butanetrione enol promotes cyclization and stabilizes the hydroxyfuranone form. The effect of these groups on the keto–enol tautomerism is obscured because of the cyclization. On the other hand, the 1,4-dimesityl compound and its bromo derivative[2] do not cyclize because of the excessive steric hindrance, and in these types the keto–enol reactions can be investigated without this complication. It seemed desirable to study a few more examples of this type, and the present report deals with the preparation and alkylation of the 3-methyl derivative.

The 3-methyl triketone enol (V) was first obtained as a minor product in the alkylation of the silver salt of 1,4-dimesityl-1,2,4-butanetrione enol.[3] A better method of preparation has now been devised which also demonstrates the structure of the product. This synthesis started from dimesitoylmethylethylene (I) which was made from mesaconyl chloride by the Friedel–Crafts reaction. Bromination gave *cis*-bromodimesitoylmethylethylene (II).[4] The bromo compound reacted with sodium methoxide to give two enol methyl ethers which from their mode of formation must be the *cis*- and *trans*-isomers (III and IV). Acid hydrolysis of these ethers, or alkali hydrolysis of the bromo unsaturated diketone itself (II), gave the desired triketone enol (V) in good yield.

The triketone enol (V) is yellow in color, gives a red color with ferric chloride and reacts rapidly with bromine and with diazomethane. It is strongly acidic as is shown by its solubility in sodium carbonate and it gives an unstable brilliant yellow silver salt. It shows no tendency to cyclize to a hydroxyfuranone.

The methylation with diazomethane gave four isomeric compounds. Two of these proved to be the *cis*- and *trans*-2-methyl ethers (III and IV) which were obtained as mentioned above by the action of sodium methoxide on the bromo unsaturated diketone (II). One was assigned the *cis*-configuration (III) on the basis of its instability and conversion by means of methanolic hydrogen chloride into the other which was stable and therefore was assumed to be *trans* (IV). The inversion in the opposite direction from *trans* to *cis* was accomplished by exposure to sunlight in pure methanol.

The other two of the four isomeric methylation products were shown also to be enol ethers by the facile acid hydrolysis to the enol (V). By difference they must be the structurally isomeric *cis*- and *trans*-4-methyl ethers (VI and VII). The *cis–trans* relationship was confirmed by the inversion of one (the stable) into the other (the labile) by the action of sunlight; unfortunately, inversion in the opposite direction was not accomplished. We are assuming tentatively that the labile form



(1) du Pont Fellow, 1939–1940. Present location, Jackson Laboratory, du Pont de Nemours Co., Wilmington, Del.

(2) (a) Lutz and Wood, THIS JOURNAL, **60**, 705 (1938); (b) Lutz and Terry, *J. Org. Chem.*, **7**, 274 (1942).

(3) Lutz and Terry, *ibid*, **7**, 320 (1942).

(4) Lutz and Terry, THIS JOURNAL, **64**, 2426 (1942).

is that one which has the mesityl and mesitylglyoxyl groups on the same side of the molecule, namely, VI.

One striking fact was observed in this series, namely, that the enol (V) reacted readily and quantitatively with methanolic hydrogen chloride to give the *labile* 4-methyl ether (VI). This type of reaction does not take place with dimesitylbutanetrione enol itself (the diphenyl analogs all give the alkoxyfuranones under these conditions). There is analogy for direct etherification of a strongly acidic enolic hydroxyl in the case of hydroxynaphthoquinone, where etherification to 2-methoxy-*p*-naphthoquinone takes place under these conditions.[5] In the case in hand it is perhaps surprising that the labile 4-methyl ether should be the one formed.

The formation of all of the four possible isomeric ethers in the reaction between the enol (V) and diazomethane calls to mind the formation of three of the four possible isomeric ethers in the similar methylation of the dimesitylbutanetrione enol itself.[3] It is clear from these results that there is no simple stereochemical relation between the products of methylation and the presumably chelated enols from which they were made.

Alkylation of the silver salt of the enol (V) was of interest because it was expected to produce results closer to those obtained in the case of dimesitylbutanetrione silver enolate than to those obtained in the case of the diphenyl analog. The dimesityl triketone silver enolate underwent chiefly oxygen-alkylation at the 4-oxygen whereas the diphenyl analog was found to undergo mainly carbon-alkylation. The results in the present case were approximately as predicted. Dimesitylmethylbutanetrione silver enolate reacted with methyl iodide to give a mixture of carbon and oxygen-alkyl derivatives. The carbon-alkyl derivative (VIII) was obtained in a yield of 30%. The oxygen-alkyl derivative was obtained in 65% yield and was the expected 4-enol methyl ether, but it was the stable stereoisomer-B (VII).

In summary of the alkylation results it may be said that diazomethane reacts with the enol to give all four 2- and 4-enol ethers; methanolic hydrogen chloride gives the labile 4-enol ether; and the silver salt with methyl iodide gives the stable 4-enol ether along with a lesser but sizeable yield of the carbon-alkyl derivative. The marked tendency to react at the 4-oxygen is noteworthy.

(5) Fieser, THIS JOURNAL, **48**, 2922 (1926).

Experimental

1,4-Dimesityl-3-methyl-1,2,4-butanetrione Enol (V).—A suspension of 4.5 g. of the *cis*-2-enol methyl ether (III) in 40 cc. of concd. acetic acid, 10 cc. of concd. hydrochloric acid and 5 cc. of water was stirred vigorously at room temperature for three hours. The solution became bright yellow, and 4.25 g. (98%) of bright yellow needles separated (m. p. 120–122°). When the reaction mixture was refluxed the yields were smaller and a larger amount of non-crystalline material formed. Repeated crystallizations from methanol brought the melting point to 124.5–125°.

Anal. Calcd. for $C_{23}H_{26}O_3$: C, 78.86; H, 7.5. Found: C, 78.40, 78.81; H, 7.23; 7.39.

Alternative preparations are as follows.

(a) A suspension of 1.5 g. of the *cis*-bromo unsaturated diketone (II) in 75 cc. of 90% methanol and 1.5 g. of sodium hydroxide was refluxed for ten minutes after solution was complete. The purple solution was acidified with dilute hydrochloric acid, diluted with water and extracted several times with ether. The ether extract was shaken four times with 25-cc. portions of 5% sodium hydroxide. Acidification of the alkaline solution and extraction with ether removed the enol which was isolated as a partly crystallized residue upon evaporation of the solvent. Crystallization from ethanol gave 0.8 g. (64%).

In a similar experiment using 80% methanol and refluxing for one hour, largely non-crystalline material was obtained along with a 30% (by weight) yield of a colorless solid which upon repeated crystallization from ethyl acetate melted at 234° (it contained no halogen). *Anal.* C, 81.98; 81.73; H, 6.90; 6.77. This compound has not been investigated.

(b) The action of methyl iodide on the dimesitylbutanetrione silver enolate in isopropyl ether (refluxing for two hours) gave the carbon-methyl derivative (V) in 7% yield.

(c) Hydrolysis of the *cis*-2-enol methyl ether by means of saturated methanolic hydrogen chloride gave the enol (V) in 81% yield.

The enol (V) gave a deep maroon color with alcoholic ferric chloride. It is soluble in aqueous sodium carbonate.

The sodium enolate did not crystallize from a methanol solution. It proved to be quite soluble in water and alcohol, in contrast to the sodium salt of the parent dimesitylbutanetrione enol. **The silver salt** (bright yellow) was precipitated from an aqueous or methanolic solution of the sodium salt by the addition of silver nitrate; it darkened rapidly on standing and was black within twenty minutes.

Hydroxylamine in pyridine or in methanol was without action, as also was semicarbazide and 2,4-dinitrophenylhydrazine in ethanol.

Methylation by Diazomethane.—Two grams of the enol (V) was added to 50 cc. of ether containing 0.4 g. of diazomethane. After the vigorous reaction subsided the solution was allowed to stand overnight and was washed with dilute hydrochloric acid and with water. Upon evaporation of the ether in a current of dry air, an oil was obtained from which digestion with ethanol produced a crystalline precipitate (0.72 g. or 44%) which proved to be the main product, the 2-enol methyl ether-A (*cis*) (III) (described under this

compound). A second fraction (0.18 g., 9%) was then obtained and shown to be the *trans*-2-enol methyl ether (IV) (described under that compound). Upon standing the filtrate deposited a third compound (yield 15%) which was found to be the *cis*-4-enol methyl ether (VI) (described under that compound). Careful manipulation of the residues produced a fourth and more soluble isomer in a 30% yield. This was obtained from 90% ethanol and was shown to be the 4-enol methyl ether-B (*trans*) (VII) (described under that compound).

Alkylation of the Silver Enolate with Methyl Iodide.—A methanol solution of 1.2 g. of the enol (V) and one equivalent of sodium methoxide was treated with 3.5 cc. of methyl iodide. The mixture was stirred mechanically and maintained at 0°. An aqueous solution (65 cc.) of 2% silver nitrate was added slowly and stirring was continued for three hours while the mixture was allowed to come to room temperature. The mixture was then heated on a water-bath at 60° for one hour, filtered from silver iodide, diluted with water and extracted with ether. The ether solution was shaken three times with 20-cc. portions of 10% sodium hydroxide which removed the unchanged enol present (0.34 g. was recovered). Evaporation of the ether gave a bright yellow solid which was washed with methanol; yield 0.58 g. (65%). This proved to be the 4-enol methyl ether-B (*trans*) (VII). From the methanol solution 0.3 g. (37%) of bright yellow crystals of the dimethyltriketone (VIII) was isolated (see that compound).

***cis*-1,4-Dimesityl-3-methyl-1,2,4-butanetrione 2-Enol Methyl Ether (III).**—This compound was obtained as described under the methylation of the enol with diazomethane (yield 44%). It was obtained in better yield as follows.

A mixture of 2.5 g. of *cis*-bromodimesitoylmethylethylene (II) and 50 cc. of methanol containing 2 g. of dissolved sodium was stirred for two hours at room temperature. The colored solution was concentrated and diluted with water slowly; 0.22 g. (12%) of pale yellow crystals separated and was identified as the *trans*-2-enol methyl ether-B (described below). Further concentration of the filtrate produced 1.08 g. (58%) of a more soluble and colorless product. This was recrystallized repeatedly from methanol and melted at 134.5–135°. This latter compound was obtained in almost quantitative yield by exposing a methanol solution of the *trans*-isomer-B (V) to the action of sunlight for eight hours.

Anal. Calcd. for $C_{24}H_{28}O_3$: C, 79.12; H, 7.74; OCH_3, 8.5. Found: C, 78.93; H, 7.63; OCH_3, 8.79, 8.44.

Hydrolysis of 4 g. in a mixture of concd. acetic acid, 10 cc. of concd. hydrochloric acid and 5 cc. of water, at room temperature (three hours) or under refluxing for fifteen minutes, gave nearly quantitative yields of the enol (V).

The enol ether (III) was recovered unchanged after (a) exposure to sunlight for six hours in chloroform containing a trace of iodine; and (b) treatment with alcoholic sodium acetate under reflux for seven hours.

Treatment of 0.5 g. of the compound for five days with saturated methanolic hydrogen chloride gave two crystalline fractions. The first (0.3 g.) was the *trans*-isomer-B (IV), and the second (0.15 g.) the enol (V).

***trans*-1,4-Dimesityl-3-methyl-1,2,4-butanetrione 2-Enol Methyl Ether-B (IV).**—This compound was obtained as described above in 12% yield by the action of sodium methoxide on the *cis*-bromo unsaturated diketone (II), and in 9% yield by the action of diazomethane on the enol (V). It was obtained also in 60% yield by the action of saturated methanolic hydrogen chloride on the *cis*-isomer-A (III) at room temperature for five days (as described above). The *trans*-isomer-B was purified by repeated crystallizations from ligroin, 85% methanol, and methanol; pale yellow crystals of m. p. 156.5–157°.

Anal. Calcd. for $C_{24}H_{28}O_3$: OCH_3, 8.52. Found: OCH_3, 8.48.

Hydrolysis of 0.5 g. by a mixture of 10 cc. of concd. acetic acid, 3 cc. of concd. hydrochloric acid and 2 cc. of water at room temperature for three hours gave 0.3 g. (6%) of nearly pure enol (V).

***cis*-(?)-1,4-Dimesityl-3-methyl-1,2,4-butanetrione 4-Enol Methyl Ether-A (VI).**—A solution of 0.45 g. of the enol (V) in saturated methanolic hydrogen chloride was allowed to stand for five days at room temperature. Evaporation in an air stream gave 0.44 g. (92%) of product which was crystallized repeatedly from methanol and obtained as colorless prisms of m. p. 142°.

Anal. Calcd. for $C_{24}H_{28}O_3$: C, 79.12; H, 7.74; OCH_3, 8.52. Found: C, 78.25; H, 7.99; OCH_3, 8.33.

This compound was obtained also in 15% yield in the methylation of the enol with diazomethane, as described above. It was also obtained by the action of sunlight for seven hours on a methanol solution of the *trans*-isomer-B (VII).

Hydrolysis of 0.25 g. by 25 cc. of concd. acetic acid, 4 cc. of concd. hydrochloric acid and 3 cc. of water under reflux for fifteen hours gave 0.2 g. (83%) of nearly pure enol (V). Treatment of the ether (VI) with methanolic potassium hydroxide under reflux for five hours was without effect. This ether was not changed by exposure to sunlight for six hours in chloroform containing a trace of iodine.

***trans*-(?)-1,4-Dimesityl-3-methyl-1,2,4-butanetrione 4-Enol Methyl Ether-B (VII).**—This isomer was prepared as described above by the action of methyl iodide on the silver enolate and also by the action of diazomethane on the enol. Upon repeated crystallization from methanol it was obtained as pale yellow needles of m. p. 119.5–120°.

Anal. Calcd. for $C_{24}H_{28}O_3$: C, 79.12; H, 7.74; OCH_3, 8.52. Found: C, 78.57; H, 8.09; OCH_3, 8.79.

Hydrolysis of 0.25 g. in the concd. acetic–hydrochloric acid–water mixture (refluxing for one and one-half hours) gave 0.21 g. (81%) of nearly pure enol (V). The compound was recovered unchanged after treatment with (a) methanolic potassium hydroxide (refluxing for ten hours) and (b) saturated methanolic hydrogen chloride (for three days at room temperature).

1,4-Dimesityl-3,3-dimethylbutanetrione-1,2,4 (VIII).—This bright yellow compound was obtained as described above in the methylation of the silver enolate of (V) by methyl iodide. Repeated crystallizations from ethanol brought the melting point to 132.5–133°.

Anal. Calcd. for $C_{24}H_{28}O_3$: C, 79.12; H,7 .74; OCH_3, 0. Found: C, 79.28, 79.41; H, 7.60, 7.85; OCH_3, 0.

The compound was recovered unchanged when treated with (a) the concd. acetic–hydrochloric acid–water mixture

(refluxing for thirty minutes) and (b) hydroxylamine in methanol (refluxing for ten hours).

Summary

1,4-Dimesityl-3-methyl-1,2,4-butanetrione enol has been synthesized from mesaconyl chloride.

Methylation with diazomethane gave all of the four possible methyl ethers. The *cis–trans* 2-enol methyl ethers were made in another way by the action of sodium methoxide on bromodimesitoylethylene. The configurations were determined by interconversions and relative stability. The labile 4-enol methyl ether was obtained in a second way by acid catalytic methylation of the enol; and the stable 4-enol methyl ether, along with the carbon-methyl derivative, was obtained by alkylation of the silver enolate.

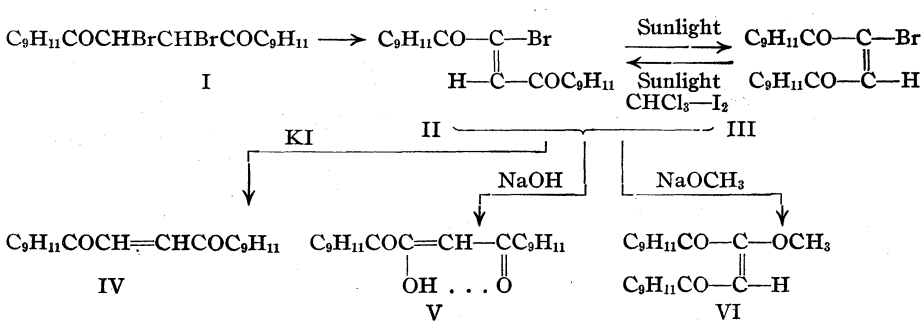
The Stereoisomeric Bromo 1,4-Dimesityl Unsaturated 1,4-Diketones

BY ROBERT E. LUTZ AND DANIEL H. TERRY[1]

This report deals with the preparation of some halogen derivatives which were made in connection with the work on 1,4-dimesityl and 1,4-dimesityl-3-methyl 1,2,4-butanetrione enols.

The 1,4-Dimesityl Series

The yellow *trans*-bromodimesitoylethylene (II) is made easily from dimesitoylethylene dibromide (I).[2] It is converted by the action of sunlight into a colorless isomer which, therefore, must be the *cis*-isomer (III). Conversion back into the *trans*-isomer was brought about by the action of sunlight on a chloroform solution containing a trace of iodine as a catalyst.



Both *cis*- and *trans*-isomers react with methanolic potassium hydroxide to give the triketone enol (V) and with sodium methoxide to give the *cis*-2-enol ether (VI). In the latter reaction no consistent stereochemical orientation is involved. 1,4-Addition probably occurs, but the intermediate 4-enolates, while theoretically capable of existing and maintaining individual configurations, would hardly be expected to do so during this reaction under alkaline conditions.[3]

The action of potassium iodide on the bromo unsaturated diketones in both cases gave *trans*-dimesitoylethylene (IV), a somewhat surprising reaction which must be attributed to the fact that these compounds contain the conjugated α-bromoketone system. The halogen in the corresponding dimesitylmethyl series is not reducible under the same conditions, however, due perhaps to an increase in the total steric hindrance by the substituted methyl group.

Chlorination of dimesitoylethylene (IV) was carried out to verify certain compounds and reactions which had been previously reported.[2,4] Phenyl iodochloride in cold chloroform converted the unsaturated diketone into the dichloride (VII) which had previously been isolated in extremely small amounts when free chlorine was used.[2] This dichloride when subjected to the action of boiling ethanol lost hydrogen chloride and gave the yellow *trans*-dimesitoylchloroethylene (IX) which can be made by the action of hydrochloric acid on dimesitoylethylene oxide[4] and by the action of phosphorus pentachloride on dimesitoylglycol (X).

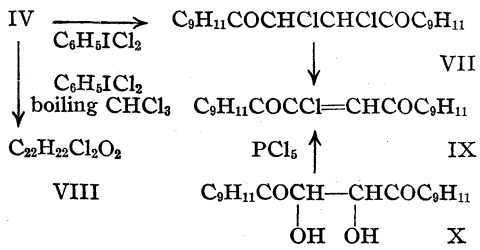
(2) Lutz, THIS JOURNAL, **48**, 2905 (1926).

(3) *Cf.* the facile rearrangement of the labile 4-enol ether [Lutz and Terry, *J. Org. Chem.*, **7**, 320 (1942)].

(4) Lutz and Wood, THIS JOURNAL, **60**, 229 (1938).

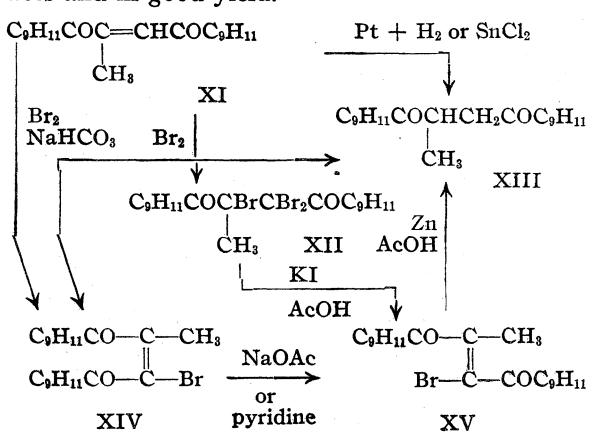


When dimesitoylethylene was treated with phenyl iodochloride in boiling chloroform, a dichloro unsaturated diketone (VIII) was obtained which was shown to involve nuclear substitution, by the resistance toward reduction by zinc and acetic acid of at least one of the halogens. This compound evidently is a derivative of IX.

The 1,4-Dimesityl-3-methyl Series

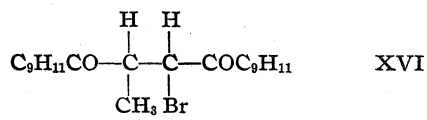
The unsaturated diketone of this series (XI) does not give a stable dibromide but reacts slowly in chloroform solution to give what appears to be the *cis*-bromo unsaturated diketone (XIV), along with two other products, the saturated diketone (XIII) and a tribromo compound which is believed to be XII. Possibly the unstable dibromide and hydrobromide are involved and, in the presence of hydrogen bromide generated during the reaction, act as α-bromoketones to give up bromine and simultaneously to undergo reduction.[5]

In order to avoid complications due to secondary bromination the same reaction was carried out in the presence of an excess of powdered sodium bicarbonate to remove hydrogen bromide. Under these conditions the *cis*-bromo unsaturated diketone was obtained relatively free from by-products and in good yield.



The structure of the *cis*-bromo unsaturated diketone (XIV) was proved by analysis and by the facile rearrangement under the influence of sodium acetate or pyridine into a stable isomer which consequently must be the *trans*-form (XV). The *trans*-compound was then reduced by means of zinc and acetic acid to the saturated diketone (XIII) which was obtained also by direct reduction of the unsaturated diketone (XI).

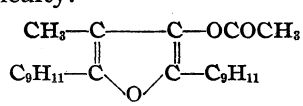
The conversion of the *trans*-unsaturated diketone (XI) to the labile *cis*-bromo unsaturated diketone (XIV) by bromination presumably involves the intermediate formation of an unstable dibromide. Obviously, in view of the production of the *labile*-stereoisomer under these circumstances this transformation is best interpreted as a *trans*-addition of bromine to give an unstable dibromide of the configuration (XVI), followed by *trans*-elimination of hydrogen bromide.



XVI

The structure of the tribromo derivative (XII) was deduced from analysis and the conversion by means of potassium iodide into the *trans*-bromo unsaturated diketone (XV).

Incidental to this work the acetoxyfuran (XVII) was made from the unsaturated diketone (XI). When the usual combination, acetic anhydride and sulfuric acid, was employed, there was produced a sulfur containing compound of empirical formula $C_{23}H_{26}O_5S$; however, when acetyl chloride was substituted for acetic anhydride, as was done in the case of dimesitoylethylene itself, the acetoxyfuran was then obtained without difficulty.



XVII

Experimental

The 1,4-Dimesityl Series

***trans*-2-Bromo-1,4-dimesityl-2-butanedione-1,4 (1,2-dimesitoylbromoethylene) (II).**—The best preparation has previously been reported.[6] The bromo compound has now been obtained in other ways as follows:

(a) A suspension of 5 g. of the dibromide of dimesitoylethylene (I) and 1.5 g. of sodium benzoate in 75 cc. of absolute ethanol was refluxed for one and one-half hours. On cooling 0.85 g. of unchanged material separated. On diluting the filtrate with water 3.5 g. (84%) of crude products separated.

(b) A mixture of 5 g. of dibromide (I), 3 g. of freshly prepared silver benzoate, and 50 cc. of isopropyl ether was

(5) *Cf.* Couper and Lutz, *J. Org. Chem.*, **7**, 79 (1942).

(6) Conant and Lutz, THIS JOURNAL, **47**, 881 (1925).

refluxed for eight hours and filtered. Evaporation gave 2.8 g. (55%) of II.

(c) A solution of 0.2 g. of the *cis*-isomer (III) in chloroform to which a crystal of iodine had been added, was exposed to sunlight for six hours; 0.05 g. of pure *trans*-isomer (II) was recovered and identified.

The following experiments were performed on the *trans*-compound (II):

(a) Treatment of 2.0 g. in 70% ethanol with 1 g. of potassium hydroxide under refluxing for one hour gave 1.6 g. (94%) of nearly pure enol (V).

(b) Treatment with a 30:5:3 concd. acetic acid–concd. hydrochloric acid–water mixture under refluxing for two hours was without result.

(c) Exposure of a solution of one gram in ethanol to sunlight for eight hours gave 0.8 g. of the *cis*-isomer.

(d) A solution of 0.15 g. in concd. acetic acid with potassium iodide reacted slowly on standing. Iodine was liberated. Upon diluting with water 0.1 g. of dimesitoylethylene separated and was identified.

(e) Acetic anhydride and a small amount of concd. sulfuric acid at 100° for five minutes was without action.

(f) A solution of sodium methoxide was added under stirring to a methanol solution of 0.75 g. of II and the reaction was allowed to continue at room temperature for thirty minutes. Dilution with water gave 0.57 g. (62%) of nearly pure product which was recrystallized and identified as the *cis*-2-enol methyl ether (VI).

***cis*-2-Bromo-1,4-dimesityl-2-butenedione-1,4 (1,2-dimesitoylbromoethylene) (III).**—An ethanol solution of 1 g. of the *trans*-isomer (II) was bleached by exposure for eight hours to sunlight. Upon evaporation and crystallization 0.8 g. of colorless *cis*-isomer was isolated. After repeated crystallization from 70% ethanol it melted at 88–89°.

Anal. Calcd. for $C_{22}H_{23}BrO_2$: C, 66.2; H, 5.8. Found: C, 66.2; H, 6.1.

The action of 0.2 g. of **potassium hydroxide** in 30 cc. of 70% methanol on 0.3 g. of III (refluxing for one hour) gave 0.23 g. (92%) of nearly pure enol (V).

Potassium iodide in cond. acetic acid at 75° converted this compound in good yield into dimesitoylethylene.

Acetic anhydride and a trace of concd. sulfuric acid at 100° for five minutes was without effect.

Sodium methoxide in methanol acting on 0.15 g. of III at room temperature for thirty minutes gave 0.11 g. (83%) of nearly pure *cis*-2-enol methyl ether (VI).

2,3-Dichloro-1,4-dimesitylbutanedione-1,4 (Dimesitoylethylene dichloride) (VII).—A solution of 2 g. of the *trans*-unsaturated diketone (IV) in 50 cc. of dry chloroform was treated with 1.8 g. of phenyliodochloride; the mixture was allowed to stand in a glass-stoppered flask for five days at room temperature, with occasional shaking. Evaporation of the resulting solution gave a colorless solid residue which was washed with ethanol; yield 0.94 g. (39%). Repeated crystallization from ethyl acetate brought the melting point to 209° (decomp.) (*cf.* ref. 2).

Anal. Calcd. for $C_{22}H_{24}Cl_2O_2$: C, 67.52; H, 6.18; Cl, 18.12. Found: C, 67.51, 66.52; H, 6.16, 5.71; Cl, 18.04.

***trans*-2-Chloro-1,4-dimesityl-2-butenedione-1,4 (Dimesitoylchloroethylene) (IX).**—The compound has been reported previously.[4] It may be obtained also as follows:

(a) A solution of 0.2 g. of the dichloro saturated diketone (VII) in 25 cc. of ethanol was refluxed for eight hours. The yellow solution was evaporated and 0.17 g. (95%) of nearly pure product was obtained. It was recrystallized and identified by mixture melting point with a sample prepared previously.[4]

(b) A solution of 0.3 g. of dimesitoylethylene glycol (X) in dry chloroform was treated with 0.2 g. of phosphorus pentachloride. A vigorous reaction took place with evolution of hydrogen chloride. The chloroform was evaporated, water added and the organic material was extracted with ether. Upon evaporation and crystallization of the residual oil from ethanol 0.2 g. of the chloro unsaturated diketone was obtained in nearly pure condition. It was identified by mixture melting point.

A Dichlorodimesitoylethylene (VIII).—A mixture of 10 g. of dimesitoylethylene, 8.6 g. of phenyliodochloride and 50 cc. of dry chloroform was refluxed for three hours. Concentration under reduced pressure gave 0.4 g. of bright yellow solid which was purified by repeated crystallization from ethyl acetate; yellow needles; m. p. 209.5–210°.

Anal. Calcd. for $C_{22}H_{22}Cl_2O_2$: C, 67.84; H, 5.65. Found: C, 68.06, 68.08; H, 5.67, 5.44.

Reduction of a small sample by zinc dust and concd. acetic acid gave a new chlorine containing compound of m. p. 166–167° which was not purified or investigated further. This sufficed to show that at least one of the chlorines of VIII was in a mesityl nucleus.

The 1,4-Dimesityl-2-methyl Series

***trans*-1,4-Dimesityl-2-methyl-2-butenedione-1,4 (1,2-Dimesitoylmethylethylene) (XI).**—The following modification of the earlier procedure[7] was used. Thirty grams of mesaconyl chloride was added dropwise over two hours to a well-stirred mixture of 120 cc. of carbon disulfide, 60 g. of finely ground anhydrous aluminum chloride and 48 g. of mesitylene. The mixture was then warmed on a water-bath for twenty minutes and poured into ice and hydrochloric acid. The carbon disulfide layer was separated and distilled, and the residue crystallized from ethanol; yield 54.6 g. (91%) melting at 88–90°. Recrystallized material melting at 96° was used in succeeding experiments.

The action of sunlight (two days) on a methanol solution was without result. Bromination according to the earlier method[8] gave much non-crystalline material and small yields of solids which were mixtures. Attempts to isolate a dibromo compound failed and it appeared likely that this desired compound was unstable and easily converted into the unsaturated bromo diketone through loss of hydrogen bromide. A typical experiment is as follows: a chloroform solution (15 cc.) of 7.2 g. of bromine was added dropwise with mechanical stirring to a solution of 15 g. of (XI) in 20 cc. of chloroform at −10°. Copious evolution of hydrogen bromide was observed and the color of bromine was discharged slowly. After the addition the mixture was allowed to stand for fifteen minutes and was evaporated under reduced pressure. The solid which appeared was washed with petroleum ether and filtered (18 g. melting at 124–126°). A portion of this (0.5 g.) upon

(7) Lutz and Taylor, THIS JOURNAL, **55**, 1168 (1933).

(8) Taylor, Dissertation, University of Virginia, 1932.

distillation in the vacuum oven at 130° gave a crystalline deposit on the cold-finger condenser of 0.3 g. (m. p. 140–142°) which was identified as the *cis*-bromo unsaturated diketone (XIV). The residue from this distillation was crystallized from ethanol and gave 0.15 g. of colorless solid of m. p. 180–182°. This is described below as tribromodimesitylbutanedione (XII). Concentration of the petroleum ether washings of the crude product (above) gave an oil which contained little halogen. This material was finally induced to crystallize by vacuum distillation at 135° onto a cold-finger condenser, followed by manipulation and seeding of the distillate. This product (0.33 g.) melted at 58–60° and was identified as the saturated diketone (XIII).

Chlorination attempts, using phenyl iodochloride, were unsuccessful.

1,4-Dimesityl-2-methylbutanedione-1,4 (XIII).—A solution of 3 g. of the unsaturated diketone (XI) in 100 cc. of ethanol was hydrogenated using 0.15 g. of platinum oxide. One molecule was absorbed rapidly. Two drops of piperidine were added and the mixture was allowed to stand for six hours under hydrogen. Filtration and evaporation gave an oil, which, upon vacuum distillation onto a cold-finger condenser and manipulation in solvents, was finally induced to crystallize. Upon repeated recrystallization from ethanol it melted at 60.5°.

Anal. Calcd. for $C_{23}H_{28}O_2$: C, 82.14; H, 8.33. Found: C, 81.72; H, 8.49.

This same compound was obtained by reduction of the unsaturated diketone (XI) by means of stannous chloride in a 3:1 mixture of concd. acetic and hydrochloric acids, and also by reduction of the *trans*-bromo unsaturated diketone (XV) by means of zinc and concd. acetic acid.

Attempts to obtain a crystalline furan through the use of hydriodic acid (sp. gr. 1.7), or refluxing acetic acid continuously saturated with hydrogen chloride, were without success. The use of acetic anhydride and sulfuric acid led to a compound of m. p. 102–103° (crystallized from ligroin) which was shown not to be the furan by analyses. This was not studied further.

2,2,3-Tribromo-1,4-dimesityl-3-methylbutanedione-1,4 (XII).—The crude material obtained as described above was partially purified by vacuum evaporation of the impurities consisting of compounds containing less halogen, and was further purified by repeated crystallization from an ethanol–ethyl acetate mixture; m. p. 188°.

Anal. Calcd. for $C_{23}H_{25}O_2Br_3$: C, 48.17; H, 4.36. Found: C, 47.85; H, 4.42.

This compound was isolated in several experiments from mixtures obtained by brominations followed by manipulations in which sodium methoxide was used. This compound did not react and remained as an insoluble residue.

Reduction of the tribromo compound (0.15 g.) in concd. acetic acid by potassium iodide (warming to 70° and then allowing to cool slowly on standing for three hours) gave 0.06 g. of nearly pure *trans*-bromo unsaturated diketone (XV) which was purified by crystallization from ethanol and identified.

***cis*-2-Bromo-1,4-dimesityl-3-methyl-2-butenedione-1,4 (XIV).**—A chloroform solution of 4.8 g. of bromine was added dropwise to a mechanically stirred solution of 10 g. of the unsaturated diketone (XI) in chloroform containing 1 g. of suspended powdered sodium bicarbonate. The temperature was maintained at 0°. The color of bromine disappeared within twenty minutes after the last addition. This solution was then washed in succession with aqueous sodium bisulfite and with water. Upon evaporation and crystallization of the residue from petroleum ether, 7.8 g. of fine colorless needles was obtained (77.7%). Repeated crystallizations from ethanol–ethyl acetate mixtures brought the melting point to 143.5–144°. From the filtrates 1.4 g. of starting material was recovered.

Anal. Calcd. for $C_{23}H_{25}O_2Br$: Br, 19.37. Found: Br, 19.55.

***trans*-2-Bromo-1,4-dimesityl-3-methyl-2-butenedione-1,4 (XV).**—A mixture of 3 g. of the *cis*-isomer (XIV), 3 g. of sodium acetate and 50 cc. of 95% ethanol was refluxed for two hours. Upon cooling and diluting with water 2.05 g. of product separated (m. p. 168–169°). Alternate crystallizations from ethanol and from ethyl acetate raised the melting point to 171–171.5°.

Anal. Calcd. for $C_{23}H_{25}O_2Br$: C, 66.85; H, 6.10. Found: C, 67.14; H, 6.14.

This compound was obtained also when sodium benzoate was substituted for sodium acetate; and it was obtained when a mixture of the *cis*-isomer and isopropyl ether and freshly precipitated silver benzoate was refluxed for twelve hours. The same transformation was effected by the action of a 1:1 mixture of pyridine and water under refluxing for one hour.

Reduction of 0.5 g. of XV by 25 cc. of concd. acetic acid and 1 g. of zinc dust under stirring for ninety minutes at room temperature gave an oil which finally was induced to crystallize after distillation in the vacuum oven at 133°. The yield was 0.16 g. and the m. p. 57–59°; it was identified by mixture melting point as the saturated diketone (XIII).

3-Acetoxy-2,5-dimesityl-4-methylfuran (XVII).—Two drops of concd. sulfuric acid were added to a suspension of 1.5 g. of dimesitoylmethylethylene (XI) in 10 cc. of acetyl chloride. The suspended solid dissolved immediately with darkening. After warming for five minutes the mixture was hydrolyzed with ice-water and neutralized with sodium carbonate. Extraction with ether and subsequent evaporation gave 0.52 g. of almost pure product. Repeated crystallization from ethanol raised the melting point to 88°. Some starting material was recovered from the residual oils.

Anal. Calcd. for $C_{25}H_{28}O_3$: C, 79.84; H, 7.49. Found: C, 79.57; H, 7.75.

When acetic anhydride was used instead of acetyl chloride in the above experiment only unchanged material was obtained.

Summary

trans-Bromodimesitoylethylene has been converted into a *cis*-form. Reactions of the stereoisomers have been studied.

The chlorination of dimesitoylethylene with phenyliodochloride gave the monochloro derivative in good yield.

Bromination of dimesitoylmethylethylene gave a *cis*-monobromo derivative from which the *trans*-isomer was made by inversion. The use of sodium bicarbonate in preventing secondary reactions during bromination is described.

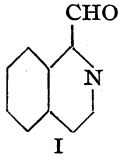
Condensation Reactions of Isoquinaldaldehyde

BY ROBERT S. BARROWS AND H. G. LINDWALL

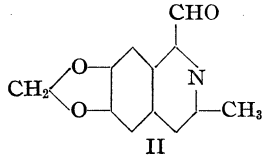
The successful use of lepidine as a source of cinchoninaldehyde[1] suggested that 1-methylisoquinoline might similarly be oxidized through the action of selenium dioxide to yield isoquinaldaldehyde (I). The method of Späth,[2] with modification, was used for the preparation of 1-methylisoquinoline. The modification involved the substitution of Raney nickel for platinized asbestos in the dehydrogenation of 1-methyl-3,4-dihydroisoquinoline. The 1-methylisoquinoline thus obtained was characterized by the preparation of several known derivatives.

The oxidation of 1-methylisoquinoline by selenium dioxide was carried out in dioxane solution with vigorous stirring; an excess of selenium dioxide was avoided. The product (I), which is volatile with steam, reacts with Tollens reagent, gives a sodium bisulfite addition product, and forms an oxime, a phenylhydrazone and a semicarbazone. The aldehyde (I) formed no hydrate.

A similar oxidation of 1,3-dimethyl-6,7-methylenedioxy-isoquinoline was carried out. The product, an aldehyde, formed a monoxime, and is tentatively assigned the structure 3-methyl-6,7-methylenedioxy-isoquinaldaldehyde (II).



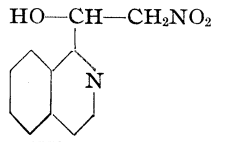
I



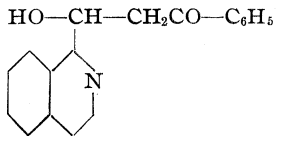
II

The condensation reactions of compound I with a series of "active methylene" compounds were studied. Condensation with nitromethane was accomplished readily to yield α-nitro-β-hydroxy-β-(isoquinolyl-1)-ethane (III).

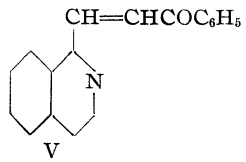
Initial attempts at condensation with acetophenone gave a mixture of products; with varied conditions, however, either IV, V, or VI could be obtained as the principal product. If the condensation of equimolecular quantities of isoquinaldaldehyde and acetophenone was carried out in the presence of sodium hydroxide for a short period of time, IV was obtained, but if longer time was allowed or if sodium ethylate was used, compound V resulted. With an excess of acetophenone and either sodium hydroxide or sodium ethylate, VI was the principal product.



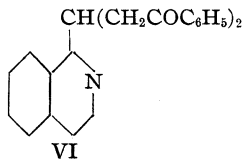
III



IV



V



VI

No product could be obtained from isoquinaldaldehyde and phenylacetic acid under conditions of the Perkin condensation, but two derivatives of phenylacetic acid were condensed under other conditions. Phenylacetonitrile and compound I yielded VII in the presence of diethylamine or sodium ethylate; ethyl phenylacetate and I gave VIII when sodium ethylate was used as the catalyst.

fate, 246–248°; hydrochloride 200–205°; chloroplatinate, 233–234°; methiodide, 208°.

Isoquinaldaldehyde (I).—To a solution of 1-methylisoquinoline (10 g.) in dioxane (17 cc.) was added, drop by drop, a solution of selenium dioxide (8.9 g.) in dioxane (90 cc.); the solutions were mixed over a period of one-half hour with agitation and gentle warming. The final mixture was then heated, with agitation, on the steam-bath for three hours. At the end of this time the solution was cooled and the precipitated selenium was removed; the bulk of the dioxane was removed under diminished pressure; the residual material was then steam distilled. The product (I) crystallized from the distillate after several hours at ice-box temperature; long white needles, m. p. 55–55.5°; yield, 42%. The product reduces Tollens reagent and forms a bisulfite addition product slowly. It is soluble in acetone, ligroin, benzene, but it is only slightly soluble in water.

Anal. Calcd. for $C_{10}H_7NO$: C, 76.49; H, 4.46; N, 8.92. Found: C, 76.40; H, 4.80; N, 8.90.

Semicarbazone of I.—Yellow plates from ethyl alcohol; m. p. 195–197°.

Anal. Calcd. for $C_{11}H_{10}N_4O$: N, 26.17. Found: N, 25.95, 26.41.

Oxime of I.—White needles from 50% ethyl alcohol; m. p. 171–172°.

Anal. Calcd. for $C_{10}H_8N_2O$: N, 16.27. Found: N, 16.01.

Phenylhydrazone of I.—Yellow needles from ethyl alcohol; m. p. 174–175°.

Anal. Calcd. for $C_{16}H_{13}N_3$: N, 17.00. Found: N, 17.19.

3-Methyl-6,7-methylenedioxy-isoquinaldaldehyde (II).—To a solution of 2.2 g. of 1,3-dimethyl-6,7-methylenedioxy-isoquinoline in 20 cc. of dioxane was added, drop by drop, a solution of 1.3 g. of selenium dioxide in 20 cc. of dioxane. The mixture was stirred and warmed gently during the addition which required one-half hour. One and one-half hours of further heating on the steam-bath were allowed. The precipitated selenium was filtered from the hot mixture and the filtrate was steam-distilled. When the bulk of the dioxane had been removed in the course of this distillation, the product (II) began to separate from the residue; yield, 34% after crystallization from toluene. Light yellow needles from ethyl alcohol; m. p. 186.5–188.5°. The product (II) reduces Tollens reagent.

Anal. Calcd. for $C_{12}H_9NO_3$: N, 6.51. Found: N, 6.64.

Oxime of II.—Needles from 50% ethyl alcohol; m. p. 215–216°.

Anal. Calcd. for $C_{12}H_{10}N_2O_3$: N, 12.17. Found: N, 11.90.

α-Nitro-β-hydroxy-β-(isoquinolyl-1)-ethane (III).—To a mixture of 0.3 g. of nitromethane and 0.32 g. of I was added diethylamine (2 drops). The solution, which became warm, was cooled and allowed to stand for two hours. A small amount of water was then added and an oil separated. Vigorous scratching caused the oil to solidify. The crude product (III) was dried on a porous tile; crude yield, 71%. The product may be crystallized from ligroin but heating in solvents causes apparent gradual decomposition; m. p. 106–107°, approx.

Anal. Calcd. for $C_{11}H_{10}N_2O_3$: N, 12.84; Found: N, 12.75.

β-Hydroxy-β-(isoquinolyl-1)-propiophenone (IV).—A few small pieces of ice were added to a solution of 0.2 g. of I and 0.17 g. of acetophenone in 8 cc. of ethyl alcohol. Then 15 cc. of 10% sodium hydroxide solution was added slowly. The solution soon became milky and after fifteen to twenty minutes a yellow crystalline product (IV) appeared; recrystallized from ethyl alcohol; m. p. 114.5–115°; yield, 85%.

Anal. Calcd. for $C_{18}H_{15}NO_2$: N, 5.05. Found: N, 4.76.

β-(Isoquinolyl-1)-acrylophenone (V). **Method A.**—Compound I (0.25 g.) was dissolved in 15 cc. of ethyl alcohol, and to this solution was added an excess of acetophenone (0.38 g.) and a small amount of ice. After then adding 6 cc. of 10% sodium hydroxide solution, the mixture was allowed to stand for one hour at room temperature. At the end of this time the product had appeared as fine yellow needles; yield, 60%; recrystallized from ethyl alcohol, m. p. 144–146°. **Method B.**—Equimolecular amounts of I (0.5 g.) and acetophenone (0.33 g.) were dissolved in 2 cc. of absolute alcohol and to this was added 5 drops of a solution of sodium ethylate in alcohol (0.05 g. of sodium per 1 cc.). At first the solution became warm and turned green but after standing the color changed to yellow and finally solidified to a crystalline mass. Treatment with bone black and crystallization from alcohol gave light yellow needles, m. p. 145.5–146°; yield 77%. A melting point determination when mixed with the product of method A showed no depression.

Anal. Calcd. for $C_{18}H_{13}NO$: C, 83.38; H, 5.04; N, 5.40. Found: C, 83.32, 83.23; H, 5.14, 4.99; N, 5.50, 5.44.

Bis-acetophenonyl-(isoquinolyl-1)-methane (VI).—Compound I (0.25 g.) and acetophenone (0.35 g.) were dissolved in 2 cc. of absolute ethyl alcohol and to this solution was added 0.5 cc. of a solution of sodium ethylate in alcohol (0.05 g. of sodium per 1 cc.). The product (VI) was removed by filtration after twenty hours. White plates from alcohol, m. p. 133–133.5°; yield, 42%. A small amount of VI was also obtained from the residual liquid after the removal of compound V in method "A" above.

Anal. Calcd. for $C_{16}H_{21}NO_2$: C, 80.90; H, 5.73; N, 3.69; mol. wt., 277. Found: C, 81.26; H, 5.57; N, 3.68, 3.84; mol. wt. (micro-cryoscopic, with camphor), 264.

α-Phenyl-β-(isoquinolyl-1)-acrylonitrile (VII).—A solution was prepared consisting of 0.4 g. of phenylacetonitrile 0.5 g. of isoquinaldaldehyde and 1 cc. of absolute ethyl alcohol. To this was added a small amount of sodium ethylate solution (three drops of solution containing 0.05 g. of sodium per 1 cc. of ethyl alcohol). After cooling and scratching the product separated as light yellow needles; recrystallized from ethyl alcohol, m. p. 96.5–97°; yield, 92%.

Anal. Calcd. for $C_{18}H_{12}N_2$: C, 84.36; H, 5.13; N, 10.93. Found: C, 84.44; H, 4.83; N, 10.94.

Ethyl Ester of α-Phenyl-β-hydroxy-β-(isoquinolyl-1)-propionic Acid (VIII).—Compound VIII was prepared by a method similar to that used in the preparation of VII.

employing ethyl phenylacetate with isoquinaldaldehyde; recrystallized from ethyl alcohol as white needles, m. p. 134.5–135.5°; yield, 45%.

Anal. Calcd. for $C_{20}H_{19}NO_3$: C, 74.72; H, 5.98; N, 4.36. Found: C, 74.46; H, 5.61; N, 4.47.

Summary

1. 1-Methylisoquinoline and 1,3-dimethyl-6,7-methylenedioxyisoquinoline are oxidized by selenium dioxide to yield isoquinaldaldehyde and 3-methyl-6,7-methylenedioxy-isoquinaldaldehyde, respectively.

2. Isoquinaldaldehyde has been found to undergo condensation reactions with nitromethane, acetophenone, phenylacetonitrile and ethyl phenylacetate.

Amino Ketones. I. Synthesis of Amino Alcohols and 1,3-Diamino Compounds from β-Amino Ketones

BY NORMAN H. CROMWELL, Q. T. WILES[1] AND O. C. SCHROEDER[2]

Although many previous investigations[3] have been concerned with the addition of various amines to α,β-unsaturated ketones, few studies have been made with the resulting β-amino ketones.

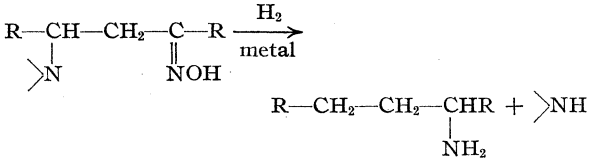
It seemed of interest to attempt the preparation of certain amino alcohols and the corresponding 1,3-diamino compounds of possible pharmacological value from such β-amino ketones by the application of certain known reactions.

The present investigation deals with the addition of certain amines to benzalacetone and benzalacetophenone and the conversion of the products to amino alcohols and 1,3-diamino compounds.

It has been found that both morpholine and piperidine add readily to benzalacetone to give, respectively, β-morpholinobenzylacetone (I) and β-piperidinobenzylacetone (II), isolated as the hydrochlorides. The preparation of β-amino ketones using high boiling, water soluble amines is best accomplished in water insoluble solvents. This allows the removal of the excess reactant amine by water washing. Conversely, the preparation of β-amino ketones from water insoluble amines such as aniline is easiest to manipulate in a water soluble solvent such as alcohol.

The oximes (III) and (IV) of the amino ketones (I) and (II) were prepared in good yields but it was necessary to take certain precautions to obtain these results. The best yields were obtained when the reaction medium was strongly basic. It was necessary that the amino ketone hydrochloride be added only after the hydroxylamine was available in the reaction medium to react immediately with the amino ketone before it could decompose to the α,β-unsaturated ketone. These amino ketoximes were amphoteric. The oximes (XIII) and (XIV), respectively, of β-morpholinobenzylacetophenone[3f] and of β-anilinobenzylacetophenone[3a] were also prepared.

Attempts to reduce these various amino ketoximes with catalytic hydrogen to the corresponding 1,3-diamino compounds were not successful. In all cases the following reaction was noted



The oximes (III) and (IV) however, were reduced in fair yields to the 1,3-diamino compounds (V) and (VI) using sodium and alcohol according to the method of Kohn.[4] The benzamides (VII) and (VIII) of these diamines were also prepared.

In order to obtain possible ephedrine-like amino alcohols the β-amino ketones (I) and (II) were reduced with sodium amalgam according to the method of Kohn.[5] These amino ketone hydrochlorides were not stable to catalytic hydrogenation though various conditions were employed.

The benzoates (XI) and (XII), isolated as the hydrochlorides, were prepared from the corresponding amino alcohols.

The studies of these reactions and products are being continued and extended.

Experimental[6]

β-Morpholino- and β-Piperidino-benzylacetones.—Benzalacetone (10 g., 0.068 mole) dissolved in petroleum ether (35 ml., b. p. 88–100°) was refluxed for fourteen hours with an excess (0.10 mole) of the corresponding amine. The mixtures were then allowed to stand in the ice chest for two days. Ether was added to dissolve any precipitated oil and the mixtures completely extracted with several portions of water to remove excess amine. The dry ether–petroleum ether solutions were then treated with dry hydrogen chloride to precipitate the white hydrochlorides (I) and (II). The hydrochloride (I) was recrystallized from methanol–dry ether mixtures while the hydrochloride (II) was recrystallized from ethanol–dry ether solutions. Both of these hydrochlorides decomposed to give benzalacetone when water solutions of them were warmed.

Amino Ketoximes, (III) and (IV).—To a cooled solution ot potassium hydroxide (48 g., 0.84 mole) in methanol (200 to 300 ml.) hydroxylamine hydrochloride (14.4 g., 0.20 mole) dissolved in water (30 ml.) was added. To this solution the corresponding β-amino ketone hydrochloride (0.044 mole) in methanol (25 ml.) was added. The reaction mixtures were allowed to stand at room temperature for two days. The precipitated potassium chloride was then removed and most of the methyl alcohol evaporated *in vacuo*. The remaining water solutions were cooled in an ice-bath and slowly neutralized with dilute hydrochloric acid. The oily solid which separated was extracted in each case with 50 ml. of ether. The impure products were obtained by evaporation of these solutions.

The products were recrystallized from petroleum ether (b. p. 35–40°)–ether solutions. Although two isomeric forms seemed to be present here, only the higher melting ones were isolated. Both of these amino ketoximes were soluble in dilute hydrochloric acid and in dilute potassium hydroxide solutions. These two substances were unstable to heat, especially in acid solutions.

Attempts to reduce these amino ketoximes to the diamines (V) and (VI) using catalytic methods were not successful. Using fifteen hundred pounds of hydrogen with Raney nickel at 40°, ethanol solutions of (III) and (IV) gave only 4-phenyl-2-aminobutane, isolated as its hydrochloride, m. p. 142°,[7] and morpholine and piperidine, respectively. Results of the same nature were obtained using pressures of fifty pounds of hydrogen and Raney nickel catalyst. In one experiment a little concd. ammonium hydroxide was added to the reduction mixture but still only these decomposition products could be isolated.

4-Phenyl-4-morpholino-2-aminobutane and 4-Phenyl-4-piperidino-2-aminobutane.—The corresponding amino ketoxime (10 g.) was dissolved in 80 ml. of ethanol and heated under reflux. Over a period of two hours 12 g. of sodium was added a piece at a time. Enough ethanol (80 cc.) was added from time to time to dissolve the sodium. The mixture was cooled and 12 ml. of water added to destroy the sodium ethoxide. The solution was cooled to 0° and neutralized with dilute hydrochloric acid. The salt was filtered off and the alcohol removed by vacuum distillation. To the thick residue, strong sodium hydroxide (50%) was added to precipitate the free base as an oil which was removed by extraction with ether. The ether solution was washed well with saturated salt solution, dried and evaporated.

The products were distilled under vacuum with an efficient pump. In each of these preparations some decomposition took place to give 4-phenyl-2-aminobutane. The formation of the diamine (VI) was also accompanied by the formation of a very high boiling, glassy-like product which was soluble in dilute hydrochloric acid but was not identified.

Both of the water-clear diamines (V) and (VI) were only slightly soluble in water but were readily soluble in dilute hydrochloric acid.

Benzamides.—The benzamides (VII) and (VIII) were prepared from the diamines (V) and (VI) by treating cooled ether solutions of them with one equivalent of benzoyl chloride. The precipitated hydrochlorides were hydrolyzed with dilute sodium bicarbonate solutions to give the benzamides. These products were recrystallized from dilute alcohol solutions. Both of these compounds were soluble in dilute hydrochloric acid solutions.

4-Phenyl-4-morpholinobutanol-2 and 4-Phenyl-4-piperidinobutanol-2.—Attempts to reduce the amino ketone hydrochlorides (I) and (II) with hydrogen and noble metal catalysts gave only very low yields of the desired amino alcohols. Decomposition, with the loss of morpholine or piperidine, respectively, occurred; the β-piperidinobenzylacetone was the least stable.

[a] B. p., at 1 mm. [b] Calcd.: Cl, 13.14. Found: Cl, 13.12. [c] Calcd.: Cl, 13.24. Found: Cl, 13.47.

Reduction was accomplished with sodium amalgam (3%). The corresponding amino ketone hydrochloride (10 g.) was dissolved in 100 ml. of water and cooled to −3°. To these solutions, over a period of one hour, sodium amalgam (190 g., 3%) was added in small portions. It was necessary to add small amounts of acid from time to time to keep the solution just acid (19 ml. of concd. hydrochloric acid and 50 ml. of water).

The acid solution was decanted from the mercury and made strongly basic with concd. sodium hydroxide (50%) to precipitate the free base. The amino alcohol (IX) was isolated and identified as its hydrochloride by passing dry hydrogen chloride into ether solutions of the base. The hydrochloride of the amino alcohol (X) was too hygroscopic to analyze, so the free base was vacuum distilled to give a water-white, thick oil which was readily soluble in dilute hydrochloric acid but only slightly water soluble.

4-Phenyl-4-morpholinobutanol-2 Benzoate Hydrochloride.—To 4.5 g. of the amino alcohol hydrochloride (IX) was added 16 g. of benzoyl chloride. This mixture was heated at 115° for two hours. The red oily mixture was cooled and mixed with dry ether to give a gummy precipitate. The gummy hydrochloride was dissolved in water and color removed from the solution with activated charcoal. The colorless solution was cooled and neutralized with strong sodium hydroxide. The precipitated oil was dissolved in ether and converted to the hydrochloride with dry hydrogen chloride. This product was recrystallized several times from alcohol (95%)–ether mixtures to give white needles (XI).

4-Phenyl-4-piperidinobutanol-2 Benzoate Hydrochloride.—To 0.80 g. of the amino alcohol (X) dissolved in 6 ml. of dry ether 0.48 g. of benzoyl chloride was added slowly. The white solid precipitate that formed immediately was recrystallized several times from a mixture of dry ether, ethyl acetate and ethanol to give white needles (XII).

β-Morpholinobenzylacetophenone Oxime (XIII).—The β-morpholinobenzylacetophenone for this experiment was prepared in 95% yields according to the method of Pollard and Stewart.[3f] This β-amino ketone (20.0 g.) was added to a mixture of 9.4 g. of hydroxylamine hydrochloride, 14.0 g. of sodium acetate, 30 ml. of water, and 200 ml. of methyl alcohol. This mixture was heated to boiling with shaking for ten minutes and then allowed to stand at room temperature for one day. The white precipitate was filtered off and washed with two portions of 50% methyl alcohol–water solution and then water, and the product dried, wt. 12 g., m. p. 178°. Recrystallization from 50% mixtures of chloroform and methanol did not change the melting point. This product was only slightly soluble in dilute sodium hydroxide, but was readily soluble in dilute hydrochloric acid.

Attempts to reduce this amino ketoxime with sodium and alcohol were not successful. The amino ketoxime was recovered unchanged.

β-Anilinobenzylacetophenone Oxime (XIV).—β-Anilinobenzylacetophenone for this experiment was prepared in good yield by the method of Tambor and Wildi.[3a] This amino ketone (10 g., 0.033 mole) was added to a mixture of hydroxylamine hydrochloride (11.4 g., 0.165 mole), potassium hydroxide (33 g., 0.60 mole) and 300 ml. of methanol and the mixture refluxed for fifty minutes. The reaction mixture was cooled and water added to give a white precipitate. Recrystallization of this product from methanol gave 7 g. of flaky white crystals. This product was not soluble in fifty, ten or five per cent. solutions of potassium hydroxide. It was also insoluble in 5% hydrochloric acid but dissolved in the concd. acid.

Summary

1. Two new β-aminobenzylacetones have been prepared and procedures for preparing oximes of β-amino ketones discussed.

2. General methods for preparing β-amino alcohols and 1,3-diamino compounds from α,β-unsaturated ketones have been investigated.

3. Two new amino alcohols with their corresponding benzoates and two new 1,3-diamines with their corresponding benzamides have been prepared.

Studies on D-Galactosan <1,5>β<1,6>

BY RAYMOND M. HANN AND C. S. HUDSON

The hexose anhydride, D-galactosan <1,5>β<1,6>, was first synthesized by Micheel[1] by the action of hot aqueous barium hydroxide upon 2,3,4,6 - tetraacetyl - D - galactopyranosido - trimethyl-ammonium bromide; the over-all yield of the anhydride, based on the crystalline acetobromo-D-galactose employed, was 38%. Micheel also reported that he obtained a small amount of the same anhydride by the pyrolysis of β-D-galactose at temperatures of 270 to 360° and a pressure of 3 millimeters.[2] The <1,5><1,6> structure was assigned by Micheel on the basis that acetobromo-D-galactose contains the 1,5 ring and that the 1,6 ring is probably more stable than the 1,3 and 1,4 rings; the <1,5><1,6> structure was also the only probable one containing two adjacent hydroxyl groups in the *cis*-position, which seemed necessary in order to account for the ready formation of a monoacetone compound (m. p. 151–152°; $[\alpha]^{20}_{D}$ −73.3° in chloroform). These inferences of Micheel were proved to be correct by the work of McCreath and Smith[3]; they isolated as a by-product in the preparation of 1,2:3,4-diacetone galactose a monoacetone galactosan agreeing in physical properties with the one described by Micheel, and by methylation they converted it to a sirupy monomethyl-monoacetone-D-galactosan, which, upon hydrolysis with strong acid, formed the known crystalline 2-methyl-D-galactopyranose[4]; the monomethyl-monoacetone-D-galactosan, upon selective mild acid hydrolysis and subsequent methylation, formed a crystalline trimethyl-D-galactosan, which, upon complete acid hydrolysis, yielded crystalline 2,3,4-trimethyl-galactopyranose monohydrate. The ring structure of the parent galactosan is therefore <1,5><1 6> and the β-configuration is assigned to the 1,6 ring, as first proposed by Micheel because the space formula indicates a high probability for this configuration. The monoacetone derivative is accordingly 3,4-isopropylidene-D-galactosan <1,5>β<1,6>, as originally inferred by Micheel.

Recently we[5] have found that the pyrolysis of α-lactose monohydrate, under the experimental conditions previously used for the preparation of D-mannosan <1,5>β<1,6> from vegetable ivory, yields a distillate containing both levoglucosan and D-galactosan <1,5>β<1,6>. The anhydrides are readily separable through the fact that the galactosan, but not the glucosan, condenses with acetone; average yields of 12.3 g. of levoglucosan and 20.7 g. of 3,4-isopropylidene-D-galactosan <1,5>β<1,6> have been obtained by the pyrolysis of a 200-g. charge of lactose monohydrate; economy in price of starting material, simplicity and speed of experimental procedures, and the relatively high yields of the desired products, thus combine to make this procedure of pyrolysis an excellent method for obtaining an abundant supply of these two sugar anhydrides at relatively low cost. In the case of the galactosan, such a result is of special importance; the galactosan and its acetone derivative are now inexpensive and readily accessible substances, suit-

(1) Micheel, *Ber.*, **62**, 687 (1929).

(2) Ordinary galactose is the α-form; we have shown (THIS JOURNAL, **63**, 2241 (1941)) that its pyrolysis gives good yields of D-galactosan <1,5>β<1,6>. We find that the yield of levoglucosan (D-glucosan <1,5>β<1,6>) is independent of the form of anhydrous glucose (α or β) that is pyrolyzed. The melting of such α- or β-forms establishes equilibrium between them, as may be inferred from an old record by C. Tanret (*Bull. soc. chim.*, [3] **13**, 734 (1895)). We have repeated his experiment under more precise control. The glassy melts which were obtained by heating samples of pure α- and β-D-glucose at 170° for fifteen minutes were cooled and then dissolved in water at 20°; the specific rotations after seven minutes were essentially alike (+53 and +50), representing the equilibrium rotation of glucose.

(5) Hann and Hudson, *ibid.*, **63**, 1484 (1941).

able for synthetic studies in the preparation of new compound sugars possessing a linkage at the second carbon atom of galactose.

Although the structure of D-galactosan<1,5>-β<1,6> has been firmly established through the methylation studies of McCreath and Smith, it seemed desirable to seek confirmation of it by application of the periodate methods previously employed in this Laboratory in studies on D-glucosan (levoglucosan),[6] D-altrosan,[7] and D-mannosan.[8] It was found that the oxidation of the anhydride by per-iodic acid or sodium meta-periodate proceeded with the reduction of two molecular equivalents of the oxidant and the generation of a molecular equivalent each of formic acid and L′-oxy-D-methylene-diglycolic aldehyde; the latter compound, upon further oxidation with bromine water in the presence of strontium carbonate, formed strontium L′-oxy-D-methylene-diglycolate, the same crystalline salt that had been obtained previously from D-glucosan, D-altrosan and D-mannosan. This result proves that the same structure and β<1,6> configuration are common to the four hexose anhydrides; the galactosan is therefore D-galactosan<1,5>β<1,6>, and the conclusions of the previous investigators are confirmed by this independent method.

The present investigation has been extended to include the preparation of several new derivatives of D-galactosan<1,5>β<1,6>; by customary procedures 3,4-isopropylidene-D-galactosan<1,5>β<1,6> has been converted into its 2-substituted acetyl, benzoyl and tosyl derivatives, all of which are crystalline; by selective mild acid hydrolysis the isopropylidene group of these compounds is removed and, although the 2-acetyl-D-galactosan<1,5>β<1,6> could not be crystallized, it was possible to crystallize 2-benzoyl- and 2-tosyl-D-galactosan<1,5>β<1,6>; migration of the acyl groups does not appear to occur under the experimental conditions of the hydrolysis since the monobenzoate, upon treatment with acetone and anhydrous copper sulfate, regenerates 2-benzoyl-3,4-isopropylidene-D-galactosan<1,5>β<1,6> in high yield. The 2-benzoyl-D-galactosan<1,5>β<1,6> yielded by suitable reactions, crystalline 3,4-diacetyl and 3,4-ditosyl derivatives; by treatment with benzoyl chloride, it formed a crystalline 2,3,4-tribenzoyl-D-galactosan<1,5>β<1,6>, which was identical with the tribenzoate obtained by direct benzoylation of D-galactosan<1,5>β<1,6>. The 2-tosyl-D-galactosan<1,5>β<1,6> is a compound of particular interest, since studies now in progress indicate that upon detosylation it forms a compound (m. p. 132–133°; $[\alpha]^{20}D$ −84° in water), which gives correct carbon and hydrogen analyses for an anhydro-D-galactosan<1,5>β<1,6>; its behavior thus parallels that of 4-tosyl-D-mannosan<1,5>β<1,6>, which is known[9] to form an anhydro-D-mannosan<1,5>β<1,6>, presumably 3,4-anhydro-D-talosan<1,5>β<1,6>, upon detosylation.

We express our appreciation to Dr. A. T. Ness for performing the microchemical analyses in connection with this study.

Experimental

D-Glucosan<1,5>β<1,6> and 3,4-Isopropylidene-D-galactosan<1,5>β<1,6> from α-Lactose Monohydrate.—Three successive charges of 75, 65 and 60 g. of α-lactose monohydrate were pyrolyzed in the apparatus and under the experimental condition specified[8] for the preparation of D-mannosan<1,5>β<1,6> from vegetable ivory. The combined pyrolysates, a dark colored sirup, was dissolved in 200 cc. of water and the solution, after clarification by filtration through a layer of 45 g. of decolorizing carbon on a Büchner funnel of 171 mm. diameter, was concentrated *in vacuo* to a thick sirup; a solution of the sirup in 75 cc. of acetone was poured in a thin stream into an additional 325 cc. of acetone, and, after decantation from a small amount of precipitated gum, the acetone solution was agitated with 40 g. of anhydrous copper sulfate for twenty-four hours; the copper sulfate was removed by filtration and the filtrate was concentrated *in vacuo* to a magma of the consistency of honey; the magma was thinned with 25 cc. of isopropyl alcohol and the crystalline product (24.0 g.), which was mainly 3,4-isopropylidene-D-galactosan<1,5>β<1,6>, was separated by filtration and preserved for final purification as described later in this paragraph. The filtrate was concentrated *in vacuo* to remove the isopropyl alcohol, and the resulting sirup was transferred to a crystallizing dish with the aid of 20 cc. of warm acetone; crystallization, which occurred spontaneously as the solution cooled, was allowed to progress for twenty-four hours in the refrigerator and the precipitate (13.6 g.), which was nearly all levoglucosan, was then separated by filtration. The further purification of the products was conducted as follows: the levoglucosan fraction was refluxed for ten minutes with 5 parts of chloroform, in which 3,4-isopropylidene-D-galactosan<1,5>β<1,6> is readily soluble and levoglucosan practically insoluble, and the crystalline levoglucosan was removed by filtration; to the chloroform filtrate the 3,4-isopropylidene-D-galactosan<1,5>β<1,6> fraction previously isolated and additional chloroform to maintain a volume of 5 cc. of solvent for each gram of solid were added and the mixture was refluxed for ten

minutes, and then allowed to stand for several hours at room temperature; the levoglucosan was removed by filtration and the 3,4-isopropylidene-D-galactosan <1,5>β-<1,6> was recovered by concentration of the chloroform filtrate. The average yield of levoglucosan from 200 g. of lactose monohydrate was 12.3 g. (13%) and that of 3,4-isopropylidene-D-galactosan <1,5>β<1,6> was 20.7 g. (18%). The latter compound may be crystallized from 3 parts of water or 5 parts of ethyl acetate; it melted at 151–152° and showed a specific rotation[10] of −72.9° in chloroform (*c*, 0.87). Micheel[1] records a melting point of 151–152° and a specific rotation of −73.3° in chloroform (*c*, 1.4), and McCreath and Smith[3] record the same melting point and a specific rotation $[\alpha]^{19}D$ of −72.5° in chloroform (*c*, 1.7) for 3,4-isopropylidene-D-galactosan <1,5>β-<1,6>.

2-Acetyl-3,4-isopropylidene-D-galactosan<1,5>β-<1,6>.—A solution of 2.0 g. of 3,4-isopropylidene-D-galactosan <1,5>β<1,6> in a mixture of 10 cc. of pyridine and 10 cc. of acetic anhydride was allowed to stand overnight at room temperature and then poured upon crushed ice. The crystalline acetyl derivative (2.0 g.; 83%) which separated was recrystallized from 50 parts of boiling water and obtained as colorless plates, which melted at 136–137° and had a specific rotation of −51.4° in chloroform (*c*, 0.88).

Anal. Calcd. for $C_{11}H_{16}O_6$: C, 54.09; H, 6.60; CH_3CO, 17.6. Found: C, 54.36; H, 6.49; CH_3CO, 17.5.

2-Benzoyl-3,4-isopropylidene-D-galactosan<1,5>β<1,6>.—To an ice-cold solution of 3.0 g. of 3,4-isopropylidene-D-galactosan <1,5>β<1,6> in 10 cc. of pyridine, benzoyl chloride (1.9 cc.; 1.1 molecular equivalents) was added dropwise; the reaction mixture was allowed to stand overnight at room temperature and then poured upon crushed ice to precipitate the crystalline benzoyl derivative. The yield was 3.7 g. (82%). The substance deposited from its solution in 5 parts of alcohol in fine needles which melted at 119–120° and exhibited a specific rotation of +6.3° in chloroform (*c*, 0.84).

Anal. Calcd. for $C_{16}H_{18}O_6$: C, 62.74; H, 5.92; C_6H_5CO, 34.3. Found: C, 62.96; H, 5.92; C_6H_5CO, 34.7.

2-Tosyl-3,4-isopropylidene-D-galactosan<1,5>β<1,6>.—This compound was obtained in quantitative yield by the action of *p*-toluene-sulfonyl chloride (1.4 g.; 1.5 molecular equivalents) on a solution of 1.0 g. of 3,4-isopropylidene-D-galactosan <1,5>β<1,6> in 6 cc. of pyridine. It was recrystallized from 8 parts of alcohol in the form of quadrilateral plates, which melted at 118–119° and showed a specific rotation of −63.7° in chloroform (*c*, 0.92).

Anal. Calcd. for $C_{16}H_{20}O_7S$: C, 53.92; H, 5.66. Found: C, 53.85; H, 5.61.

D-Galactosan<1,5>β<1,6> from 3,4-Isopropylidene-D-galactosan<1,5>β<1,6>.—A solution of 20.0 g. of 3,4-isopropylidene-D-galactosan <1,5>β<1,6> in 220 cc. of 0.1 *N* hydrochloric acid was allowed to stand for twenty-four hours at 20°, during which period the specific rotation reached a constant value of −17.9°, equivalent to a rotation of −22.4° for D-galactosan <1,5>β<1,6>. The solution, which was devoid of reducing power (negative Fehling test), was treated with silver carbonate to remove the hydrochloric acid and then concentrated *in vacuo* to dryness. The yield of D-galactosan <1,5>β<1,6> was 14.5 g. (91%) and this material required no further purification for use in synthetic work. After recrystallization to constant physical properties from 5 parts of alcohol, it melted at 223–224° and showed a specific rotation of −22.0° in water (*c*, 1.96). Micheel[1] records a melting point of 220–221° and a specific rotation $[\alpha]^{21}D$ of −21.9° in water (*c*, 2.14).

Anal. Calcd. for $C_6H_{10}O_5$: C, 44.44; H, 6.22. Found: C, 44.51; H, 6.28.

Per-iodic Acid Oxidation of D-Galactosan<1,5>β-<1,6>.—A solution of 5.6199 g. of D-galactosan<1,5>β-<1,6> in 75 cc. of water was cooled in an ice-bath and 122 cc. of 0.625 *M* aqueous per-iodic acid (2.2 molecular equivalents) was gradually added. The oxidation was allowed to proceed at 20° for twenty-four hours and the volume was adjusted to 250 cc. by the addition of water. The titration of a 5-cc. aliquot for excess per-iodic acid revealed that 2.02 molecular equivalents of oxidizing agent had been reduced. The specific rotation of the oxidation product, calculated as L′-oxy-D-methylene-diglycolic dialdehyde, was −13.9°. This value is in good agreement with those reported for the per-iodic acid oxidation of levoglucosan,[6] D-altrosan <1,5>β<1,6>[7] and D-mannosan <1,5>β-<1,6>,[8] namely, −15.0°, −14.5° and −14.9°, and −14.2°, respectively. The sirupy aldehyde was isolated and further oxidized by bromine water in the presence of strontium carbonate in the usual way; crystalline strontium L′-oxy-D-methylene-diglycolate pentahydrate was obtained in a yield of 4.7 g. (38%). This salt, after two recrystallizations from water, gave a specific rotation of +27.7° (*c*, 0.6), a value near that of +28.1° recorded by Richtmyer and Hudson for the same salt obtained from D-altrosan <1,5>β<1,6>. When 0.5731 g. of the pentahydrate was dissolved in 25 cc. of *N* hydrochloric acid the specific rotation of the resulting solution of free L′-oxy-D-methylene-diglycolic acid was +7.9°, in close agreement with the values of +8.0°,[6] +7.9°,[7] and +7.8°[8] previously reported.

Anal. Calcd. for $C_5H_4O_6Sr \cdot 5H_2O$: C, 17.78; H, 1.19; Sr, 25.94; H_2O, 26.67. Found: C, 17.67; H, 1.16; Sr, 25.90; H_2O, 26.45.

Sodium Metaperiodate Oxidation of D-Galactosan<1,5>β<1,6>.—To an ice-cold solution of 0.5900 g. of D-galactosan <1,5>β<1,6> in 25 cc. of water, 20 cc. of 0.546 *M* aqueous sodium periodate (3.00 molecular equivalents) was added and the oxidation reaction allowed to proceed at 20° for twenty-four hours. The volume was adjusted to 50 cc. with water and a 5-cc. aliquot, upon analysis, indicated the consumption of 2.00 molecular equivalents of the periodate during the oxidation; the titration of a further 10-cc. aliquot with 0.1 *N* sodium hydroxide, using methyl red as an indicator, consumed 7.15 cc. of alkali, equivalent to the production of 0.98 molecular equivalent of formic acid as a product of the oxidation. D-Galactosan <1,5>β<1,6> would be expected to reduce

(10) All of the crystalline compounds described in the experimental part were recrystallized to constant melting point (cor.) and specific rotation $[\alpha]^{20}D$; *c* is the concentration in grams in 100 cc. of solution; the tube length was 4 dm.

two equivalents of periodate and form one equivalent of formic acid.

2,3,4-Tribenzoyl-D-galactosan<1,5>β<1,6>.—A solution of 1.0 g. of D-galactosan <1,5>β<1,6> in 10 cc. of pyridine was cooled in an ice–salt bath and 2.35 cc. (3.3 molecular equivalents) of benzoyl chloride was added dropwise. The reaction mixture was allowed to stand at room temperature for twenty-four hours and poured upon crushed ice; the crystallization of the thick sirup which precipitated was difficult but was finally attained by the alternate addition and slow evaporation of small amounts of methyl alcohol. The tribenzoate deposited from its solution in 20 parts of methyl alcohol in the form of glistening prisms, which melted at 89–90° and showed a specific rotation of +84.8° in chloroform (*c*, 1.05).

Anal. Calcd. for $C_{27}H_{22}O_8$: C, 68.35; H, 4.67; C_6H_5CO, 66.5. Found: C, 68.41; H, 4.63; C_6H_5CO, 66.2.

2,3,4-Tritosyl-D-galactosan<1,5>β<1,6>.—To an ice-cold solution of 2.0 g. of D-galactosan <1,5>β<1,6> in 20 cc. of pyridine, 7.8 g. of tosyl chloride (3.3 molecular equivalents) was added and the reaction mixture allowed to stand for twenty-four hours at room temperature. The gum which separated upon addition of the pyridine solution to water gradually crystallized over a period of two weeks and yielded 6.3 g. of a granular powder. By fractional crystallization, first from aqueous acetic acid and finally from alcohol, a yield of 2.0 g. (26%) of tritosyl-D-galactosan <1,5>β<1,6> was separated from the mixture of partially tosylated galactosans. The tritosyl compound deposited from its solution in 4 parts of alcohol in the form of small needles which melted at 103–104° (cor.) and showed a specific rotation of −51.1° in chloroform (*c*, 1.26). These constants were not changed by further recrystallization.

Anal. Calcd. for $C_{27}H_{28}O_{11}S_3$: C, 51.91; H, 4.52; S, 15.40. Found: C, 51.76; H, 4.70; S, 15.31.

2-Benzoyl-D-galactosan<1,5>β<1,6>.—A solution of 2.5 g. of 2-benzoyl-3,4-isopropylidene-D-galactosan <1,5>-β<1,6> in 25 cc. of 20% acetic acid was refluxed for two and one-half hours; upon cooling, the solution deposited 1.5 g. (68%) of 2-benzoyl-D-galactosan. The benzoate was recrystallized from 5 parts of alcohol or 15 parts of 20% acetic acid; it formed prisms which melted at 164–165° and had a specific rotation of +47.2° in chloroform (*c*, 0.8). The presence of other monobenzoylated-D-galactosans in the product, as a result of a conceivable acyl migration, would seem to be excluded, since (as described in the following paragraph) a nearly quantitative yield of authentic 2-benzoyl-3,4-isopropylidene-D-galactosan <1,5>β<1,6> may be obtained from it by treatment with acetone and anhydrous copper sulfate. Upon further benzoylation, the 2-benzoyl-galactosan yields the 2,3,4-tribenzoyl-D-galactosan <1,5>β<1,6> previously described.

Anal. Calcd. for $C_{13}H_{14}O_6$: C, 58.64; H, 5.30; C_6H_5CO, 39.5. Found: C, 58.68; H, 5.23; C_6H_5CO, 39.2.

2-Benzoyl-3,4-isopropylidene-D-galactosan<1,5>β<1,6> from 2-Benzoyl-D-galactosan<1,5>β<1,6>.—A solution of 1.0 g. of the 2-benzoyl-D-galactosan <1,5>β<1,6> in 25 cc. of acetone was refluxed with 5.0 g. of anhydrous copper sulfate for three hours. The copper sulfate was separated by filtration and the filtrate was concentrated to a dry crystalline residue. The reaction product was recrystallized from 5 cc. of alcohol and gave a yield of 1.0 g. (91%) of 2-benzoyl-3,4-isopropylidene-D-galactosan <1,5>β<1,6>, identical in melting point and specific rotation with the substance obtained by direct benzoylation of 3,4-isopropylidene-D-galactosan <1,5>β<1,6>. A mixed melting point showed no depression.

2-Benzoyl-3,4-diacetyl-D-galactosan<1,5>β<1,6>.—A solution of 1.0 g. of 2-benzoyl-D-galactosan <1,5>β<1,6> in a mixture of 10 cc. of pyridine and 10 cc. of acetic anhydride was allowed to stand at room temperature for eighteen hours and then poured upon crushed ice. The precipitated 2-benzoyl-3,4-diacetyl-D-galactosan (1.3 g., quantitative) was separated by filtration and recrystallized from 10 parts of alcohol. It formed needles which melted at 103–104° and rotated +85.4° in chloroform (*c*, 0.9).

Anal. Calcd. for $C_{17}H_{18}O_8$: C, 58.28; H, 5.18. Found: C, 58.48; H, 5.13.

2-Benzoyl-3,4-ditosyl-D-galactosan<1,5>β<1,6>.—This substance was obtained by tosylation of the monobenzoyl-D-galactosan <1,5>β<1,6> by the usual method; recrystallized from 5 parts of alcohol, it was obtained in prisms which melted at 119–120° and rotated +78.0° in chloroform (*c*, 0.8).

Anal. Calcd. for $C_{27}H_{26}O_{10}S_2$: C, 56.42; H, 4.55; S, 11.16. Found: C, 56.43; H, 4.56; S, 11.07.

Summary

The pyrolysis of α-lactose monohydrate under reduced pressure forms a sirup from which, after condensation with acetone, yields of 13% of levoglucosan and 17.5% of 3,4-isopropylidene-D-galactosan <1,5>β<1,6> were obtained. Selective mild acid hydrolysis converts the latter compound into the known D-galactosan <1,5>β<1,6>. Confirmation of the ring structure and configuration of the galactosan was obtained by periodate oxidative procedures. A number of new derivatives of 3,4-isopropylidene-D-galactosan <1,5>β<1,6> and of D-galactosan <1,5>β<1,6> have been prepared and described.

BETHESDA, MD. RECEIVED JULY 31, 1942

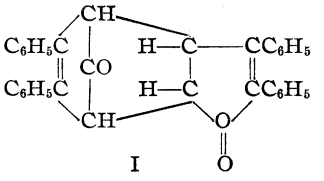
The Behavior of Certain Carbonyl Bridge Compounds with Alkaline Hydrogen Peroxide

BY C. F. H. ALLEN AND J. W. GATES, JR.

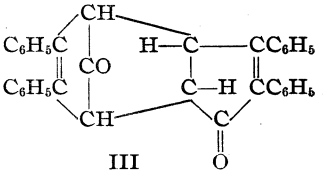
Some time ago[1] it was shown that when the bimolecular product I, that results from treatment of anhydroacetonebenzil with acidic dehydrating agents, was treated with chromium trioxide in acetic acid, poor and varying yields of an isomer were obtained. This new substance also lost carbon monoxide on heating, to give an indanone II having two phenyl groups on the same carbon atom. It was furthermore concluded that the isomerism was due to space relations. Since many new facts about the reactions of the bimolecular product are now available,[2] as a result of which the structure has been slightly modified,[2b] it was necessary to re-examine the "oxidation product" isomer III. During the course of this work degradation and synthesis established the correctness of the structure previously assigned to the indanone.

When the bimolecular product I is stirred at room temperature with a cold alkaline solution of hydrogen peroxide, a peroxide IV is formed; this contains four extra atoms of oxygen. It loses this oxygen almost explosively when heated, but seems stable at room temperature. Upon treatment with hydrogen bromide, bromine is liberated and the bimolecular product regenerated. It likewise liberates iodine from potassium iodide in acetic acid. When it is dissolved in acetic acid, oxygen is evolved and the "oxidation product" isomer III, previously secured with difficulty by means of chromic acid, was formed. These reactions are practically quantitative.

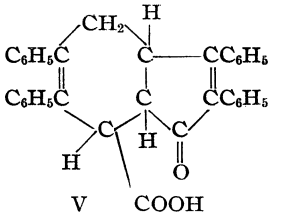
Both isomers I and III give the same derivatives; thus, with alkaline reagents the acid V results, phenylmagnesium bromide gives the same carbinol, and in the Grignard machine both show one active hydrogen and one addition. The only difference is in the results of pyrolysis: both lose carbon monoxide, but one gives the indanone II and the other its isomer VI, by way of two intermediate isomeric unsaturated ketones.[2] Since the same derivatives are obtained from both, the only difference being the result of pyrolysis, the difference between the isomers must be of a spatial nature. That is, the position of the hydrogens on the bond common to the two rings appears to be the significant factor, and, as concluded in the earlier paper,[1] the two substances are presumably geometrical isomers, as represented in I and III.



I



III



V

The above formulas differ from those previously assigned[1] only in the interchange of the angular phenyl group and one hydrogen atom at the other end of an allylic system. The fact that both give the same derivatives is explained on the basis of catalysis by acidic or basic substances present in all reactions. The only reaction carried out in the absence of a possible catalyst is the heating, and this leads quantitatively to a different product in each instance. The previous suggestion that the bimolecular product was a mixture has been abandoned,[2] but the reasons[1] for assigning it a *cis*-configuration I are retained.

The indanone II, in which the grouping —CH_2-CO— had been proved previously, has now been degraded to a lactone VII and to a hydrocarbon XI, both of which have been synthesized by reactions that leave no doubt as to their structures. The synthesis from the known keto acid VIII also establishes the position of the side chain.

The diketone IX resulting from the action of

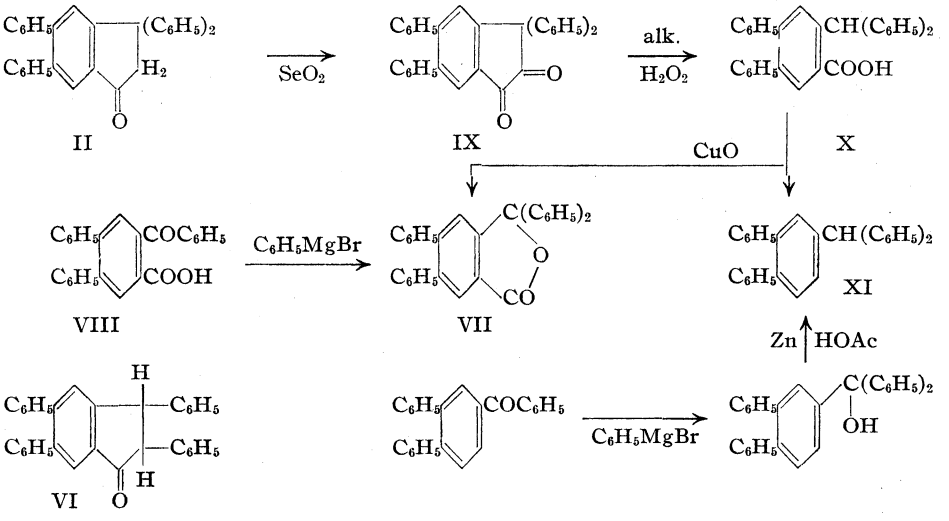
(1) Allen and Rudoff, *Can. J. Res.*, **B15**, 321 (1937).

(2) Allen and Gates, THIS JOURNAL, **64**, (a) 2120 (1942); (b) **64**, 2123 (1942).

selenium dioxide on the indanone is readily cleaved by alkaline hydrogen peroxide to the acid X. When the latter is treated under decarboxylating conditions with copper carbonate (or oxide), a portion loses the carboxyl group and gives the triphenylmethane derivative XI; this was synthesized, as shown in the outline, from 3,4-diphenylbenzophenone. The remainder of the product is the lactone VII, evidently formed by oxidation of the triphenylmethane hydrogen atom of X to hydroxyl, followed by closing of the lactone ring. The interrelation and lactone synthesis are shown in the chart.

CHART I

DEGRADATION OF THE INDANONE II; SYNTHESIS OF TWO PRODUCTS

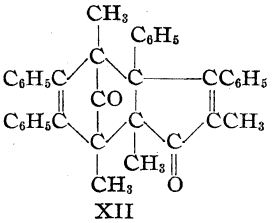


It is obvious that there has been a 1,2-shift of a phenyl group during the decarbonylation of the bimolecular product isomer III; this rearrangement must have been due to the heating. It has been shown previously that there was no rearrangement during the decarbonylation of the isomer I, by accomplishing the removal of the bridge carbonyl by the action of sodium methoxide at the boiling point of methanol[2a] and securing the same end-product in both reactions, the indanone VI; the phenyl groups are linked to the same carbon atoms in I and in VI.

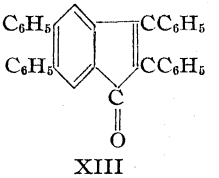
The behavior of the indandione IX toward alkaline hydrogen peroxide is similar to that of the simpler 3,3-diphenylindandione-1,2, as described by Gagnon[3] but neither of these is in agreement with the results of Koelsch.[4] In the work described in this paper, all variations of experimental procedure always gave the same product, but the yields were much improved by the use of Gagnon's technique; the intermediate aroylformic acid was not isolated.

The indandione IX gives a quinoxaline with *o*-phenylenediamine, instead of the anil[1]; the last molecule of water is held very tenaciously. This observation may account for the disagreement reported on the quinoxaline of 3,3-diphenylindandione-1,2.[3,4] The diketone IX also gives a crystalline glycol XVIII with excess phenylmagnesium bromide.

Evidence as to the structure of the peroxide is not decisive. A homologous bimolecular product XII[5] that has no hydrogen in the positions *alpha* to the carbonyl group does not give a peroxide; neither does it show active hydrogen in the Grignard machine. Thus these two anomalous properties must be related in some way to the carbonyl bridge and adjacent hydrogen. The most obvious relation is that of an enol, and such has already been suggested[2b] to account for the active hydrogen. It is also well established that highly substituted enols are capable of forming peroxides.[6] These, however, have but two atoms of oxygen, whereas the bimolecular product peroxide has four.



XII



XIII

The isomer III does not form a peroxide; this suggests that the space relations also have an influence upon its formation.

During the preparation of the isomeric bimolecular product III by the action of chromic acid,[1]

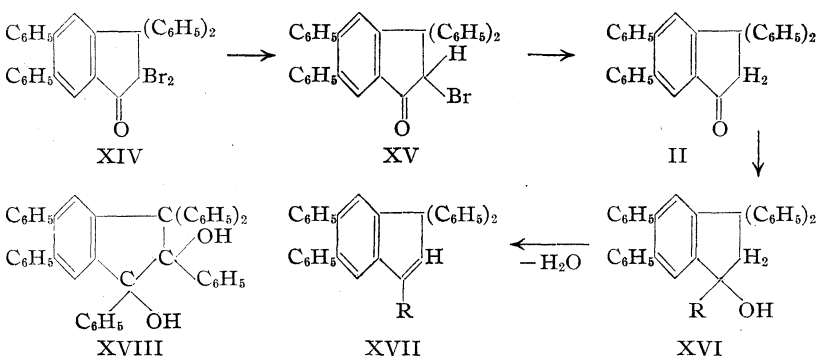
substances of varying melting points resulted, all of which, upon analysis, were found to contain varying amounts of oxygen, and which gave no depression of melting point on admixture; upon heating, they all gave the indanone II practically quantitatively. This suggests that they were a single substance plus oxygen; the maximum value, plus four oxygen atoms, was only obtained by the use of alkaline hydrogen peroxide. A variety of products, which will be described in detail in a later paper, resulted when tetraphenylindenone, XIII, was treated with alkaline hydrogen peroxide. A true peroxide appears to be formed primarily, however.

The proof of the —CH_2CO— group in the rearranged indanone II previously proved in several ways has received confirmation in this paper through stepwise reduction of the dibromo substitution product XIV by means of the Grignard reagent. This is characteristic of α-haloketones[7]; one halogen is removed at a time, so the monobromoketone XV can be isolated as an intermediate during the process.



The indanone II gave carbinols XVI with Grignard reagents. On dehydration these gave hydrocarbons XVII. These are isomeric with other hydrocarbons[2] of which the structures are still in doubt, obtained from closely related carbinols; however, the non-identity shows that in the others there must be a different arrangement of phenyl groups around the indene ring.

Experimental

The Peroxide IV.—In a solution of 500 cc. of alcohol, 50 cc. of water and 8 g. of sodium hydroxide, was suspended 42 g. of bimolecular product I; to this was added 50 cc. of 16% hydrogen peroxide with vigorous stirring and the temperature kept below 30° for two hours. Then it was chilled externally by ice, filtered, rinsed with a little methanol, and air-dried. The yield was 40–42 g. It softens about 80°, gradually decomposing up to 200°.

Anal. Calcd. for $C_{34}H_{24}O_6$: C, 77.8; H, 4.5. Found: C, 77.3; H, 4.5.

The peroxide liberates the halogen from potassium iodide or hydrogen bromide in acetic acid, with regeneration of the bimolecular product, but if an acetic acid solution is heated to boiling, the solid dissolves with evolution of gas, and on cooling, the isomeric indenone III separates in rods which melt at 215°.

Anal. Calcd. for $C_{34}H_{24}O_2$: C, 87.9; H, 5.2. Found: C, 87.9; H, 5.1.

This melting point was not lowered on admixture with samples of widely varying melting points from chromic acid oxidation; these specimens melted with decomposition all the way up to 264° and contained fractional amounts of oxygen not corresponding with exactly one or two equivalents. Regardless of the melting point, each gave the same indanone II on decarbonylation and loss of oxygen.

The isomeric bimolecular product III no longer forms a peroxide; on heating at 260–270°, 3,3,5,6-tetraphenylindanone-1 II is formed practically quantitatively. It also gave the acid V with alcoholic potash, confirmed by conversion to its methyl ester, and the same phenyl carbinol[2b] with phenylmagnesium bromide and decomposition by iced ammonium chloride and corresponding hydrocarbon[2b] on dehydration above 300°.

The Quinoxaline of the Diketone IX.—This was obtained as previously described,[1] but recrystallized from benzene–ligroin. Before analysis it was dried at 100° *in vacuo* over phosphorus pentoxide for nineteen hours.

Anal. Calcd. for $C_{39}H_{26}N_2$: C, 89.7; H, 5.0. Found: C, 89.6; H, 5.2.

Cleavage of the Diketone IX.—To a suspension of 27 g. of the diketone[1] in 600 cc. of alcohol was added a solution of 12 g. of sodium hydroxide in 75 cc. of water; after cooling in ice and stirring for a half hour all had dissolved. Then 75 cc. of 16% hydrogen peroxide was added and after an additional two hours the solution was diluted with 600 cc. of water, filtered and the filtrate acidified with acetic acid. After extracting with chloroform and appropriate manipulation, 16 g. (61%) of the acid X, (4,5-diphenyl-2-benzhydrylbenzoic acid) m. p. 258–259°, was collected. The yield by this variation in procedure is much better than when sodium peroxide is used.[1] The acid dissolves in *dilute* alkali only.

Anal. Calcd. for $C_{32}H_{24}O_2$: C, 87.3; H, 5.5. Found: C, 87.5; H, 5.5.

The methyl ester, prepared in the usual manner, separates in rods from benzene–methanol; m. p. 165°.

Anal. Calcd. for $C_{33}H_{26}O_2$: C, 87.2; H, 5.7. Found: C, 87.5; H, 5.5.

The Lactone VII (3,4-Diphenyl-diphenylphthalide). (a) Synthesis.—This was accomplished by treatment of

[a] Prisms. [b] Needles. [c] Tiny rods.

2-benzoyl-4,5-diphenylbenzoic acid VIII[8] with phenylmagnesium bromide, decomposing the complex with ammonium chloride, and recrystallizing from acetic acid. It forms rods; m. p. 180°.

Anal. Calcd. for $C_{32}H_{22}O_2$: C, 87.7; H, 5.0. Found: C, 87.7; H, 4.9.

(b) **From the Acid X.**—An intimate mixture of 15 g. of the acid and 2 g. of copper carbonate was heated at 260–265° for a half hour, and the cooled melt extracted with hot benzene; it was filtered from metallic copper and diluted with ligroin. The lactone was deposited in a yield of 20%. From the filtrate 3,4-diphenylbenzhydrylbenzene XI crystallized in a 30% yield. It forms needles and rods from acetic acid, m. p. 143°.

Anal. Calcd. for $C_{31}H_{24}$: C, 93.9; H, 6.1. Found: C, 93.9; H, 6.0.

The hydrocarbon XI was also synthesized from 3,4-diphenylbenzophenone and phenylmagnesium bromide; the oily carbinol was reduced by zinc and acetic acid.

The lactone is unaffected by bromine, acetyl chloride and chromic acid. It is reduced to the acid X by zinc and acetic acid.

2-Bromo-3,3,5,6-tetraphenylindenone, XV, was obtained when the dibromoketone XIV[1] was treated with excess phenylmagnesium bromide in the usual manner. It separates in needles from benzene, m. p. 240°. The yield was 60%. Repetition of the treatment on this bromoketone gave the indanone II.

(8) Allen, A. C. Bell, A. Bell and VanAllan, THIS JOURNAL, **62**, 656 (1940).

Anal. Calcd. for $C_{33}H_{23}OBr$: C, 76.9; H, 4.5; Br, 15.5. Found: C, 76.7; H, 4.4; Br, 15.4.

The carbinols, XVI, were secured by the usual procedure, decomposing the organometallic complex with ammonium chloride. The corresponding hydrocarbons XVII were produced by refluxing 4 g. of the carbinols in 50 cc. of 2% sulfuric acid in acetic acid for a half hour. Their properties are collected in Table I.

The glycol, 1,2,3,3,5,6-hexaphenylindandiol-1,2, XVIII, was prepared from the diketone IX and an excess of phenylmagnesium bromide in butyl ether for six hours at 100°.

Summary

The bimolecular product, formed by the action of acidic dehydrating agents on anhydracetonebenzil, forms a peroxide, upon treatment with alkaline hydrogen peroxide. This substance loses its oxygen and gives an isomer in acetic acid solution. The isomer affords a previously described indanone on decarbonylation.

The indanone has been degraded to known products, the syntheses of two of which are described. It has also been converted into a carbinol and hydrocarbon isomeric with some closely related substances.

Deamination of 5-Amino-8-nitroisoquinoline[1]

BY BERTRAM KEILIN AND W. E. CASS[2]

In an attempt to prepare 8-nitroisoquinoline, 5-acetylaminoisoquinoline[3] was nitrated and the resulting acetylaminonitroisoquinoline hydrolyzed to an aminonitroisoquinoline. When the aminonitroisoquinoline was diazotized in hydrochloric acid solution and treated with hypophosphorous acid,[4] there was obtained 8-chloroisoquinoline, identified by analysis and by comparison with a known sample of 8-chloroisoquinoline.[5]

In the preceding diazotization-deamination, the nitro group was displaced by chlorine, nitrous acid being evolved. This displacement of the nitro group possibly occurred during diazotization,

(1) Constructed, in part, from the B.A. research paper of Bertram Keilin, New York University, University College, 1942.

(2) Present address: Research Laboratory, General Electric Company, Schenectady, New York.

(3) Craig and Cass, THIS JOURNAL, **64**, 783 (1942).

(4) Adams and Kornblum, *ibid.*, **63**, 188 (1941).

(5) Pomeranz, *Monatsh.*, **18**, 1 (1897), prepared, but did not analyze, 8-chloroisoquinoline by ring closure of *o*-chlorobenzalaminoacetal.

because it was noted that an excess of nitrous acid was always present in the diazotized solution, even when less than the theoretical amount of sodium nitrite had been added. Since the replacement of the nitro group by chlorine resulted in the formation of 8-chloroisoquinoline, the structure, 5-amino-8-nitroisoquinoline, was assigned to the starting material. Other examples of the displacement of a nitro group, labilized by the diazonium group, have been observed in the case of dinitroanisidines[6] and 1-nitro-2-aminonaphthalene.[7]

Several further attempts to prepare 8-nitroisoquinoline from 5-amino-8-nitroisoquinoline were made without success. Diazotization in dilute or concentrated sulfuric acid and deamination with alcohol or hypophosphorous acid failed to lead to 8-nitroisoquinoline. The use of acetic and sulfuric acids as a diazotization medium[8] and alcohol deamination likewise failed, possibly as a result of the low solubility of 5-amino-8-nitroisoquinoline in glacial acetic acid.

Experimental

All melting points are corrected.

5-Acetylamino-8-nitroisoquinoline.—Finely powdered and thoroughly dried 5-acetylaminoisoquinoline[9] (18.6 g., 0.1 mole) was added slowly with mechanical stirring to 100 cc. of concentrated sulfuric acid maintained at 0–10°. When all of the acetylaminoisoquinoline had dissolved, a cool solution of 11.1 g. (0.11 mole) of potassium nitrate in 40 cc. of concentrated sulfuric acid was added with constant stirring during the course of forty-five minutes, the mixture being maintained at 15–20°. After the addition of the potassium nitrate–sulfuric acid was complete, the reaction mixture was allowed to stand at 15–20° for an additional forty-five minutes and then poured onto excess cracked ice. The acid solution was neutralized with ammonium hydroxide, more ice being added as necessary to keep the solution cool. The precipitated crude product was filtered and recrystallized from alcohol, using decolorizing charcoal, as yellow-brown needles; yield, 11.2 g; m. p. 225–227°. By concentration of the mother liquor, an additional 5.2 g. of substance of m. p. 224–226° was recovered, making the total yield 16.4 g. (71%). Further recrystallizations from alcohol gave yellow needle clusters of m. p. 226–228°.

Anal. Calcd. for $C_{11}H_9O_3N_3$: C, 57.14; H, 3.92; N, 18.18. Found: C, 57.3; H, 3.8; N, 18.1.

5-Amino-8-nitroisoquinoline Hydrochloride.—A solution of 15 g. of 5-acetylamino-8-nitroisoquinoline in 150 cc. of 20% hydrochloric acid was boiled under reflux for twenty-five minutes. The reaction mixture was cooled and the orange-red crystalline precipitate filtered. This substance proved to be the monohydrate of 5-amino-8-nitroisoquinoline hydrochloride. The crude yield was 15.6 g. (97%). The substance was recrystallized from water plus a small amount of hydrochloric acid as orange needles, m. p. 288–290° (dec.). On standing in a vacuum desiccator over sulfuric acid, the product became orange-red in color and lost its water of hydration. (This color change was also observed during the melting point determination for the hydrated salt.) The anhydrous salt melted at 289–291° (dec.).

Anal. Calcd. for $C_9H_8O_2N_3Cl \cdot H_2O$: H_2O, 7.39. Found: H_2O, 7.3, 7.4. Calcd. for $C_9H_8O_2N_3Cl$: N, 18.63; Cl, 15.71. Found: N, 18.5; Cl, 15.7.

5-Amino-8-nitroisoquinoline.—Neutralization of a hot aqueous solution of the preceding hydrochloride with ammonium hydroxide caused the formation of a voluminous precipitate of the free base in nearly quantitative yield. The substance crystallized from alcohol as orange needles, m. p. 268–270° (dec.).

Anal. Calcd. for $C_9H_7O_2N_3$: C, 57.14; H, 3.73; N, 22.22. Found: C, 57.3; H, 3.7; N, 22.1.

Treatment of 5-amino-8-nitroisoquinoline with warm dilute hydrochloric acid caused the formation of the hydrate of its hydrochloride salt (m. p. 288–290° (dec.)). Likewise the substance, heated with acetic anhydride, was transformed into 5-acetylamino-8-nitroisoquinoline (m. p. 226–228°).

8-Chloroisoquinoline.—A suspension of 4.88 g. (0.02 mole) of the hydrate of 5-amino-8-nitroisoquinoline hydrochloride in 30 cc. of concentrated hydrochloric acid was cooled to −10–0° and, with stirring, a solution of 1.3 g. (0.019 mole) of sodium nitrite in 10 cc. of water was slowly added. As diazotization proceeded, the color of the solution lightened and the suspended aminonitroisoquinoline hydrochloride dissolved. A starch–iodide test for nitrous acid was at all times positive. After the addition of the nitrite, the solution was stirred and cooled for five minutes and then 20 cc. of ice-cold 50% hypophosphorous acid was added. Nitrogen and some oxides of nitrogen were evolved. The reaction mixture was allowed to stand in an icebox six hours, then overnight at room temperature and finally was poured on ice and made basic with 20% sodium hydroxide solution. Steam distillation of the mixture separated a colorless oil which, on standing in the icebox, crystallized in long fine needles. The crude yield was 2.3 g. (70%); m. p. 54–55°. The substance crystallized from petroleum ether as small, white prisms of m. p. 55.5–56.5° (Pomeranz[5] reported m. p. 55°). The substance showed no depression in a mixed melting point with a sample of 8-chloroisoquinoline, prepared by ring closure, described below.

Anal. Calcd. for C_9H_6NCl: C, 66.07; H, 3.70; N, 8.56; Cl, 21.67. Found: C, 66.0; H, 3.6; N, 8.5; Cl, 21.2.

Picrate.—Recrystallized from alcohol as hair-fine yellow needles; m. p. 189.5–191.5°. No depression was observed

(8) Hodgson and Walker, *ibid.*, 1620 (1933).

(9) In the preparation of large amounts of 5-acetylaminoisoquinoline,[3] it was observed that this substance, recrystallized from dilute alcohol, lost its crystalline appearance on standing in a vacuum desiccator over sulfuric acid. Analysis indicated that the substance crystallized as a hemi-hydrate. *Anal.* Calcd. for $C_{11}H_{10}ON_2 \cdot {}^1/_2H_2O$: H_2O, 4.62. Found: H_2O, 4.6.

in a mixed melting point with the picrate of 8-chloroisoquinoline prepared by ring closure.

Anal. Calcd. for $C_{15}H_9O_7N_4Cl$: N, 14.27. Found: N, 14.0.

o-Chlorobenzalaminoacetal.—Equimolar amounts of *o*-chlorobenzaldehyde and aminoacetal[10] were heated in an oil-bath at 110° until the liberated water was driven off. The product, distilled under reduced pressure, was obtained as an almost colorless oil in 95% yield; b. p. 114–117° (2 mm.) (oil-bath at 150–160°).

Anal. Calcd. for $C_{13}H_{18}O_2NCl$: C, 61.05; H, 7.10; N, 5.48. Found: C, 60.7; H, 7.0; N, 5.3.

8-Chloroisoquinoline.—The method of Tyson,[11] using sulfuric acid and phosphorus pentoxide, was employed for the ring closure of *o*-chlorobenzalaminoacetal. The method of working up the product, however, was modified as follows. The cooled sulfuric acid reaction mixture (from 20 g. of *o*-chlorobenzalaminoacetal) was poured on ice and made basic with ammonium hydroxide. The basic solution was extracted with three 200-cc. portions of ether. The combined ether extracts were then extracted with 100 cc. of 6 *N* hydrochloric acid. The hydrochloric acid solution was evaporated to dryness on the steam-bath, made basic with potassium carbonate solution and steam distilled. There was obtained 8-chloroisoquinoline of m. p. 55–56° in 9% yield. The picrate crystallized from alcohol as very fine yellow needles of m. p. 189.5–191.5°.

(11) Tyson, *ibid.*, **61**, 183 (1939).

Summary

1. The preparation of 5-amino-8-nitroisoquinoline has been described.

2. Deamination of 5-amino-8-nitroisoquinoline in hydrochloric acid has been shown to yield 8-chloroisoquinoline.

NEW YORK, N. Y. RECEIVED JULY 28, 1942

[CONTRIBUTION FROM THE NICHOLS CHEMISTRY LABORATORY OF NEW YORK UNIVERSITY]

2-Phenyloxazole; *para*-Substituted Derivatives[1]

BY JEROME J. ROSENBAUM AND W. E. CASS[2]

In an extension of previously reported work[3] on the synthesis of ortho-substituted derivatives of 2-phenyloxazole, *p*-nitrobenzalaminoacetal was treated with sulfuric acid and phosphorus pentoxide. The product isolated from this reaction proved to be 2-(*p*-nitrophenyl)-oxazole. Oxidation of this substance yielded *p*-nitrobenzamide. By reduction of the nitro group there was obtained 2-(*p*-aminophenyl)-oxazole, from which several derivatives were prepared. Deamination of 2-(*p*-aminophenyl)-oxazole resulted in the formation of 2-phenyloxazole, identical with the substance obtained by the deamination of 2-(*o*-aminophenyl)-oxazole.[3] Nitration of 2-phenyloxazole resulted in the formation of 2-(*p*-nitrophenyl)-oxazole.

The preparation of 2-(*p*-nitrophenyl)-oxazole was also accomplished by treatment of *p*-nitrobenzoylaminoacetal with sulfuric acid and phosphorus pentoxide. Unlike the case of the corresponding ortho derivative,[3] this alternate method of preparation gave 2-(*p*-nitrophenyl)-oxazole in yields comparable to those obtained from *p*-nitrobenzalaminoacetal.

Pharmacological tests on 2-(*p*-sulfanilamidophenyl)-oxazole were carried out by the Merck Institute for Therapeutic Research, Rahway, New Jersey. In staphylococcal infections in mice, this compound was not particularly effective in comparison with sulfathiazole. In streptococcal infections, although some activity was shown, the compound was not as effective as sulfanilamide.

Experimental

All melting points are corrected.

***p*-Nitrobenzalaminoacetal.**—Equimolar amounts of *p*-nitrobenzaldehyde and aminoacetal[3] were heated in an oil-bath at 110–120° until the liberated water was driven off. The reaction mixture was allowed to cool somewhat and twice its volume of dry ether was added. Cooling of the ether solution with dry-ice resulted in the precipitation of *p*-nitrobenzalaminoacetal in 80–87% yield. Further recrystallization from ether gave white plates of m. p. 56–57°, b. p. 165–168° (2 mm.) (oil-bath 200–210°).

Anal. Calcd. for $C_{13}H_{18}O_4N_2$: C, 58.62; H, 6.81; N, 10.52. Found: C, 58.7; H, 6.5; N, 10.6.

2-(*p*-Nitrophenyl)-oxazole from *p*-Nitrobenzalaminoacetal.—The reaction of *p*-nitrobenzalaminoacetal with sulfuric acid and phosphorus pentoxide was carried out following the method used in the preparation of 2-(*o*-nitrophenyl)-oxazole.[3] The crude product, however, was not purified by steam distillation but by recrystallization from alcohol, using decolorizing charcoal. 2-(*p*-Nitrophenyl)-oxazole was thus obtained as yellowish needles in 40% yield, m. p. 163.5–164.5°.

(1) Constructed, in part, from the B.A. research paper of Jerome J. Rosenbaum, New York University, University College, June, 1942.
(2) Present address: Research Laboratory, General Electric Company, Schenectady, New York.
(3) Cass, THIS JOURNAL, **64**, 785 (1942).

Anal. Calcd. for $C_9H_6O_3N_2$: C, 56.85; H, 3.18; N, 14.73. Found: C, 56.8; H, 3.3; N, 14.6.

2-(*p*-Nitrophenyl)-oxazole was weakly basic, dissolving in concentrated hydrochloric or sulfuric acid, but reprecipitating on dilution of the solution with water. The substance could be recrystallized from benzene as stout yellowish needles. A test for the nitro group was positive. Steam distilled, the substance passed over as small white crystals, which, however, crystallized from benzene as yellowish needles.

Oxidation of 2-(*p*-nitrophenyl)-oxazole was carried out using potassium permanganate or bromine water as previously described for the oxidation of 2-(*o*-nitrophenyl)-oxazole.[3] In each case the product of oxidation, recrystallized from water plus a small amount of ammonium hydroxide, was identified as *p*-nitrobenzamide by a mixed melting point determination with an authentic sample of *p*-nitrobenzamide (m. p. 199–202°).

2-(*p*-Nitrophenyl)-oxazole from *p*-Nitrobenzoylaminoacetal.—*p*-Nitrobenzoylaminoacetal[4] (10.8 g., 0.038 mole) was added slowly with constant stirring to 70 cc. of concentrated sulfuric acid cooled to −5°. This cold solution was allowed to drop during eight minutes onto a mixture of 25 g. of phosphorus pentoxide and 6 cc. of sulfuric acid in a flask fitted with an efficient reflux condenser and maintained at 180–190° in an oil-bath. The flask was occasionally shaken and, after the addition was complete, the reaction mixture was allowed to stand twenty-five minutes at 180–190°. After cooling, the reaction mixture was poured on ice and made basic with ammonium hydroxide. The crude product was filtered and recrystallized from alcohol, using decolorizing charcoal. There was obtained 3.3 g. (45%) of product as almost white needles of m. p. 163.5–164.5°. This substance showed no depression in a mixed melting point determination with 2-(*p*-nitrophenyl)-oxazole prepared from *p*-nitrobenzalaminoacetal.

2-(*p*-Aminophenyl)-oxazole.—Hydrogenation of a suspension of 2-(*p*-nitrophenyl)-oxazole in absolute ethanol was carried out, using Raney nickel, as previously described for the corresponding ortho derivative.[3] After filtration of the catalyst and evaporation of the alcohol under reduced pressure, the crude product (obtained in nearly quantitative yield) was recrystallized several times from benzene as white needles of m. p. 121–123°.

Anal. Calcd. for $C_9H_8ON_2$: C, 67.49; H, 5.04; N, 17.49. Found: C, 67.5; H, 5.0; N, 17.5.

The reduction of 2-(*p*-nitrophenyl)-oxazole was also carried out using stannous chloride. A solution of 5 g. (0.0263 mole) of the nitro compound in 22.5 cc. of concentrated hydrochloric acid was added to 18.5 g. (0.0812 mole) of stannous chloride dissolved in 22.5 cc. of concentrated hydrochloric acid. The reaction mixture was warmed on the steam-bath and then, with cooling, made strongly basic with 33% sodium hydroxide solution. The precipitated crude product was obtained in 92% yield.

Unlike the corresponding ortho derivative,[3] 2-(*p*-aminophenyl)-oxazole in alcohol solution did not show fluorescence in daylight. In ultraviolet light, however, a bluish fluorescence was observed.

(4) Löb, *Ber.*, **27**, 3093 (1894).

Derivatives of 2-(*p*-Aminophenyl)-oxazole.—The picrate and the acetyl, benzoyl and acetylsulfanilyl derivatives of 2-(*p*-aminophenyl)-oxazole were prepared as previously described for the corresponding ortho derivatives,[3] essentially the same yields being obtained. These derivatives are listed in Table I.

TABLE I

2-(—)-oxazole	M. p., °C.	*Anal.* Calcd.	N, % Found
p-Aminophenyl, picrate[a,c]	182.5–184 (dec.) $C_{15}H_{11}O_8N_5$	17.99	18.0
p-Acetylaminophenyl[a,d]	191.5–192.5 $C_{11}H_{10}O_2N_2$	13.86	13.9
p-Benzoylaminophenyl[a,e]	163.5–164.5 $C_{16}H_{12}O_2N_2$	10.60	10.7
p-(N^4-Acetylsulfanilamido)-phenyl[b,d]	226.5–228 $C_{17}H_{15}O_4N_3S$	11.76	11.7

[a] Recrystallized from 50% alcohol. [b] Recrystallized from absolute alcohol. [c] Yellow needles. [d] Needles. [e] Plates or prisms.

2-(*p*-Sulfanilamidophenyl)-oxazole.—Hydrolysis of 2-(*p*-(N^4-acetylsulfanilamido)-phenyl)-oxazole was effected by boiling the substance under reflux with ten times its weight of 12% hydrochloric acid for thirty minutes. By neutralization of the solution with ammonium hydroxide the product was precipitated in 95% yield. The substance was recrystallized from 50% alcohol, using decolorizing charcoal, as small plates; m. p. 191.5–192.5°.

Anal. Calcd. for $C_{15}H_{13}O_3N_3S$: C, 57.13; H, 4.16; N, 13.33. Found: C, 57.2; H, 4.1; N, 13.2.

2-Phenyloxazole.—Deamination of 2-(*p*-aminophenyl)-oxazole, as described previously for the corresponding ortho derivative,[3] resulted in the formation of 2-phenyloxazole (b. p. 226–228°) in 34% yield. The picrate (m. p. 115–116°) prepared from this substance showed no depression in a mixed melting point with the picrate of 2-phenyloxazole previously prepared.[3]

Nitration of 2-Phenyloxazole.—To 0.2 g. of 2-phenyloxazole in 5 cc. of concentrated sulfuric acid was added 0.2 g. (excess) of potassium nitrate. The mixture was stirred until the potassium nitrate was dissolved, allowed to stand one hour at room temperature and then warmed to 70° for ten minutes. Ice was added and the mixture neutralized with ammonium hydroxide. The crude yield was 0.2 g. (77%); however, the product was impure as was shown by its low melting point (below 100°). Recrystallization from alcohol followed by recrystallization from benzene and ligroin gave a small amount of yellowish needles of m. p. 162.5–164°. No depression was observed in a mixed melting point with 2-(*p*-nitrophenyl)-oxazole prepared from *p*-nitrobenzalaminoacetal.

Summary

1. Certain para-substituted derivatives of 2-phenyloxazole have been prepared.

2. Pharmacological tests on 2-(*p*-sulfanilamidophenyl)-oxazole have been reported.

NEW YORK, N. Y. RECEIVED JULY 28, 1942

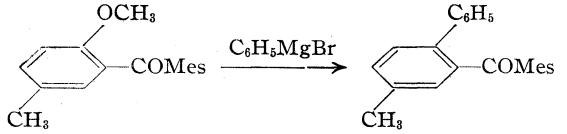
[CONTRIBUTION FROM THE NOYES CHEMICAL LABORATORY, UNIVERSITY OF ILLINOIS]

ortho Alkylation and Arylation of Mesityl Aryl Ketones

BY REYNOLD C. FUSON AND S. B. SPECK

The action of aryl Grignard reagents on mesityl aryl ketones[1] and aryl mesitoates[2] has been shown to bring about *ortho* arylation. The change evidently involves 1,4 addition followed by oxidation of the addition product, although the manner in which the latter transformation occurs has not been determined. It amounts to the elimination of a molecule of hydrogen from the dihydrobenzenoid compound or its enol form.

A method has now been discovered whereby the arylation can be effected smoothly and in high yields. It consists simply in the use of mesityl *o*-methoxyaryl ketones. An example is the conversion of 2-methoxy-5-methylbenzoylmesitylene (I) to 2-phenyl-5-methylbenzoylmesitylene (II) by the action of phenylmagnesium bromide.



I II

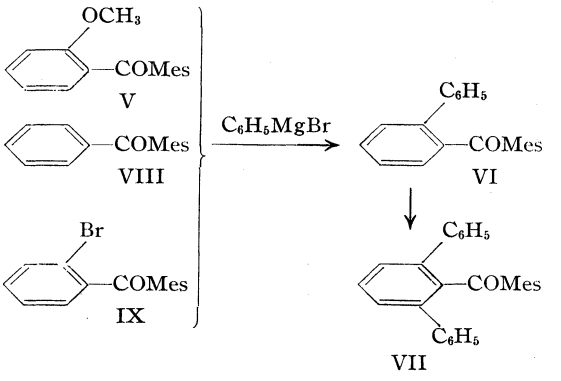
The reaction proceeded readily and in good yield at room temperature.

ortho-Alkylation could be effected also. When ethylmagnesium bromide was used the product was 2-ethyl-5-methylbenzoylmesitylene (III).

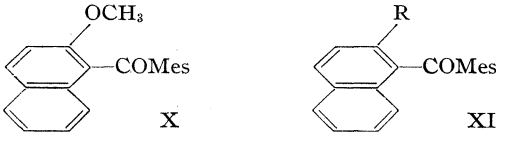
III IV

As was to be expected, phenylmagnesium bromide at higher temperatures brought about diphenylation to produce 2,6-diphenyl-3-methylbenzoylmesitylene (IV).

Similar results were obtained with 2-methoxybenzoylmesitylene (V). One or two phenyl groups could be introduced, the products being VI and VII, respectively. The monophenyl derivative (VI) had been obtained, though in lower yield, by the action of phenylmagnesium bromide on benzoylmesitylene (VIII).[1] It is significant that the 2-bromo derivative (IX) yielded the diphenylated ketone, VII. Presumably, this transformation involves the monophenyl ketone (VI) as an intermediate.

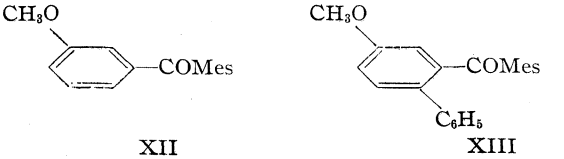


The conversion of the methoxyl compound (V) to the monophenyl ketone takes place much more readily than the introduction of the second phenyl group, *i. e.*, the transformation of VI to VII. The two processes are evidently dissimilar in nature. In order to simplify the study of the replacement of methoxyl groups, the investigation was extended to 1-mesitoyl-2-methoxynaphthalene (X) which has no second *ortho* position. This ketone reacted smoothly with phenylmagnesium bromide to yield 1-mesitoyl-2-phenylnaphthalene (XI, R = C_6H_5).



In a similar manner methyl, ethyl, *n*-butyl and α-naphthyl groups were introduced by use of the appropriate Grignard reagents. The yields varied from 56 to 80%.

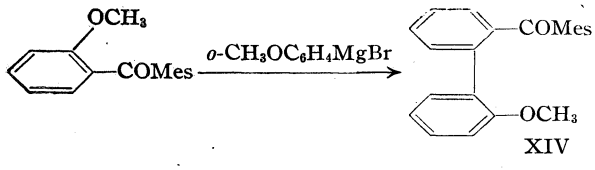
An attempt to replace a methoxyl group in a meta position was unsuccessful. 3-Methoxybenzoylmesitylene (XII) reacted with phenylmagnesium bromide to yield a methoxy compound, which probably has the structure represented by XIII.



(1) Fuson, Armstrong and Speck, *J. Org. Chem.*, **7**, 297 (1942).
(2) Fuson, Bottorff and Speck, THIS JOURNAL, **64**, 1450 (1942).

This is in contrast to the action of phenylmagnesium bromide on V, the ortho isomer of XII, to produce *o*-phenylbenzoylmesitylene (VI).

The new reaction served to establish the structure of 2-(2-methoxyphenyl)-benzoylmesitylene (XIV) reported previously.[2] It was found possible to obtain it by condensing 2-methoxybenzoylmesitylene with *o*-methoxyphenylmagnesium bromide.



XIV

The new method for introducing alkyl and aryl radicals into an aromatic ring appears to depend on 1,4 addition of the Grignard reagent followed by the elimination of the elements of methanol. The ether is a vinylog of methyl mesitoate and would, therefore, be expected to react with the Grignard reagent in an analogous manner. This suggests also the alternate possibility that the replacement of the methoxyl group might be the result of simple metathesis.

Experimental[3]

1-Mesitoyl-2-methoxynaphthalene (X).—A solution of 76 g. of mesitoyl chloride in 90 cc. of carbon disulfide was added slowly to a mixture of 75 g. of β-naphthyl methyl ether, 63 g. of aluminum chloride and 150 cc. of carbon disulfide. The mixture was stirred at room temperature for about twelve hours and then treated with an ice–hydrochloric acid mixture. The organic layer was separated and washed with dilute sodium hydroxide solution and water. The solvent was removed by evaporation, and the solid product, 1-mesitoyl-2-methoxynaphthalene, was recrystallized from ethanol. The yield of 1-mesitoyl-2-methoxynaphthalene was 65 g. The ketone crystallized from alcohol in yellow plates; m. p. 109–110°.

Anal. Calcd. for $C_{21}H_{21}O_2$: C, 82.57; H, 6.95. Found: C, 82.97; H, 6.49.

2-Methoxy-5-methylbenzoylmesitylene (I).—This compound was prepared by the Friedel–Crafts method in a manner similar to the foregoing. From 36.6 g. of 4-methylanisole and 54.6 g. of mesitoyl chloride was obtained 54 g. of the methoxy ketone. It crystallized from ethanol as light green needles; m. p. 103°.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.55; H, 7.52. Found: C, 80.63; H, 7.44.

***m*-Methoxybenzoylmesitylene.**—This ketone was prepared from *m*-methoxybenzoyl chloride and mesitylene by the Friedel–Crafts method. The yield was 58% of the theoretical. The compound separated from ethanol as colorless crystals; m. p. 76°.

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.29; H, 7.10. Found: C, 80.15; H, 7.36.

***o*-Methoxybenzoylmesitylene (V).**—The Grignard reagent prepared from 14 g. of magnesium and 85 g. of *o*-bromoanisole in 250 cc. of dry ether was added slowly, with stirring, to a solution of 72 g. of mesitoyl chloride in 200 cc. of dry ether. Heat was generated and a white precipitate formed. The mixture became semi-solid when all the reagent had been added. It was decomposed with dilute acid and washed with successive portions of water, dilute sodium hydroxide, and more water. The solvent was removed by evaporation and the residue crystallized from alcohol. The yield was 30 g. of *o*-methoxybenzoylmesitylene, which separated from ethanol in light yellow-green crystals; m. p. 112–113°.

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.29; H, 7.10. Found: C, 80.15; H, 7.23.

Action of Grignard Reagents on Mesityl *o*-Methoxyaryl Ketones.—The experimental procedures for the reactions are very similar and can be indicated by a detailed description of two representative procedures.

2-Methoxy-5-methylbenzoylmesitylene and Phenylmagnesium Bromide.—A solution of 13.4 g. of 2-methoxy-5-methylbenzoylmesitylene in 60 cc. of dry benzene was added slowly to the reagent prepared from 3 g. of magnesium and 16.0 g. of bromobenzene in 30 cc. of dry ether and the mixture was heated under reflux for eight hours. The temperature remained at about 60°. The color of the solution changed successively to green, deep blue and, finally, dark red. The reaction mixture was treated with cold dilute hydrochloric acid. The organic layer was washed with dilute acid and water and the solvent removed by evaporation. The viscous red oil was distilled under reduced pressure. About 3.5 g. of a solid was isolated from a fraction of the distillate. This substance crystallized from alcohol in colorless needles. It had the composition of 2,6-diphenyl-3-methylbenzoylmesitylene (IV).

Table I lists this and five other condensations that were carried out in a similar manner with 2-methoxybenzoylmesitylene and 2-methoxy-5-methylbenzoylmesitylene. Yields, melting points and analytical data are given for the products.

1-Mesitoyl-2-methoxynaphthalene and Ethylmagnesium Bromide.—A solution of 7.6 g. of 1-mesitoyl-2-methoxynaphthalene in 25 cc. of dry ether was added over a period of ten minutes to the reagent prepared from 1.2 g. of magnesium and 4.2 g. of ethyl bromide in 30 cc. of dry ether and 20 cc. of dry benzene. The stirring was continued for an additional fifteen minutes. The color of the reaction mixture became pale green and later changed to orange-red. A large amount of a white precipitate formed. The mixture was treated with an ice–hydrochloric acid mixture and the organic layer washed with water. The solvent was removed by evaporation and the solid residue taken up with alcohol and allowed to crystallize. A yield of 6 g. of 1-mesitoyl-2-ethylnaphthalene was obtained. This substance separated from aqueous alcohol in colorless crystals.

This and four other condensations are shown in Table II. Melting points, yields and analytical data are given for the products.

(3) Micronalyses by Miss Margaret McCarthy and Miss Theta Spoor.

[a] Recrystallized from ethanol. [b] Recrystallized from a mixture of benzene and ethanol. [c] 1-Mesitoyl-2-methylnaphthalene was prepared also from 2-methyl-1-naphthoyl chloride and mesitylene by the Friedel–Crafts method and by the condensation of 2-methyl-1-naphthoyl chloride with mesitylmagnesium bromide. These syntheses were carried out by Mr. B. C. McKusick.

Action of Phenylmagnesium Bromide on m-Methoxybenzoylmesitylene.—A solution of 6.4 g. of m-methoxybenzoylmesitylene in 50 cc. of dry benzene was added to a solution of Grignard reagent prepared from 1.5 g. of magnesium, 8.0 g. of bromobenzene and 25 cc. of dry ether. The mixture was heated for eight hours under reflux, during which time it developed a red-brown color. Decomposition in the usual manner and distillation of the product yielded 0.5 g. of a solid that, after recrystallization from petroleum ether (b. p. 60–120°), melted at 194–195° (cor.). It was probably 2-phenyl-5-methoxybenzoylmesitylene.

Anal. Calcd. for $C_{23}H_{22}O_2$: C, 83.59; H, 6.72. Found: C, 83.59; H, 7.02.

Summary

It has been found that when 2-methoxyaryl mesityl ketones are treated with a Grignard reagent the methoxyl group is smoothly replaced by the hydrocarbon radical of the Grignard reagent. The reaction occurs with either alkyl or aryl Grignard reagents.

The Bromination of 4-Phenylphenyl Chloroacetate

BY STEWART E. HAZLET, LEE C. HENSLEY AND HERMAN JASS

Earlier work[1] on the bromination of 4-phenylphenyl acetate and benzoate in the presence of iron as a catalyst showed that the acetyloxy radical caused 2-orientation while the larger benzoyloxy group promoted 4′-orientation in the biphenyl nucleus. A study has now been made of the corresponding ester of chloroacetic acid in order to see whether the spatial or other possible influence of this intermediate-sized radical were large enough to inhibit 2-orientation. The results in carbon tetrachloride and 1,1,2-trichloroethane show that the chloroacetyloxy group had a steric effect, *i. e.*, caused the bromine to enter the 4′-position. Abnormal results were found, however, when the reaction was carried out in acetic acid.

Experimental Part

4-Phenylphenyl Chloroacetate.—Seventy-eight grams of 4-phenylphenol was dissolved in a solution containing 63 ml. of pyridine and 126 ml. of 1,4-dioxane; the solution was cooled to 5°, and 52 ml. of chloroacetyl chloride was added in small portions. The mixture was allowed to stand overnight, and it was then gradually warmed to 115° and heated at that temperature for three and one-half hours. Again it was allowed to stand overnight at room temperature. The ester was extracted from the reaction mixture with three 50-ml. portions of boiling benzene. The combined extracts were washed with water, with 10% hydrochloric acid and 5% sodium hydroxide solutions, and finally with water, and then dried with anhydrous sodium sulfate in the presence of Norite. A yield of 82.8 g. (73.2%) was obtained after removal of the benzene by distillation. After two recrystallizations from ethanol, the product, colorless needles, melted at 116–117°. The compound was also purified by distillation; b. p. 185° (3 mm.). The melting point of the distillate was 116–117°.

Anal. Calcd. for $C_{14}H_{11}O_2Cl$: Cl, 14.4. Found: Cl, 14.3.

4-Phenylphenyl Bromoacetate.—This compound was prepared in 75.7% yield by a method essentially the same as that used for the preparation of the analogous chloro compound. The product was purified by recrystallization from ethanol and by distillation; b. p. 185° (3 mm.) and m. p. 112–112.5°. It was in the form of colorless needles, almost identical with 4-phenylphenyl chloroacetate. It is interesting to note that this bromoacetate and the corresponding chloroacetate, when mixed, melt without depression.

Anal. Calcd. for $C_{14}H_{11}O_2Br$: Br, 27.5. Found: Br, 27.6.

Chloroacetates of Bromophenylphenols.—By treatment of the appropriate phenols with one and one-half to two equivalents of chloroacetyl chloride in the presence of a little more than enough dry pyridine to combine with all of the hydrogen chloride liberated and usually in the presence of 1,4-dioxane, the esters shown in Table I were obtained.

TABLE I

CHLOROACETATES OF THE BROMOPHENYLPHENOLS

Phenol used	Yield, %	Solvent	Crystal form, colorless	M. p., °C.	Formula	Analyses, % Cl + Br Calcd.	Found
2-Bromo-4-phenyl-[2]	46	Ligroin (70–90°)	Short, hexagonal prisms	60.5–62	$C_{14}H_{10}O_2ClBr$	35.5	35.5
2,6-Dibromo-4-phenyl-[2]	67.5	Ligroin (70–90°)	Needles	83 – 84	$C_{14}H_9O_2ClBr_2$	48.3	48.3

Bromination of 4-Phenylphenyl Chloroacetate in Glacial Acetic Acid ("Analytical Reagent").—(A) Fifteen grams of 4-phenylphenyl chloroacetate was dissolved in 110 ml. of glacial acetic acid ("analytical reagent"). The solution was heated to 100°, a trace of iron powder was added, and 4.1 ml. of bromine dissolved in 25 ml. of glacial acetic acid was introduced dropwise over a period of thirty minutes. Mechanical stirring, which had been provided, was continued for six hours while the mixture was heated at 118° (±2°). After standing overnight at room temperature, the dark red reaction mixture was poured into 600 ml. of water, and extraction with three 70-ml. portions of benzene followed. The combined benzene extracts were washed with 5% sodium hydroxide solution and water and dried with anhydrous sodium sulfate in the presence of Norite; the material in this solution constituted *Fraction A-I.* The alkaline solution, mentioned above, was acidified and extracted with benzene—*Fraction A-II.*

(B) A second bromination was carried out in the same manner as described above, but the reaction mixture was not poured into water, and the major portion of the acetic acid was removed by distillation under reduced pressure. The residue was dissolved in ether, and the solution was shaken with solid sodium bisulfite and allowed to stand overnight with this reagent in the presence of Norite. After filtering, the ether was removed by distillation. The

residue was next distilled at low pressure. *Fraction B-I* distilled at 80–82° (5 mm.); *Fraction B-II* was collected at 137° (2 mm.); no other material distilled at this pressure up to 160° where the distillation was stopped.

The compounds isolated from these various fractions are represented below in Table II; only very small amounts of purified products were obtained.

TABLE II

Fraction	Compound	M. p., °C.[a]
A-I	4-Phenylphenyl chloroacetate	111.5–112.5
A-II[b]	4-Phenylphenol	154 –158
	2,6-Dibromo-4-phenylphenol	85 – 86
B-I	Chloroacetic acid	45 – 48
B-II	4-Phenylphenyl acetate	83 – 85

[a] Identification by means of a mixed melting point determination with an authentic sample was made in each case. [b] Separated by fractional crystallization.

Bromination of 4-Phenylphenyl Chloroacetate in Specially Treated Glacial Acetic Acid.—Ten grams of 4-phenylphenyl chloroacetate was dissolved in 30 ml. of acetic acid which had been freshly distilled from phosphorus pentoxide. A trace of iron powder and then 3.3 ml. of bromine were added. The reaction mixture was stirred and heated at 115–120° for ten hours. The acetic acid was removed by distillation at reduced pressure, and the residue solidified on cooling. After one crystallization from 70–90° ligroin, the product was obtained as colorless, granular crystals; 8.25 g. (70% yield). Ethanol was used for recrystallizations, and colorless needles resulted; m. p. 110–111.5°. Qualitative analysis (sodium fusion method) gave a test for bromine.

Anal. Calcd. for $C_{14}H_{11}O_2Br$: Br, 27.5. Found: Br, 27.5.

When the product was mixed with 4-phenylphenyl bromoacetate, a melting point of 111–112.5° was observed.

Hydrolysis of 4-Phenylphenyl Bromoacetate.—To further prove the identity of the material assumed to be 4-phenylphenyl bromoacetate, a sample of the product obtained by the bromination of 4-phenylphenyl chloroacetate in specially treated glacial acetic acid was hydrolyzed. When the phenol which was obtained (m. p. 159–161°) was mixed with a carefully purified sample of 4-phenylphenol there was no softening below 161°, and the mixture melted between 161.5 and 163°. Thus its identity as 4-phenylphenol was established.

Bromination of 4-Phenylphenyl Chloroacetate in Carbon Tetrachloride.—Four and eight-tenths grams of the chloroacetate was dissolved in carbon tetrachloride, a trace of powdered iron was added, the mixture was heated to 75°, and 1.2 ml. of bromine was added dropwise with stirring. After the mixture had been heated for four hours at 70 to 80°, it was poured into water and extracted first with ether and then with chloroform. From the ether solution there was obtained 0.8 g. of product; m. p. 139–141°. The chloroform extract yielded 0.8 g. of product; m. p. 139.5–141.5°. The total yield was 1.6 g. (26%). Because mixtures of the two samples melted without depression, they were combined and recrystallized from ethanol; needles were obtained, m. p. 141–142.8°. This compound was shown to be 4-(4-bromophenyl)-phenyl chloroacetate; a mixture of it and 4-(4-bromophenyl)-phenyl chloroacetate, prepared as described in a previous paragraph, melted without depression.

Hydrolysis of 4-(4-Bromophenyl)-phenyl Chloroacetate.—A small amount of the reaction product obtained by the bromination of 4-phenylphenyl chloroacetate in carbon tetrachloride solution was hydrolyzed, and the crude phenolic product was dissolved in pyridine and converted to 4-(4-bromophenyl)-phenyl benzoate as described previously.[2] The product, after crystallization from methanol, melted at 191° and there was no depression when mixed with a known sample of the benzoate.

Bromination of 4-Phenylphenyl Chloroacetate in 1,1,2-Trichloroethane.—The procedure for this bromination was the same as that carried out in carbon tetrachloride as described above except that after the reaction had been carried out in 1,1,2-trichloroethane, the mixture was washed with water, and then the solvent was removed by distillation. The yield of crude product was nearly quantitative but, after recrystallizations from ethanol, the needles which melted at 141–142.5° represented only a 60% yield of 4-(4-bromophenyl)-phenyl chloroacetate.

Summary

1. The bromination of 4-phenylphenyl chloroacetate in different solvents led to a variety of products: (a) glacial acetic acid ("analytical reagent")—4-phenylphenyl chloroacetate, 4-phenylphenyl acetate, 2,6-dibromo-4-phenylphenol, 4-phenylphenol and chloroacetic acid; (b) specially treated glacial acetic acid—4-phenylphenyl bromoacetate; (c) carbon tetrachloride—4-(4-bromophenyl)-phenyl chloroacetate; (d) 1,1,2 - trichloroethane—4 - (4 - bromophenyl) - phenyl chloroacetate.

2. The behavior in carbon tetrachloride and 1,1,2-trichloroethane in part confirms the earlier suggestion that steric effects may determine the positions taken by substituents entering an ester molecule of the type represented.

3. Several related compounds which had not been reported previously have been prepared and some of their properties reported.

PULLMAN, WASHINGTON RECEIVED JULY 18 1942

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF NORTHWESTERN UNIVERSITY]

Physiologically Active Phenethylamines Containing a Tertiary Hydroxyl

BY C. M. SUTER AND ARTHUR W. WESTON[1]

It has been found that the introduction of an alkyl group into the *beta* position of phenethylamines[2] or α-methylphenethylamines[3] lowers the toxicity without appreciably affecting the physiological action. The extension of this study to include the effect of alkylating the carbon atom bearing the hydroxyl in amines of the type $C_6H_5CH(OH)CH(R)NHR$ (R is H or CH_3) seemed of interest.

Despite the great number of ephedrine derivatives that have been prepared, only one reference[4] to the desired alkylephedrines, $C_6H_5C(OH)(R)CH(CH_3)NHCH_3$ (R is CH_3 or C_2H_5), was found. A report on the vasoconstricting action of these compounds was also included. Similarly, only the methyl derivatives of *nor*ephedrine, $C_6H_5C(OH)(CH_3)CH(CH_3)NH_2$,[5] and of its isomer $C_6H_5C(OH)(CH_3)CH_2NHCH_3$ (I)[6,7] have been described. Of the other possible series of amines, $C_6H_5C(OH)RCH_2NH_2$(II), the methyl,[4,8,9,10] ethyl,[4,10] butyl,[11] and cyclohexyl[11] compounds have been prepared and some preliminary pharmacological data reported.[4,11] More recently the 2,5-dimethoxy derivatives of I and II[12] have been synthesized.

In the present investigation representatives of three series of amines containing a tertiary hydroxyl in which the *beta* group is alkyl, alkenyl, or cycloalkyl have been prepared and some preliminary data on their toxicity and other pharmacological properties obtained.[13] All these compounds were synthesized by the reaction of a suitable Grignard reagent upon the aminoketone hydrochlorides. This method of preparing hydroxyamines has been used by other investigators.[4,5,11,12,14] Although some of the compounds contained two asymmetric carbon atoms only one racemic modification was formed. This behavior also occurs in the reaction between amino ketones and aryl Grignard reagents[15] and has been attributed to the effect of the adjacent carbon atom bearing the amino group.

$$C_6H_5COCH(R)NHR'\cdot HCl \xrightarrow[\text{then } H_2O]{R''MgX} C_6H_5C(OH)(R'')CH(R)NHR'$$

The hydroxyamines were not isolated but were converted directly into their hydrochlorides and purified by crystallization. The yields were very good. The reaction of *t*-butylmagnesium chloride upon α-methylaminopropiophenone gave a mixture of amines whose hydrochlorides could not be separated readily. Apparently both reduction and addition had taken place.[16]

The toxicities[13] of the amine hydrochlorides were determined on white mice by the method outlined earlier.[17] The results are listed in the last three columns of Table I. For comparison purposes 2-amino-1-phenyl-1-propanol and ephedrine are included.

Preliminary data obtained from investigating the effect of these compounds on rabbits, dogs and guinea pigs indicate that in general their pressor activity is similar to that of ephedrine and phenylpropanolamine although the effect may be more transient. Tachyphylaxis was noted in all tests with these compounds. In accordance with the previous observations[2,3] the presence of an alkyl group *beta* to the amino group greatly reduces the toxicity without apparently impairing the activity.

Three of the *nor*ephedrine derivatives, the *n*-butyl, *n*-hexyl, and cyclohexyl compounds, were examined for surface anesthesia on the rabbit's cornea.[18] Some anesthesia was produced by the *n*-butyl and cyclohexyl compounds in 3% solution but this was accompanied by a marked irritation which was particularly pronounced in the *n*-butyl

[a] Previously prepared by reduction of oxime, m. p. 183.5° (cor.) ref. 10; ref. 4, m. p. 184–186°. [b] Ref. 11, m. p. 151–152°. [c] Ref. 5, m. p. 244°. [d] Melted with decomposition. [e] This material forms a dihydrate which retained water of crystallization even after two hours at 100° and 40 mm. After drying at 140° for nine hours the solvent was lost but was regained when exposed to the air for a day. *Anal.* Calcd. for $C_{15}H_{24}ONCl\cdot 2H_2O$: H_2O, 11.78. Found: H_2O, 12.46. [f] Ref. 4, m. p. 245–248°. [g] Ref. 4, m. p. 192°. [h] Since the agreement between our m. p. values and those given in the literature was not always entirely satisfactory, analyses for previously known compounds are included. The disagreement probably occurs because the "melting points" are decomposition temperatures and hence vary with the rate of heating. [i] The allylmagnesium bromide was prepared according to the procedure of Gilman and McGlumphy, *Bull. soc. chim.*, **43**, 1322 (1928).

and *n*-hexyl compounds and was evident even in 1% solutions. Because of this undesirable effect only preliminary tests were made.

Experimental

Aminoketone Hydrochlorides.—The ω-aminoacetophenone hydrochloride was prepared by hydrolysis of the product obtained from phenacyl bromide and hexamethylenetetramine.[19] α-Aminopropiophenone hydrochloride was obtained by reduction of the corresponding isonitroso compound[20] with stannous chloride[21] while the N-methyl derivative was obtained by the action of methylamine upon α-bromopropiophenone.[22]

Reaction of Aminoketone Hydrochlorides with Grignard Reagents.—The preparation of β-ethyl*nor*ephedrine is described as a typical example. A Grignard reagent was prepared from 5.3 g. (0.24 mole) of magnesium and a slight excess of ethyl bromide so that no unused magnesium remained. To the ether solution was added at 0° with stirring 10 g. (0.054 mole) of α-aminopropiophenone hydrochloride. Stirring was continued for several hours and the mixture was allowed to stand overnight.[23] A two-layer system formed. After hydrolysis with ice and dilute sulfuric acid the ether layer was removed and evaporated to dryness but left no residue. The aqueous layer was made alkaline, the amine extracted with ether, the ether layer dried over sodium sulfate and made acid with hydrogen chloride gas. The weight of air-dried material, m. p. 210–212° (dec.), was 10.8 g. or 93% of the theoretical amount. Crystallization from an acetone-alcohol mixture gave 8.8 g., m. p. 219–221° (dec.). Further crystallization raised the m. p. only slightly to 220.5–222° (dec.). Essential data for this and other similar compounds are listed in Table I. All melting points are corrected. The yields given are for the crude products.

(23) This was unnecessary as there was little evidence of reaction after a few hours of stirring. In the case of the higher alkyl Grignards, however, it was sometimes necessary to reflux the mixture as unreacted solid remained after the addition.

Summary

1. Twelve β-hydroxyphenethylamine derivatives in which the hydroxyl group is tertiary have been prepared by the action of aliphatic Grignard reagents upon aminoalkyl phenyl ketone hydrochlorides. Seven of the amines are new compounds.

2. Toxicity data of these amines toward white mice indicate that they are less toxic than the corresponding hydroxy amines having no *beta* alkyl group.

3. A preliminary report on other pharmacological properties of these compounds has been made.

On the Epimeric 7-Hydroxycholesterols

BY O. WINTERSTEINER AND WILLIAM L. RUIGH

It has been shown recently that 7(α)- and 7(β)-hydroxycholesterol as well as the corresponding ketone, 7-ketocholesterol, are formed from cholesterol by autoxidation in aqueous colloidal solution.[1,2] In connection with studies on the mechanism of this reaction it seemed of interest to determine whether the reduction of the ketone acetate with aluminum isopropylate, which is the customary method for preparing 7(α)-hydroxycholesterol,[3] also yields the 7(β)-epimer, as it does in the case of 7-ketoepicholesterol.[4] 7(β)-Hydroxycholesterol has been so far accessible only by permanganate oxidation of cholesteryl acid phthalate,[5] a method which in our hands has given a yield of only 10% or less.

At first we searched for the 7(β)-diol in the resinous mother liquor material remaining after separation of the crystalline portion of the hydrolyzed reduction product which according to Windaus, *et al.*,[3] should be essentially 7(α)-hydroxycholesterol. We were unable to isolate the desired compound from such fractions, which instead yielded two other substances to be described later. We therefore turned our attention to the crystalline fraction which is obtained by precipitating the ethereal solution of the crude hydrolyzed reduction product with petroleum ether. These crystalline products, with melting points at 165–174°, were consistently found to be levorotatory ($[\alpha]_D$ −11 to −16°), which was surprising in view of the fact that the dibenzoate and the 7-monobenzoate[6] of the 7(α)-diol have specific rotations of +104 and +94°, respectively. "7-Hydroxycholesterol," presumed to be the α-epimer, has so far been described only in a patent by Windaus and Schenk.[7] According to these authors it melts at about 178°, but the specific rotation was not given. We found that fractions rich in 7(β)-hydroxycholesterol could indeed be obtained from the crude crystalline preparations by using a comparatively large amount of hot methanol for recrystallization. Further purification yielded substantial quantities of the levorotatory 7(β)-diol. The identity of the compound was confirmed by the preparation of the dibenzoate.

Recrystallization of the crude diol mixture from ether or acetone yielded a mass of fine long needles, m. p. 174–176°, answering the description of Windaus and Schenk[7] for 7(α)-hydroxycholesterol, but retaining the levorotation of the starting preparation. Further recrystallization from small volumes of methanol did not change these properties. On benzoylation of this material 7(α)-hydroxycholesterol dibenzoate was obtained as the sole product in 67% yield, proving that the mixture consisted preponderantly of the 7(α)-epimer. There remained to be re-investigated the claim of Windaus and Schenk that hydrolysis of the dibenzoate yields again the substance melting at 178°. Our hydrolysis product was a gelatinous mass with a specific rotation of +4.6°, which proved to be much more difficult to crystallize than the epimeric mixture. It eventually yielded a small amount of needles melting at 178.5° and possessing a specific rotation of +7.2°. Benzoylation of the amorphous product resulted in the formation of the dibenzoate in almost theoretical yield. Acetylation in pyridine yielded quantitatively the higher melting (m. p. 107°) of the two forms of the diacetate mentioned in the patent of Windaus and Schenk. We conclude that 7(α)-hydroxycholesterol is a slightly dextrorotatory substance which is much more soluble in organic solvents than the 7(β)-epimer and cannot be as readily obtained in crystalline form. The presence of small amounts of the 7(β)-epimer evidently improves its capacity to crystallize, probably due to the formation of mixed crystals. From the specific rotations it appears that the crude crystalline diol mixtures contain up to 20% of the 7(β)-epimer. In regard to the over-all yield of the latter compound from cholesterol the route *via* 7-ketocholesterol is inferior to the oxidative method of Barr, *et al.*; it is of practical value only if the α-epimer is also desired.

The differences between the specific rotations of 7(α)- and 7(β)-hydroxycholesterol (Δ = 98°), and especially of the corresponding dibenzoates

(Δ = 201°) and diacetates (Δ = 227°) are unusually large for epimers and indicate a marked deflection of valency angles of carbon atom 7 in one or both epimeric forms. It seemed of interest to determine whether this factor influences the speed of ester hydrolysis at C_7, relative to that at C_3, in the two epimeric dibenzoates. 7(α)-Benzoxycholesteryl benzoate on hydrolysis with cold methanolic sodium ethylate solution yields almost quantitatively the 7-monoester.[6]

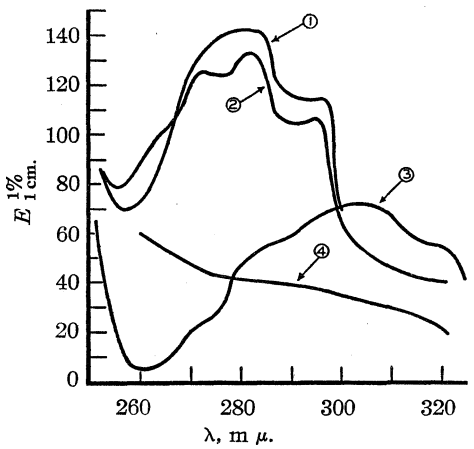

Fig. 1.—Absorption curves in ether solution of crude products formed from: ①, 7(α)-benzoxycholesterol, boiling dimethylaniline[6]; ②, 7(α)-benzoxycholesterol, pyrolysis[6]; ③, 7(β)-benzoxycholesterol, pyrolysis; ④, 7(β)-benzoxycholesterol, boiling dimethylaniline.

When the 7-epimeric dibenzoate was subjected to the same treatment, the result was similar in that a monobenzoate was the sole hydrolysis product. The method used for ascertaining the position of the benzoxy group in the 7(α)-monobenzoate, namely, conversion into 7-dehydrocholesterol, gave inconclusive results, but proof that the new monoester was likewise a 7-benzoate was adduced by reductive removal of the benzoxy group. Extending the observation of Barr, *et al.*,[5] that 7(β)-hydroxycholesterol on catalytic reduction yields cholestanol, we found that the dibenzoates of both 7(α)- and 7(β)-hydroxycholesterol are reduced under similar conditions to β-cholestanyl benzoate. When applied to the new monobenzoate the reaction yielded β-cholestanol, while from a mixed ester, the acid succinate-benzoate, β-cholestanyl acid succinate was obtained.

It is thus clear that stereochemical factors do not play a role in the relative inertness of the ester linkage at C_7 toward alkaline hydrolyzing agents. However, the ease with which benzoic acid can be cleaved from the two epimeric 7-monobenzoates, either by pyrolysis or by treatment with high-boiling amines, to form 7-dehydrocholesterol is definitely influenced by the configuration at C_7. This is illustrated in Fig. 1, which shows the absorption spectra of the crude products obtained by these reactions. The 7(α)-monobenzoate in both reactions yielded products containing 50% or more dehydrosterol, as measured by the extinction at 283 mμ.[6] In contrast, the 7(β)-monobenzoate on pyrolysis gave rise preferentially to a compound with a maximum at 305 mμ, which is probably identical with the cholestatriene obtained under similar conditions by Windaus and Naggatz[4] from 7(α)-benzoxyepicholesteryl benzoate and by Eckhardt[8] from 7(α)-hydroxycholesteryl benzoate. The reaction product obtained from the 7(β)-monobenzoate by boiling with dimethylaniline gave an uncharacteristic curve without any clearly differentiated maxima. Further fractionation with digitonin showed that a small amount of 7-dehydrocholesterol was present. We also found that by lowering the pressure during the pyrolysis from 1 to about 0.01 mm., some dehydrosterol was formed in addition to the entity absorbing at 305 mμ. Quite analogous results were obtained in both reactions with the two 7-epimeric dibenzoates. These findings justify the conclusion that 7(β)-hydroxycholesterol is greatly inferior to the 7(α)-epimer as a starting product for the preparation of 7-dehydrocholesterol.

Spectrographic examination of the non-crystallizable portion of the reduction product revealed the presence of two light-absorbing entities, with maxima around 240 and 280 mμ, respectively. The absorption at 240 mμ is not merely due to unchanged 7-ketocholesterol, since after treatment of the mixture with Girard's reagent it was found to be associated for the most part with the non-ketonic fraction. From one batch of reduced material a crystalline compound of the composition $(C_{27}H_{44})_2O$ was isolated, the spectrum of which exhibited a high, sharply defined maximum at 243 mμ. This substance was dextrorotatory ($[\alpha]_D$ +92°), and gave an intense Lifschütz color reaction. These properties are compatible with the structure either of a di-$\Delta^{4,6}$-cholestadienyl-3-ether or a di-$\Delta^{3,5}$-cholestadienyl-7-ether. A decision between these alternative structures cannot be made on the basis of the rotation rule which

(8) Eckhardt, *Ber.*, **71**, 461 (1938).

in general permits to distinguish between Δ^4- and Δ^5-compounds containing only one ethylenic bond.[9] $\Delta^{4,6}$-Cholestadiene[10] obeys this rule by being dextrorotatory, but $\Delta^{4,6}$-cholestadienol-3(β) and its esters are levorotatory.[11] On the other hand, in the yet undescribed $\Delta^{3,5}$-cholestadienol-7, and especially in its esters and ethers, the sign of rotation might well depend, as in the 7-hydroxycholesterols, on the configuration of C_7.

The dicholestadienyl ether is undoubtedly only an incidental by-product formed in small amounts, the isolation of which was facilitated by its comparative stability. We have spectroscopic and other evidence that the parent alcohol is likewise present among the reduction products, but repeated attempts to effect its isolation were unsuccessful.

The compound absorbing in the region around 280 mμ was not, as might have been supposed, $\Delta^{3,5}$-cholestadienone-7, but was identified as the epimeric $\Delta^{4,6}$-cholestadienone-3. The formation of the 3-ketone from 7-ketocholesteryl acetate by the action of aluminum isopropylate is obviously preceded by ester hydrolysis, which is known to occur under these conditions.[7] The mechanism of the subsequent oxidation at C_3 probably follows the same pattern as the dismutation of dehydroisoandrosterone to testosterone described by Oppenauer,[12] with the 7-keto group in the present case functioning as the hydrogen acceptor. Migration of the double bond from the 5–6 to the 4–5 position, followed by dehydration of the 7-hydroxy group, could then occur under the tendency to establish a triply conjugated system. Alternatively, the precursor may be 7(β)-hydroxycholesterol, which is capable of rearranging into Δ^6-cholestenediol-3(β),5[2]; the latter compound is known to yield $\Delta^{4,6}$-cholestadienone-3 on oxidation with acetone and aluminum phenolate.[13]

Experimental

7(β)-Hydroxycholesterol.—Twenty-five grams of 7-ketocholesteryl acetate was reduced with isopropyl alcohol (500 cc.) and aluminum isopropylate (43 g.) in the usual manner.[3] The mixture was poured into 3 liters of 2% aqueous potassium hydroxide solution, allowed to stand for two hours at room temperature, and extracted with ether. The washed and dried ether solution was evaporated to 75 cc. On addition of 300 cc. of pentane, a precipitate of fluffy needles formed on standing (7.8 g., $[\alpha]_D$ −15.5°, 1.80% in chloroform). Recrystallization from methanol (70 cc.) yielded 1.27 g. of material with an $[\alpha]_D$ −70.6°, 1.0% in chloroform. After three more crystallizations from methanol, 577 mg. of 7(β)-hydroxycholesterol, m. p. 184–185°, $[\alpha]_D$ −84° (0.99% in chloroform) was obtained. The melting point of a mixture with a preparation obtained by the procedure of Barr, *et al.*,[5] showed no depression.

The results obtained on another batch of reduced 7-ketocholesteryl acetate were similar. The crude crystalline diol mixtures (m. p. 173–174°, $[\alpha]_D$ −14.3°, 1.33% in chloroform) did not materially change its properties on recrystallization from acetone, or from a small volume of methanol. Recrystallization from a larger amount of the latter solvent yielded 7(β)-hydroxycholesterol, m. p. 177–178.5°, $[\alpha]^{23}_D$ −87.6° (0.96% in chloroform).[14] The preparation lost 3.4% of solvent on drying *in vacuo* at 100° for one hour.

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 80.52; H, 11.52. Found: C, 80.74; H, 11.73.

One hundred milligrams was benzoylated with pyridine and benzoyl chloride. The resulting product melted at 151–152.5°. The melting point of a mixture with authentic 7(β)-benzoxycholesteryl benzoate, m. p. 151–152.5°[15] showed no depression ($[\alpha]^{23}_D$ −107.5° (0.66% in chloroform)).

Anal. Calcd. for $C_{41}H_{54}O_4$: C, 80.60; H, 8.92. Found: C, 80.94; H, 9.01.

7(α)-Hydroxycholesterol.—Five grams of 7(α)-benzoxycholesteryl benzoate was refluxed in 100 cc. of 5% methanolic potassium hydroxide solution for six hours. The hydrolysis product, recovered by ether extraction, was a white amorphous mass melting at 167–170°, $[\alpha]_D$ +4.6° (0.85% in chloroform). Five hundred milligrams was treated with various solvents, and finally a small amount of needles, m. p. 177–178.5°, was obtained from ether. On recrystallization from the same solvent, the melting point became less sharp (55 mg., m. p. 169–177°, $[\alpha]_D$ +7.2° (1.0% in chloroform)). 250 mg. of the amorphous preparation yielded on re-benzoylation 327 mg. of crude dibenzoate, m. p. 169.5–170.5° (85%). On acetylation in pyridine, a *diacetate* melting at 105–106° was obtained in theoretical yield; on recrystallization from ether–methanol the compound separated as blunt prisms, m. p. 106–107°, $[\alpha]^{27}_D$ +51.8° (1.1% in chloroform).

(12) Oppenauer, *Acta Brevia Neerland. Physiol. Pharmacal, Microbiol.*, **7**, 176 (1937); *Rec. trav. chim.*, **56**, 137 (1937).

(13) Bergström and Wintersteiner, *J. Biol. Chem.*, **143**, 503 (1942).

(14) 7(β)-Hydroxycholesterol, m. p. 186° contains 1 mole of methanol of crystallization; the methanol-free form melts at 154–157° and forms mixed crystals of intermediate melting points and methanol content with the high-melting modification (*cf.* Wintersteiner and Ritzmann, *J. Biol. Chem.*, **136**, 697 (1940)). The specific rotation is, therefore, a better criterion of purity than the melting point, which may show erratic changes on recrystallization if the more stable low-melting modification is once present. The highest specific rotation observed for the methanol-containing form was −91.2° (*loc. cit.*). Barr, *et al.*, gave −86.4°, which is closer to the values found in the present work.

(15) The melting point of this preparation had been previously reported as 155–157° (Wintersteiner and Ritzmann, ref. 14). The higher value is incorrect and was traced to a standardized thermometer which had become defective.

Anal. Calcd. for $C_{31}H_{50}O_4$: C, 76.48; H, 10.36. Found: C, 76.29; H, 10.27.

7(β)-Benzoxycholesterol.—To one gram of 7(β)-benzoxycholesteryl benzoate in 20 cc. of benzene was added a solution of sodium methylate (0.66 g.) in absolute methanol (33 cc.). The mixture was allowed to stand at 25° for seventeen hours. The hydrolysis product was recovered by ether extraction. The oily ether residue was dissolved in a few cc. of warm ether. On standing in the refrigerator, the solution deposited crystals, the amount of which increased on addition of 30 cc. of pentane. Another crop was obtained from the mother liquor material by repetition of this process. Altogether 744 mg. (90%) of 7(β)-benzoxycholesterol was recovered in form of fine needles, which melted at 145–146°, $[\alpha]^{26}D$ −201° (1.04% in chloroform). It is not precipitated by digitonin in 90% ethanol, a behavior also shown by the 7(α)-monobenzoate.

Anal. Calcd. for $C_{34}H_{50}O_3$: C, 80.58; H, 9.95. Found: C, 80.15; H, 9.95.

The absorption spectrum in alcohol confirmed the presence of only one benzoxy group: $\epsilon_{231\ m\mu}$ = 12,500, $\epsilon_{272\ m\mu}$ = 705. 7(β)-Hydroxycholesterol dibenzoate, $\epsilon_{231\ m\mu}$ = 28,000, $\epsilon_{272\ m\mu}$ = 1480.

Benzoylation in pyridine yielded the diester, 7(β)-benzoxycholesteryl benzoate, m. p. 150–151.5°.

The monoester (101 mg.) dissolved in acid-free ethanol (15 cc.) was shaken with palladium black (51 mg.) in a hydrogen atmosphere. The hydrogen uptake was extremely slow, and shaking had to be continued for several days for completion of the reaction. After filtering and evaporation of the solvent the reaction product was taken up in ether, and the latter extracted with sodium carbonate solution, from which was recovered 17.6 mg. of benzoic acid, m. p. 121°. The material recovered from the ether phase was purified by means of digitonin. Decomposition of the digitonide (253 mg.) yielded a crystalline product which after two recrystallizations from ethanol melted at 139.5–140° and did not depress the melting point of authentic β-cholestanol, m. p. 140.5°. The acetate prepared from this material melted at 108.5–109.5°, as did a mixture with authentic β-cholestanyl acetate of the same melting point.

7(β)-Benzoxycholesteryl 3,5-Dinitrobenzoate.—The mixed ester was prepared in the usual manner. It crystallized from benzene–alcohol as needles, m. p. 178.5–179.5°; $[\alpha]^{23}D$ −88.2° (1.0% in chloroform).

Anal. Calcd. for $C_{41}H_{52}O_8N_2$: C, 70.26; H, 7.48; N, 4.00. Found: C, 70.59; H, 7.84; N, 4.24.

7(β)-Benzoxycholesteryl Acid Succinate.—A solution of 70 mg. of the monoester and 300 mg. of succinic anhydride in 3 cc. of pyridine was refluxed for two hours. The acid ester was recovered in the usual way by extraction from ether with potassium carbonate solution, acidification and transfer into ether (73.4 mg.). Recrystallization of the ether residue from methanol yielded small needles melting at 150–151°.

Anal. Calcd. for $C_{38}H_{54}O_6$: C, 75.20; H, 8.97. Found: C, 75.20; H, 8.98.

Ninety-one mg. of 7(β)-benzoxycholesteryl acid succinate was hydrogenated for seventeen hours in a mixture of ethanol (5 cc.) and glacial acetic (3 cc.) with palladium black (45 mg.). The crystalline portion of the reaction product (32 mg.) was recrystallized once from methanol and formed plates melting at 165–167°, $[\alpha]^{26}D$ +13.0° (0.61% in chloroform). An authentic sample of β-cholestanyl acid succinate of the same melting point had an $[\alpha]^{26}D$ of +13.2°. The melting point of the mixture showed no depression.

Dicholestadienyl Ether.—The mother liquor of the crystalline diol mixture from the reduction of 40 g. of 7-ketocholesterol was concentrated to a sirup, which was acetylated in pyridine and chromatographed in pentane solution according to the scheme described in a previous paper.[2] About 5 g. of material passed into the first washings with pentane. When dissolved in a small volume of warm benzene–ethanol 1:2 it deposited a crystalline product (600 mg., m. p. 150–160°). Several crystallizations from ethyl acetate yielded rosets of small needles melting at 158–160°, $[\alpha]D$ +90.6° (0.90% in chloroform). The compound is readily soluble in ether, benzene and hexane, sparingly soluble in ethyl acetate, and practically insoluble in methanol and ethanol. It remained unchanged on boiling in 5% methanolic potassium hydroxide solution, and was not adsorbed from hexane solution by aluminum oxide. Its chromogenic potency in the Lifschütz reaction is about equal to that of 7(β)-hydroxycholesterol.

Anal. Calcd. for $C_{54}H_{88}O$: C, 86.10; H, 11.78; mol. wt., 752.7. Found: C, 86.29, 86.25; H, 11.58, 11.84; mol. wt. (Rast), 663.

The absorption spectrum of the compound shows a high and very narrow band (indicative of the presence of two identical chromophoric groups) at 243 mμ, ε = 54,000 (in ether). The curve shows an inflection at about 249 mμ (ε = 48,000). These properties are in accord with the spectrographic data for $\Delta^{4,6}$-cholestadienyl-3-acetate, $\epsilon_{239\ m\mu}$ = 26,000[11] and of $\Delta^{4,6,22}$-ergostatrienyl acetate, $\epsilon_{240\ m\mu}$ = 27,000.[16]

On hydrogenation in ethyl acetate solution with platinum oxide as catalyst, 2 moles of hydrogen was consumed per sterol residue. No crystalline products could be obtained from the reaction product. It failed to be adsorbed on aluminum oxide, and was purified by precipitation from ether solution with acetone (m. p. 148–162°, $[\alpha]D$ +44°, Lifschütz reaction negative). The analysis indicated the composition $C_{27}H_{46-48}O_{1/2}$. Obviously, a mixture of isomeric reduced ethers had been formed.

$\Delta^{4,6}$-Cholestadienone-3.—In the hope to effect a separation of the dicholestadienyl ether by its insolubility in methanol, 12.7 g. of pentane-soluble mother liquor material from another reduction batch was dissolved in 50 g. of hot methanol. The oil which separated on cooling (2.9 g.) was dissolved in hexane and chromatographed on aluminum oxide in the usual manner. The fractions eluted with benzene–hexane 1:4, together 460 mg., were crystalline, and on recrystallization from 90% alcohol yielded heavy plates melting at 80–81°, which gave no depression of the melting point on admixture of $\Delta^{4,6}$-cholestadienone-3, m. p. 80–81°, prepared by the method of Dane, Wang and Schulte.[17]

Anal. Calcd. for $C_{27}H_{42}O$: C, 84.65; H, 11.07. Found: C, 84.45; H, 11.18.

(16) Güntzel, *Ber.*, **72**, 1317 (1939).

(17) Dane, Wang and Schulte, *Z. physiol. Chem.*, **245**, 80 (1937).

The semicarbazone melted at 228–229°; the mixture with an authentic sample showed no depression.

The ultraviolet absorption properties of the ketone ($\epsilon_{285\ m\mu}$ = 26,000, in ethanol) and of the semicarbazone ($\epsilon_{305\ m\mu}$ = 46,000, in dioxane) closely agreed with those of the authentic preparations.[13]

We are indebted to Dr. N. H. Coy of the Vitamin Laboratory of E. R. Squibb and Sons for the spectrographic measurements, and to Miss Mildred Moore for able technical assistance.

The microanalyses were carried out by J. F. Alicino, Fordham University.

Summary

The crystalline, levorotatory product obtained by reduction of 7-ketocholesteryl acetate with aluminum isopropylate is a mixture of 7(α)- and 7(β)-hydroxycholesterol containing up to 20% of the latter epimer. Free 7(α)-hydroxycholesterol, in contradistinction to its esters, is only slightly dextrorotatory. It cannot be as readily obtained in crystalline form as the β-epimer or the epimeric mixture.

7(β)-Benzoxycholesteryl benzoate on hydrolysis with sodium methylate in the cold yields quantitatively 7(β)-benzoxycholesterol. The position of the benzoxy group was proved by its reductive removal, since the monoester, unlike its epimer, 7(α)-benzoxycholesterol, is not amenable to conversion into 7-dehydrocholesterol.

Two by-products of the reduction of 7-ketocholesteryl acetate, a dicholestadienyl ether and $\Delta^{4,6}$-cholestadienone-3, have been isolated. Possible mechanisms for the formation of the latter compound are discussed.

The Chemistry of Acrylonitrile. I. Cyanoethylation of Active Methylene Groups

BY HERMAN ALEXANDER BRUSON

The reactions of acrylonitrile with amines,[1] phenols,[2] hydrogen sulfide,[3] butadiene[4] and halogens[5] have been described almost exclusively in the patent literature. Concerning the chemical behavior of acrylonitrile with other types of compounds, very little is known.

Because of its extremely reactive double bond, acrylonitrile condenses readily with a variety of organic compounds having labile hydrogen atoms or active methylene groups. These reactions occur in the presence of small quantities of alkaline condensing agents and are of the Michael type. The unique property of acrylonitrile in this respect is that it seeks out every available reactive hydrogen atom and by direct addition introduces the $-CH_2-CH_2-CN$ group in place thereof.

A powerful alkaline catalyst which is effective for promoting the cyanoethylation of many types of organic compounds is trimethylbenzylammonium hydroxide which is employed in the form of an aqueous 40% solution known as "Triton B" (Trade Mark). In some cases sodium or potassium methylate, 30% methanolic potassium hydroxide, or even aqueous 40% sodium hydroxide are effective, but the solubility of "Triton B" and its high degree of alkalinity renders it particularly effective where the other alkalies either fail to initiate the reaction at all or to give good yields.

In this paper, the condensation of acrylonitrile with compounds having the reactive methylene or methenyl grouping $C{=}C{-}\underset{|}{C}H{-}C{=}C$ in a carbocycle is described.[6] Such a grouping is present in fluorene, indene, cyclopentadiene, anthrone, the fulvenes and many of their substituted derivatives.

In the presence of a catalytic amount of "Triton B," acrylonitrile readily condenses with fluorene to yield *bis*-9,9-(β-cyanoethyl)-fluorene (I).

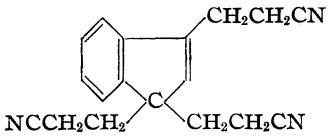
(6) See also Bruson, U. S. Patent 2,280,058 (1942).

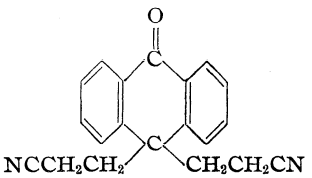
Indene likewise adds acrylonitrile in the presence of "Triton B" to yield a liquid di-cyanoethylation product and crystalline tris-(β-cyanoethyl)-indene very probably, (II) even when 1:1



(II)

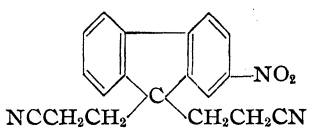
molecular proportions of the reactants are employed.

Anthrone similarly adds two moles of acrylonitrile to form meso-bis-(β-cyanoethyl)-anthrone (III).



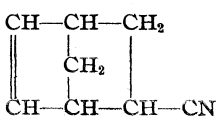
(III)

These reactions take place at room temperature with evolution of heat. In order to prevent excessive polymerization of the acrylonitrile and to allow the condensation to proceed smoothly to completion, resort to cooling and the use of inert solvents such as dioxane or tertiary butanol have been found helpful, particularly if the reactive methylene compound is a high melting solid. In dioxane solution for example, 2-nitro-fluorene condenses readily with acrylonitrile in the presence of "Triton B" to form *bis*-9,9-(β-cyanoethyl)-2-nitro-fluorene (IV) almost quantitatively.



(IV)

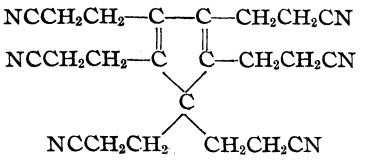
The reaction of acrylonitrile with cyclopentadiene was of particular interest because in the absence of a catalyst, a Diels–Alder adduct (V)



(V)

is formed by 1,4-addition. This adduct is a colorless, relatively low boiling liquid and forms spontaneously and almost quantitatively with considerable evolution of heat when the two components are mixed in equimolecular proportions.

However, in the presence of "Triton B" as the catalyst, the formation of the Diels–Alder type of adduct is so far repressed that each of the six hydrogen atoms in the cyclopentadiene molecule adds to acrylonitrile to form a crystalline hexacyanoethylation product (VI) melting at 203°,

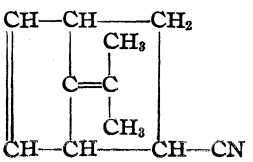


(VI)

accompanied by a mixture of lower poly-cyanoethylation products of cyclopentadiene, boiling much higher than the Diels–Alder adduct.

This unexpected reaction of cyclopentadiene can best be explained by a resonating system of double bonds making all the methylene and methenyl hydrogen atoms equally active, or by a mechanism involving a shift of the residual methylene hydrogen atom to a contiguous carbon atom as soon as the first cyanoethyl group is introduced, thus forming new reactive methylene groups successively around the cycle as each cyanoethyl group enters. When the resonating system is interrupted as for example by dimerization of the cyclopentadiene or by adduct formation with the loss of a double bond, then acrylonitrile no longer can add to the methenyl groups remaining. Neither dicyclopentadiene nor the adduct (V) reacted with acrylonitrile in the presence of Triton B. The peculiar shifting of a hydrogen atom in the cyclopentadiene nucleus has already been pointed out by Ziegler and Crössmann[7] to explain the activity of various fulvenes.

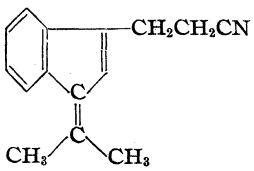
In order to test the activity of a resonating fulvene system toward acrylonitrile, dimethylfulvene was treated with acrylonitrile in the absence and in the presence of Triton B. In the former case, the expected crystalline Diels–Alder type adduct (VII) was isolated, but in the presence of Triton B higher cyanoethylation products of dimethyl-



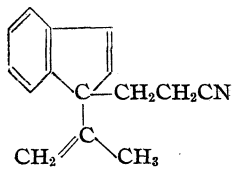
(VII)

fulvene were obtained in impure form. However, ω,ω-dimethylbenzofulvene[8] reacted with acrylonitrile in the presence of Triton B to yield a crystalline cyanoethylation product, corresponding to the formula VIII-A or VIII-B, whereas without the Triton B only resinous adducts were obtained.

(7) Ziegler and Crössmann, *Ann.*, **511**, 89 (1934).
(8) Thiele and Merck, *ibid.*, **415**, 260 (1918).



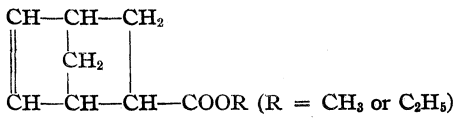
(VIII-A)



(VIII-B)

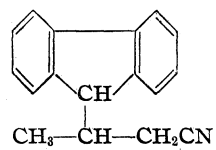
The pure poly-cyanoethylation products I, II, III and VI were each converted into their respective polycarboxylic acids IX, X, XI and XII by alkaline hydrolysis.

Attempts to replace acrylonitrile by acrylic esters such as methyl acrylate or ethyl acrylate in the above experiments so as to obtain the corresponding poly-(carbalkoxy-ethyl) derivatives were unsuccessful. Cyclopentadiene and the acrylic esters gave only the Diels–Alder type adducts (XIII) regardless of whether Triton B was used as the catalyst or not.



(XIII)

Crotononitrile reacted in the presence of Triton B with indene or cyclopentadiene to give poorly-defined, resinous cyano-alkylation products. With fluorene, however, a crystalline cyano-alkylation product, XIV, was obtained.



(XIV)

Not only does acrylonitrile cyanoethylate each available hydrogen atom of carbocylic compounds of the types described above, but also each reactive hydrogen atom of a methyl, methylene, or methenyl group which is contiguous to a nitro or carbonyl group as in the nitro-paraffins or ketones; furthermore as in the reactive methylene groups of malonic esters, malonamides, cyanacetic esters, cyanacetamides, benzyl cyanides, benzyl sulfonamides, α,β-unsaturated nitriles and amides. These will be described in later papers.

Experimental

(I) **Bis-9,9-(β-cyanoethyl)-fluorene.**—Acrylonitrile (111.3 g.) was added dropwise during the course of one hour to a rapidly stirred solution consisting of 166 g. of fluorene, 500 g. of dioxane, and 5 g. of aqueous 40% trimethylbenzylammonium hydroxide. The reaction temperature was maintained between 30 and 40° by occasional cooling with ice-water. The mixture was then stirred for three hours longer at room temperature to complete the condensation. At the end of this time, the dark brown solution obtained was neutralized with dilute hydrochloric acid and, without interrupting the stirring, 800 cc. of water was added to precipitate the product in granular form. The precipitate was filtered off and air dried; crude yield 250 g. Upon recrystallization once from 500 g. of ethanol, the product separated as yellowish crystals m. p. 118–119°; yield 201 g. or 74%. One more recrystallization from ethanol using Norite gave the pure compound as colorless needles m. p. 121°. *Anal.* Calcd. for $C_{19}H_{16}N_2$: C, 83.78; H, 5.92; N, 10.29. Found: C, 84.03; H, 5.76; N, 10.33. It is readily soluble in benzene, chloroform, acetone, ethyl acetate or dioxane at 25°. It is insoluble in ether, and is only slightly soluble in cold methanol or ethanol, but dissolves readily on heating.

(II) **Tris-1,1,3-(β-cyanoethyl)-indene.**—To a mixture of 69.5 g. of indene (0.6 mole), 100 g. of dioxane, and 4 g. of aqueous 40% trimethylbenzylammonium hydroxide there was added dropwise during two hours 95.4 g. of acrylonitrile (1.8 mole) while the reaction mixture was stirred and cooled to 25–30°. After the addition, the dark solution was stirred at room temperature for an hour and then acidified to litmus with dilute hydrochloric acid. The mixture was shaken with an equal volume of ethylene dichloride and a little water. The aqueous layer was discarded, and the ethylene dichloride layer washed with water and then evaporated to dryness under reduced pressure on a steam-bath. The residue was a dark red, viscous oil weighing 147 g. Upon distillation in high vacuum, two main fractions were obtained as follows

I. 210–220° (2 mm.) 18 g. pale yellow oil
II. 280–290° (1 mm.) 58 g. viscous reddish oil

Fraction I analyzed 12.76% N, corresponding to di-(β-cyanoethyl)-indene, $C_{15}H_{14}N_2$ (calcd.: N, 12.61).

Fraction II crystallized on standing. Upon recrystallization from ethanol using "Norite" for decolorizing, it separated in colorless crystals, m. p. 65°.

Anal. Calcd. for $C_{18}H_{17}N_3$: C, 78.50; H, 6.23; N, 15.26. Found: C, 78.80; H, 6.09; N, 15.39.

(III) **Meso-bis-(β-cyanoethyl)-anthrone.**—Acrylonitrile (15.9 g.) was added dropwise during thirty minutes to a stirred solution consisting of 29.1 g. of anthrone, 100 g. of dioxane and 3 g. of aqueous 40% trimethylbenzylammonium hydroxide while the reaction mixture was maintained at 40°. A deep red solution resulted. This was stirred for one hour longer at 35° and then allowed to stand eighteen hours. The mixture was then acidified with dilute hydrochloric acid whereupon the red color disappeared. The crystalline product was filtered off, washed and dried; yield 40 g. After crystallization from glycol monoethyl ether ("Cellosolve"), it formed colorless prisms, m. p. 215°. *Anal.* Calcd. for $C_{20}H_{16}N_2O$: C, 79.92; H, 5.37; N, 9.32. Found: C, 80.36; H, 5.45; N, 9.49.

(IV) **Bis-9,9-(β-cyanoethyl)-2-nitro-fluorene.**—To a solution of 20 g. of 2-nitrofluorene, 150 g. of dioxane and 2 g. of aqueous 40% trimethylbenzylammonium hydroxide there was added dropwise during twenty minutes 10.6 g. of acrylonitrile, while the reaction mixture was stirred and cooled to 35–40°. The mixture was then stirred for two hours longer and finally neutralized with dilute hydrochloric acid. The crystalline product was filtered off,

washed and dried; yield 21 g. Upon recrystallization from glycol monoethyl ether it formed yellow needles, m. p. 236–237°. *Anal.* Calcd. for $C_{19}H_{15}N_3O_2$: C, 71.90; H, 4.77; N, 13.12. Found: C, 72.40; H, 4.80; N, 13.09.

(V) **3-Cyano-1,4-endomethylene-cyclohexene-5.**—To 33 g. of cyclopentadiene in a flask under a reflux condenser, there was added 26.5 g. of acrylonitrile. After standing for about ten minutes the mixture became warm and began to boil. The exothermal reaction lasted for about a half hour. The mixture was allowed to stand for four hours thereafter and then distilled in vacuum at 11 mm. A colorless oil came over at 80–85° (11 mm.), yield 49.5 g.; $n^{25}D$ 1.4876; d^{25}_{25} 1.0066. *Anal.* Calcd. for C_8H_9N: N, 11.76. Found: N, 11.70. It crystallizes in an ice-bath but is liquid at room temperature.

(VI) **Hexa-(β-cyanoethyl)-cyclopentadiene.**—Acrylonitrile (106 g.) was added dropwise during two hours to a stirred, cooled mixture of 66 g. of cyclopentadiene, 100 g. of dioxane, and 4 g. of aqueous 40% trimethylbenzylammonium hydroxide while the reaction temperature was maintained at 20–25°. The mixture was stirred three hours longer at 20°, then neutralized with dilute hydrochloric acid. During the condensation the mixture became almost black but bleached to a yellow color on the addition of the acid. The crystalline product was filtered off. It was a tan-colored powder; yield 34 g. Upon recrystallization from glycol monomethyl ether it separated in colorless needles, m. p. 203°. *Anal.* Calcd. for $C_{23}H_{24}N_6$: C, 71.84; H, 6.30; N, 21.86. Found: C, 71.80; H, 6.26; N, 21.93.

The original filtrate was washed with water, dried and distilled in vacuum. Only a small amount boiled below 90° at 11 mm. The bulk distilled from 100 to 280° (1 mm.) with some decomposition and considerable residue but a clean fractionation was not accomplished.

(VII) **3-Cyano-1,4-endo-isobutenylidene-cyclohexene-5.**—A mixture of 50 g. of dimethylfulvene and 25 g. of acrylonitrile was gently heated on a water-bath under reflux for several hours until no further refluxing occurred. The viscous reddish product was distilled in vacuum at 1 mm. At 95–100° (1 mm.) an amber-colored oil came over which gradually crystallized; yield 35 g. Upon recrystallization from petroleum ether using Norite for decolorization, the product was obtained as colorless crystals, m. p. 87°. Calcd. for $C_{11}H_{13}N$: C, 82.96; H, 8.24; N, 8.80. Found: C, 83.20; H, 8.03; N, 8.90.

VIII-A or VIII-B. Cyanoethylated Dimethylbenzofulvene.—To a solution of 44 g. ω,ω-dimethylbenzofulvene, 44 g. of dioxane and 3 g. of Triton B, acrylonitrile (15 g.) was added dropwise while stirring at 25–35°. The mixture was stirred for four hours after the exothermal reaction had ceased, and then neutralized with dilute hydrochloric acid, taken up in ethylene dichloride, and washed and dried *in vacuo* at 100°. The residual oil weighing 61 g. was distilled in vacuum at 1 mm. The main fraction came over at 180–230° (1 mm.) and solidified in the receiver; yield 13 g. Upon recrystallization from methanol the product was obtained as yellow crystals, m. p. 121°. Calcd. for $C_{15}H_{15}N$: C, 86.07; H, 7.23; N, 6.69. Found: C, 85.90; H, 7.11; N, 6.64.

(IX) **Bis-9,9-(β-carboxy-ethyl)-fluorene.**—A mixture of 16 g. of sodium hydroxide, 400 cc. of water and 40 g. of (I) was boiled under reflux with rapid stirring, for twelve hours. The solution was bleached with charcoal, cooled, filtered, and the filtrate acidified hot with hydrochloric acid. The white precipitate (yield 41 g. air-dried) was recrystallized from ethanol. It separated in colorless crystals, m. p. 273–274°. *Anal.* Calcd. for $C_{19}H_{18}O_4$: C, 73.51; H, 5.85. Found: C, 73.70; H, 5.83.

(X) **Tris-1,1,3-(β-carboxy-ethyl)-indene.**—A mixture of 23 g. of potassium hydroxide, 225 cc. of water and 27 g. of (II) was stirred and boiled under reflux for three hours. The clear solution was bleached with charcoal, filtered and acidified with hydrochloric acid. The product separated as a resinous solid which became crystalline after being dissolved in hot water and allowed to separate slowly on cooling. After several recrystallizations from hot water, the melting point remained unchanged at 161–162°. *Anal.* Calcd. for $C_{18}H_{20}O_6$: C, 65.03; H, 6.07. Found: C, 64.80; H, 5.97.

(XI) **Bis-meso-(β-carboxy-ethyl)-anthrone.**—A mixture of 12 g. of sodium hydroxide, 120 cc. of water, 70 cc. of ethanol, and 27 g. of (III) was stirred rapidly and boiled under reflux for seven hours. The solution was cooled, filtered, and the filtrate acidified with hydrochloric acid. The product separated as an oil which rapidly solidified; yield 27 g. Upon recrystallization from dilute ethanol (75% H_2O + 25% ethanol) it separated in colorless flakes which sinter at 220° and decompose at 230°. *Anal.* Calcd. for $C_{20}H_{18}O_5$: C, 70.97; H, 5.36. Found: C, 71.10; H, 5.41.

(XII) **Hexa-(β-carboxy-ethyl)-cyclopentadiene.**—A mixture of 140 g. of sodium hydroxide, 1000 cc. of water and 184 g. of (VI) was boiled under reflux for eighteen hours. The dark solution was treated with Norite, filtered, and the filtrate acidified with concd. hydrochloric acid (350 g.) and cooled to 5°. The white crystalline precipitate was filtered off, washed on the filter with 200 cc. of ice-water and dried in an oven at 60°; yield 199 g. of crude acid containing 0.09% ash. It may be purified by recrystallization from four times its weight of water by chilling the solution to 5°. The purified analytical sample formed colorless crystals, m. p. 180–181°. It is readily soluble in alcohol and in warm water. *Anal.* Calcd. for $C_{23}H_{30}O_{12}$: C, 55.39; H, 6.07. Found: C, 55.40; H, 5.93.

(XIII) **3-Carbomethoxy-1,4-endomethylene-cyclohexene-5.**—A mixture of 33 g. of cyclopentadiene and 43 g. of methyl acrylate was placed in a flask under a reflux condenser. After standing for about thirty minutes the mixture began to boil. After boiling had ceased, the mixture was allowed to stand for twenty-four hours and was then distilled under reduced pressure. The product came over at 71–73° (8 mm.) as a colorless oil of strong characteristic valerian odor; yield 64 g. or 84%; $n^{25}D$ 1.4745; d^{25}_{25} 1.0543. *Anal.* Calcd. for $C_9H_{12}O_2$: iodine no., 167. Found: 170.

The corresponding ethyl ester (XIII, R is C_2H_5) was prepared in the same manner as above from ethyl acrylate and cyclopentadiene. It is a colorless oil of b. p. 84–85° (10 mm.), $n^{25}D$ 1.4675; d^{25}_{25} 1.0268. *Anal.* Calcd. for $C_{10}H_{14}O_2$: saponification no., 338. Found: 338. It is also formed in 85% yield instead of the expected poly-(carbethoxy-ethyl) derivative when ethyl acrylate is added to cyclopentadiene containing "Triton B."

(XIV) 9-(β-Cyano-isopropyl)-fluorene.—To a stirred solution of 83 g. of fluorene, 250 g. of dioxane, and 10 g. of "Triton B," there was added dropwise 67 g. of allyl cyanide during the course of one hour while the exothermal reaction was maintained at 38–47° by intermittent cooling. The mixture was then heated at 45–50° for six hours longer, cooled, rendered acid to congo red indicator with dilute hydrochloric acid, taken up in its own volume of ethylene dichloride and washed thoroughly with water. The ethylene dichloride layer was evaporated to dryness and the residual dark oil distilled in vacuum. After a small forerun of unchanged fluorene, the main fraction boiled between 190° and 220° (1–2 mm.) and weighed 60 g. It formed a yellow balsam which gradually solidified to a crystalline mass. After recrystallization from methanol, the pure product was obtained as colorless crystals melting at 92–93°. *Anal.* Calcd. for $C_{17}H_{15}N$: C, 87.50; H, 6.49; N, 6.00. Found: C, 87.51; H, 6.38; N, 6.07.

The same product is obtained by using crotononitrile in place of allyl cyanide.

Acknowledgment.—The analyses of the above products were performed by Mr. C. W. Nash, and much of the experimental work was done by Mr. Thomas Riener of these Laboratories.

Summary

1. Acrylonitrile condenses in the presence of strong bases, notably aqueous trimethylbenzylammonium hydroxide ("Triton B") as a catalyst, with reactive carbocyclic methylene or methenyl compounds such as fluorene, indene, anthrone, cyclopentadiene and fulvenes to replace each reactive hydrogen atom by a β-cyanoethyl radical.

2. The preparation and properties of bis-(β-cyanoethyl)-fluorene, tris-(β-cyanoethyl)-indene, bis-(β-cyanoethyl)-anthrone, hexa-(β-cyanoethyl)-cyclopentadiene, and the corresponding carboxylic acids obtained therefrom by hydrolysis are described, as well as the cyanoethylation product of dimethylbenzofulvene and certain Diels–Alder type adducts of acrylonitrile and acrylic esters.

3. Allyl cyanide or crotononitrile condensed with fluorene to a 9-(β-cyano-isopropyl)-fluorene.

The Rearrangement of 1,1,3,3,5,5-Hexamethylcyclohexatriol-2,4,6 to Hexamethylbenzene

BY ERLE B. AYRES AND CHARLES R. HAUSER

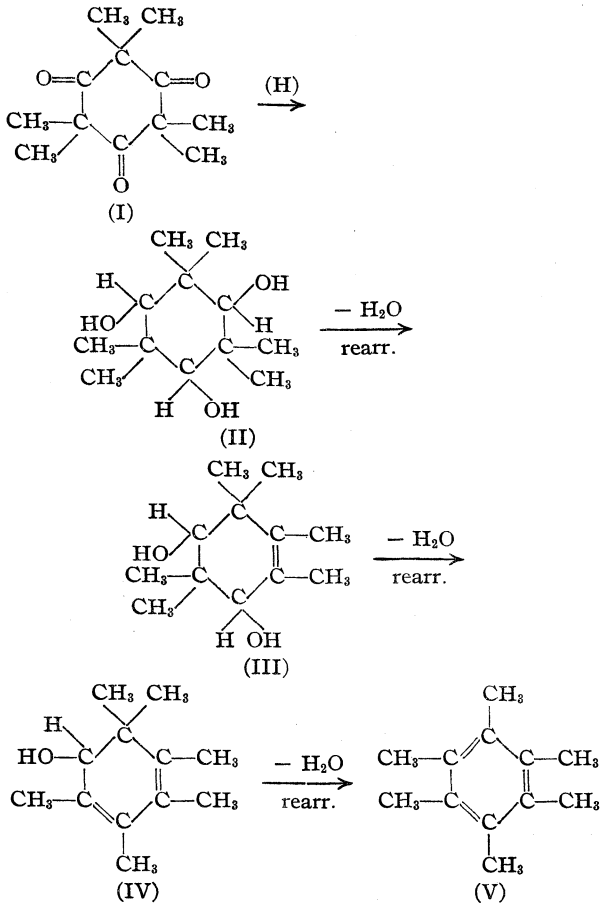
In another investigation in this Laboratory a method was developed for the synthesis of hexamethylcyclohexatrione-1,3,5 (I) in an over-all yield of approximately 25% starting with ethyl isobutyrate and isobutyryl chloride.[1] It seemed possible that the cyclohexatrione (I) might be reduced to the triple neopentyl system, 1,1,3,3,5,5-hexamethylcyclohexatriol-2,4,6 (II), which might be made to undergo a triple dehydration and rearrangement to form hexamethylbenzene (V). This transformation, which represents a new route from an aliphatic to an aromatic compound, has been realized.

The cyclohexatrione (I) was reduced catalytically[2] in good yield to the cyclohexatriol (II), which was probably a mixture of two stereoisomers; in one of the isomers the three hydroxyl groups are arranged on one side of the ring, and in the other, two hydroxyl groups are on one side and the third hydroxyl on the opposite side of the ring. In the present study no attempt has been made to separate the two isomers after a substance was obtained the melting point of which was not raised by further recrystallization. The cyclohexatriol was dissolved in sulfuric acid, giving a colored mixture from which practically pure hexamethylbenzene in approximately 20% yield was extracted with ligroin. Other products were present in the sulfuric acid layer but were not identified in the present investigation. The rearrangement was also carried out in warm phosphoric acid, but the yield of hexamethylbenzene was very low. Treatment of the cyclohexatriol with thionyl chloride gave only tarry material from which no hexamethylbenzene could be isolated.

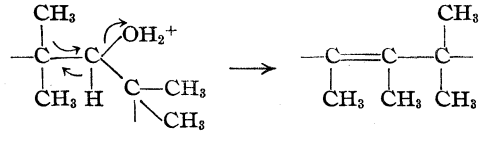
The conversion of the hexamethylcyclohexatriol (II) to hexamethylbenzene (V) probably involves

(1) The methods are described by Hudson and Hauser (THIS JOURNAL, 61, 3567 (1939). Better yields were subsequently obtained (Hudson, Ph.D. Thesis, Duke University (1941)) as follows: for ethyl isobutyryl isobutyrate, 74%; for ethyl 2,2,4,4,6-pentamethyl-3,5-diketoheptanoate, 72%; for hexamethylcyclohexatrione-1,3,5, 52%.

(2) The authors are indebted to Dr. Homer Adkins of the University of Wisconsin for carrying out this reduction.



three separate reactions,[3] each consisting of the removal of a hydroxyl group (as a molecule of water from the oxonium ion formed by the addition of a proton to the hydroxyl), the shift of a methyl group with its attached electron pair, and the loss of a proton to form a double bond,[4] thus[5]



It is obvious that the monodehydration of (II) can give only one cyclic product (III). Of the hydroxyl groups in (III), the one in the α-position to the double bond might be preferentially lost because of the possibility of allylic resonance in the resulting carbonium ion. Shift of a methyl group would give (IV), which contains conjugated double bonds. The third rearrangement should follow only the course giving hexamethylbenzene. In view of the several side reactions that one might expect to occur in the conversion of (II) to (V), it is not surprising that the yield of hexamethylbenzene is only 20%.

(3) Although it would appear improbable that the three dehydrations and rearrangements take place simultaneously, the possibility is not entirely excluded; the triply charged oxonium ion required could probably be formed in low concentration, and such a reaction would involve considerable driving force in forming the aromatic ring.

(4) See especially Whitmore, THIS JOURNAL, **54**, 3274 (1932).

(5) Whitmore and Stahly, *ibid.*, **55**, 4153 (1933), found that di-*t*-butylcarbinol, which is analogous to the section of (II) represented above, yields the expected olefin only under mild conditions; instead, a tertiary butyl group is eliminated as a carbonium ion. It is possible that this type of reaction occurs also with compound (II).

Experimental

1,1,3,3,5,5-Hexamethylcyclohexatriol-2,4,6.—This substance was prepared by the reduction[2] of hexamethylcyclohexatrione-1,3,5 (15.3 g.) over copper chromite for five hours at 200 atm. at 200°. The triketone took up approximately three molecular equivalents of hydrogen. An alcoholic suspension of the reduction product yielded on filtering 7.0 g. of silky white crystals, m. p. 242–246° after some softening at 170°. Evaporation of the filtrate yielded 7.7 g. of slightly gummy solid; total yield of crude product, 14.7 g. (93%). After several recrystallizations from alcohol or, better, from acetone, the crystals melted at 251.0–251.5°. The substance could also be purified by sublimation.

Anal.[6] Calcd. for $C_{12}H_{24}O_3$: C, 66.63; H, 11.18. Found: C, 66.85; H, 11.03.

Dehydration and Rearrangement of 1,1,3,3,5,5-Hexamethylcyclohexatriol-2,4,6.—To 15 cc. of ice-cold concentrated sulfuric acid was added 1.00 g. of 1,1,3,3,5,5-hexamethylcyclohexatriol-2,4,6. The color of the mixture became pale yellow and then reddish to red-brown during two hours. At one point there seemed to be very little suspended material; then the quantity of fine white platelets appeared to increase. After standing for two days at room temperature, the mixture was extracted with purified ligroin (b. p. 54–64°). After washing, drying and removing the ligroin under partial pressure, there was left an oil which solidified completely to 0.15 g. (19.4%) of white crystalline solid, m. p. 164–165°; a mixed melting point with a sample of Eastman Kodak hexamethylbenzene (m. p. 164–165°) was the same. The sulfuric acid layer was poured over crushed ice and the oily mixture extracted with ether. Upon washing the ether with sodium bicarbonate solution, drying and evaporation, there remained a trace of unidentified material.

In another experiment, 1,1,3,3,5,5-hexamethylcyclohexatriol-2,4,6 (1.00 g.) was warmed over a steam-bath with 85% phosphoric acid. From a ligroin extract of the mixture was obtained a very small amount of impure hexamethylbenzene and small amounts of solids which decomposed at about 200° and were perhaps phosphoric esters. An experiment carried out using thionyl chloride yielded only tarry material.

Summary

1,1,3,3,5,5-Hexamethylcyclohexatriol-2,4,6 on treatment with sulfuric acid undergoes partly a triple dehydration and rearrangement of the neopentyl type, yielding hexamethylbenzene.

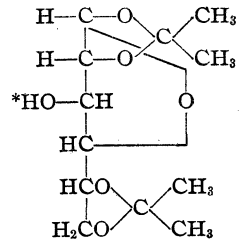
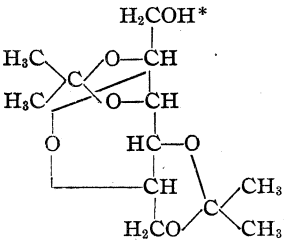
The Rates of Reaction of Diacetone Glucose, Diacetone Galactose and Diacetone Sorbose with *p*-Toluenesulfonyl Chloride in Pyridine Solution[1]

BY ROBERT C. HOCKETT AND MASON L. DOWNING

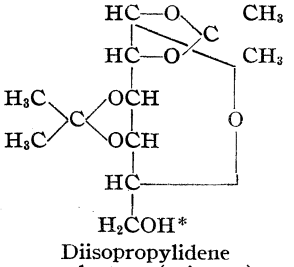
In a previous publication[2] the "selective" action of triphenylchloromethane upon primary alcohols in pyridine solution as compared with the action of this chloride upon secondary alcohols, was interpreted as a difference in the rates of reaction of such alcohols under the conditions employed. This view was supported by direct rate measurements by polarimetric means upon the reactions between trityl chloride[3] and the diisopropylidene derivatives of D-glucose, L-sorbose and D-galactose, respectively, in pyridine solution. All these compounds reacted when an eight to one molecular proportion of the chloride was used, the reactions were pseudounimolecular, and the times of half-change were in the ratio 226:6.6:1 in the order of their names.



Diisopropylidene D-glucose (secondary)



Diisopropylidene L-sorbose (primary)



Diisopropylidene D-galactose (primary)

On account of an apparent tendency among chemists to regard triphenylchloromethane as a quite peculiar or exceptional reagent, we thought it worth while to extend the study to an investigation of the rates of reaction of *p*-toluenesulfonyl chloride with the same sugar derivatives under the same conditions.[4] Such a study has yielded results which are compared with the previous ones below.

TABLE I

Substance	Rate constant (hours and dec. logs) Trityl (21°)	Rate constant (hours and dec. logs) Tosyl (23 ± 2°)	Times of half-change, hours Trityl (21°)	Times of half-change, hours Tosyl (23 ± 2°)
Diacetone glucose	0.00016	0.0149	1880.0	20.20
Diacetone sorbose	0.0055	0.5160	54.7	0.583
Diacetone galactose	0.036	1.038	8.3	0.272

1.00 g. substance in 50.0 pyridine solution 8:1 ratio of chloride; 2-dm. tube. $K = \frac{1}{t} \log_{10} \frac{\alpha_0 - \alpha_\infty}{\alpha_t - \alpha_\infty}$.

The obvious conclusions are two: *p*-toluenesulfonyl chloride reacts faster with all the substances than does trityl chloride under the same conditions; the velocity ratios are of the same order of magnitude for the three substances in their reactions with either chloride. The rate ratio for the diacetone glucose and diacetone sorbose is 34.7/1 in the reaction with trityl chloride and 34.4/1 in the reaction with *p*-toluenesulfonyl chloride. Thus the latter appears to be equally "selective." More strictly speaking, the selectivity is a characteristic of the alcohols rather than of the halides.

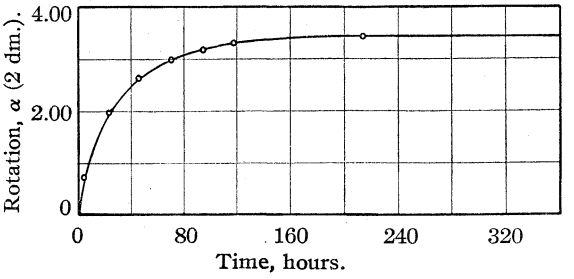


Fig. 1.—Diacetone-glucose and tosyl chloride at 23 ± 2°.

Much evidence is accumulating which tends to show that benzoyl chloride, acetic anhydride and other agents show much the same kind of selection.[5]

An extension of these measurements to other temperatures is in progress.

We express our indebtedness to Hoffmann-La Roche, Inc., of Nutley, N. J., for a quantity of diacetone-L-sorbose.

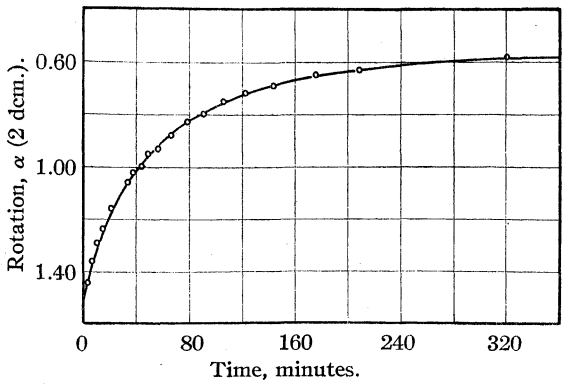

Fig. 2.—Diacetone-sorbose and tosyl chloride at 23 ± 2°.

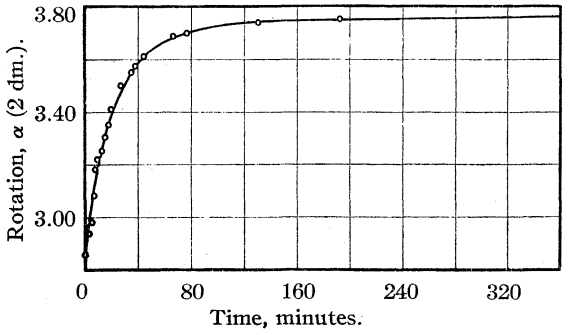

Fig. 3.—Diacetone-galactose and tosyl chloride at 23 ± 2°.

Experimental

1,2;5,6-Diisopropylidene-D-glucofuranose.—A sample of this substance obtained from the Corn Products Refining Co., contained a considerable amount of monoacetone glucose. It was dissolved in water and extracted three times with very small portions of benzene to remove colored impurities. After a treatment with decolorizing carbon, the colorless aqueous solution was extracted five times with chloroform; the extract was dried with sodium sulfate, filtered, and concentrated to crystallization. The product after a recrystallization from benzene and drying, melted from 109.5–110° (cor.) and rotated[6] −17.6° (*c*, 2.040; H_2O).

1,2;3,4-Diisopropylidene-D-galactopyranose.—This was prepared exactly as described previously.[2]

2,3;4,6-Diisopropylidene-L-sorbofuranose.—The dark-brown distillate supplied by Hoffmann-LaRoche was dissolved in ether and most of the coloring matter was removed by extractions with 20% KOH solution and then by carbon treatment. Almost colorless crystals were obtained when the dried ether extract was evaporated. A final recrystallization from petroleum ether (b. p. 30–60°) yielded white crystals melting from 77.5–78.5°.

Toluenesulfonyl Chloride.—Eastman Kodak Co. product melting 68.5–69.0° (cor.) was employed.

Pyridine.—A colorless fraction dried over KOH and boiling at 115.3–115.5° was used.

The Rate Measurements.—The method described for the case of triphenylchloromethane was duplicated.[2] The reactions took place in a constant-temperature room at 23 ± 2°.

Summary

1. The rates of reaction of *p*-toluenesulfonyl chloride with diacetone glucose, diacetone sorbose and diacetone galactose at a molar ratio of 8 to 1 in pyridine solution, have been measured polarimetrically.

2. The reactions were pseudounimolecular and gave times of half-change in the ratio 74.2: 2.1: 1 in the order named.

3. The "selectivity" of *p*-toluenesulfonyl chloride toward primary hydroxyl groups as compared with secondary ones is of the same order as the "selectivity" of triphenylchloromethane.

Solubilities of Orthanilamide, Metanilamide and Sulfanilamide[1a]

BY R. H. KIENLE AND J. M. SAYWARD[1b]

In connection with a broad program of research on chemotherapeutic agents of the sulfanilamide type, a study of certain physical chemical properties of sulfanilamide and its therapeutically inactive isomers was undertaken. Any distinction found between the active para compound and the inactive ortho and meta isomers might contribute to the explanation of the therapeutic activity of sulfanilamide.

(1a) Presented at the 103rd meeting of the American Chemical Society, Memphis, Tenn., April, 1942.

(1b) Present address: Stamford Research Laboratories, American Cyanamid Company, Stamford, Connecticut.

The present paper reports on the water-solubilities of the three sulfanilamide isomers. The results led to dilatometry and manometric drying of the solid phase of sulfanilamide. Microscopical and X-ray investigation of the three isomers is expected to be published at a later date by our Laboratories. Solubilities were also determined at 37° in buffered solutions.

Experimental

Materials.—Sulfanilamide (U. S. P.) from plant production was recrystallized from alcohol and from hot water.

Orthanilamide was synthesized by standard methods

from *o*-nitrochlorobenzene by oxidizing the disulfide, amidating and reducing. The product was recrystallized repeatedly from hot water (using traces of hydrosulfite to prevent discoloration), once from diluted alcohol, and once from cold diluted acetone.

Metanilamide was prepared from nitrobenzene by converting to the sulfonyl chloride, amidating and reducing. It was recrystallized repeatedly from hot water (also using hydrosulfite), from hot alcohol and from hot diluted acetone.

Titration with nitrite indicated that the products were 100.0 ± 0.3% pure. Elementary analyses and mixed melting point determinations with materials furnished by Dr. E. H. Northey[2] confirmed these values.

Buffered solutions used in measuring solubility at various *p*H values are listed with their ionic strengths (calculated from dissociation constants) in Table III.

Determination of Solubilities.—Half-filled bottles containing excess solid were rotated, usually overnight, in a water thermostat controlled to ±0.02° by an all-glass mercury–toluene regulator. Equilibrium was approached usually from above and during twelve hours or more (overnight); exceptions are indicated in Table I and Fig. 1. It will also be noted that approach toward equilibrium from below and shorter runs in general gave equivalent results. Sampling was accomplished by forcing the solution, with air pressure, through a glass wool immersion filter into a 15–25-cc. pycnometer immersed in the bath. The pycnometer (resembling a pipet bulb) was closed by two stopcocks, cleaned, dried, cooled and weighed, after which the contents were flushed into a volumetric flask. Duplicate aliquots were acidified (10 cc. of concentrated hydrochloric acid per 25-cc. sample), iced below 15°, and titrated with *N*/25 sodium nitrite to first blue on starch–iodide paper.

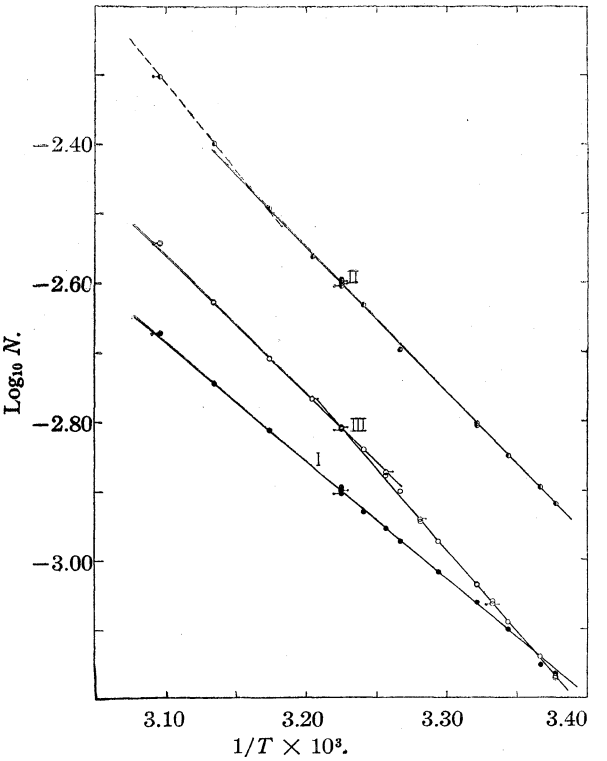

Fig. 1.—Solubility of sulfanilamide isomers in water; I, ●, orthanilamide; II, ◐, metanilamide; III, ○, sulfanilamide; ○–+ equilibrium approached from below; ●–○, duration of experiment less than twelve hours.

In buffered solutions at 37° the solubility was determined by drawing the sample directly into a volumetric pipet, yielding results on a volume basis.

Accuracy of the experimental results, based on the estimated error in weighing and in titration, is taken to be about ±0.01 g./100 g. of solution. This corresponds to ±0.012 × 10^{-3} in mole fraction (±0.0024 in log *N*); these limits are indicated by the size of the circles in Fig. 1. The precision of the results has been calculated in those cases where several determinations were carried out at one temperature. Values of 2 σ vary from 0.01 to 0.03 g./100 g.—see Table I. The consistency with which the experimental points fall on straight lines in the log *N* *versus* 1/*T* plot, Fig. 1, is also indicative of the degree of reproducibility.

Dilatometry.—The dilatometers were of the Bouyoucos type, 100-ml. capacity, with ground stoppers. They were suspended with capillaries immersed in a glass thermostat controlled to ±0.1°. They were charged with about 35 g. of sulfanilamide hydrate crystals (large plates formed from a 1.75% solution by slow cooling below 40°) suspended in toluene or Solvesso No. 2. Readings of the capillary level were taken periodically until essentially con-

stant at each temperature. Above 37° this required many hours.

Manometric Drying.[3]—The apparatus consisted of a mercury manometer, cold trap and vacuum pump connected to a flask in a thermostat at 21°. In the flask was placed a thin layer of ground-up, wet crystals prepared as for dilatometry. During evacuation, pressures were read at intervals (four minutes after closing the connection to the pump). After a definite fall in pressure a sample of the crystals was removed and analyzed both by drying at 110° and by titrating with nitrite.

Results

Solubilities of orthanilamide, metanilamide and sulfanilamide, as directly determined by weight in the temperature range 23–50°, are given in Table I. Values of 2 σ were calculated where duplicate data made this possible.

Solubilities by volume do not differ from values on the weight basis by more than 0.01 g./100 cc. This follows as, over the range 23–50°, the densities of the solutions varied only as follows: orthanilamide, 0.999 to 0.995; metanilamide, 1.000 to 1.001; sulfanilamide, 0.999 to 0.996 g./100 cc.

The experimental aqueous solubility data are plotted in Fig. 1, using $\log_{10} N$ and $1/T$ as coordinates. The discontinuity in the curve for sulfanilamide indicates a phase transition, which was confirmed by dilatometry (see below) as well as by the microscopical and X-ray investigations. Manometric drying, reported below, has shown the transition to involve a monohydrate.

A possible discontinuity at about 43° in the case of metanilamide is also shown. Dashes have been used for the higher temperature line, because only two points determine it, and the 50° point is perhaps unreliable since equilibrium was approached during only 3.3 hours. If the dashed line is correct, the main portion of the curve represents a metastable equilibrium, for it corresponds to higher solubilities than would the extension of the dashed line. (In the microscopical work, various modifications of the anhydrous solid phases of all three isomers were observed. In preparing crystals for this examination it appeared that a transformation for metanilamide may occur near 43°.)

Equations expressing the relation of temperature and solubility, in terms of mole fraction, have been derived from the straight lines of Fig. 1. The general equation is

$$\log N = a(1/T) + b \qquad (1)$$

where N is mole fraction and T is degrees absolute. Values of the constants, a and b, are given in Table II. Solubility as g./100 g. of solution may be derived from mole fraction by the relation

$$S = (17{,}214N)/(18.02 + 154N) \qquad (2)$$

Differential heats of solution have been calculated from the lines of Fig. 1, using the Schröder equation

$$\log N_2 - \log N_1 = \frac{\Delta H}{4.575}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \qquad (3)$$

where ΔH is heat of solution in calories per mole, values for which appear in Table II. Taking the heat of transition as the difference between the heats of solution of the two forms, the heat absorbed by the hydrate → anhydrous transition of sulfanilamide at 37° is 1810 cal./mole.

TABLE II

Compound	Heat of solution, cal./mole	Constants for solubility equation a	b
Orthanilamide	7,820	−1710	2.615
Metanilamide	9,570	−2091	4.156
Sulfanilamide (< 37°)	10,860	−2373	4.844
Sulfanilamide (> 37°)	9,050	−1978	3.570

Qualitative independent evidence of the transition of sulfanilamide, indicated by the solubility data, was sought in a dilatometric investigation. Such was found, there being a distinct increase in volume, evidenced by a discontinuity in the temperature–volume curve, which occurred within 2–4° above 37°. Suspended or negligible rate of transformation close to the transition point accounts for the higher temperature observed in these experiments. Figure 2 portrays the curves obtained from two such experiments.

It had been noticed early that platy sulfanilamide crystals grown at ordinary temperatures changed when exposed to air (or to alcohol or acetone), becoming opalescent, even at room temperature. This change could be forestalled in a saturated or a controlled humidity (such as over 18% sulfuric acid). Crystals rinsed with alcohol gave evidence of water content in rough moisture determinations. Manometric dehydration was undertaken to determine the composition of the hydrate thus indicated.

Hydrate existence of orthanilamide or metanilamide had not been indicated either by change in appearance or by weight loss on drying, so manometric drying was not carried out in these cases.

In Fig. 3 is a graph of observed vapor pressure as wet crystals of sulfanilamide hydrate were

(3) These measurements were carried out by Drs. W. L. Seaman and J. J. Freeman, of the Calco Laboratories, to whom grateful acknowledgment is made.

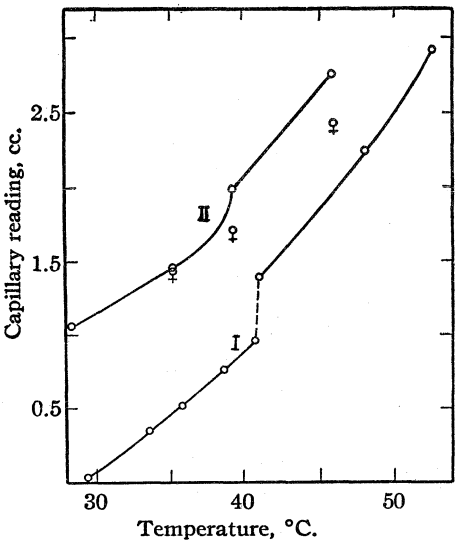

Fig. 2.—Dilatometry of sulfanilamide monohydrate: O, final readings; ♀, non-equilibrium points one hour after temperature change (Curve II).

dried at 21°, plotted against time. The first plateau, of course, corresponds to saturated solution wetting the crystals. After a sudden fall in pressure, another step occurs; crystals removed from the system at this point analyzed 9.4% water by drying and 9.1% by titration; theory for the monohydrate is 9.4%. Such a determination was carried out on two samples, from separate preparations of crystals, with the same results. Further dehydration, during which the temperature was raised to 30° and alcohol–carbon dioxide used on the cold trap, reduced the pressure to a few tenths of a millimeter. Drying at 110° of a sample removed at this point showed only 0.5% loss in weight.

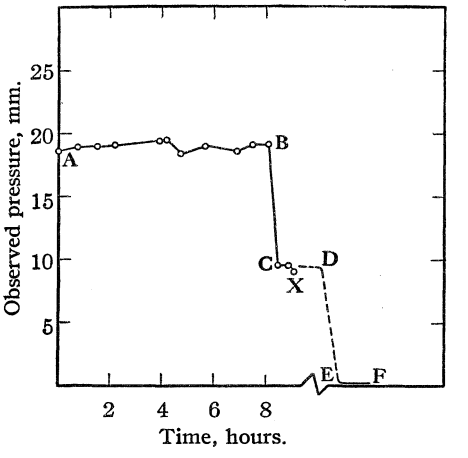

Fig. 3.—Manometric drying of sulfanilamide monohydrate: A-B, wet crystals; C-D, monohydrate; E-F, anhydrous solid; sample removed at X contained 9.4% of water; A-B and C-D at 21°, E-F at 30°.

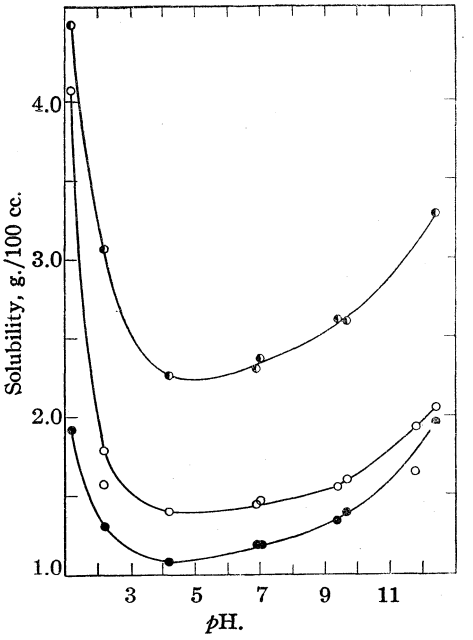

Fig. 4.—Solubility of sulfanilamide isomers in buffer solutions at 37°: ●, orthanilamide; ◐, metanilamide; O, sulfanilamide.

Solubility data at 37° in buffered solutions of various *p*H values appear in Table III. Figure 4 shows solubility to be minimum at *p*H 4.5–5.0. Solubility increases markedly above *p*H 9 and below *p*H 3. Sulfanilamide shows an especially great increase below *p*H 2. Different buffers of the same *p*H may give different results (Table III); the curves in Fig. 4 were drawn for corresponding buffers for the three isomers.

TABLE III

Discussion

Several types of sulfanilamide crystals have been noted by Van Zyp.[4] Undoubtedly one of these

(4) Van Zyp, *Pharm. Weekblad*, **75**, 585 (1938).

is the hydrate form, but neither composition nor temperature conditions of formation were specified.

Polymorphism of sulfanilamide has been described by Watanabe,[5] working in Japan. By means of X-ray study three forms of the solid were defined. The crystals studied were all obtained from alcohol; hence Watanabe could not have obtained the hydrate which is the main feature of this investigation.

Since 37° is body temperature, the sulfanilamide hydrate or transition thereof may hypothetically bear some relation to therapeutic activity, perhaps as a water carrier in biological coupled reactions or as an energy transfer mechanism.

The behavior in buffers bears out the hypothesis that sulfanilamide and its isomers may behave as ampholytes, with minimum solubility at an "isoelectric point" (pH 4.5–5.0 at 37°). The solubility increase for sulfanilamide at pH 1.2 appears to be exceptionally large.

The similarity of "isoelectric point" of sulfanilamide with that of blood serum proteins may be involved in therapeutic activity.

(5) Watanabe, *Naturwissenschaften*, **29**, 116 (1941); *Chem. Abs.*, **36**, 695 (1942).

The authors are indebted to Dr. G. L. M. Christopher for help rendered in the preparation of this paper and to Dr. M. L. Crossley for the encouragement to carry through this type of investigation.

Summary

1. The aqueous solubilities of orthanilamide, metanilamide and sulfanilamide have been determined in the range 23–50°.

2. Heats of solution calculated from the solubility data are: orthanilamide 7820; metanilamide 9570; sulfanilamide below 37°, 10,860, above 37°, 9050 cal./mole.

3. The discontinuity in the solubility curve of sulfanilamide at 37° represents a transition, confirmed by dilatometry, and shown by analysis to involve a monohydrate.

4. Solubilities in buffered solutions of pH 1.2 to 12.4 at 37° exhibit a minimum for all three isomers at pH 4.5–5.0, with striking increase above pH 9 and below pH 3, especially for sulfanilamide below pH 2.

Reactions in Solutions Containing O_3, H_2O_2, H^+ and Br^-. The Specific Rate of the Reaction $O_3 + Br^- \longrightarrow$

BY HENRY TAUBE

When ozone and bromide ion are mixed in acid solution, the net reaction

$$O_3 + 2H^+ + 2Br^- = O_2 + Br_2 + H_2O$$

takes place so rapidly that a direct measure of the specific rate is not possible. In the present paper, experiments on the measurement of this specific rate by an indirect method are reported. The system studied contained acid, O_3, Br^- at a relatively low concentration and H_2O_2. Hydrogen peroxide possesses the properties that at low (Br^-), it rapidly reduces bromine to Br^-,[1] that the reaction with Br^- under the present conditions is negligibly slow, and that the direct interaction with ozone is also slow.[2] The net reaction which takes place in this mixture is

$$H_2O_2 + O_3 = 2O_2 + H_2O \qquad (A)$$

It has been shown[2] that this reaction is accelerated by Br^-, and that the catalytic decomposition of ozone

$$2O_3 = 3O_2 \qquad (B)$$

which accompanies reaction A in a mixture of H_2O_2, O_3 and acid is suppressed by low concentrations of Br^-.

The experiments consisted of a study of the variation of the rate of A with (O_3), (H_2O_2), (H^+) and (Br^-). Analysis of the data showed that three distinct paths are available for reaction A. Mechanisms for these paths, consistent with the data, and with other work in this field are proposed.

Experimental

Acid solutions of O_3 at 0° were prepared as described[2]; redistilled water was used for the most part. Merck's inhibitor free Superoxol was used to make up the solution of H_2O_2. A stock supply of sodium perchlorate solution was prepared by neutralizing perchloric acid with C. P. sodium carbonate.

(1) Bray and Livingston, THIS JOURNAL, **50**, 1663 (1928).
(2) Taube and Bray, *ibid.*, **62**, 3357–3373 (1940).

The method of handling the solutions was the same as that described in the earlier article. Usually nine cells were filled for a single experiment; these were placed in an ice-bath shielded from light and analyzed at intervals. The time of emptying, less than one-tenth minute, was small compared to the shortest interval between successive quenchings, one and one-half minutes.

The rates were obtained by plotting the values of (O_3) or (H_2O_2) against time in minutes, and measuring the slopes at intervals on the curve. Each experiment yields values of the rates for a fairly wide range of (O_3) and (H_2O_2); for each experiment a table was computed listing corresponding values of time, (H_2O_2), (O_3), rates and suitable functions of these variables. The system is not nearly as sensitive to traces of impurities as it is in the absence of Br^- and results were reproducible.

All experiments were carried out at 0°. Except where otherwise stated, the ionic strength was maintained at 0.20 by the addition of sodium perchlorate solution. The units used throughout are: concentration in moles per liter and time, t, in minutes.

In all experiments for which rate data are presented, (H^+) and (Br^-) were sufficiently high to eliminate reaction B almost completely, so that $\Delta(H_2O_2) = \Delta(O_3)$. For the analysis in most cases the cell content was forced into an acidified solution of sodium bromide, and potassium iodide and ammonium molybdate solutions were then added. After the hydrogen peroxide had reacted completely with the iodide ion, the total iodine (equivalent to the sum of the ozone and hydrogen peroxide) was determined. One cell in each run was allowed to proceed to completion, and the final concentration of the reagent in excess then determined. This permitted the concentration of hydrogen peroxide and ozone at any time to be calculated from the corresponding value of their sum. Orienting experiments showed that this method gave the same results as the method of separate analysis.[2]

In most of the experiments, (Br^-) added was small compared to (H_2O_2) or (O_3); when (Br_2) was appreciable, appropriate corrections were made in calculating the concentration of ozone and hydrogen peroxide.

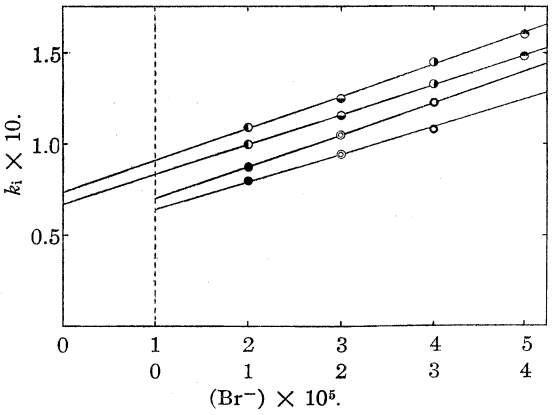

Fig. 1.—Variation of k_i with (Br^-); $\mu = 0.20$: $(H_2O_2) = 12.5 \times 10^{-4}$ M. The lower row of values for the abscissa refers to lines 3 and 4, the lines being numbered from top to bottom. Points represented by the same symbol are results of the same experiment; the upper one always is a result later in an experiment after (O_3) has decreased to the designated value. To eliminate (H_2O_2) as a variable, the data were corrected to the recorded value of (H_2O_2) using the law of variation with (H_2O_2) demonstrated in Fig. 2; the maximum correction was about 6%.

line	$(O_3) \times 10^4$	$(H^+) \times 10^3$	slope

Results

Figure 1 presents data on the variation of the rate of reaction A with (Br^-) at low values of (H^+) and at low values of the ratio $(O_3)/(H_2O_2)$. The specific rate k_i, which is plotted as ordinate, is defined by

$$-d(H_2O_2)/dt = -d(O_3)/dt = k_i(O_3)$$

For each line in the figure, the only variable is the concentration of Br^-. The results show that the rate law consists of at least two terms. One of these varies directly with (Br^-); its value is given by the slope of the straight lines through points of constant (H^+), (H_2O_2) and (O_3) and varying (Br^-). The slopes of the lines (*cf.* table under Fig. 1) are nearly constant and independent of (H^+). The slight variation as (O_3) decreases and time increases is discussed in connection with Fig. 2. The other term represented by the intercept on the vertical axis is independent of (Br^-); the variation of this term with (H^+) over a wide range is discussed below.

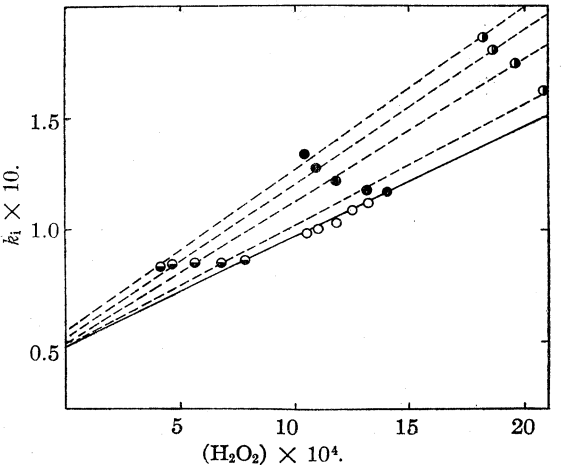

Fig. 2.—Variation of k_i with (H_2O_2), at 3×10^{-5} M Br^-, 1.16×10^{-2} M $HClO_4$, $\mu = 0.20$. All points from one experiment are distinguished by the same symbol. The open circles distinguish an experiment in which the method of handling the solutions was changed (see text). Numbering the lines from top to bottom: for line 1, $(O)_3 = 0.5 \times 10^{-4}$ M; for 2, 1.0×10^{-4} M; 3, 2×10^{-4} M; 4, 3.25×10^{-4} M; 5, 4.2×10^{-4} M.

Figure 2 shows the variation of k_i with (H_2O_2) at 1.16×10^{-3} M $HClO_4$, 3×10^{-5} M Br^- and low values of the ratio $(O_3)/(H_2O_2)$. Along each line, the only variable is (H_2O_2); from line to line, (O_3) differs. It is again apparent that there are at least two terms in the rate law. The peroxide independent term, which is represented by the finite limiting value of $k_i = 0.048 \pm 0.002$ at zero peroxide, can be identified with the bromide dependent term of Fig. 1. This follows since the coefficient obtained by dividing the value of the intercept by the concentration of $Br^-(0.048/3 \times 10^{-5}) = 1600$ is the same as the slope of the lines in Fig. 1. The peroxide dependent part of the rate law then corresponds to the (Br^-) independent term of Fig. 1.

The experiment in Fig. 2 represented by the open circles was an experiment in which five cells were rapidly and consecutively filled. During the experiment, the ozone concentration fell to one-third of its initial value; these points are seen to fall in line with the initial points in the other experiments and prove that k_i is independent of (O_3) (*i. e.*, rate is proportional to (O_3)) for these conditions. In all the other experiments, the process of filling the cells was interrupted to make analyses. This probably occasioned a loss of ozone from the main body of the solution and the variation of k_1, *ca.* 40% for an 8-fold variation in (O_3), with (O_3) shown by the lines through these points is therefore mainly due to this cause; these results have been included for the sake of completeness, but the lower line is taken as the best representation of the rate of reaction for these conditions.

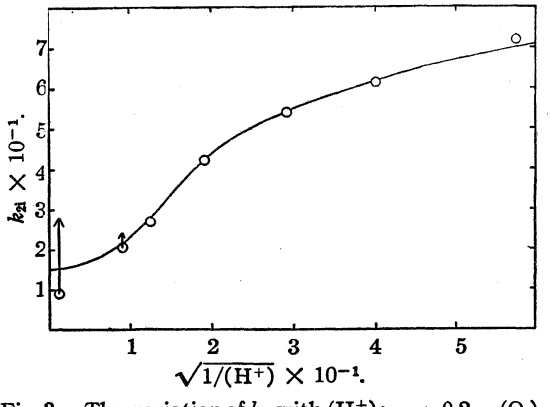

Fig. 3.—The variation of k_{2i} with (H^+); $\mu = 0.2$. $(O_3) = 3.0 \times 10^{-4}$ M, H_2O_2 = *ca.* 14.0×10^{-4} M for the series. $(Br^-) = 2 \times 10^{-5}$ M except in the two experiments at lowest H^+ where it was 5×10^{-5} M. In the two experiments at high (H^+), the bottom of the arrow is the value if the maximum correction for path III is applied; top is the value if no correction for path III is applied (see text).

The results of Figs. 1 and 2 may be summarized by the equation

$$k_i = 1600 \pm 100\,(Br^-) + k_H\,(H_2O_2) \quad \text{(I)}$$

Line 2 in Fig. 1 passes through the most accurate data and the slope of this line was taken as the numerical coefficient of the first term of rate law I.

In rate law I, k_H is not a true constant but varies with (H^+). A number of experiments were performed to study this variation; these results are presented in Fig. 3. At values of $(H^+) < 1.15 \times 10^{-3}$ M, (Br^-) was raised to 5×10^{-5} M to suppress reaction B. k_H, at any value of (H^+) within the range for which rate law I is valid, can readily be calculated by the use of this equation from the measured value of k_i. As will be shown later, at high (H^+), Br^- is present at the steady state largely as Br_2, and a new path for reaction A is available. Corrections, consistent with the later findings, are applied to the experimental values k_i to allow for these effects; these corrections are necessary only at the two highest values of (H^+). There is an uncertainty in applying the correction for the new path due to bromine in the present range of values for $(O_3)/(H_2O_2)$; the uncertainty is in such a direction that k_H is greater than the plotted value. For the point at highest (H^+), k_H may well be twice as great as the plotted value; for the next point, only slightly greater. In spite of this uncertainty, the results indicate that k_H approaches limiting values both at high and at low (H^+).

When (H^+) and the ratio $(O_3)/(H_2O_2)$ are increased, the kinetics of the reaction change radically. In Fig. 4, the results of a series of experiments for this concentration region are presented. To represent these results, it was found convenient to define a specific rate k_{ii} (not necessarily a constant) by the equation

$$-d(H_2O_2)/dt = k_{ii}\sqrt{(H_2O_2)(O_3)}$$

A single experiment is represented by a series of points starting at the right and usually covers a 6–12 fold change in the concentration of hydrogen oxide. The lines have been drawn in to conform to the rate law

$$k_{ii} = 1.26\sqrt{(Br_2)/(H^+)} + 1.41 \times 10^2\sqrt{(Br_2)(H_2O_2)} \quad \text{(II)}$$

$((Br_2) = (Br^-)_0/2$ where $(Br^-)_0$ is the concentration of bromide ion added) and represent the data with satisfactory fidelity except at the lowest

value of (H^+) investigated in this series (upper part of the figure).

In preliminary work, the law of variation with the concentration of added Br^-, $(Br^-)_0$, was tested over a wider range than is done in Fig. 4. These data are presented in Table I. The results, though not strictly comparable with those of Fig. 4 (the ionic strength was less and (H^+) was not accurately known) are consistent with them. These results again show that k_{ii} varies directly with $\sqrt{(Br_2)}$.

TABLE I

VARIATION OF k_{ii} WITH ADDED Br^-

$HClO_4$ is *ca.* 0.15 *M* and μ is *ca.* 0.15. $(H_2O_2)_0 = 3.6 \times 10^{-4}$ *M*.

40	7.17	2.64	.59
100	6.87	4.20	.59
300	6.90	7.80	.63

Discussion

The rate laws obtained show that at each of the extremes—low (H^+), low $(O_3)/(H_2O_2)$ and high (H^+), high $(O_3)/(H_2O_2)$—there are two paths for reaction A.

The first term of rate law I and the first term of rate law II both follow from the non-chain path represented by the following reactions (arrows designate rate determining steps).

PATH I

$$Br^- + O_3 \xrightarrow{k_1} BrO^- + O_2 \qquad (1)$$

$$H^+ + BrO^- = HBrO$$

$$Br_2 + H_2O \overset{K_{Br_2}}{\rightleftharpoons} HBrO + H^+ + Br^-$$

$$H_2O_2 + HBrO \xrightarrow{k_2} H^+ + Br^- + H_2O + O_2 \qquad (2)$$

When reaction 1 is the sole rate determining step (*i. e.*, (Br_2) and $(HBrO) \ll (Br^-)$), the simple rate law corresponding to the first term of rate law I follows. It will be shown that this condition is realized in the experiments at low values of (H^+) and $(O_3)/(H_2O_2)$. The numerical coefficient of this term therefore gives the value of k_1; thus, the rate of interaction of O_3 and Br^- at 0° and $\mu = 0.2$ is 1600 ± 100 l. mole^{-1} min.$^{-1}$.

The following considerations show that at low (H^+) and low $(O_3)/(H_2O_2)$, $(Br^-) \gg (HBrO)$. At the steady state, $k_1(O_3)(Br^-) = k_2(H_2O_2)(HBrO)$ and $(Br^-)/(HBrO) = k_2(H_2O_2)/k_1(O_3)$.

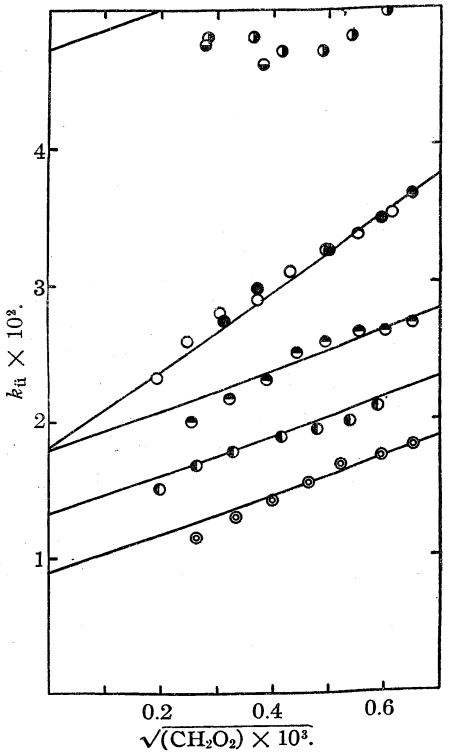

Fig. 4.—Variation of k_{ii} with (H_2O_2), (O_3), (H^+), $(Br^-)_0$ at high $(O_3)/(H_2O_2)$ and $\mu = 0.20$. All points obtained from a single experiment are distinguished with the same symbol.

Symbol	◎	◐	◓	●	○	◒	◑
$(O_3)_0 \times 10^4$	16.46	12.3	14.32	7.54	15.11	14.45	13.2
$(H^+) \times 10^2$	20.1	8.86	4.48	20.2	20.2	0.63	0.63
$(Br^-)_0 \times 10^5$	2	2	2	8	8	2	2

Bray and Livingston,[1] from an analysis of Balint's[3] measurements on the rate of reaction of bromine and peroxide at 0°, report for $k_2K_{Br_2}$ a value of $6.2 \times 10^{-4} \pm 9\%$. For the same ionic strength (zero) Liebhafsky[4] reports K_{Br_2} at 0° $= 6.9 \times 10^{-10}$. Thus $k_2 = 9 \pm 1 \times 10^5$.[5] When this value is substituted in the above expression together with $k_1 = 1600$, $(Br^-)/(HBrO) = 560$ when $(H_2O_2) = (O_3)$. For the experiments under consideration (H_2O_2) always exceeded (O_3) by more than a factor of 3 and (HBrO) becomes correspondingly less compared to (Br^-).

To show that (Br_2) is small for the same conditions, the expression for the steady state concentration of Br^- when the hydrolysis is not complete and when $(HBrO) \ll (Br^-)$ (*i. e.*, $(O_3)/(H_2O_2)$ does not exceed *ca.* 25) is derived; the result is

(3) Balint, Thesis (in Hungarian), University of Budapest, 1910.

(4) Liebhafsky, THIS JOURNAL, **56**, 1500 (1934).

(5) This is the value calculated for $\mu = 0$; the value $\mu = 0.2$ should not differ widely since both molecules are neutral.

$$(Br^-) = \frac{\left(K^2_{Br_2} + 8(Br^-)_0 K_{Br_2} \frac{k_1}{k_2} (H^+) \frac{(O_3)}{(H_2O_2)}\right)^{1/2} - K}{4 \frac{k_1}{k_2}(H^+)\frac{(O_3)}{(H_2O_2)}} \quad (III)$$

Using the values $k_1 = 1600$, $k_2 = 9 \times 10^5$ and K_{Br_2}[6] $= 1.1 \times 10^{-9}$, $(Br_2) = [(Br^-)_0 - (Br^-)]/2$ is calculated to be 5×10^{-7} for the most extreme case presented in Fig. 1 [lower right-hand point in Fig. 1; $(H^+) = 2.65 \times 10^{-3}$, $(Br^-)_0 = 3 \times 10^{-5}$, $(O_3)/(H_2O_2) = 0.148$]. The point under consideration is actually below the line through the other points; this effect may be attributed to the fact that some of the Br^- is in the form of Br_2 and the maximum rate is thus not observed.

A rate law of the form of the first term of rate law II follows from the mechanism above when (Br^-) and (HBrO) are small compared to (Br_2). It can readily be shown by using Equation III that this condition is realized for all the experiments in Fig. 4 except the two in the upper part of the diagram.

The rate law derived from the mechanism for this condition is

$$\frac{-d(H_2O_2)}{dt} = \sqrt{k_1 k_2 K_{Br_2}} \sqrt{\frac{(Br_2)}{(H^+)}} \sqrt{(O_3)(H_2O_2)}$$

where $(Br_2) = (Br^-)_0/2$. This has exactly the same form as the first term of rate law II. Comparing the coefficients of the theoretical and experimental laws we obtain the result: $k_1 k_2 K_{Br_2} = 1.60$. From the measured value of 1600 for k_1 and the estimated value of 1.1×10^{-9} for K_{Br_2} at $\mu = 0.20$ and 0°, we obtain for k_2 a value of 9.0×10^5. The agreement with the value of $9 \pm 1 \times 10^5$ calculated from Balint's results is good confirmation for the interpretation of the data. The limits of accuracy for the value of k_2 from the present work are about the same as for Balint's.

On the interpretation given, a discrepancy in the observed direction between the experimental points and those predicted by rate law II is expected at 6.3×10^{-3} M H^+ (experiments at the top of Fig. 4) since (Br^-) and (Br_2) have comparable values. However, a quantitative comparison of theoretical and experimental results is not possible since the contribution to the rate by the path corresponding to the second term of rate law II cannot be calculated accurately for this range of values for $(O_3)/(H_2O_2)$.

(6) Liebhafsky's value of $K_{Br_2} = 6.9 \times 10^{-10}$ for 0° and low ionic strength is corrected approximately for the change to $\mu = 0.2$ by dividing by γ^2_{HBr}. Livingston's value (THIS JOURNAL, **48**, 45 (1926)) of γ_{HBr} at $\mu = 0.2$ and 25° was used.

While the non-chain reactions of Path I give a consistent explanation for the first terms of both rate laws I and II, the last terms of these rate laws are best interpreted by chain reactions. Although the rate corresponding to the second term of rate law I is proportional to $(H_2O_2)(O_3)$, it cannot be explained by the direct interaction of ozone and hydrogen peroxide. The specific rate of interaction of these substances is 0.14 while k_H at 2.6×10^{-3} M is *ca.* 50. Experiments with inhibitors support the assumption of chain reactions. Table II presents data showing the effect of methanol in decreasing k_H.

TABLE II

EFFECT OF CH_3OH ON k_i AT 1.15×10^{-3} M $HClO_4$, 3×10^{-5} M Br^-, 4.18×10^{-4} M O_2

$(CH_3OH) \times 10^4$	$(H_2O_2) \times 10^4$	k_i	k_H
0	12.53	0.109	49
4	11.39	.076	25
10	11.18	.074	23
20	12.45	.074	21

Ethanol and phosphorous acid give similar results (the limiting value of k_H differing however for the different inhibitors) and a similar decrease in the rate under the conditions for which rate law II is valid is also observed. The fact that k_H (and the coefficient of the second term of rate law II) are not reduced to very low values is not inconsistent with the assumption of long chains. The radical which results from the reaction of the active intermediate with the "inhibitor" may itself catalyze the reaction[7a]; cases are known in which the resulting chains are longer than the original ones.[7b]

A rate expression of the form of rate law I follows (on the assumption of long chains) from the series of reactions (3)–(7).

PATH II

Chain initiating step

$$H_2O_2 + O_3 \xrightarrow{k_3} HO + HO_2 + O_2 \quad (3)$$

Chain continuing steps

$$HO_2 + O_3 \xrightarrow{k_4} HO + 2O_2 \quad (4)$$

$$HO + H^+ + Br^- = H_2O + Br \quad (5)$$

$$Br + H_2O_2 \xrightarrow{k_6} H^+ + Br^- + HO_2 \quad (6)$$

Chain breaking step

$$HO_2 + Br \xrightarrow{k_7} H^+ + Br^- + O_2 \quad (7)$$

Reactions 3 and 4 have been made plausible by other work[2]; 5, 6 (and 7 under limited conditions)

(7a) Taube and Bray, ref. 2, p. 3362.
(7b) Taube and Bray, ref. 2, p. 3363

find their exact analogy in experiments with $H_2O_2 + O_3 + Cl^-$.[2] Reaction 6 furthermore is a probable step in the photoreaction between peroxide and Br_2.[8] Br is presumably the intermediate which reacts with the inhibitors; the photochemical experiments of Dhar and Battacharya[9] indicate that Br and methanol do react.

If the reactions

PATH III

$$Br_2 + O_3 + H_2O \longrightarrow HO + Br + BrOH + O_2$$
$$\text{or } HO_2 + Br + Br^- + H^+ + O_2 \quad (8)$$
$$Br + Br \longrightarrow Br_2 \quad (9)$$

are substituted for the chain initiating and chain breaking steps, respectively, of Path II, the resulting mechanism (again assuming long chains) leads to a rate law of the form of the second term of rate law II. The following considerations show that these changes are not unreasonable. In going from the conditions for which rate law I is valid to those of II, (H^+), and (O_3) are increased, (H_2O_2) is decreased. (Br_2) increases markedly with respect to (H_2O_2), and reaction (8) becomes more probable than (3) on concentration considerations. Furthermore, increasing the ratio $(O_3)/(H_2O_2)$ increases $(Br)/(HO_2)$ and the chain breaking step (9) becomes more probable than (7).

It must be stressed that the second terms of rate laws I and II are limiting laws valid only for the extreme concentration ranges considered, where one or the other of the chain breaking steps (7) and (9) operate. Experiments which because of their complexity are not reported in detail suggest that in the intermediate range both chain breaking steps operate.

The variation of k_H with (H^+) observed in Fig. 3 can be explained if it is assumed the HO_2 is a fairly strong acid with $K_{diss.}$ *ca.* 10^{-2}. On this basis, at $(H^+) = 0.1\ M$, the free radical is present mainly as HO_2 and a limit for k_H at high (H^+) is expected; at $(H^+) = 10^{-3}\ M$, O_2^- will be the reactant, undergoing reactions similar to those of HO_2, and a limit for k_H at low acid will also result. Weiss,[10] Latimer[11] and Bray[12] suggest values of *ca.* 10^{-6}, *ca.* 10^{-6} and *ca.* 8×10^{-8}, respectively, but the evidence available for these low dissociation constants does not suffice to exclude the higher value indicated by the new kinetic data.[13] The experiments of Callow, Griffith and McKeown[8] and of Taube and Bray[2] on chain reactions of HO_2 do not give a clue to the value of K_{HO_2} since the substance was not involved in the chain breaking steps for the concentration range in which quantitative results were available.

In conclusion, a correlation of the present results with those obtained in the O_3, H_2O_2, H^+ and Cl^- system[2] may be interesting. In that case, the non-chain path corresponding to Path I contributed little to the reaction, due to the fact that the specific rate of interaction of O_3 and Cl^- is much less than that for O_3 and Br^- — 0.023 compared to 1600. For the same reason, (Cl_2) at the steady state was always very small, and the path corresponding to Path III was absent. The path analogous to Path II accounted for most of the reaction at high Cl^-; however, to eliminate HO, (Cl^-) had to be increased to such an extent that complications due to the formation of Cl_2^- appeared. Analogous to the behavior in the present system, there appeared to be a change (at low Cl^-) from $Cl + Cl \rightarrow$ as chain breaking step to $HO_2 + Cl \rightarrow$ when the ratio $(O_3)/(H_2O_2)$ was decreased. Finally, the system with Br^- present is less sensitive to stray impurities than with Cl^-, since Br is less reactive than Cl.

The author is grateful to Professor William C. Bray for helpful discussions of this work.

Summary

The rate of reaction A is studied over a wide range of the variables (O_3),(H_2O_2), (H^+) and (Br^-) at 0° and limiting rate laws, valid for extreme conditions, are obtained.

Three paths are necessary and sufficient to interpret the data. The results are consistent with the following conclusions:

Path I, a non-chain path, involves oxidation of Br^- by O_3 to BrO^-, and reduction of hypobromous acid by peroxide. The specific rate of the former reaction is found to be 1600 ± 100, and the value of 9×10^5 obtained for the latter reaction agrees with the value reported in the

(12) Bray, THIS JOURNAL, **60**, 86 (1938).

(13) An alternative explanation, suggested by the Referee, for the variation of k_H with (H^+) is that HO_2 forms a complex $HO_2 \cdot H^+$. Evidence for or against the existence of such a complex with a dissociation constant of 10^{-2} could not be found in the literature.

literature. No evidence is found for the oxidation by O_3 of Br^- by a free radical process.

Paths II and III are chain paths initiated by reaction of ozone with peroxide and bromine, respectively, to produce free radicals. The chain continuing steps are the same for both paths; the nature of the chain breaking step depends on the ratio $(O_3)/(H_2O_2)$. An explanation of the variation of the rate by Path II with (H^+) is afforded by the assumption that HO_2 is a fairly strong acid with $K_{diss.}$ *ca.* 10^{-2}.

The System Sodium Nitrate–Dioxane–Water at 25°

BY B. SELIKSON AND J. E. RICCI

In connection with studies on the solubilities of salts in dioxane-water mixtures the formation of a two liquid system was observed in high dioxane solutions saturated with sodium nitrate. The experimental study of the phase relationships of such ternary systems involving a solid and two liquid components is in general rendered difficult by the problem of analysis for one of the liquid components in addition to the usually simple determination of the solid component. For solids forming no solid solvates with the liquid components the solubility curve is easily determined as a binary problem by using mixed solvents of known composition. Under favorable circumstances a binodal curve in such a system may be established by the synthetic method of titration with one of the liquid components, as in the system potassium carbonate–dioxane–water studied by Kobe and Stong.[1] Otherwise the analytical problem has usually been solved through the measurement of some physical property of the solution, or of the distillate from some ternary solution or phase, for the determination of the ratio of the two liquid components; examples of such properties are the refractive index (used for the study of the system lithium chloride–dioxane–water, by Lynch[2]), the density, or even the solubility of some reference salt in the unknown mixture of the two liquids. For more precise work it is desirable to attempt some direct determination of one of the liquid components. In the system silver nitrate–dioxane–water,[3] in which a solid dioxanate of silver nitrate appears at 25°, water was determined directly gravimetrically, with fairly accurate results, by volatilization of the solvents and absorption of water in barium monoxide. In the present system, a more rapid and possibly more exact method was attempted, by the application of the Karl Fischer reagent for the direct volumetric determination of water.[4]

Materials and Analysis.—The sodium nitrate was a C. P. sample used without further purification, after grinding and drying at 110°. The dioxane was treated and dried as described in previous similar investigations.[5] The Karl Fischer reagent (active ingredients: iodine, sulfur dioxide and pyridine, in methanol as solvent) prepared according to the directions of Smith, Bryant and Mitchell,[6] was used with synthetic "anhydrous" methanol as back-titrating solution, and was standardized against a standard solution containing a known weight of pure water in the same methanol. The water content of the methanol and the effective titer of the reagent itself were calculated from a set of titrations using 1, 2 and 5 ml. (all at least in duplicate) of the standard solution of water (1 ml. containing 0.01793 g. of H_2O by preparation). The titer of the Karl Fischer reagent was found to fall with time, as expected (from 0.002582 to 0.001986 g. of water per ml. in fifty-eight days); in the actual use of the reagent, however, standardization titrations against the standard water solution were always run just before and just after any set of analyses, all being done within a few hours at most, so that the error from such changing strength could be kept low. It was found, moreover, that the water content of the back-titrating methanol also changed (increased) with time, so that a curve of this effect was used to estimate the water content of the methanol for some of the standardizations for which there had not been a satisfactory simultaneous determination of the water equivalent of the methanol. These corrections were, of course, small, inasmuch as relatively only small volumes of the methanol were used in back-titration, and the change in its water titer was only from 0.00033 to 0.00056 g. of water per ml., in the same period of fifty-eight days.

Solubility Determinations.—The methods for the preparation of complexes, temperature control, attainment of equilibrium, sampling of liquids for analysis and approximate density determination, were as used in previous investigations.[3] The equilibrium solutions were analyzed

for sodium nitrate by evaporation to constant weight at 100–150°. For the determination of water weighed samples of the ternary solutions were diluted with dioxane in 25-ml. volumetric flasks, and suitable aliquots (usually 1 or 2 ml., requiring on the average about 15 ml. of titrating solution) were analyzed by means of the Karl Fischer reagent. Preliminary experiments had established that neither dioxane nor sodium nitrate interfered with the water determination. Addition of definite volumes of dioxane during standardizations showed the presence of only a very small amount of water in the dioxane, amounting to a practically negligible correction of only about 0.02 ml. of the reagent per ml. of dioxane.

Except for an occasional loss of sample, the solutions were all analyzed in duplicate for each of the two components determined. Five of the analyses (which were generally made after a day or two of rotation of the complexes) were repeated after a few more days or longer, to verify the attainment of equilibrium. The values listed in the table are the final average compositions thus determined for each point on the isotherm. The isothermally invariant solutions saturated with sodium nitrate were analyzed from three different complexes. The relative disagreement in the duplicate determinations of sodium nitrate were generally very small, as expected; for the water determination the disagreement of duplicates averaged 3–4 parts per 1000. The average absolute error in the water determination may be estimated from the algebraic extrapolations of the eight tie-lines for single liquids saturated with sodium nitrate as solid phase. These tie-lines extrapolate to 100% sodium nitrate with an average deviation of 0.31% calculated as water; conversely, assuming the solid phase to be pure sodium nitrate, as it evidently is, the average absolute error of the determination of the water content of these solutions is calculated to be 0.08%.

Results.—The results of the solubility determinations are listed in Table I and shown graphically in Fig. 1. The compositions are given in terms of weight per cent.

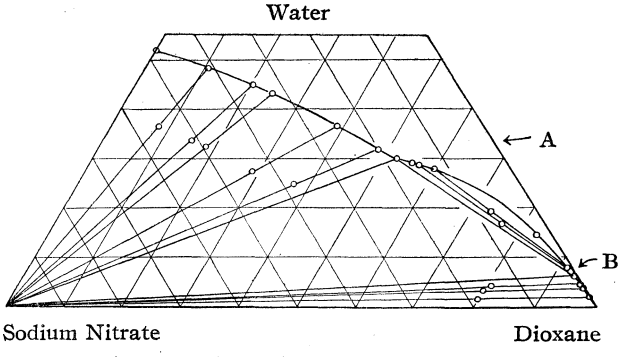

Fig. 1.—System sodium nitrate–dioxane–water at 25°.

Discussion.—On the basis of the diagram and of the algebraic extrapolation of tie-lines, the only solid phase is seen to be unsolvated sodium nitrate. The solubility curve of this solid, however, is seen to be broken by a rather flat binodal region in which immiscible liquids are formed. The isothermally invariant conjugate liquids in equilibrium with excess of solid sodium nitrate have the following compositions

	% $NaNO_3$	% H_2O	Density
Lower layer	17.84	30.03	1.146
Upper layer	0.443	6.16	1.072

Two pairs of conjugate solutions in the binodal area, not saturated with solid sodium nitrate, were determined by direct and complete analysis of the equilibrium phases formed from known mixtures of the three components (complexes 11 and 12 of Table I). The two tie-lines so obtained are sufficient to indicate that the plait point of the binodal curve must lie considerably over toward the dioxane-rich side. Two other points on the binodal curve (numbers 10 and 13 of Table I) were determined synthetically by a kind of titration: addition of solid sodium nitrate, in successive small portions, with shaking, to known weights of suitable mixtures of water and dioxane. The appearance of a turbidity indicating the formation of a second liquid marked a point on the binodal curve. In experiment no. 13 the liquids so formed were almost immediately approximately equal in volume, indicating proximity to the plait point, which, however, was not further investigated.

The last five values (a-e) listed in Table I were obtained in some earlier more precise work on the effect of water on the solubility of sodium nitrate in dioxane, using more highly purified dioxane and sodium nitrate. These mixtures were rotated for at least two weeks, and were analyzed in duplicate, and only for sodium nitrate, the percentage of water in the equilibrium solutions being calculated from the exact composition of the mixed solvent, prepared by weight. An enlarged plot of these special points for this region of the system is shown in Fig. 2, in which the shape of the curve is seen to be similar to the corresponding portion of the solubility curve of silver nitrate in dioxane containing small amounts of water.[3]

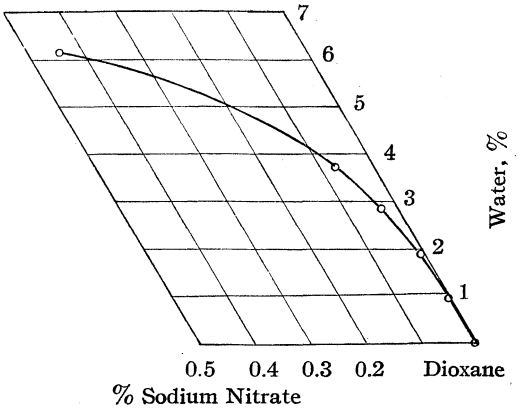

Fig. 2.—Effect of water on solubility of sodium nitrate in dioxane, at 25°.

Summary

The solubility relationships in the ternary system sodium nitrate–dioxane–water at 25° have been investigated, using a direct analytical determination of water in the equilibrium liquids by means of the Karl Fischer reagent. A small region of immiscible liquids appears, for solutions containing between 52.13 and 93.40% dioxane and between 17.84 and 0.44% sodium nitrate. Exact determinations are also given for the solubility of sodium nitrate in dioxane containing very small percentages of water.

The Relative Surface Tension of Potassium Chloride Solutions by a Differential Bubble Pressure Method[1]

BY F. A. LONG AND G. C. NUTTING

The surface tensions of dilute aqueous solutions of electrolytes have been investigated recently by a capillary height[2] and by a ring method.[3] Both show a minimum in the surface tension at about 0.001 normal although the depth of the minimum is considerably larger for the ring method. To explain the discrepancy of these results from the theoretical Onsager–Samaras[4] prediction, two different types of explanations have been advanced. Dole[5] and also Bikerman[6] have developed theories on the assumption that the results are true surface tensions. Langmuir[7] postulated that the true surface tension did not have a minimum and that the experimental results were due to the neglect of the zeta potential at the silica–solution interface. This theory has been discussed in more detail by Jones and Frizzell.[8]

The present paper reports an investigation of the surface tension of dilute potassium chloride solutions using another method of measurement. The procedure employed is a differential adaptation of the maximum bubble pressure method and is in essence a modification of the method devised by Warren.[9]

The Method.—For a capillary tube small enough so that the bubble formed is a true hemisphere the equation for the maximum bubble pressure method is

$$P_{max.} = gd\rho + (2\gamma/r) \qquad (1)$$

where d is the depth of immersion of the tube, ρ is the density difference between the liquid and the gas, γ is the surface tension and r is the radius of the tube. As this equation indicates the method is free from any assumption about the contact angle. Warren evolved a differential adaptation of this method by using two identical capillaries connected to a single source of gas under a slight pressure. These capillaries were immersed below the liquid surfaces of two different vessels, one containing pure solvent and the other the solution whose relative surface tension was to be measured. The heights of the vessels and thus the depths of immersion of the capillaries were varied with micrometer screws until bubbles came alternately from the two tubes. The maximum pressure in the bubbles is then the same and by measuring the depths to which the two tubes are immersed and the densities of the solutions, the ratio of the two surface tensions can be obtained.

The method used in the present work eliminates the difficult task of measuring the depths of immersion with precision and substitutes a measurement of surface areas and volumes. A sketch of the apparatus is given in Fig. 1. In this figure A and A′ are two similar circular glass vessels of about two-liter capacity and inner cross sections of about 250 sq. cm. The walls of these vessels are very nearly perpendicular. C is a bent T made of Pyrex glass through which gas flows. The two ends of this T that dip into the solutions have identical capillary exits from which the bubbles emerge. Saturated nitrogen gas under a pressure of a few cm. of water enters the other opening of the T and its rate of flow is regulated by a valve V which is an ordinary Hoke needle valve. The glass rod R which dips into the right vessel is attached to a screw of known pitch. Each vessel contains a stirrer, S and S′. In the actual setup the two vessels rest on a very rigid framework which allows them to be immersed in a constant temperature water-bath. The T apparatus is attached rigidly to the same framework. The stirrers and the rod R are attached to a separate rigid frame. L and L′ are close fitting glass lids with holes for the tubes and rods.

(9) Warren, *Phil. Mag.*, [7] **4**, 358 (1927).

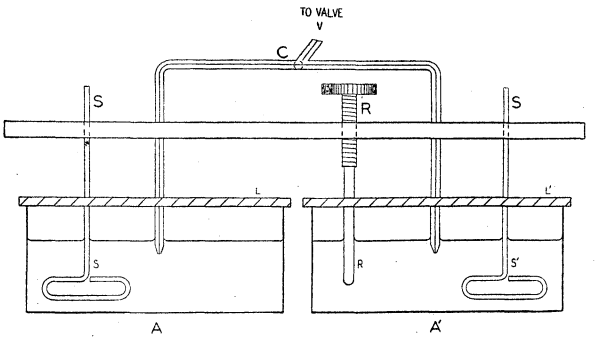

Fig. 1.—Differential bubble pressure apparatus.

The cross sectional areas of the two vessels were obtained by eight measurements of their diameters, taken at the height to which 1000 ml. of solution came. The net areas were obtained by subtracting the cross sectional areas of the rods and tubes that were present in the actual setup.

The tips of the T apparatus were obtained by breaking a selected piece of capillary tubing with a very nearly circular cross section. Tubes were used only if the breaks were smooth and perpendicular to the axis of the tube. By using two ends of a given break it was certain that the two orifices had the same diameter. The circularity and the diameter of the orifices were determined by six different measurements with a traveling microscope. Tubes were rejected if any diameter differed by more than 1% from the average. The diameter of the capillaries as measured by a traveling microscope is certainly not accurate to more than a few tenths of a per cent. but as will appear later, this is sufficient. Before use the area of the ends of the capillaries was reduced to approximately four sq. mm. by tapering the ends on a grinding wheel.

To make a surface tension determination the two vessels are filled with just less than 1000 ml. of water, placed in the water-bath and the stirrers, rod, lids and T apparatus are put in place. After an hour or so has elapsed, to ensure temperature equilibrium, a slow current of gas is allowed to pass into the T apparatus. This gas is at a constant pressure of 10 to 12 cm. of water and the valve V is adjusted so that bubbles form from one of the orifices at a constant rate of one bubble every twenty to forty seconds. Water is added to the vessels until a single drop will cause the bubbles to shift from one orifice to the other. The water in the two vessels is stirred, allowed two to four minutes to equilibrate and then the rod R is turned so that bubbles come with equal frequency from the two orifices. This indicates equal maximum bubble pressures and represents the zero point for the apparatus. The position of the rod R (which is equipped with a scale to measure the distance it is immersed) is a measure of this balance point. Three or four further determinations of this zero point are made. Usually the apparatus will show a constant balance for an hour or more. Since the two vessels contain only water, at the balance point the depths of immersion of the two tips are identical.

After the zero point is established, a few ml. of a potassium chloride solution of known concentration is added to one of the vessels from a weight pipet. This shifts the bubbling entirely over to the other orifice. Water is added to the other vessel, again from a weight pipet, until

the bubbles just shift back to the first orifice. The two vessels are then stirred and the final adjustment to a new balance, the condition where bubbles come from both orifices with equal frequency, is made by changing the position of the rod R. This new balance is checked as before to see whether it remains constant. If so the apparatus is disassembled, the depths to which the tips are immersed is determined to about 0.1 mm. and the final volume of the dilute potassium chloride solution in the one vessel is determined to about two ml.

The equation for the calculation of the relative surface tension follows directly from equation (1). At the initial balance since both vessels contain water and since the orifices are identical the equality of maximum pressures means that $d_0 = d_1 = d$. At the final balance point there is again a state of equal maximum bubble pressure. Hence

$$P_{\max.} = g\rho_0(d + \Delta d_0) + \frac{2\gamma_0}{r_0} = g\rho_1(d + \Delta d_1) + \frac{2\gamma_1}{r_1} \quad (2)$$

where the subscript zero refers to the water and the subscript one to the potassium chloride solution. Neglecting for the moment the zeta potential effect, $r_0 = r_1$. Δd_0 and Δd_1 are the increases in depth of immersion of the two tips. These can be calculated precisely from the surface areas of the two vessels and the volume increases caused by the additions of water and salt solution and by the change in position of rod R. A transformation gives

$$\frac{\gamma_1}{\gamma_0} = RST = 1 + \frac{gr}{2\gamma_0}[d(\rho_0 - \rho_1) + (\Delta d_0\rho_0 - \Delta d_1\rho_1)] \quad (3)$$

For dilute electrolyte solutions, when the capillaries are immersed only slightly, the last term involving the precisely known Δd's is considerably larger than the one involving d which is less precisely known.

For large capillaries the measured radius should not be used in the above equation; instead the problem should be solved by the use of the Bashforth and Adam tables.[10] For water solutions and for tubes of radius smaller than 0.07 cm., a corrected radius can be obtained from the Schrödinger[11] approximation

$$\frac{2\gamma}{g\rho} = rh\left(1 - \frac{2r}{3h} - \frac{r^2}{6h^2}\right)$$

For the capillaries used in the present work an effective radius was calculated for water by means of this equation and then used for the work with dilute solutions. This corrected radius differs so slightly from the measured value that the calculation is hardly necessary. More important is the fact that the difference in the correction for pure water and for dilute electrolyte solutions is quite negligible so that it is justifiable to use the same value of the radius for both.

Precision of the Method.—In order to illustrate the errors of the method, the data and calculations for a determination of the relative surface tension of a solution of 0.0048 molar potassium chloride are given in Tables I, II and III. The errors given for the original data are estimated but they are subsequently treated as probable errors.

TABLE I

PRELIMINARY MEASUREMENTS AND ESTIMATED ERRORS

Net surface area of left dish	= 247.74 ± 0.3 sq. cm.
Net surface area of right dish	= 247.06 ± 0.3 sq cm.
Capillary radius	= 0.0427 ± 0.0002 cm.
One turn of rod R	= 0.0407 ± 0.0004 cc.

TABLE II

Data for a determination of the relative surface tension of 0.0048 M potassium chloride. The initial potassium chloride solution was 1.086 ± 0.001 M and its density was 1.04667 ± 0.00005.

Data	
Initial balance of R	= 16.2 ± 0.1 turn
KCl solution added to left	= 4.6385 ± 0.0002 g. = 4.4316 ± 0.0002 cc.
Water added to right	= 4.4737 ± 0.0002 g. = 4.4869 ± 0.0002 cc.
New balance of R	= 18.4 ± 0.2 turns
Final volume of KCl solution	= 1000 ± 2 ml.
Final immersion of capillaries	= 0.67 ± 0.01 cm.
Derived data	
Volume on right due to rod R	= 0.0895 ± 0.0085 cc.
Net volume increase on right	= 4.5764 ± 0.0090 cc.
Δd_0, inc. of immersion on right	= 0.018481 ± 0.00005 cm.
Molar volume change on left (due to dilution of KCl)	= −0.0097 ± 0.0001 cc.
Net volume increase on left	= 4.4219 ± 0.0003 cc.
Δd_1, inc. of immersion on left	= 0.017849 ± 0.00002 cm.
Concentration of final KCl	= 0.00481 ± 0.00001 M
Density of final KCl	= 0.997304 ± 0.000005

TABLE III

CALCULATION OF RST BY EQUATION 4 FROM THE DATA OF TABLE II

$$\begin{aligned} RST &= 1 + \frac{gr}{2\gamma_0}[d(\rho_0 - \rho_1) + (\Delta d_0\rho_0 - \Delta d_1\rho_1)] \\ &= 1 + 0.289[0.65(-0.000230) + (0.018481\ \rho_0 - 0.017849\rho_1)] \\ &= 1 + 0.289[-0.000149 + 0.000626] \\ &= 1.000138 \pm 0.000016 \end{aligned}$$

An inspection of the data in Tables II and III shows that the largest errors arise from the determination of the position of the rod R and from the measurement of the surface areas. Errors in concentration, density and molar volume correction, which are unimportant in this example, become more important as the concentration increases

(10) Adam, "Physics and Chemistry of Surfaces," 2nd edition, p. 365.

(11) Schrödinger, *Ann. Physik*, **46**, 413 (1915).

but remain relatively small up to 0.05 molar potassium chloride.

The error in the surface areas can be examined by making a determination in the same way as for a salt solution but adding water to both vessels. For solutions of equal density equation 3 reduces to

$$RST = 1 + \frac{gr\rho_0}{2\gamma_0}(\Delta d_0 - \Delta d_1) \qquad (4)$$

Thus if the vessels both contain water ($\Delta d_0 - \Delta d_1$) should be zero. For one pair of vessels, a series of fourteen water determinations gave an average Δd difference of only 0.00002 cm. and it was concluded that the measured areas were mutually consistent. For a second pair of vessels, a series of twelve water determinations gave a Δd difference of 0.0015 cm. and this value was used to reduce the value of the area of one vessel by 0.38 sq. cm.

A more important function of these water determinations is to test the over-all behavior of the apparatus. For example, a series of fourteen water determinations gave a mean deviation of ($\Delta d_0 - \Delta d_1$), irrespective of sign, of 0.000032 cm. This figure agrees fairly well with the estimated error listed in Table III and clearly indicates that the apparatus shows a rather consistent behavior.

The inherent sensitivity of the apparatus can be tested by finding the least change in the immersion of the rod R, and thus the least height change, that will cause the bubble flow to shift from predominantly one capillary to predominantly the other. Lack of sensitivity is the cause of the error in the position of R which is shown in Table II to be the most important source of error in a determination. It has been found that various pairs of capillary tips show quite different sensitivities. For a good set of tips 0.1 turn of R will shift the bubble flow and the shift is reversible in the sense that a constant zero is maintained. For a poor set as much as 0.8 turn of R may be necessary. Tips that needed over 0.4 turn to cause a shift of bubble flow were not used in the surface tension determinations and one of the functions of the frequent water determinations was to test the sensitivity.

Errors from contamination are decreased in the present apparatus due to the fact that the bubbles are formed below the main surface of the liquids and are formed continuously. Even so, all parts of the apparatus were cleaned with hot chromic acid solution before every experiment. The only exception to this was that a surface tension determination was often preceded by a water run. No lubricated valves of any sort were used. The weight pipets used to introduce solutions were constructed on a siphon principle to eliminate stopcocks.

Temperature Control.—The temperature coefficients of the surface tension of water and of salt solutions are quite similar so that for this type of differential apparatus it is only important that the temperature of a given determination be constant. Actually the water-bath was maintained at 25 ± 0.01° and since any temperature fluctuations are damped by the lagging effect of the thick glass vessels errors due to temperature variation are well within the limit of other errors.

One factor which might affect the temperature equality is the heat of dilution of the added solution. The data[12] for potassium chloride and for sucrose indicate that for solutions below 0.01 molar this factor is negligible. However for more concentrated solutions or for solutions with large heats of dilution this effect can be of some importance.

Bubble Rate.—Since the present procedure involves a continuous flow of gas it is a dynamic method as contrasted with a truly static method like the capillary rise. Whether such a dynamic method will measure the true equilibrium surface tension of a solution depends upon the rate at which the bubbles flow and upon the speed with which the final surface tension is established. It seems reasonable that for solutions of materials like simple salts or sucrose where the adsorption is small and for which no barrier to diffusion seems probable the surface tension will be established in a very short time. Some experimental evidence is available which justifies this. Working with fairly concentrated sodium chloride solutions, Bond and Puls[13] concluded that the equilibrium surface tension is established in less than 0.003 second. From a fairly rough equation they calculated that the actual time is probably of the order of 10^{-10} seconds.

If the work of Bond and Puls gives the correct order of magnitude for the time required to reach equilibrium, then a bubble rate of the order of one every few seconds should allow ample time. To test this, experiments have been done with bubble rates ranging from one every five seconds to one

(12) Landolt–Börnstein, Erg. IIb, pp. 1538, 1545.
(13) Bond and Puls, *Phil. Mag.*, [7] **24**, 864 (1937).

every two minutes. Table IV gives the surface tension results for four potassium chloride solutions, all close to 0.0024 molar. As nearly as possible these four runs were carried out in an identical fashion. The same apparatus assembly and the same initial potassium chloride solution were used. The only difference was in the bubble rate. The constancy of the results for a ten-fold variation of bubble rate strongly suggests that both bubble rates are slow enough to allow the equilibrium surface tension value to be reached.

TABLE IV

COMPARISON DETERMINATIONS OF THE SURFACE TENSION OF 0.0024 *M* POTASSIUM CHLORIDE

Seconds per bubble	Molar concn.	*RST*
90	0.00229	1.000097
100	.00235	1.000099
9	.00249	1.000072
9	.00241	1.000106

Measurements of the surface tension of sugar solutions also afford evidence that the equilibrium surface tension is attained. The results obtained for sucrose with a rate of one bubble every twenty to forty seconds are in quite good agreement with Jones and Ray's truly static results. Since sucrose is a large molecule with a rather small diffusion coefficient it would be expected to afford a more severe test than electrolytes like potassium chloride. Consequently on the basis of these results and the previously mentioned work, it is concluded that for solutions of simple salts, sucrose and similar molecules a bubble rate of one every twenty seconds or slower will give equilibrium surface tension values.

Preparation of Materials.—The water used in all this work was conductivity water prepared in a Barnstead conductivity water still. No attempt was made to free the water from carbon dioxide. Occasional determinations of the conductivity of the water gave an average value of 0.8×10^{-6} mho. This water was stored in a settling tower similar to the type used by Jones and Ray.[2]

The nitrogen gas used for the bubbles was taken from a tank of water-pumped nitrogen and was passed through absorbent cotton and then through washing towers containing chromic acid and sodium hydroxide. It was finally passed through several washing towers containing water to saturate it with water vapor, into a twelve liter reservoir flask and so to the valve. The pressure of the gas was maintained at a constant value by maintaining a continuous flow of about 1 cc. per minute and letting the excess flow out of the system through a T tube immersed to a depth of 15 cm. in mineral oil.

Reagent grade potassium chloride was used without any preliminary recrystallization since the work of Jones and Ray indicated that small amounts of other salts would not affect the results. The salt was, however, fused in platinum dishes to remove any organic matter. Solutions were obtained by transferring weighed amounts of the fused potassium chloride to volumetric flasks and making the solutions up to the required volumes.

Sucrose Measurements.—Several measurements were made with sucrose in the range 0.001 to 0.01 molar. The capillary tips used in this work had radii of 0.0427 cm. The necessary density and molar volume data were obtained from Landolt–Börnstein.[14] The experimental results are shown graphically in Fig. 2 in which the data of Jones and Ray are plotted as solid circles for comparison. It is obvious that the values are a quite linear function of concentration and also that they agree rather well with the Jones and Ray data.

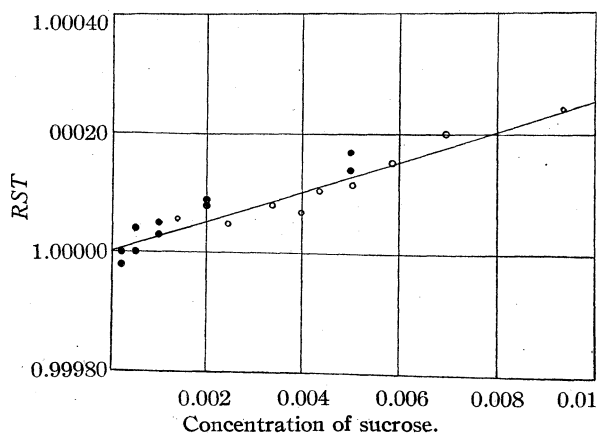

Fig. 2.—The relative surface tension of sucrose solutions. The open circles are from this investigation; the solid circles are taken from the results of Jones and Ray.

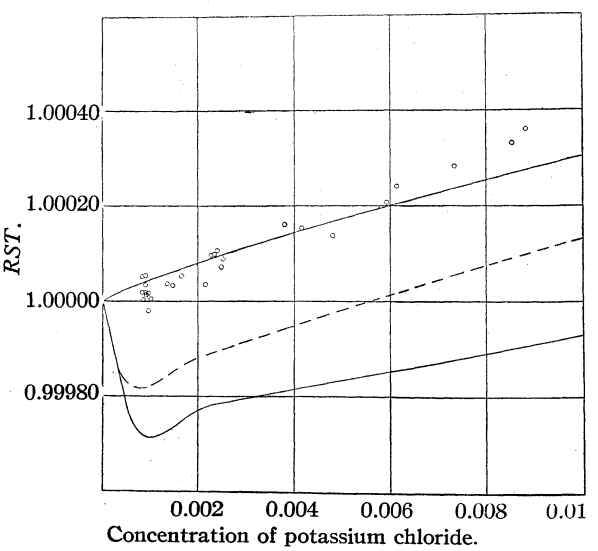

Fig. 3.—The relative surface tension of potassium chloride solutions. The points give the results of this research. The uppermost curve is the theoretical Onsager and Samaras prediction; the dotted curve is that given by Jones and Ray; the lowest curve is the one given by Dole and Swartout.

(14) Landolt–Börnstein, Vol. I, p. 428; p. 463.

Potassium Chloride Measurements.—A fairly large number of measurements on potassium chloride solutions were made. Several different starting solutions of the salt were used, ranging from 0.2 to 1 *M*. Four different sets of capillary tips were used but their size was close to $r = 0.042$ cm. Densities were calculated from the equation of Jones and Ray and the molar volume data were taken from the work of Geffcken.[15] The results are shown graphically in Fig. 3, where for comparison the curves of Jones and Ray and of Dole and Swartout as well as the theoretical Onsager–Samaras curve are also given.

The data in Fig. 3 show a wide deviation from the other two experimental curves. The minimum at 0.001 *M* is not present although there does seem to be a slight concavity in the curve near this concentration. For concentrations greater than 0.001 *M* the results roughly parallel those of Jones and Ray but they lie much higher. The deviation is, of course, well outside the experimental error and there seems to be no constant error which will explain the difference.

In order to see if the variation between the present results and those of the previous workers was maintained at higher concentrations, two determinations were made for approximately 0.05 molar solutions. The data are given in Table V where, for comparison, the figures of Jones and Ray and of Schwenker[16] (0°) are also given. The determinations at this concentration are less accurate than those for more dilute solutions primarily because the heat of dilution of the initial 3.86 molar potassium chloride solution is large enough to introduce an error due to temperature changes. Because of this error the first two surface tension values in Table V may be too large by as much as five in the last figure but even so the data show that the parallelism between the Jones and Ray data and the present work is approximately maintained.

TABLE V

POTASSIUM CHLORIDE RESULTS FOR MORE CONCENTRATED SOLUTIONS

Work	Concentration	*RST*	
Present	0.0437	1.00142	
Present	.0512	1.00179	
Jones and Ray	.0437	1.00123	(interpolated)
Jones and Ray	.0512	1.00146	(interpolated)
Schwenker at (0°)	.05	1.00141	

Discussion

The most obvious feature of the data for the relative surface tension of potassium chloride is the wide variation from the results of Jones and Ray and of Dole and Swartout. There is no minimum in the surface tension–concentration curve and in general the values agree fairly well with the Onsager and Samaras predictions.

There are several possible explanations for the disagreement. A conceivable one is that the data obtained with the bubble pressure apparatus are not true equilibrium values due to the speed with which bubbles are formed. If this were true the results could not be compared with the static values of Jones and Ray. However, for several reasons this explanation seems unlikely. The previously mentioned experiments with sucrose and with varying bubble rates both indicated equilibrium. The fact that the values parallel those of Jones and Ray at higher concentrations also indicates equilibrium since even if equilibrium were attained slowly in the region of the Jones and Ray minimum it should be attained much more rapidly in the region of negative adsorption where presumably the image forces predominate.

Another explanation for the discrepancy that suggests itself is that the contact angle does not stay at zero with salt solutions and that the minimum found by Jones and Ray and Dole and Swartout arises from failure to consider the variation of the contact angle. However, this explanation also seems rather unlikely. The contact angle of pure water against glass or fused silica is undoubtedly zero.[17] To account for the Jones and Ray minimum a change in contact angle to about 1° would be necessary. Although small, this is an angle which should be easily detected. More serious is the implication with respect to the spreading coefficient of water on silica or glass. A change of contact angle from 0 to 1° in going from water to a dilute salt solution would indicate either a large change in the spreading coefficient or an initial condition of W_{sl}, the work of adhesion, almost identical with 2γ. Neither of these seems very probable.

A third explanation for the difference between the bubble pressure results and those obtained by Jones and Ray is that the reason for the minimum observed by the latter is the one proposed by Langmuir, a change in the effective radius of the capillary as the concentration of electrolyte changes. Since this change of effective radius is caused by the zeta potential at the glass-solution

interface it should enter for the bubble pressure method also. But there are reasons why the effect should be smaller for the bubble pressure apparatus. The capillaries are of Pyrex instead of fused silica and it is probable that the Pyrex-solution zeta potential is smaller than for fused silica. In addition the capillary is larger by a factor of three than that of Jones and Ray and this will also decrease the importance of the zeta potential contribution. A third point is that the position of the meniscus is quite different for the bubble pressure method. In the capillary height apparatus the meniscus is formed completely within the capillary tube. In the bubble pressure apparatus the bubble extends down into the bulk of the solution and is in contact with glass only at the end of the tube. Although as formulated by Langmuir the effect of the zeta potential is treated in terms of a layer of solution along the capillary it can alternatively be discussed in terms of its effect on the radius at the lowest point of the meniscus. Because the region of close approach of the meniscus to the capillary wall is much less for the bubble pressure method it is very probable that the perturbation from the wall-solution zeta potential will be less. Thus the difference between the two methods of measurement seems likely to be due to a difference in the extent of the contribution of the zeta potential.

Summary

1. A differential maximum bubble pressure apparatus for the precise measurement of relative surface tensions is described. The relative surface tension values for dilute aqueous sucrose solutions, obtained with the apparatus, are similar to those obtained by the capillary height method.

2. The relative surface tension of potassium chloride solutions is considerably different from that obtained by previous workers. No minimum in the surface tension–concentration curve is observed and the results agree fairly well with the Onsager–Samaras predictions.

3. Explanations for the lack of agreement of the various results are considered and it is concluded that the most likely is the effect of the zeta potential as postulated by Langmuir.

The Heat Capacity of Benzene-d_6[1,2]

BY WALDEMAR T. ZIEGLER AND D. H. ANDREWS

Several years ago Lord, Ahlberg and Andrews made a semitheoretical calculation[3] of the heat capacities of crystalline benzene and benzene-d_6 based upon the spectroscopically determined frequencies[4] of the molecules in the gaseous state and certain assumptions concerning the contribution of lattice vibrations and the process of lattice expansion to the heat capacity. The agreement between the calculated and experimental values of C_p for crystalline benzene over the temperature range 4–270°K. may be described as very good, clearly indicating the general correctness of the frequency assignments for benzene. At that time certain of the fundamental frequencies of both benzene and benzene-d_6 were in doubt. Since then, the work of Langseth and Lord on the deuterated benzenes[5] has appeared which resulted in several changes in the frequency assignments previously made. These changes produce an almost insignificant change in the calculated values of C_p for crystalline benzene,[6] but decrease the calculated C_p values for benzene-d_6 by about 2% at 270°K.

It seemed to us of interest to determine the heat capacity of crystalline benzene-d_6 in order that the results might be compared with those predicted by a calculation of the type described above. Through the kindness of Dr. C. K. Ingold of University College, London, we obtained a loan of about 5 ml. of benzene-d_6 with which to carry out the measurements. The semi-micro heat conduction

calorimeter described by Stull[7] was used for the experimental determination of the heat capacity as it required only a 5-ml. sample, yet gave results accurate to 1–2%. Measurements were made throughout the temperature range 100–320°K.

Experimental

The experimental apparatus, operating procedure and method of calculation employed were identical with those described by Stull.[7]

Calibration of Calorimeter.—The temperature scale used by Stull was checked by determinations of the melting points of benzene, toluene, cyclohexane and aniline, and the transition in crystalline cyclohexane at 186°K. On the basis of these and other measurements described below we have estimated our temperature scale to be correct to ±0.3° below 180°K. and ±0.1° in the range 180–320°K. with respect to the International Temperature Scale (0°C. = 273.10°K.).

Benzene, 99.99 mole per cent. pure, was used as a primary standard for the calibration of the calorimeter. It was assumed to have the heat capacity values listed in Table II. The heat capacities of cyclohexane, aniline and toluene were measured to serve as a check on the operating procedure, since the heat capacities of these substances are known with good accuracy from absolute measurements.

Table I presents a summary of the melting points and heats of transition obtained for the various substances studied. The agreement with previously observed values is seen to be reasonably good, and served as another check on the accuracy of the calorimetric method.

On the basis of these comparisons it was concluded that the calorimeter would yield values of C_p benzene-d_6 probably accurate to about 2%.

Materials: Benzene.—A C. P. "thiophene-free" material was first distilled through a five-foot column made entirely of Pyrex glass and packed with small glass helices similar to those described by Young and Jasaitis.[8] The middle portion was then fractionally recrystallized six times, about one-fifth of the material being discarded each time. The resulting product was dried over phosphorus pentoxide for two weeks, refractionated and a fraction boiling over a range of about 0.03° collected. This material was used in all subsequent measurements. It melted very sharply, and from the observed premelting was judged to be 99.99 mole % pure.[8a]

Benzene-d_6.—This material was loaned to us by Professor C. K. Ingold of University College, London. As received, the sample (approximately 5 ml.) was labeled as being 99.8 mole per cent. pure benzene-d_6, but containing a trace of water. This was removed by distillation from phosphorus pentoxide in a vacuum. The sample was handled with all possible precautions to reduce exchange reactions to a minimum. From the observed premelting of the dry sample its purity was calculated to be 99.8 mole %. The benzene-d_6 melted at 6.7°.

Cyclohexane.—An Eastman Kodak Co. product was fractionally recrystallized eight times and then fractionally distilled through a small Vigreux column. The purity calculated from the observed premelting was 99.9%.

Toluene.—C. P. toluene was twice distilled from the five-foot packed column previously described, dried over phosphorus pentoxide for three days and finally redistilled. From the observed premelting its purity was estimated to be 99.7 mole %.

Aniline.—A C. P. product was fractionally distilled through a Vigreux column, recrystallized twice, and finally refractionated through the Vigreux column. The product was water white, and from its premelting was judged to be 99.85 mole % pure.

Experimental Results

Measurements of the heat capacity of benzene-d_6 were made throughout the temperature range 100–320°K. at approximately 6° intervals. 4.537 g. (0.05392 mole) of benzene-d_6 was used in each of the three series of measurements made. The experimental results obtained at each temperature (*i. e.*, mid-point of heating interval) in the three series of measurements were averaged[9] to obtain the values of C_p listed in Table II. The C_p values of crystalline benzene-d_6 listed in the last column of Table III were read from a smooth curve through the data of Table II.

The heats of fusion of benzene and benzene-d_6 were also measured, the results being 2370 and 2340 cal. mole^{-1}, respectively (see Table I). These values have been corrected for premelting and are probably accurate to 1–1.5%.

TABLE I

Substance	Melting point, °C. This research	Melting point, °C. Others	Heat of fusion (cal. mole^{-1}) This research	Heat of fusion (cal. mole^{-1}) Others
Benzene	5.50	5.50[a]	2370	2349[a]
Benzene-d_6	6.70	6.8[b]	2340	
Cyclohexane[g]	−86.8	−87.2[c]	1630	1604[c]
	6.2	6.2[c]	652	623[c]
Toluene	−95.2	−95.15[d]	1565	1582[d]
Aniline	− 5.9	− 6.0[e]		
		− 6.3[f]	2610	2521[f]

[a] Huffman, Parks and Daniels, THIS JOURNAL, 52, 1547 (1930). [b] Ingold, Raisin and Wilson, *J. Chem. Soc.*, 915 (1936), state that C_6D_6 melts 1.3° above benzene. [c] Parks, Huffman and Thomas, THIS JOURNAL, 52, 1032 (1930). [d] Kelley, *ibid.*, 51, 2738 (1929). [e] Lang, *Proc. Roy. Soc.* (London), A118, 138 (1928). [f] Parks, Huffman and Barmore, THIS JOURNAL, 55, 2733 (1933). [g] The data in the first line for cyclohexane are for a crystalline transition.

(7) Stull, THIS JOURNAL, 59, 2726 (1937).

(8) Young and Jasaitis, *ibid.*, 58, 377 (1936).

(8a) The estimation of purity from the observed premelting was based upon the assumption that no solid solution was formed and that all of the impurity was present in (ideal) solution after a small fraction of the benzene had melted. The purity of the other substances studied was estimated in a similar manner.

(9) This averaging is possible when measurements are made with a heat conduction calorimeter due to the fact that the temperature intervals traversed are always the same.

Discussion of Results

The experimental values of C_p for crystalline benzene-d_6 have been compared with those calculated by means of the expression (see ref. 3)

$$C_p = C_v + [aC_{v(L)} + bC_{v(Vib.)}]^2 T \qquad (1)$$

In this expression $C_v = C_{v(L)} + C_{v(Vib.)}$ and T is the absolute temperature. $C_{v(L)}$ represents the contribution of torsional and translational motions of the molecules, considered as units of the molecular lattice, to the heat capacity at constant volume, and is assumed to be given by the expression $6D(\Theta/T)$, where $D(\Theta/T)$ is the Debye heat capacity function for one degree of freedom. Θ has been taken as 140°.[3]

$C_{v(Vib.)} = \sum_{i=30} E(\Theta_i/T)$, where $E(\Theta/T)$ is the Einstein heat capacity function, represents the contribution of the internal vibrational frequencies of the molecule to the heat capacity (at constant volume). The internal frequency assignments used were those of Langseth and Lord.[10]

The constants a and b (assumed temperature independent) were given the values 0.0090 cal.$^{-1/2}$ and 0.0057 cal.$^{-1/2}$, respectively, by analogy with crystalline benzene (see ref. 6).

The results of the calculation are presented in Table III together with the experimental values. The calculations also have been made for the range 10–100°K. in order to show the relative importance of the terms $C_{v(L)}$, $C_{v(Vib.)}$ and $C_p - C_v$.

(10) See ref. 5, Table XVIII. Frequencies no. 14 and 15 were taken as 1550 and 850 cm^{-1}, respectively.

TABLE III

HEAT CAPACITY OF BENZENE-d_6

260	11.75	13.15	8.49	33.39	31.6
270	11.76	14.05	9.33	35.14	33.6

[a] Calculated from Eq. (1).

Examination of Table III shows that there is good agreement (within experimental error) between the calculated and observed values of C_p in the range 100–170°K., but that there is a general trend for the calculated values of C_p to become greater than the observed for increasing temperatures, the calculated value of C_p being about 6% too large in the neighborhood of the melting point.

The reason for this discrepancy is not immediately apparent. Since the agreement is quite good in the range 100–170°K., it seems likely that both the contributions arising from lattice vibrations and from the *lowest* internal frequencies have been accurately evaluated. Above 170°K. the higher frequencies as well as the expansion term $(C_p - C_v)$ begin to play a more important role,

so that discrepancies at the higher temperatures presumably have their origin in one or both of these components of C_p. We conclude, then, that one or more of the medium-valued frequencies, possibly ν 17,[11] have been assigned values somewhat too low, and/or that the constant b in the expansion formula[12] has been set somewhat too high.

Acknowledgment.—The authors wish to thank Dr. R. C. Lord, Jr., of the Department of Chemistry for many helpful discussions.

(11) See ref. 5, p. 68.

(12) The constant a which gives the lattice portion of the expansion term, presumably is essentially correct because of the satisfactory agreement below 170°K.

Summary

1. The heat capacity of benzene-d_6 has been measured throughout the temperature range 100–320°K. with an accuracy of about 2%.

2. A comparison of the experimentally observed values of C_p with those calculated by a semi-theoretical method indicates that the low frequencies in the benzene-d_6 molecule have been correctly assigned.

3. The possibility that one or more of the medium-valued frequencies have been assigned values which are too low is presented.

The Halogenation of *m*-Diphenylbenzene. II. The Monoiodo Derivative[1]

BY WALTER A. COOK AND KATHRYN HARTKOFF COOK

In a previous communication[2] the authors reported the preparation and proof of structure of the monochloro and monobromo derivatives of *m*-diphenylbenzene. The present communication describes the preparation of the analogous monoiodo derivative from the corresponding amine. The latter compound was prepared by ammonolysis of the monochloro and monobromo derivatives.

Experimental

Ammonolysis Experiment.—The ammonolysis studies were carried out in a steel bomb of 500-ml. capacity, electrically heated and equipped with a bimetallic thermoregulator, safety diaphragm valve, pressure gage and Hoke pressure regulator valve. The details of a typical run are given as follows: 12 g. of 4-chloro-*m*-diphenylbenzene, 340 ml. of 28% aqueous ammonia, 2 g. of cuprous chloride, 1.26 g. of calcium oxide and 2 g. of copper tinsel were heated with continuous agitation for thirty hours at 190° and 800–850 pounds pressure. After cooling the bomb contents were transferred to a 600-ml. beaker, the aqueous ammonia layer decanted and the reaction residue washed with water. The reaction product was dissolved in ether, filtered and saturated with dry hydrogen chloride gas. The precipitated and dried crude 4-amino-*m*-diphenylbenzene hydrochloride weighed 6 g. The ether layer, after subsequent washing with water and evaporation, yielded 2.5 g. of unreacted monochloro derivative. The combined yields of crude amine hydrochloride from several runs was purified by moistening with dil. hydrochloric acid and allowed to stand for several hours in contact with glacial acetic acid. After filtration it was washed with diluted hydrochloric acid and water. It was then converted into the free base with 6 *N* potassium hydroxide solution containing a trace of ammonium hydroxide and filtered. Recrystallization from 95% ethanol yielded pure 4-amino-*m*-diphenylbenzene, m. p. 74°. Similarly a specimen of the amine prepared by the Wardner and Lowy[3] method, and purified as described above, melted at 74°, although these authors reported a value of 64°. Mixed melting points of these products as well as a specimen of the amine prepared by Dr. Russell Jenkins[4] of Monsanto Chemical Co. agree with our value of 74°. The structure of the amine was recently reported by France, Heilbron and Hey,[5] although they were unable to solidify their specimen. A phenylthiourea derivative of 4-amino-*m*-diphenylbenzene was prepared in the usual way; m. p. 135°.

Anal. Calcd. for $C_{25}H_{20}N_2S$: N, 7.36; S, 8.43. Found: N, 7.51; S, 8.60.

4-Iodo-*m*-diphenylbenzene.—From 28 g. of the corresponding amine hydrochloride, 18.6 g. of a pale yellow oil b. p. (1 mm.) 235–240° (cor.) was obtained by diazotization and treatment with potassium iodide in the usual manner. The oil solidified after standing for several days and on crystallization from absolute ethanol melted at 67°.

Anal. Calcd. for $C_{18}H_{13}I$: I, 35.65. Found: I, 35.41.

Attempts to oxidize this compound to a substituted phenylbenzoic acid resulted in such small yield of product that it could not be isolated.

The authors acknowledge the helpful assistance of Professor D. E. Anderson in the design and construction of the bomb in which the ammonolysis studies were undertaken.

Summary

1. The preparation and properties of 4-iodo-*m*-diphenylbenzene are described.

(1) Presented before the Division of Organic Chemistry at the Memphis meeting of the American Chemical Society, in April, 1942.

(2) Cook and Cook, THIS JOURNAL, **55**, 1212 (1933).

(3) Wardner and Lowy, *ibid.*, **54**, 2510 (1932).

(4) Private communication to the authors.

(5) France, Heilbron and Hey, *J. Chem. Soc.*, 1283–1292 (1939).

2. Further proof of the structure of Wardner and Lowy's mononitro and monoamino derivatives is presented.

3. A corrected m. p. of 74° for 4-amino-*m*-diphenylbenzene is reported. For characterization purposes, the phenylthiourea derivative is also described.

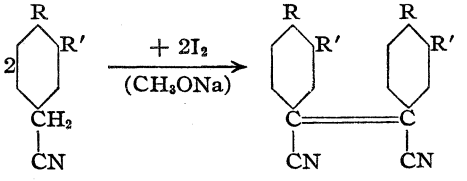
Symmetrical Cyanostilbenes

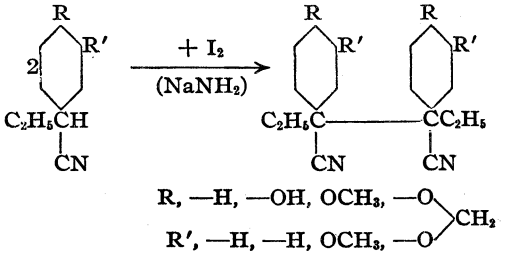
BY JOSEPH B. NIEDERL AND ALBERT ZIERING[1]

In a previous communication[2] the preparation of unsymmetrical cyanostilbenes was presented. The purpose of this communication is to give report on the preparation of symmetrical and variously ring and side-chain substituted cyanostilbenes and dihydrostilbenes related in structure to diethylstilbestrol. The ring substituents included the following: nitro, amino, hydroxy, acetoxy, methoxy, dimethoxy and methylenedioxy groups, while the side-chain substituents comprised either hydrogen or ethyl groups. The method of preparation of these compounds consisted in self-condensation of the respective benzyl nitriles by means of iodine in the presence of sodium methoxide or sodium amide as follows[3]

Dicyanostilbenes



Dicyanodihydrostilbenes:



Experimental

α,α′-Dicyanostilbenes.—One-tenth mole of the respective benzyl nitrile (*p*-methoxy-3,4-methylenedioxy-3,4-dimethoxy) was dissolved in 65 cc. of absolute methyl alcohol. To this solution 25.4 g. of iodine, dissolved in 130 cc. of absolute ether, was added, followed by the dropwise addition of a solution of 4.6 g. of sodium in 70 cc. of absolute methyl alcohol.[3] The precipitated solid was filtered and recrystallized from ethyl acetate. All dicyanostilbenes were colored and gave positive unsaturation tests with potassium permanganate dissolved in acetone; yields, 35% (approx.). The 4,4′-dihydroxy derivative was prepared by diazotizing the corresponding amine,[4] acetylating the resulting solid and then hydrolyzing the acetate with alkali to the phenolic derivative.

α,α′-Dicyanodihydrostilbenes.—One-tenth mole of phenylethylacetonitrile was added dropwise to a suspension of sodamide (0.1 mole) in 150 cc. of anhydrous ether. The mixture was refluxed until the evolution of ammonia had ceased. To this was then added slowly 0.05 mole of iodine in 100 cc. of absolute ether.[3] The precipitated solid was filtered, washed with water and recrystallized from ethanol. All dicyanodihydrostilbenes were colorless and the unsaturation tests with potassium permanganate in acetone were negative; yields, 25% (approx.).

Piperonylethylacetonitrile was treated in the same manner and the final reaction product was recrystallized from dioxane; yield, 25%.

The piperonylethylacetonitrile was prepared by first treating 3,4-methylenedioxybenzyl nitrile with diethyl carbonate in the presence of sodium at 60° in benzene to yield the ethyl piperonylcyanoacetate (b. p. 161° at 3 mm.). This ester was then ethylated in the usual manner with ethyl iodide and sodium ethoxide in absolute ethanol to give the ethyl piperonylethylcyanoacetate (m. p. 72°) which was then hydrolyzed with alkali in the cold to the piperonylethylcyanoacetic acid (m. p. 110°). The acid was decarboxylated by heating to 180°. The resulting piperonylethylacetonitrile boiled at 174° at 15 mm.

The corresponding phenolic derivative was prepared by nitrating phenylethylacetonitrile with fuming nitric acid at 0° to yield the *p*-nitrophenylethylacetonitrile (b. p. 165° at 3 mm.). The nitro compound was converted to the dihydrostilbene by means of iodine and sodium methoxide.[3] The resulting dihydrostilbene was then reduced to the amine, which was then diazotized and finally hydrolyzed to the phenolic derivative, which was recrystallized from benzene containing a little alcohol.

Physiological Tests.—All compounds were subjected to the Fluhmann[5,6] test for estrogenic activity. Most re-

Phenylmercapto-thiazolines

BY JOSEPH B. NIEDERL AND WILLIAM F. HART

The condensation of allyl- and methallyl mustard oils with phenols yielded thiazolinephenols as shown in previous publications.[1,2] The same condensation procedure has now been applied to the reaction between allyl mustard oil and various thiophenols.

There were obtained excellent yields of hydrochlorides which analyzed correctly for the expected salts of thiazoline-thiophenols. From these, picrates were prepared which also analyzed as expected. However, when an attempt was made to prepare the free bases by neutralization of a solution of the hydrochlorides with sodium carbonate, hydrolysis occurred, one of the products being the thiophenol, and the other, 5-methyl-thiazolidone-2.

From these hydrolysis products it appears that the products of these condensations are the hydrochlorides of 5-methyl-2-phenylmercapto-thiazolines, instead of the expected thiazoline-thiophenols. The hydrochlorides of these thio-ethers are remarkably stable to acid treatment. The compounds, however, are completely hydrolyzed in dilute sodium bicarbonate solution.

Experimental

Condensation.—Allyl mustard oil was condensed with thiophenol, thio-*o*-cresol and thio-*m*-cresol in the manner previously described.[2] Condensation was usually complete within one week. The product was taken up in water, the acid solution extracted several times with ether, and the ether extracts discarded. The acid solution was then evaporated to dryness on a water-bath, yielding the hydrochloride in a quite pure form. The hydrochlorides were washed several times with dry acetone, and then recrystallized from 95% ethyl alcohol several times until the melting point was constant.

The picrates were made by adding a filtered, saturated picric acid solution to an equal volume of filtered aqueous solution of the hydrochloride. The resulting crystalline precipitate was washed several times with water, dried and recrystallized once from 95% ethyl alcohol.

Hydrolysis.—Twenty grams of the hydrochloride of the thio-*m*-cresol condensation product was dissolved in water, and the solution was made distinctly alkaline with sodium bicarbonate. A blue oil separated, which was removed by ether extraction and the ether extracts were in turn extracted with 10% hydrochloric acid, which removed the blue color. The ether solution was washed, dried, and the solvent removed by distillation. The residue was an almost quantitative yield of 10.5 g. of thio-*m*-cresol, which was identified by the boiling point, and by oxidation to di-*m*-cresyl di-sulfide with 3% hydrogen peroxide in acetone solution.

The hydrochloric acid extract was used to acidify the

original aqueous solution and this solution was evaporated to dryness on the steam-bath. The residue was exhaustively extracted with absolute alcohol, and the residual sodium chloride was discarded. Upon evaporation of the alcohol there was obtained an oil, which was soluble in dry acetone. This oil became crystalline on long standing in a desiccator, after which treatment with dry acetone yielded two fractions. The acetone insoluble fraction upon analysis proved to be the hydrochloride of 5-methyl-2-hydroxythiazoline. The acetone soluble fraction, which melted at 39°, proved to be its acid insoluble keto form. It was recrystallized from dry acetone and benzene.

Summary

Thiophenols on condensation with allyl mustard oil have been found to yield phenylmercaptothiazolines, in contrast with phenols, which yield thiazolinephenols. These heterocyclic thio-ethers do not rearrange in the presence of the usual acidic rearranging agents, but are readily hydrolyzed in alkaline solution.

The Sterols of Alfalfa Seed Oil. II. Isolation of β-Spinasterol and δ-Spinasterol

BY L. CARROLL KING AND CHARLES D. BALL

In a previous communication[1] from this Laboratory the isolation of α-spinasterol from the unsaponifiable fraction of alfalfa seed oil was reported. In addition to α-spinasterol we have now obtained two other isomeric sterols, β-spinasterol[2] and a third substance whose properties indicate that it has not before been isolated. Since this new sterol is closely related to the known α- and β-spinasterols in structure and properties we have designated it as δ-spinasterol.

In order to separate these three isomeric substances, the crude alfalfa seed oil sterols were dissolved in a large excess of acetic anhydride. On cooling this mixture, the acetates of α-spinasterol and β-spinasterol separated as flaky crystals and were filtered off while the δ-spinasteryl acetate remained for the most part in the acetic anhydride mother liquors. α-Spinasterol and β-spinasterol were separated by taking advantage of the greater solubility of the latter in 85% ethanol.

Each of the three isomeric spinasterols was isolated from two different sources—first, from Hardigan alfalfa seed oil and second, from Grim alfalfa seed oil. The crude sterols from Hardigan alfalfa seed oil consisted of about 23% α-spinasterol, 39% β-spinasterol and 6% δ-spinasterol. The amounts of the corresponding substances isolated from the crude sterols of Grim alfalfa seed oil were 17, 28 and 4.5%, respectively.

The chemical reactions and relationships of α-, β- and δ-spinasterol are summarized in Fig. 1.

δ-Spinasterol was purified by fractional crystallization from 95% ethanol and from methanol. The purest product obtained had a melting point of 142–143° and $[\alpha]^{19}D$ 6.15°. It precipitated with digitonin and gave a positive Liebermann–Burchard test.

The analytical data for δ-spinasterol and its derivatives indicated the formula $C_{29}H_{47}OH \cdot {}^1/_2H_2O$ for the sterol. On catalytic reduction of the acetate in acetic acid solution, a compound identical with α-stigmastenyl acetate[3] (I) was obtained. δ-Spinasterol is, therefore, a doubly

* Formula according to Fernholz and Ruigh.[3]

unsaturated sterol having the same structural configuration as α-spinasterol except for the position of the double bonds. It has one double bond located at position Δ8:14 or in a position from which it can shift easily into the Δ8:14 configuration, when in the presence of hydrogenating catalysts.

The identity of the β-spinasterol isolated from alfalfa seed oil with that isolated from spinach fat is indicated by correspondence in physical properties, Table I, and also by similar behavior when subjected to catalytic reduction.

TABLE I

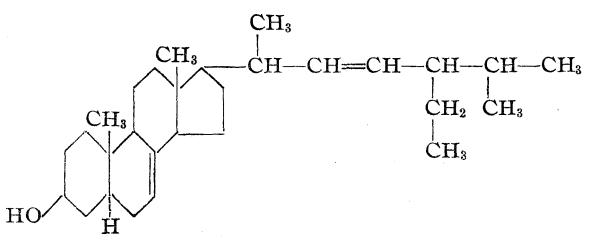
	M. p., °C.	$[\alpha]_D$ in $CHCl_3$, °C.	$[\alpha]_{5461}$, °C.
β-Spinasterol (isolated from alfalfa seed oil)	148–150	5.9	...
Acetate	153–155	5.1	...
Benzoate	181–183	7.5	...
β-Spinasterol (isolated from spinach fat)	145–148	...	7.65
Acetate	150–154	...	7.2

The β-spinasterol isolated from spinach fat gave analytical data for the formula $C_{29}H_{47}OH$·

$^1/_2H_2O$ or $C_{29}H_{47}OH$. On catalytic reduction of the acetate in acetic acid solution α-stigmastenyl acetate (I) was obtained. β-Spinasterol is, therefore, a doubly unsaturated sterol, related in structural configuration to α-spinasterol except for the position of the double bonds.

Recently Kuwada and Yosiki[4] reported that the bessisterol, isolated by them[5,6] from the rhizomes of *Mormordica cochinchenses* Spreng, was identical with α-spinasterol. The correspondence in chemical and physical properties of bessisterol and α-spinasterol is very good except that the specific rotation of bessisterol is $[\alpha]_D$ −13.5°, and that of bessisteryl acetate is $[\alpha]_D$ −13.47°, whereas the specific rotation of α-spinasterol is usually reported at $[\alpha]_D$ +1.7° to −3.5° and α-spinasteryl acetate at $[\alpha]_D$ −4.7°. In this Laboratory α-spinasterol was repeatedly recrystallized from methanol and from chloroform–methanol in an attempt to bring its rotation to a value similar to that reported for bessisterol. This attempt was unsuccessful; the best value obtained was $[\alpha]_D$ −2.7°. An attempt to obtain α-spinasteryl acetate with a specific rotation similar to the value reported for bessisteryl acetate also failed.

Fernholz and Ruigh[3] proposed for α-spinasterol the structures (II) and (III). It is of



III

interest to note that the specific rotation of structure II, calculated according to the method of Bernstein, Kauzmann and Wallis,[7] is $[\alpha]_D$ 8.2° while that of structure III is $[\alpha]_D$ −10.9. Neither of these values can be correlated with the observed value for α-spinasterol, but structure III is in fair agreement with the observed value for bessisterol.

Experimental

1. Separation of Crude Sterols from the Unsaponifiable Fraction.—One hundred and fifty grams of crude unsaponifiable material from Hardigan alfalfa seed oil, prepared as directed by King and Ball,[1] was dissolved in enough ethyl ether to make about 500 cc. A stream of water vapor[8] was passed through the solution until a slight turbidity occurred. After the mixture had stood overnight at 5°, the crystalline mass which separated was filtered off and recrystallized from ethyl ether. The original mother liquors and those from the subsequent recrystallizations were concentrated somewhat and the whole process repeated. In this way 26 fractions were obtained.

The 26 solid fractions weighing about 47 g. were nearly free of colored oily material. The first fraction isolated melted about 158°; subsequent fractions had lower and lower melting points, while the last fractions had very indefinite melting ranges in the vicinity of 60°. These crude solid fractions were combined and classified into two groups, those melting above 120° (Fraction A) and those melting below 120° (Fraction B). Fraction B appeared to consist of hydrocarbons, sterols and other alcohols. Further work on it is in progress in this Laboratory.

2. Fractionation of the Crude Steryl Acetates from Cold Acetic Anhydride.—The crude sterol fractions melting above 120° (Fraction A) were combined and dissolved in acetic anhydride (30 cc. per gram). This mixture was heated one hour, allowed to stand overnight, and then filtered. The solid steryl acetates (Fraction A_1) so obtained consisted mostly of α-spinasteryl and β-spinasteryl acetates; yield 24.5 g.; m. p. 152–157°.

The acetic anhydride mother liquors from the above were hydrolyzed by heating with water. The solid steryl acetates precipitated by this treatment (Fraction A_2) were filtered off and dried; yield 2.9 g.; m. p. 122–127°.

3. Separation and Identification of α-Spinasterol and β-Spinasterol. α-Spinasterol.—The crude acetates, m. p. 152–157° (Fraction A_1), were hydrolyzed by boiling one hour with 5% alcoholic potassium hydroxide. The reaction mixture was poured into water and extracted with ethyl ether. The ether solution was washed with water and evaporated to dryness on the steam-bath. The crude sterols obtained were dissolved in just sufficient boiling 85% ethanol to effect complete solution. After about twelve hours the crystalline material was separated, redissolved in a minimum amount of boiling 85% ethanol and let stand again. This procedure was repeated ten times. The resultant crystalline material was then recrystallized from methanol, and from chloroform–methanol; m. p. 168.5–169°; $[\alpha]^{27}D$ −2.7° (556 mg., 10 cc. chloroform, l = 2 dm., $\alpha^{27}D$ −0.30°, *average* reading).

α-Spinasteryl Acetate.—A quantity of α-spinasterol was dissolved in acetic anhydride and the mixture heated one hour. On standing the crystalline acetate separated. The product was filtered off and recrystallized from 95% ethanol; m. p. 180–182°; $[\alpha]^{21}D$ −6.4° (52.9 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{21}D$ −0.34°, *average* reading).

α-Spinasteryl Benzoate.—Five hundred milligrams of α-spinasterol was dissolved in 1.5 cc. of pyridine and 0.5 cc. of benzoyl chloride added. The mixture was heated in a boiling water-bath two hours and allowed to stand twelve hours at room temperature. The product was recovered and recrystallized twice from 95% ethanol; yield 350

(8) A small amount of water greatly facilitates the separation of the sterols from the oily mixture. These sterols tend to crystallize with one-half mole of water, if water is available.

mg.; m. p. 196–199°; $[\alpha]^{19}D$ 2.1° (51.6 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{19}D$ 0.11°, *average* reading).

β-Spinasterol.—The combined mother liquors from the isolation of α-spinasterol were evaporated to a small volume and water added. The precipitate was filtered off and taken up in just enough boiling 85% ethanol to effect solution. After standing overnight at room temperature the solid material was filtered off. From the mother liquors a fraction, corresponding to the β-spinasterol of Heyl and Larsen,[2] was isolated. On recrystallization from 95% ethanol, flaky transparent crystals appeared; m. p. 148–150°. In melting they lost water of crystallization at 110–125°; $[\alpha]^{20}D$ 5.9° (52.7 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{20}D$ 0.31°, *average* reading). The substance formed an insoluble precipitate with digitonin.

Anal. Calcd. for $C_{29}H_{47}OH \cdot {}^1/_2H_2O$: C, 82.58; H, 11.72. Found: C, 82.56; H, 11.98.

Anhydrous β-Spinasterol.—β-Spinasterol as isolated above was heated at 50° *in vacuo* for seven days. The product was free of water of crystallization; m. p. 148–150°.

Anal. Calcd. for $C_{29}H_{47}OH$: C, 84.38; H, 11.73. Found: C, 84.35; H, 12.12.

β-Spinasteryl Acetate.—One hundred milligrams of β-spinasterol was dissolved in acetic anhydride and the mixture heated one hour. On standing several hours at room temperature the crystalline acetate separated. The product was filtered off and recrystallized from 95% ethanol; m. p. 153–155°; $[\alpha]^{19}D$ 5.1° (44.7 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{19}D$ 0.23°, *average* reading).

Anal. Calcd. for $C_{31}H_{50}O_2$: C, 81.88; H, 11.097. Found: C, 81.83, 81.54; H, 10.92, 11.38.

β-Spinasteryl Benzoate.—Five hundred milligrams of β-spinasterol in 1.5 cc. of pyridine was treated with 0.5 cc. of benzoyl chloride. The mixture was heated two hours on a boiling water-bath, allowed to stand overnight, and then handled as usual. The product was recrystallized from a mixture of ethyl ether and ethanol; yield 450 mg.; m. p. 181–183°; $[\alpha]^{19}D$ 7.5° (56.0 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{19}D$ 0.42°, *average* reading).

Anal. Calcd. for $C_{36}H_{52}O_2$: C, 83.65; H, 10.15. Found: C, 83.81; H, 10.25.

Hydrogenation of β-Spinasteryl Acetate.—Nine hundred and fifty milligrams of β-spinasteryl acetate was dissolved in 25 cc. of glacial acetic acid and shaken for two hours in an atmosphere of hydrogen while in the presence of 100 mg. of Adams catalyst.[9] An additional portion of catalyst was added and the reaction continued about two hours more. The reaction mixture was filtered and the filtrate diluted with water. The product was then separated off and taken up in ethyl ether. The ether solution was washed with water, and the solvent removed by evaporation on the steam-bath. The product was recrystallized from 95% ethanol; yield 625 mg.; m. p. 115–116°; $[\alpha]^{17}D$ 9.6° (53.1 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{17}D$ 0.51°, *average* reading).

Anal. Calcd. for $C_{31}H_{52}O_2$: C, 81.50; H, 11.48. Found: C, 81.90; H, 11.64.

This compound gave no depression in melting point when mixed with an authentic specimen of α-stigmastenyl acetate (prepared from authentic α-spinasterol).[10]

α-Spinastenol (α-Stigmastenol).[3]—The acetate mentioned above was hydrolyzed with 5% alcoholic potassium hydroxide. The product was recovered as usual and recrystallized from methanol; m. p. 111–112°; $[\alpha]^{15}D$ 21.2° (53.7 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{15}D$ 1.14°, *average* reading).

Anal. Calcd. for $C_{29}H_{49}OH$: C, 83.97; H, 12.13. Found: C, 84.05; H, 12.28.

There was no depression in melting point when a specimen of this substance was mixed with authentic α-stigmastenol.

4. Fractionation of the Material Soluble in Cold Acetic Anhydride.—The crude acetates (Fraction A_2), m. p. 122–127°, were hydrolyzed with 5% alcoholic potassium hydroxide. The reaction mixture was poured into water and the product extracted with ethyl ether. The ether soluton was evaporated to dryness and the residue fractionally crystallized from ethanol. The more soluble fractions yielded a crystalline substance; m. p. 122–125°; $[\alpha]^{20.5}D$ −4.8° (48.7 mg., 2 cc. chloroform, l = 2 dcm., $\alpha^{20.5}D$ −0.23°, *average* reading). This material was not further studied.

δ-Spinasterol.—The less soluble top fractions from the above fractionation gave a product with a melting point of 142–143°. This substance, after repeated crystallization from methanol, gave a substance which appeared to be a chemical individual; m. p. 143–144°; $[\alpha]^{19}D$ 6.2° (49.6 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{19}D$ 0.31°, *average* reading).

Anal. Calcd. for $C_{29}H_{47}OH \cdot {}^1/_2H_2O$: C, 82.58; H, 11.72. Found: C, 82.80, 82.33; H, 12.03, 11.94.

This substance formed an insoluble precipitate with digitonin and gave a positive Liebermann–Burchard test.

δ-Spinasteryl Acetate.—The sterol, m. p. 143–145°, was dissolved in a small amount of acetic anhydride and heated one hour. On standing at room temperature the acetate crystallized out. It was recrystallized from 95% ethanol; m. p. 132–133.5°; $[\alpha]^{16}D$ 0.8° (49.7 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{16}D$ 0.04°, *average* reading).

Anal. Calcd. for $C_{31}H_{50}O_2$: C, 81.88; H, 11.097. Found: C, 81.42, 81.74; H, 11.30, 11.54.

This acetate on hydrolysis gave the sterol; m. p. 143–145°.

δ-Spinasteryl Benzoate.—Two hundred and ninety milligrams of the sterol was dissolved in 1 cc. of pyridine and treated with 0.5 cc. of benzoyl chloride. The mixture was heated two hours on a boiling water-bath and allowed to stand overnight at room temperature. The product was recovered as usual, and recrystallized four times from ethanol; m. p. 165–168° (softening gradually to a viscous liquid); $[\alpha]^{19}D$ 11.1° (50.4 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{19}D$ 0.56°, *average* reading).

Anal. Calcd. for $C_{36}H_{52}O_2$: C, 83.65; H, 10.15. Found: C, 83.20; H, 10.37.

Hydrolysis with 5% alcoholic potassium hydroxide gave the original sterol, m. p. 143–145°, and the sterol recovered from the benzoate was converted to the acetate; m. p. 131–134°.

(9) Gilman and Blatt, "Organic Syntheses," Collective Volume I, 2nd ed., John Wiley and Sons, Inc., New York, N. Y., page 463.

(10) We are indebted to Dr. H. G. Kolloff of the Upjohn Research Laboratories who very kindly supplied us with a specimen of α-spinasterol.

Hydrogenation of δ-Spinasteryl Acetate.—One hundred milligrams of δ-spinasteryl acetate was dissolved in 10 cc. of glacial acetic acid and shaken for one hour in an atmosphere of hydrogen in the presence of 50 mg. of Adams catalyst. The product was recovered and recrystallized twice from 95% ethanol; yield 40 mg.; m. p. 111–112°; $[\alpha]^{24}D$ 8.6° (44.5 mg., 2 cc. chloroform, l = 2 dm., $\alpha^{24}D$ 0.38°, *average* reading). This product when mixed with an authentic specimen of α-stigmastenyl acetate showed no depression in melting point.

Summary

1. From the unsaponifiable portion of Hardigan alfalfa seed oil we have isolated three isomeric sterols of formula $C_{29}H_{48}O \cdot {}^1/_2H_2O$: namely, α-spinasterol, β-spinasterol and a new sterol which was designated as δ-spinasterol.

2. Several derivatives of each of the sterols have been prepared and the physical constants and analysis observed.

3. Each of the three isomeric sterols can be reduced to α-stigmastenol.

[CONTRIBUTION FROM THE DEPARTMENT FOR INORGANIC AND ANALYTICAL CHEMISTRY OF THE HEBREW UNIVERSITY]

Catalysts for Peroxide Decomposition[1]

BY M. BOBTELSKY AND A. E. SIMCHEN

Introduction.—In a previous paper[2] some facts were given relating to the catalytic decomposition of hydrogen peroxide in the presence of complex cobalt citrates acting as catalysts. One of them, pink in color, is stable and without catalytic activity; in the presence of hydrogen peroxide it is transformed into a green complex and simultaneously oxygen is evolved by the decomposition of the hydrogen peroxide. Gasometric experiments showed that the velocity of this evolution depends on the velocity with which the green complex is produced.

Nature of the Cobalt Citrate Complexes.—Our first concern was to ascertain the nature of the cobalt citrate complexes. This was accomplished by means of conductometric titrations of solutions of mono-, di- and tri-sodium citrates containing cobaltous ions.

These titrations were carried out with a Lautenschläger "Lyograph," in a cell of constant 0.52 with platinized and calcined platinum electrodes at 15 and 30°. The solutions of mono- and di-sodium citrates were prepared by mixing solutions of tri-sodium citrate and citric acid.

Figures 1 and 2 give some of our results. The breaks in curves 3 and 4 (Fig. 1) at 0.5 cc. of 1 M solution prove the presence of a compound with $Co^{++}/Ci^{---} = 1$. The small slope before the break indicates formation of undissociated molecules. Qualitative tests show that sodium hydroxide has no effect on the cobalt in these solutions. Figure 2 shows breaks in curves 8 and 9 at 1.5 cc. of 1 M NaH_2Ci and 0.75 cc. of 1 M Na_2HCi. These results prove that *only tertiary Ci^{---} ions take part in the formation of the complexes.*

The Catalytic Decomposition of Hydrogen Peroxide in Presence of Cobalto-citrate Complexes.—There are two phenomena to be elucidated: the transformation of the pink into the green complex and the catalytic decomposition of the hydrogen peroxide.

There are several possibilities as to the mechanism of the transformation of the pink complex. Hydrogen peroxide may not take part in an oxidation–reduction reaction, since experiments prove that cobalt is divalent in the green complex too (see below). Another possibility is that a peroxidized compound may be temporarily produced and then transposed into the green form.

The catalytic decomposition to hydrogen peroxide may also take place in several ways: hydrogen peroxide may add to the green complex forming an unstable addition compound; or oxygen atoms may add to the green complex and the resultant compound decomposes later, or the divalent cobalt may be oxidized to a higher valence and then immediately be reduced to Co^{++} with evolution of oxygen.

To test the various possibilities the quantities of two of the reactants, Co^{++}, Ci^{---} and hydrogen peroxide were kept constant and that of the third reactant was varied and the resultant changes in the system were measured by different

(1) An extensive revision of the original manuscript, chiefly concerned, however, with the presentation, was required and this was carried out under the Editor's direction. Under the disturbed international conditions now prevailing, it appeared impractical to obtain the authors' approval of this revision, and, to avoid delay, this revised version is therefore published on the Editor's responsibility.—THE EDITOR.

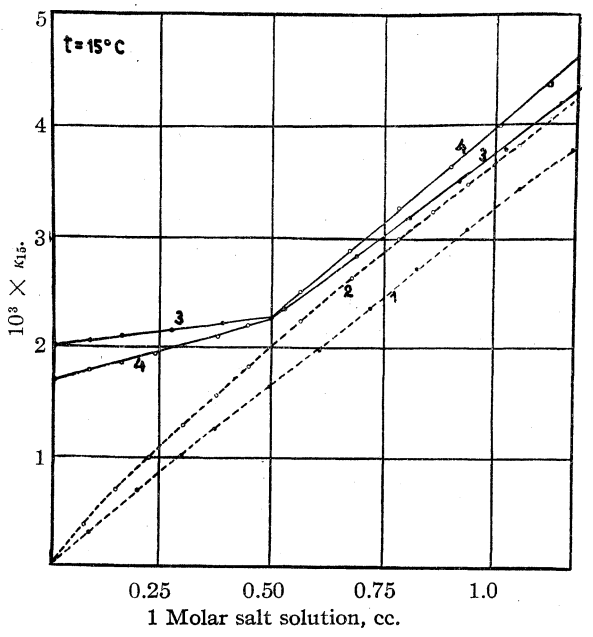

Fig. 1.—Conductometric titration curves, $t = 15°$: (1) 50 cc. of H_2O with $CoCl_2$ 1 m.; (2) 50 cc. of H_2O with Na_3Cl 1 m.; 50 cc. of Na_3Ci 0.01 m. with $CoCl_2$ 1 m.; (4) 50 cc. of $CoCl_2$ 0.01 m. with Na_3Ci 1 m.

methods. Optical measurements could not be made during an experiment because of the evolution of oxygen; they could, however, be carried out in solutions in which all of the hydrogen peroxide had decomposed.

(a) **Preliminary Experiments.**—The decomposition of hydrogen peroxide by the pink cobalto-citrate complex with simultaneous transformation of pink into green complex goes easily when the hydrogen peroxide is added to solutions containing more than 1 mole of tri-sodium citrate per mole of cobaltous chloride; in solutions with an excess of cobaltous ions the decomposition of hydrogen peroxide takes place very slowly.

Thus, *e. g.*, 20 cc. of a solution 0.1 *M* in cobaltous chloride and 0.05 *M* in tri-sodium citrate became green ninety minutes after addition of 1.5 cc. of hydrogen peroxide. At greater dilutions light-brown precipitates were formed.

(b) **Gasometric Experiments.**—Experiments with variable quantities of citrate. The results plotted in Fig. 3 show that the velocity of decomposition of hydrogen peroxide tends to zero for the ratio $Na_3Ci/Co^{++} = 1$. General composition of the solutions used in obtaining Fig. 3: x cc. of 1 *M* cobaltous chloride + y cc. of 1 *M* tri-sodium citrate + $(9 - x - y)$ cc. of water and 1 cc. of 2 *M* hydrogen peroxide (added last). The results for $x = 0.50$ cc. are plotted in Fig. 3 (those of $x = 0.25$ cc. are similar).

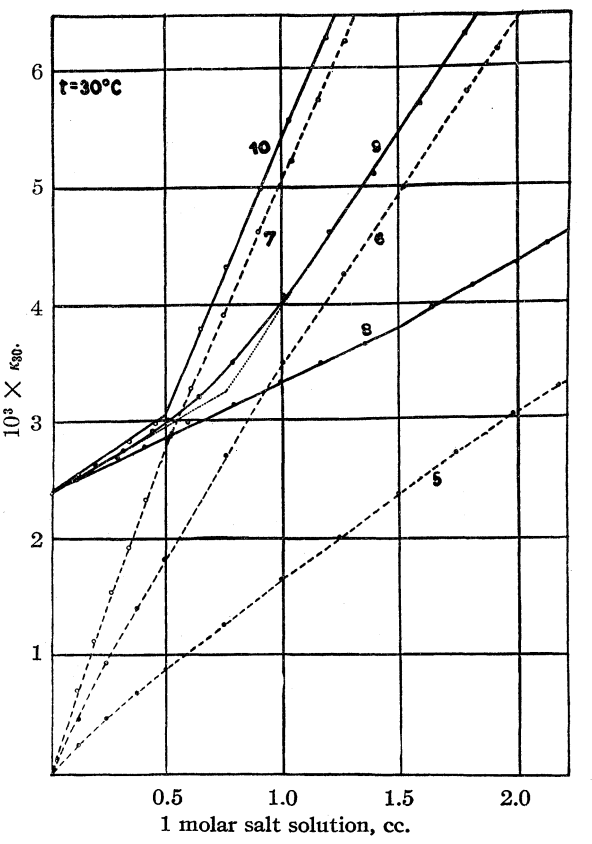

Fig. 2.—Conductometric titration curves, $t = 30°$: (5) 50 cc. of H_2O with NaH_2Ci 1 m.; (6) 50 cc. of H_2O with Na_2HCi 1 m.; (7) 50 cc. of H_2O with Na_3Ci 1 m.; (8) 50 cc. of $CoCl_2$ 0.01 m. with NaH_2Ci 1 m.; (9) 50 cc. of $CoCl_2$ 0.01 m. with Na_2HCi 1 m.; (10) 50 cc. of $CoCl_2$ 0.01 m. with Na_3Ci 1 m.

Experiments with Variable Quantities of Hydrogen Peroxide.—General composition of the solutions: 2 cc. of 0.2 *M* cobaltous chloride and 3 cc. of 0.2 *M* tri-sodium citrate + $(5 - x)$ cc. of water and x cc. of 1 *M* hydrogen peroxide (added last). The molar ratio $(H_2O_2)/(Co^{++})$ varied between 0.25 and 3.0. In every case 100% of the disposable oxygen of the hydrogen peroxide was evolved and the solution contained the green cobalto-citrate complex. Thus *no oxygen is used for the transformation of the pink into the green complex.* We may therefore conclude: (1) *in the final green solution the cobalt is only in the divalent state, and* (2) *citrate ion is not attacked during the reaction.*

The gasometric experiments were carried out with a specially constructed apparatus used in this Laboratory[3] permitting measurements up to 20 cc. with a precision of 0.02 cc. and enabling two experiments to be done simul-

taneously. The apparatus consists of two reaction vessels (glass flasks of 250-cc. volume) suspended on a rocking device seated in a water thermostat (±0.05°) and joined through rubber pressure tubes and three-way glass stopcocks to two micro-gas burets (seated in larger concentric glass tubes filled with water at room temperature). The reaction vessels are closed, after having introduced the reaction mixture, by means of rubber stoppers traversed by semi-capillary glass tubes (joined to the rubber tubes). In each rubber stopper a glass hook of about 5 cm. length is inserted on which a little glass bucket may be suspended containing the reactant to be added last. After having brought the reaction vessels to the thermostat temperature, the little glass bucket is thrown off the glass hook by sudden jarring; the mechanical rocking is then started and the evolution of gas recorded.

(c) **Conductometric Experiments.**—General composition of the solutions (30°): 1 cc. of 1 *M* cobaltous chloride + *x* cc. of 1 *M* tri-sodium citrate + *y* cc. of 1 *M* hydrogen peroxide (added last) + (49 − *x* − *y*) cc. of water. All initial conductivity values of the mixtures with hydrogen peroxide were lower than the corresponding values for solutions containing water in place of the peroxide. The latter has a depressing action on conductivities of electrolytes.[4] From the different results obtained we show in Fig. 4 only one series with $x = 1.5$ cc. in which the concentration of peroxide was varied. In all cases the conductivity

(4) M. Bobtelsky and A. E. Simchen, THIS JOURNAL, **64**, 454 (1942).

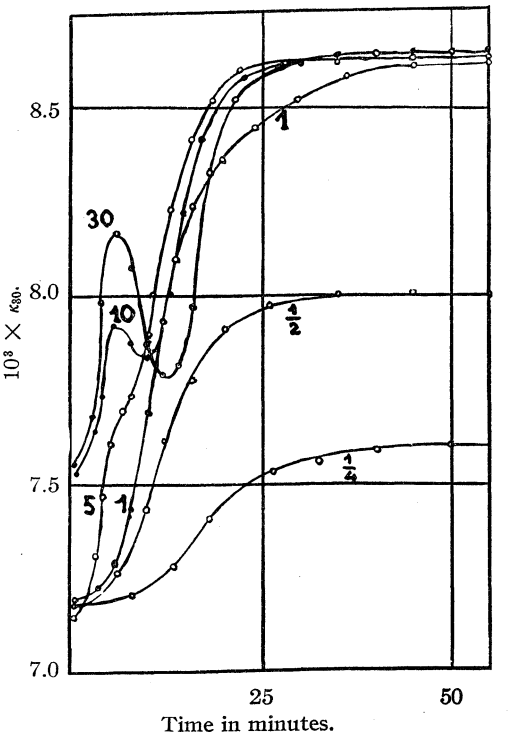

Fig. 4.—Conductivity × 10^3 *vs.* time, at 30°—composition: 1 cc. of $CoCl_2$ 1 m. + 1.5 cc. of Na_3Ci 1 m. + (47.5 − *x*) cc. of H_2O + *x* cc. of H_2O_2 1 m. Numbers on curves represent cc. of H_2O_2.

increases during the reaction until a constant maximum value is attained in about forty minutes. The numbers on the curves of Fig. 4 show the molar ratio $(H_2O_2)/(Co^{++})$ which varies from 0.25–30. It is of interest that only when the ratio is ≧ 1 do we get a constant maximum of conductivity; as we shall see later we have in all these last cases 100% of the green complex. *Thus the reaction is proven to be* $1Co^{++}/1Ci^{---}/1H_2O_2$.

The appearance of relative maxima and minima of conductivity in the experiments made with greater quantities of hydrogen peroxide is the result of a specific influence of hydrogen peroxide on the conductivity of electrolytes as shown in another paper.[4] These maxima and minima are fairly reproducible and reappear after addition of hydrogen peroxide to the green cobalto-citrate complex. The lower branch of the curve, before the relative maximum is attained, does not reappear upon fresh additions of hydrogen peroxide; it corresponds to the transformation of the pink into the green complex. When carrying out gasometric and conductometric experiments of the same composition and at the same temperature (Fig. 5), it is seen that the relative maxima and

minima of conductivity do not appear in the gasometric curve at all.

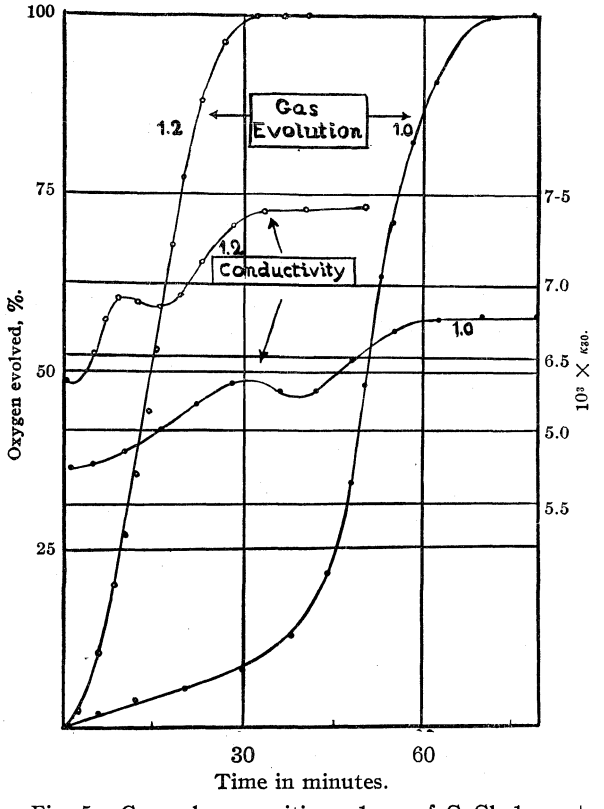

Fig. 5.—General composition: 1 cc. of $CoCl_2$ 1 m. + x cc. of Na_3Ci 1 m. + 10 cc. of H_2O_2 1 m. + $(39 - x)$ cc. of H_2O. Numbers on curves represent cc. of Na_3Ci 1 m.

(d) **Optical Measurements.**—Composition of the five solutions: 1 cc. of 1 *M* cobaltous chloride + 1.5 cc. of 1 *M* tri-sodium citrate + $(47.5 - x)$ cc. of water + x cc. of 1 *M* hydrogen peroxide (added last). x = 0.33, 0.67, 1.0, 2.0 and 3.0 cc. After complete decomposition of hydrogen peroxide the solutions are a mixture of the pink and the green complex. The measured percentages of green complex are plotted in Fig. 6. It is easily seen that here too the final value is obtained for $H_2O_2/Co^{++} = 1$.

The colorimetric measurements were made in a two-color colorimeter of the Duboscq type, of Hellige, using two solutions for comparison. Measurements were made at room temperature one hour after preparation in a layer 30 mm. thick. The solutions for comparison were (1) a green complex solution obtained in the above way with x = 6.0 cc. of 1 *M* peroxide (giving 100% green complex); (2) a pink complex solution without hydrogen peroxide (100% pink complex).

From the results of the conductometric as well as the colorimetric measurements the following conclusions may be drawn: the reaction between

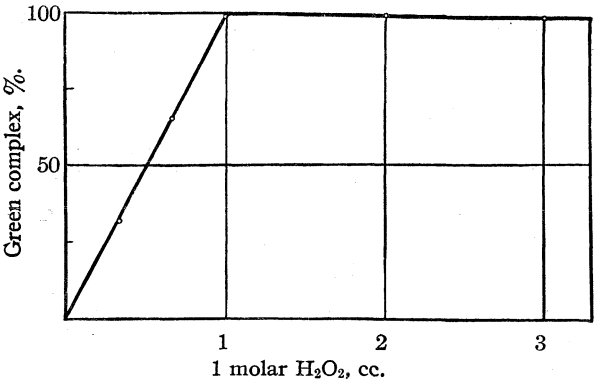

Fig. 6.—Green complex, %, *vs.* cc. of H_2O_2 1 m.—composition: 1 cc. of $CoCl_2$ 1 m. + 1.5 cc. of Na_3Ci 1 m. + $(47.5 - x)$ cc. of H_2O + x cc. of H_2O_2 1 m.

hydrogen peroxide and the pink cobalto-citrate complex in the ratio $1Co^{++}/1Ci^{---}/1H_2O_2$ must go to completion almost immediately and there is no free hydrogen peroxide present during the slow transformation of the pink into the green complex.

(e) **Influence of Concentrated Neutral Salts.**—The influence of ammonium nitrate and chloride on the catalytic decomposition of hydrogen peroxide by cobalto-citrate complexes has been studied by Bobtelsky and Rappoport.[2] We give in Fig. 7 results of some gasometric experiments made with and without ammonium nitrate (the chloride gives analogous results). At a concentration of 3 *N* the rate of oxygen evolution has a maximum and then diminishes with increasing concentration. The influence of electrolyte at lower concentration may be in the stabilization of the cobalto-citrate complex (similar to citrate ion concentration in excess). In the presence of highly concentrated electrolyte (>3 *N*) the green

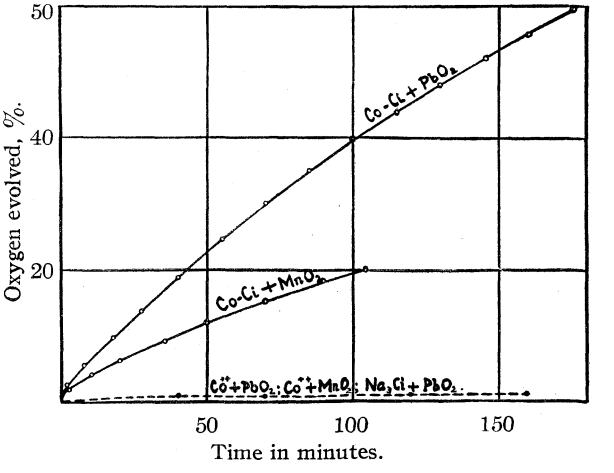

Fig. 7.

cobalto-citrate complex changes through a blue to a brick-red solution and this color remains stable for months.

Action of the Cobalto-citrate Complexes on the Solid Peroxides PbO_2 and MnO_2.—The catalytic decomposition of solid peroxides by the action of cobalto-citrate complexes was investigated by shaking the finely powdered peroxides at constant temperature (30°) with the pink and with the green complex and measuring the volume of oxygen evolved. A slow transformation of the pink complex into the green takes place with simultaneous evolution of oxygen. The last reactant added to the reaction mixture was either the cobaltous solution or the powdered lead dioxide. Composition of the reaction mixtures: with PbO_2: 4 cc. 1 *M* $CoSO_4$[5] + 12 cc. of 1 *M* Na_3Ci + 4 cc. H_2O + 0.5 g. PbO_2; with MnO_2: 4 cc. of 1 *M* $CoSO_4$ + 12 cc. of 1 *M* Na_3Ci + 4 cc. H_2O + 0.2 g. of MnO_2.

Figure 8 shows that more than half the peroxide oxygen is evolved from lead dioxide in two and one-half hours; lead dioxide is decomposed more quickly than manganese dioxide.

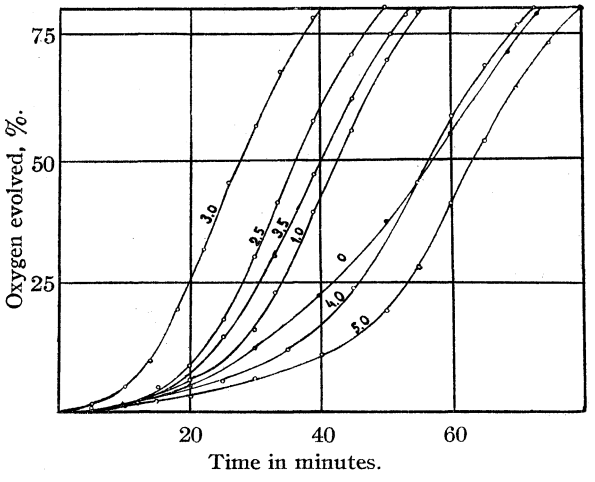

Fig. 8.—Influence of NH_4NO_3—composition: besides NH_4NO_3 the solutions contained per 20 cc.: 0.5 cc. of $CoCl_2$ 1 m. + 0.75 cc. of Na_3Ci 1 m. + 2 cc. of H_2O_2 1 m. Numbers on the curves represent the final concentration of NH_4NO_3; t = 15°.

In the decomposition of solid peroxides it is probably not possible to speak of an addition of these substances to the pink complex; therefore, we probably have, during the formation of the green complex, *a transitory oxidation of the pink complex* followed by decomposition with evolution of oxygen. It may well be that a similar path is followed during the reaction with hydrogen peroxide.

Shaking lead peroxide with a solution of the green complex formed by the action of excess hydrogen peroxide on a cobalto-citrate mixture showed that even after one and one-half hours no oxygen was evolved. *The green complex does not decompose these solid peroxides.*

The absorption spectrum of the green complex from the solid peroxides is identical with that of the green complex from hydrogen peroxide.

Comparison of Behavior of Cobalto-citrate and -tartrate Complexes.—(a) Qualitative experiments were made with Co^{++}- and di-sodium tartrate solutions. On mixing the two solutions a pink solution was obtained; its absorption spectrum was measured (Fig. 9) and compared to the absorption spectrum of the pink cobalto-citrate complex solution. Upon addition of hydrogen peroxide to the tartrate solution (*e. g.*, 0.5 cc. of 1 *M* cobaltous chloride + 1 cc. of 1 *M* di-sodium tartrate + 25 cc. of water to which was added 4.5 cc. of 1 *M* hydrogen peroxide) a pink precipitate is formed. In the presence of still greater quantities of hydrogen peroxide the solution becomes brownish-green with precipitate and oxygen is evolved.[6]

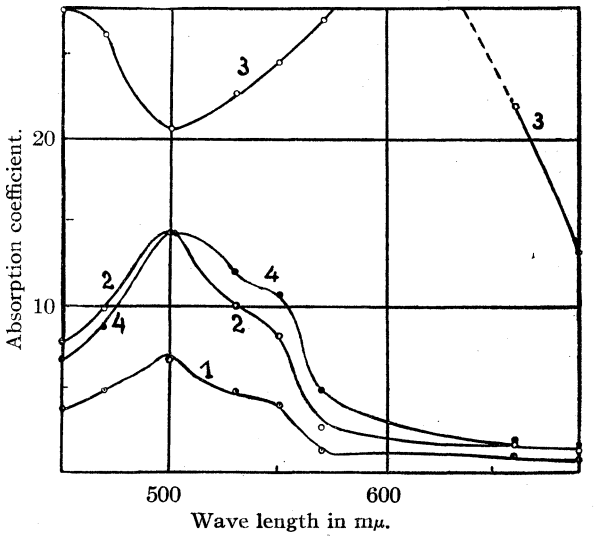

Fig. 9.—Light absorption curves: (1) $CoCl_2$; (2) pink cobalto-citric complex; (3) green cobalto-citric complex; (4) pink cobalto-tartaric complex.

(b) Conductometric titrations were carried out in solutions of 50 cc. of 0.01 *M* di-sodium tartrate

(5) Cobaltous chloride yields exactly the same values.

(6) Only a part of the disposable oxygen could be obtained, the tartrate having been attacked (unpublished results of M. Bobtelsky and L. Bobtelsky-Chaykin).

with 1 *M* cobaltous chloride and of 50 cc. of 0.01 *M* cobaltous chloride with 1 *M* di-sodium tartrate. In both cases breaks were obtained at exactly $Ta^{--}/Co^{++} = 1$ and $Ci^{---}/Co^{++} = 1$. At these points the Co^{++} ions as well as a part of the tartrate or citrate ions are bound with one another very strongly (sodium hydroxide gives no reaction with Co^{++}). From this fact the following computations can be carried out. The observed conductivities of 0.01 molar solutions were (30°): $CoCl_2$, $\kappa = 2.35 \times 10^{-3}$; Na_3Ci, $\kappa = 2.86 \times 10^{-3}$; Na_2Ta, $\kappa = 2.04 \times 10^{-3}$; and at 15°, $CoCl_2$ $\kappa = 1.70 \times 10^{-3}$; Na_3Ci, $\kappa = 2.0 \times 10^{-3}$. The ionic mobilities from a table are: $^1/_3$ Ci^{---}, 60.3; $^1/_2$ Co^{++}, 43; Cl^-, 65.4; Na^+, 43.5; $^1/_2$ Ta^{--}, 55; acid Ta^-, 31. Table I is deduced from these values.

TABLE I

Ionic loss	$\kappa \times 10^3$ (15°) Calcd.	Found	$\kappa \times 10^3$ (30°) Calcd.	Found
$^1/_2Co^{++} + {}^1/_3Ci^{---}$	2.98		4.16	
$1\ Co^{++} + {}^1/_3\ Ci^{---}$	2.64	2.30	3.70	3.10
$1\ Co^{++} + {}^2/_3\ Ci^{---}$	2.25		3.15	
$^1/_2\ Co^{++} + {}^1/_2\ Ta^{--}$			3.36	
$1\ Co^{++} + {}^1/_2\ Ta^{--}$			2.89	3.02
$1\ Co^{++} + 1\ Ta^{--}$			2.32	
$^1/_2\ Co^{++} + HTa^-$			3.11	

It appears from the table that the last assumption is most probable in the case of citrate. There are several possibilities for the tartrate.

(c) Conductometric titrations of cobalto-tartrate complexes by sodium hydroxide and hydrochloric acid. The pink cobalto-citrate complex as well as the green complex was conductometrically titrated with 1 *N* sodium hydroxide and with 1 *N* hydrochloric acid (50 cc. complex solution contained 1 cc. of 1 *M* cobaltous chloride + 1.2 cc. of 1 *M* tri-sodium citrate). The titrations with hydrochloric acid did not give clear-cut phenomena; during this titration of the green complex solution, a slow transformation takes place of the green color into the color of cobaltous ions and the complex is destroyed (this is valid for the pink complex also).

The results of titrations with sodium hydroxide are plotted in Fig. 10. In the case of the pink complex there is a neat break at $NaOH/Co^{++} = 1$. In the case of the green complex there is probably a break at about $NaOH/Co^{++} = 2$.

The experiments described in this paper lead us to the conclusion that in the green complex, the cobalt is present in the *divalent* state. This green complex is an extremely active catalyst for the

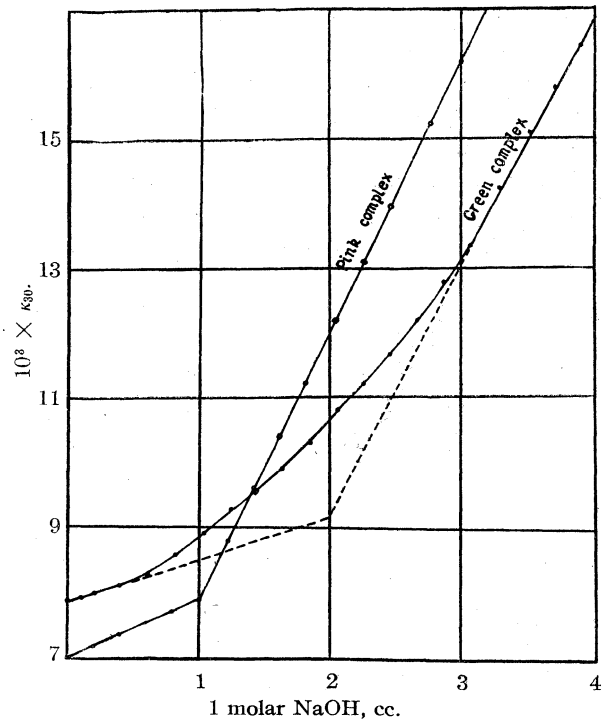

Fig. 10.—Conductometric titration curves with NaOH, at 30°: pink complex—1.0 cc. of $CoCl_2$ 1 m. + 1.2 cc. of Na_3Ci 1 m. + 47.8 cc. of H_2O titrated with NaOH 1 *n;* green complex: 1.0 cc. of $CoCl_2$ 1 m. + 1.2 cc. of Na_3Ci 1 m. + 42.8 cc. of H_2O + 5 cc. of H_2O_2 1 m., titrated one hour after preparation with NaOH 1 m.

decomposition of hydrogen peroxide. It is formed after a previous oxidation of the pink cobalto-citrate complex during which an intermediary peroxidized compound is produced and gradually transformed into the green complex, releasing the whole of the disposable oxygen at the same time. The green complex obtained in this complicated way is soluble in water and quickly catalyzes the decomposition of hydrogen peroxide (without itself being attacked) at concentrations as low as 10^{-6} mole g./l.

It is of interest to note that the ferric ion[7] shows in some respects a similar behavior, giving with tri-sodium citrate two[8] complexes, one of which is without catalytic activity while the second has a strong catalytic action.

The other citrate complexes of 2- or 3-valent cations (Cu^{++}, Mn^{++}, Ni^{++}, UO_2^{++}, Ce^{+++}, Pb^{++}, Al^{+++}, Mg^{++}, Ba^{++}, Cd^{++}, Zn^{++}) show scarcely any catalytic action upon the decomposition of hydrogen peroxide, they give generally one complex $Ci^{---}/Me^{++} = 1$; ferric ion on the

(7) M. Bobtelsky and B. Kirson, *Compt. rend.*, **208**, 1577 (1939).
(8) M. Bobtelsky and A. E. Simchen, *ibid.*, **208**, 1646 (1939).

other hand gives the complexes $(Fe_2Ci_3)^{---}$ (inactive) and $(Fe_3Ci_2)^{+++}$ (active). With cobalt, *both complexes, the green as well as the pink, contain divalent Co, in the ratio of* $Ci^{---}/Co^{++} = 1$, but they differ in their internal structure. The green cobalto-citrate complex proved to be the most sensitive catalyst of all the complex citrates studied by us for the decomposition of hydrogen peroxide.

The study of the structure of the citrate complexes compared with that of tartrate complexes will be the object of a special article. Di-sodium tartrate too yields with hydrogen peroxide a green complex which catalyzes the decomposition of the peroxide, but the tartrate is simultaneously attacked by the peroxide, gives a precipitate and is therefore unfit for study. The parallel study of Co^{++} and Fe^{+++}-citrate and -tartrate complexes gives a possibility for a deeper insight into the structure of these substances. It might be supposed that in the case of citrate (with only one oxy-group) complexes the hydrogen of the oxy-group is replaced by a metal valence and a stable compound is thus produced, while in the active form the metal may be found in another way through a secondary valence to the oxy-anion.

By comparison with cobalto-ammonia complexes which also catalyze the decomposition of hydrogen peroxide,[2] it seems probable that the structural difference between pink and green cobalto-citrate complexes is that in the case of the green complex the cobalt atom is linked to the citrate by a secondary valence, while the linking is much stronger in the case of the pink complex.

Summary

A mixture of Co^{++} and Ci^{---} ions (pink complex) with hydrogen peroxide in the ratio $1Co^{++}/1Ci^{---}/1H_2O_2$ immediately leads to a pink peroxidized compound (without change of color), which decomposes gradually with liberation of all the disposable oxygen into a green divalent cobalt citrate complex. This green complex can also be obtained by peroxidizing the pink cobalto-citrate complex with lead or manganese dioxide instead of hydrogen peroxide. The green cobalto-citrate complex thus obtained acts as an extremely active catalyst (the most active of all the complex citrates) for the decomposition of hydrogen peroxide, but it cannot decompose lead or manganese dioxides. During all these operations the citrates are not attacked at all while corresponding reactions with tartrates lead to attack of the tartrate ion.

The properties of the complexes were studied by gasometric, photometric and conductometric methods.

NOTES

The Catalytic Effect of Electrolytes on Solvolytic Reactions

BY L. F. AUDRIETH, L. D. SCOTT AND O. F. HILL

In a series of publications from this Laboratory[1] it has been demonstrated experimentally that ammonolytic and aminolytic reactions, involving the action of ammonia and amines upon esters, are catalyzed, respectively, by ammonium and amine salts presumably acting as acids in these solvents. In order to characterize still further the catalytic effects of various classes of substances upon solvolytic reactions in general, the influence of electrolytes (salts) upon the reactions (a) between *n*-butylamine and ethyl phenylacetate and (b) between liquid ammonia and ethyl benzoate were subjected to study. The experimental results presented below show (a) that additions of relatively small quantities of various neutral salts speed up effectively the conversion of the esters into the corresponding solvolytic products; (b) that the catalytic effect of equimolar concentrations of these salts is not nearly as marked as for the corresponding "onium" salts; and (c) that the findings heretofore considered as evidences for acid catalysis in basic solvents by the solvated proton may be but special cases of what might more properly be regarded as examples of electrolyte catalysis.

(1) See Glasoe, Scott and Audrieth, THIS JOURNAL, **63**, 2965 (1941), for earlier articles.

Experimental

The experimental procedures employed in studying these reactions have already been described in previous publications.[2,3] The data presented in Table I constitute a summary of the results obtained using various electrolytes, and electrolytes plus definite additions of water, in *n*-butylamine. The essential data for the reaction between liquid ammonia and ethyl benzoate are given in Table II. For purposes of comparison some data are also included in both tables of results previously reported on the catalytic effect of the corresponding "onium" salts. In both cases the observed catalytic effects are emphasized in the last column in which are given the experimentally determined half time values (in hours) for each series of runs.

Attempt to Detect Free Hydroxyl as an Intermediate in Photochemical Reactions

BY W. J. BLAEDEL,[1] R. A. OGG, JR., AND P. A. LEIGHTON

Free hydroxyl has been proposed as an intermediate in several photochemical processes.[2,3] The mechanisms of all the following processes might involve this substance (at 2537 Å.)

(1) $CH_3I + O_2 + h\nu$
(2) $H_2O_2 + h\nu$
(3) $H_2O_2 + Hg + h\nu$
(4) $H_2O + Hg + h\nu$
(5) $H_2 + O_2 + Hg + h\nu$
(6) $CH_3OH + Hg + h\nu$

In any of these processes, if the reactions by which hydroxyl disappears have low rates compared to those by which it is formed, it is conceivable that steady-state concentrations might be attained which are sufficient to be detectable by the absorption spectrum. The purpose of the following work was to detect such absorption if possible.

Experimental.—The photochemical reaction vessel was a cylindrical quartz tube, 120 cm. long, and 3.5 cm. in diameter, with plane quartz end windows. Irradiation was effected by placing two low pressure mercury arcs, each 120 cm. long and 0.7 cm. in diameter, parallel to and on opposite sides of this tube. A cylindrical aluminum reflector, open at the ends, enclosed the arcs and quartz tube.

Light from a water discharge giving the 3064 Å. hydroxyl band in emission was passed lengthwise through the reaction cell and into the slit of a 21-ft. concave grating spectrograph. The intensity of the discharge in the region containing the Q_1 $1^1/_2$ and Q_1 $2^1/_2$ lines was measured in the focal plane of the spectrograph with a sensitive photocell-amplifier system. This region shows the highest absorption at room temperature. The absorption noted in this region when the low pressure arcs were turned on was taken as a measure of the steady-state hydroxyl concentration produced.

The limit of detection of hydroxyl was determined by a method similar to that of Oldenberg and Rieke,[4] by measuring the absorption of water vapor dissociated at a high temperature. Here, the quartz cell was replaced by a cylindrical furnace with quartz end windows. Oxygen and water vapor at known pressures were passed through this furnace at about 1400° Å. The temperature distribution was measured along the furnace axis with a Pt/Pt–Rh thermocouple. Zeise's data[5] on the dissociation constants of water at various temperatures enabled a calculation of the hydroxyl distribution along the furnace axis at the high temperature. From the rotational term levels of the hydroxyl molecule,[4] the absorption of this same distribution at room temperature was calculated. This, with the

limit of absorption detectable by the photocell-amplifier system, allowed calculation of 5×10^{-5} mm. as the lowest hydroxyl pressure detectable at 25° in the 120-cm. path length of the quartz reaction vessel.

All the above reactions were studied at 25° by introducing the reactants into the quartz tube at the following pressures: reaction 1, CH_3I = 10 mm., O_2 = 1, 10, 100 mm.; reactions 2 and 3, H_2O_2 = 1.5 mm.; reaction 4, H_2O = 20 mm.; reaction 5, H_2 = 50, 140, 20 mm., and O_2 = 20, 140, 500 mm., respectively; reaction 6, CH_3OH = 10, 50, 100 mm. In the processes where mercury was required, a few drops were scattered along the bottom of the quartz cell before introducing the reactants.

Results.—No absorption due to hydroxyl was detectable in any of the reactions studied. Hence, the steady-state concentration of hydroxyl, if any, was less than 5×10^{-5} mm. in processes 2, 3, 4, 5 and 6. In processes 3, 4, 5 and 6, the mercury surface became coated with oxide. In process 1, there was a slow increase in absorption due to formaldehyde formation. Any absorption due to intermediate formation had to be sought superimposed upon this drift. This decreased the sensitivity so that for this reaction it may only be said that the steady-state pressure of hydroxyl was less than 0.0003 mm.

Photoöxidation of Methyl Iodide

BY W. J. BLAEDEL,[1] R. A. OGG, JR., AND P. A. LEIGHTON

Bates and Spence have postulated a mechanism[2] for the photoöxidation of methyl iodide which has a maximum quantum yield of two and involves the intermediate formation of free hydroxyl. This mechanism was based on a study of the products, which were iodine, paraformaldehyde, methylal and water, and on a measurement of the quantum yield as 2.3, using a chloroacetic acid actinometer, assuming its quantum yield to be unity. Since this work, experimental data from several sources indicate that this mechanism is not entirely correct.

Iredale found the photodecomposition of methyl iodide to be greatly accelerated in the presence of nitric oxide.[3] His kinetic studies on this process and a comparison of his data with those of Bates and Spence permitted the inference that the quantum yield of photoöxidation should lie below a maximum possible value of 1.6.

In the hydroxyl mechanism,[2] hydroxyl radicals disappear by the reaction $CH_3I + OH \longrightarrow CH_3OH + I$. This reaction probably has a high activation energy (15–20 kcal.) and, if the mechanism is correct, a high steady-state concentration of hydroxyl should be established. The failure to detect any hydroxyl[4] is an indication that this reaction is not an important one in the mechanism.

Lastly, the quantum yield of the chloroacetic acid actinometer has been shown to be greatly dependent on temperature,[5] being only 0.31 at 25°. Assuming that the photoöxidation quantum yield of 2.3 was measured at this temperature, the corrected value becomes only 0.71.

In the light of this evidence, suggestion of a new mechanism is possible, and the most likely is one involving the formation of a peroxide[2] as an intermediate.

$$\begin{aligned}
CH_3I + h\nu &\longrightarrow CH_3 + I && I_a \\
CH_3 + I_2 &\longrightarrow CH_3I + I && k_2 \\
CH_3 + O_2 &\longrightarrow CH_3O_2 && k_3' \\
CH_3O_2 + CH_3 &\longrightarrow CH_3OH + CH_2O && k_4' \\
2CH_3OH + CH_2O &\longrightarrow H_2C(OCH_3)_2 + H_2O \\
nCH_2O &\longrightarrow (CH_2O)_n \\
nCH_2O + h\nu &\longrightarrow (CH_2O)_n \\
2I + M &\longrightarrow I_2 + M'
\end{aligned}$$

This differs from the hydroxyl mechanism in reactions 3′ and 4′.

The rate of formation of methyl iodide, as deduced from the new mechanism is

$$-\frac{d(CH_3I)}{dt} = \frac{I_a(O_2)}{\frac{k_2}{2k_3'}(I_2) + (O_2)}$$

This is identical in form to the experimental rate equation of Bates and Spence. The maximum quantum yield of unity is in accord with the previously conflicting data of Iredale and of Bates and Spence.

A recalculation of the data of the latter authors gives $k_2/k_3' = 820$, meaning that the activation energy of process 3′ is 3.6 kcal. greater than that of process 2 at 0°.

Reaction 3′ is postulated to be a two rather than a three body process. The evidence for this lies in the data of Bates and Spence, which show that k_2/k_3' remains constant as the total pressure varies over an eight-fold range from 25 mm. to 400 mm. This would not be expected if 3′ were a three body process.

The agreement of this mechanism with the experimental data indicates that the recombination, $CH_3 + I \rightarrow CH_3I$, is negligible compared to reac-

tion 2. This is contrary to the conclusions of Iredale,[3] who interpreted his data to mean that reaction 2 was negligible compared to the recombination. However, his data may be interpreted equally well in a second way; and in this case, the results are in accord with the findings on the photoöxidation. At present, work is in progress to determine which of the two processes is predominant in methyl iodide photolysis.

Vapor Pressures of Indene, Styrene and Dicyclopentadiene

BY P. E. BURCHFIELD

The vapor pressures of indene, styrene and dicyclopentadiene were determined over temperature ranges. The pressure–temperature data were desired for the development of distillation procedure for the separation of the components of light oil solutions.

Experimental.—The compounds used in this investigation were purified by recrystallization. The process of purification and the physical properties of the purified compounds are described elsewhere.[1] The vapor pressures were determined by the method developed by Booth, Elsey, and Burchfield.[2] The temperature was measured by means of a calibrated thermometer graduated to 0.1°. The necessary stem corrections were calculated and applied.

Due to the reactive nature of the compounds studied, a time factor was imposed upon the vapor pressure measurements with the exception of those of styrene. Two pressure readings, separated by a ten-minute time interval, were taken at equal temperatures for each determination. The vapor pressures of styrene at the three highest temperatures were determined by employing a new sample for each measurement, thus reducing the possibility of error through polymerization. Depolymerization was noticeable in the case of dicyclopentadiene at 100°.

The calculated constant, determined by methods of least squares, for the simplified, integrated Clausius–Clapeyron equation, and other pertinent data, are summarized in Table I.

TABLE I

VAPOR PRESSURE DATA OF INDENE, STYRENE AND DICYCLOPENTADIENE

Compound	Clausius–Clapeyron constants A	B	No. 4 measurements	Temp. range of measurements, °C.	Average % deviation from mean
Indene	7.919	−2291	13	56.2 to 181.8	1.4
Styrene	7.929	−2103	7	33.5 to 116.3	1.1
Dichloropentadiene	7.925	−2218	6	40.1 to 90.8	0.6

A New Fructosan Isolated from *Yucca mohavensis*, Sarg.

BY KEENE P. DIMICK AND BERT E. CHRISTENSEN

Recently in connection with the chemical investigation of the *Yucca mohavensis*, Sarg. it was observed that its fructose content (3–5%) increased to as high as 60% on mild acid hydrolysis of the dried stem. This suggests the possibility of the presence of a considerable amount of fructosans which may be stored in the stem as a plant food. Further work on this material resulted in the isolation of a polyfructosan. This fructosan was first obtained from the 70% alcoholic extract of the stem of the *Yucca mohavensis* and comprised approximately 20% of the dry weight. It appeared to be similar to the compound Graminin, isolated from rye flour by Schlubach and Koenig,[1] in that it was a white hygroscopic powder, soluble in water and pyridine, and forms an addition product with ethyl alcohol.

Experimental

Isolation of the Fructosan.—The stem of the Yucca plant was stripped of its bark, cut into small pieces, dried at 60° and then ground in a small mill. The meal was then subjected to exhaustive and continuous extraction with petroleum ether, ether, absolute alcohol and 70% alcohol in the order given. The extract from the 70% alcohol, constituting 40% of the dry stem, was used in this study.

Twenty grams of the extract was dissolved in water and the solution made up to 100 ml. To this was added an equal volume of hot concentrated barium hydroxide suspension containing 20 g. of the hydrated base. When 200 ml. of 95% ethanol was added to this mixture, a heavy precipitate settled out. After cooling, the precipitate was removed and washed with 10% ethanol.

This material was suspended in 100 ml. of water, the barium removed with carbon dioxide, and the filtrate decolorized with 1 g. of charcoal. The compound was again precipitated with barium hydroxide and the treatment repeated.

To remove the last traces of barium the solution was treated with a small amount of dilute sulfuric acid until one drop would cause no further turbidity. By increasing the alcohol content of the aqueous solution the product was

(1) Schlubach and Koenig, *Ann.*, **514**, 182 (1934).

fractionally precipitated into three gummy fractions. It is important to precipitate the compound with alcohol in order to separate it from the small excess of sulfuric acid. If the solution is left even slightly acidic, the compound will completely hydrolyze to fructose.

The precipitate from each fraction was dissolved in a minimum of water and dried in a vacuum oven at 60°. These fractions appeared to be identical; yield 42%.

Anal. Calcd. for $(C_6H_{10}O_5)_x$: C, 44.4; H, 6.22. Found: C, 43.9; H, 6.27.

Preparation of the Acetate.—The acetylation was carried out by slightly modifying the directions of Haworth.[2] Three grams of the dried fructosan was added to 35 ml. of pyridine and shaken at 30° until dissolved. Thirty ml. of acetic anhydride was added slowly with stirring. The white precipitate which formed was easily redissolved. The mixture was allowed to stand at room temperature for eighteen hours and the straw colored mixture then poured into 500 ml. of ice water. The white precipitate was filtered, washed, dried over phosphorus pentoxide, and again acetylated. The acetyl content according to the method of Armstrong and Arup[3] was found to be 45.4%.

Anal. Calcd. for $(C_6H_7O_5 \cdot 3CH_3CO)_x$: C, 50.0; H, 5.5; acetyl, 44.8. Found: C, 49.8; H, 5.61; acetyl, 45.4.

Preparation of the Barium Salt.—The barium salt was prepared free from barium carbonate in the following manner. Pure fructosan was dissolved in a small amount of water and an excess of saturated barium hydroxide was added. The slightly turbid solution was filtered by suction, taking precaution against the passage of air through the filter. Alcohol was added to the now clear aqueous filtrate, and the snow-white granular precipitate was filtered immediately by suction. The precipitate was washed first with 50% ethanol, and finally with 95% ethanol. The barium salt was then allowed to air dry and was finally dried completely in a vacuum oven at 50°.

Two different samples prepared in a like manner contained 22.4 and 23.5% of barium. The barium salt of the fructosan is soluble in water.

Discussion

Although sufficient data are not on hand to suggest a possible structure for this compound, a few facts have been established.

The fructosan exists in considerable quantities in the stem of the *Yucca mohavensis*. It is very readily hydrolyzed, which suggests the possibility of a fructofuranose.

The compound appears to be similar to the graminin isolated from rye flour.

Although this fructosan was first obtained from the 70% alcohol extract, in later work it was isolated from the hot aqueous extraction of the ground and dried stem.

Benzylidene Aminomorpholine Compounds

BY LEROY DUGAN, JR.,[1] AND HELMUT M. HAENDLER

The structure of 4-aminomorpholine suggested its possible use as a reagent for organic qualitative analysis. However, the only one of its reactions which appeared satisfactory was the condensation with aromatic aldehydes to form, in general, colorless, crystalline compounds, which may be of some value for the identification of certain specific aldehydes. 4-(*p*-Aminophenyl)-morpholine undergoes similar reactions, and also reacts with *o*-hydroxyacetophenone, but the resulting compounds will probably be useful only in isolated instances.

4-Aminomorpholine was prepared by the method of Knorr and Brownsdon[2] and was kept as the hydrochloride, m. p. 164–165°. Attempts to use reducing agents other than zinc and acetic acid resulted in the formation of morpholinium chloride and ammonium chloride.

The benzylidene compounds were prepared by reaction of ether or alcohol solutions of the free amine, formed from the hydrochloride by treatment with sodium hydroxide, with ether solutions of the aldehydes.

4-(*p*-Aminophenyl)-morpholine was prepared by the general methods of Kremer, Meltsner and Greenstein,[3] and Lubs,[4] m. p. 130–131°, from the nitro compound, prepared according to Harradence and Lions.[5] The condensation products were prepared by refluxing equivalent quantities of the reactants in alcohol, followed by crystallization.

The quantitative data for the compounds formed by both of these substances are listed in Table I.

Hydrogen Exchange of Aromatic Amines with D_2O and T_2O

BY B. J. FONTANA

Ingold, Raisin and Wilson[1] first demonstrated the ready H-exchange of the *o*- and *p*- H-atoms of phenols and aromatic amines when catalyzed by dilute bases and acids, respectively. This reaction was studied extensively by Kharasch, Brown and co-workers[2] in the case of the aromatic amines. It has been concluded that the existence of the quinoidal resonance forms of the free amine or phenolate ion is the chief factor governing the labilization of the nuclear H-atoms.

The amino or phenolic character of dyes or dye intermediates should then lend these substances amenable to the above type of H-exchange. Herein are described some quantitative exchange data for both deuterium and tritium obtained concurrently with attempts to label some organic dyestuffs with tritium. Discontinuance of the latter project has prevented the accumulation of more complete data.

Experimental

Exchange.—In general, 1 g. of the compound was mixed with 1 cc. of water (containing the D or T) and, unless otherwise noted, 0.01 cc. of 36 *N* sulfuric acid. The sealed mixture was heated at 100°, usually for seven days. The water was then distilled off *in vacuo* and purified by distillation *in vacuo* from potassium permanganate and sodium carbonate.

Analysis.—In all cases the change in the D or T content of the water was determined before and after exchange. The initial mole fraction of D was either 0.99 or about 0.7; the change in density observed, in general, was from 0.01 to 0.02 g. per cc. The method of density measurement is described elsewhere.[3] Note that a 0.1% error in experiment results in a 10% error in the calculated exchange number in the case of deuterium.

The tritium[4] as recovered from the 60-inch cyclotron had an activity of approximately 600 microcuries per mole of water (about 10^{-10} *M* T_2O) and contained 0.7 mole fraction of D. The D and T exchange could thus be determined simultaneously. In some experiments this water was diluted 1000-fold with H_2O. The very weak beta-radiation from H^3, tritium,[5] requires that the activities be determined by direct introduction of the hydrogen as a gas (water vapor) inside the tube of a Geiger counter. A mixture of 1-cm. pressure of water vapor and 2 cm. of propane was very satisfactory as a counting gas. The change in activity observed, in general, amounted to 20–30%.

Results and Discussion

The experimental results are tabulated in Table I. The observed values of the exchange number are given in the columns headed nk_D and nk_T. The number of exchangeable hydrogens, *n*, is merely the number of unoccupied nuclear positions *o*- and *p*- to the activating amino groups. That only the *o*- and *p*-positions undergo exchange has been assumed in general in H-exchange of this type, and has been shown to occur conclusively in the cases of phenol and aniline by Best and Wilson.[6] The partition ratios follow, k_D for deuterium and hydrogen; and k_T for tritium and hydrogen, except in the cases of methylene blue and crystal violet where k_T is an over-all partition ratio for T, D and H. The values of nk given have been corrected, where necessary, for exchange with added catalyst, amino hydrogens (assuming k = 1.00 for D or T), for water of crystallization in the case of methylene blue and for hydrochloric acid in the experiments with benzidine.

TABLE I

EXCHANGE NUMBERS AND PARTITION RATIOS

Expt.	Compound	*n*	nk_D	k_D	k_D (cor.)	nk_T	k_T
1	Crystal violet	6	7.04	1.17	0.95	..	..

12	Benzidine·2HCl		..	..	..	2.90	0.36[h]

[a] Usual heating period plus six weeks at room temperature. [b] 0.03 cc. of 12 *N* hydrochloric acid as acid catalyst. [c] Extensive decomposition; value fortuitous? [d] Eleven days at 100°. [e] 0.02 cc. of sulfuric acid catalyst. [f] Solvent 50% ethyl alcohol (95%) and 50% water; ten days at 100°, three months at room temperature. [g] Mixture 50% benzidine and 50% benzidine·2HCl. [h] No added acid catalyst.

The k_D values for methylene blue and crystal violet have been recalculated for zero D-content of water according to the theory of Brodskiĭ.[7] The average of the five corrected values gives k_D = 1.04, which then might be compared to the values 0.90 and 1.4 for the nuclear hydrogens in phenol, obtained, respectively, by Ingold, *et al.*, and Small and Wolfenden.[8] Partial exchange of

(8) P. A. Small and J. H. Wolfenden, *J. Chem. Soc.*, 1811 (1936).

the meta hydrogens might account for the latter high value. Using the average value of $k_D = 1.2$ (uncorrected) and the values for the over-all k_T's observed in experiments 2 and 5, the partition ratio for T and D is calculated to be approximately 1.2. The corresponding calculation for the k of T and H is very sensitive to experimental error; a value of approximately 2.0 is obtained, which seems very high. The apparent confirmation of this latter value by the results of experiments 8, 9 and 12 with benzidine is very probably fortuitous. The assumption that $k = 1.00$ for the exchange of T with amino H's is obviously questionable.

The triterated crystal violet lost only about 2% of its T-activity on standing in 2% aqueous solution for three months at room temperature. Heating this solution for seven days at 100°, with added sulfuric acid catalyst, caused a loss of 60% of the activity. The deuterated methylene blue (expt. 4) was heated with 1 cc. of water at 100° for two hours with no acid catalyst present. The calculated Δd for exchange of the $3H_2O$ of crystallization only was 0.0104, actually observed 0.0111. Such exchange was incomplete in only five minutes of heating or in twenty-four hours at room temperature.

As noted above, the values given for benzidine may not be valid. The calculated effect is a small one derived from the large observed effect due chiefly to exchange of the four amino H's. However, one interesting feature of the k values can be noted; that is, the very low values of the partition ratios in general. That these are real and not merely an indication of a slow rate of reaction is indicated first in experiment 10. Here, increased solubility was achieved by using a 50% aqueous ethyl alcohol mixture as the exchange medium. This is further substantiated by experiment 11. According to the theory and actual observations of Ingold, *et al.*,[1] on the exchange of phenol, and of Brown, *et al.*,[9] on dimethylaniline, the conditions in expt. 11 are such as to yield the maximum possible rate of exchange. The result of expt. 12 as compared to expt. 9 is also consistent with the latter theory. The lower partition ratio observed in the aqueous alcohol mixtures can be explained in part by the observation of Kharasch, Brown, *et al.*,[2,8] that k_D in pure ethyl alcohol as exchange medium is about 0.85 (as compared to approximately unity in water). The low value of k observed with benzidine seems to be in accordance with the theory of exchange activation by appearance of a negative charge on the ortho and para positions through the quinoidal resonance forms (of the free base in the case of aromatic amines). For in the case of benzidine there must be an interference between the resonances of the two groups with the aromatic nucleus, since the two resonance systems induce similar charges in the benzene rings. Such an effect does not seem to appear in the results obtained by Brown and Letang[10] with various dimethylamino-naphthalene derivatives.

A similar resonance interaction would account for the relatively small exchange observed with the symmetrical dyestuff congo red. Accordingly, it was also ascertained that under the conditions employed herein, little or no exchange occurred in the dyes trypan blue and trypan red. Other effects may also be operating here, including the steric hindrance of resonance ("peri-effect") observed in naphthalene derivatives.[9]

X-Ray and Optic Measurements on β-Lactoglobulin

BY I. FANKUCHEN

Through the courtesy of Dr. T. L. McMeekin, a large air-dried crystal of β-lactoglobulin was made available to the writer. In the only published work on this material,[1] no optic data (save the sign of the birefringence) and no correlation of the crystallographic axes with the physical directions of the crystal were given. It was thought desirable in view of McMeekin and Warner's[2] observations on shrinkage to make these measurements.

The crystals are of the orthorhombic variety designated by Crowfoot as tabular. The small-

(1) D. Crowfoot, *Chem. Rev.*, **28**, 215 (1941).

(2) T. L. McMeekin and R. C. Warner, THIS JOURNAL, **64**, 2393 (1942).

est refractive index, α, lies in the main prism face at right angles to the prism length. The other two vibration directions β and γ are parallel to the thickness and length of the crystal but could not be identified as the crystal is almost uniaxial. This agrees with Crowfoot's determination of the sign of the birefringence as negative.

The "*c*" axis was found to be 111 Å. and corresponds in direction to α, the crystal width. The crystal length, "*a*," is 60 Å. and the thickness "*b*" is 62 Å. These values agree very well with Crowfoot's cell values 110, 60 and 63 Å., respectively. This identifies the material as the lactoglobulin that Crowfoot studied, and, therefore, her unit cell measurements 154, 67.5 and 67.5 for the wet crystals can be used to determine cell shrinkage in the various crystal directions. The agreement between these shrinkages and those observed by McMeekin and Warner on the actual crystal is very good. It is also interesting to note that the approximate uniaxial optic character of the crystal agrees with the approximate tetragonal shape of the unit cell. This may, of course, be only a coincidence and have no bearing on any characteristics of the molecular arrangement.

The Hydrogenation of Disubstituted Acetylenes

BY KENNETH W. GREENLEE AND W. CONARD FERNELIUS

Campbell and Eby[1] have recently shown that the treatment of dialkylacetylenes with sodium in liquid ammonia produces the pure *trans* forms of the corresponding olefins. These investigators offer no explanation for this startling phenomenon. The following suggested mechanism seems to account satisfactorily for the observed results.

A solution of sodium in liquid ammonia contains electron ions[2]

$$Na \rightleftharpoons Na^+ + e^-$$
$$e^- + x\,NH_3 \longrightarrow e^-(NH_3)x$$

The reaction of sodium with double and triple bonds consists in the addition of electrons[3]

$$RC{\equiv}CR + e^- \longrightarrow R\bar{C}{=}\dot{C}R$$
$$R\bar{C}{=}\dot{C}R + e^- \longrightarrow R\bar{C}{=}\bar{C}R$$

followed by partial or complete ammonolysis

$$R\bar{C}{=}\bar{C}R + 2NH_3 \longrightarrow RHC{=}CHR + 2\,NH_2^-$$

In the ionic intermediate, the electrons would repel each other into positions as far apart as possible, *i. e.*, the *trans* form. The configuration once fixed in the ion (either before or after the addition of the second electron), persists in the ammonolysis (or hydrolysis) product. The pic-

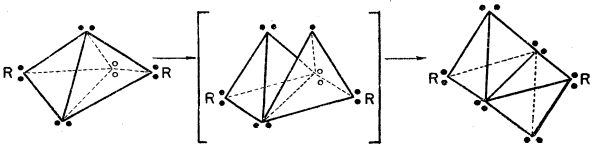

Fig. 1.

ture of one of the carbon tetrahedra turning inside out like the frame of an umbrella is the same mechanism as that frequently offered for the Walden inversion.[4]

The Nitration of 4-Phenylphenyl Benzoate

BY STEWART E. HAZLET AND HARRIS O. VAN ORDEN

Earlier studies on the bromination of esters containing diphenyl groups, including the bromination of 4-phenylphenyl benzoate,[1] have been reported from this Laboratory.[2] In the work here reported an attempt was made to compare the nitration of an ester with the bromination of the same compound. Methods of investigation were essentially the same as in previously reported work.[2] For reference compounds, the nitrophenylphenols were prepared by methods on record, and the corresponding benzoates were prepared by the action of benzoyl chloride on the nitrophenols.

Nitration of 4-phenylphenyl benzoate was effected under conditions somewhat similar to those employed in the bromination which was reported earlier,[1] and 4-(4-nitrophenyl)-phenyl benzoate resulted. The course of this nitration, then, is strictly parallel to the analogous bromination.

TABLE I

BENZOATES OF THE NITROPHENYLPHENOLS

Nitrophenylphenol used	Yield, %	Solvent	M. p., °C.	Analyses, % Calcd. C	Calcd. H	Found C	Found H
2-Nitro-4-phenyl-[3]	82	Ethanol	111[6]				
4-(4-Nitrophenyl)-[4]	Quant.	Propanol	209–210	71.4	4.1	71.2	4.8
2,6-Dinitro-4-phenyl-[5]	91.5	Propanol	157–158	62.6	3.3	62.4	4.1
2-Nitro-4-(4-nitro-phenyl)-[4]	Quant.	Propanol	151–152	62.6	3.3	62.5	4.0
2,6-Dinitro-4-(4-nitrophenyl)-[5]	60	Propanol	168	55.8	2.7	55.4	3.3

Acknowledgment is gladly made to the Dow Chemical Company, Midland, Michigan, for the supply of 4-phenylphenol used in this work.

The Nitrophenylphenyl Benzoates.—These benzoates were prepared by treating the necessary phenols with benzoyl chloride in the presence of pyridine. The individual compounds are described in Table I.

Nitration of 4-Phenylphenyl Benzoate.—Ten grams of 4-phenylphenyl benzoate[1] dissolved in 80 ml. of glacial acetic acid was treated with a mixture of 5 ml. of fuming nitric acid and 2.5 ml. of concentrated nitric acid, which was added slowly at room temperature. The mixture was stirred and heated gently for a short time on an electric heater. After cooling, filtering and one recrystallization from glacial acetic acid, 4.8 g. of product was obtained. Several more recrystallizations from glacial acetic acid gave lustrous colorless plates which melted at 208–210°. A mixture of equal amounts of this product and 4-(4-nitrophenyl)-phenyl benzoate melted without depression at 209–211°.

Some Reactions of Morpholine[1]

BY ALVIN R. INGRAM[2] AND W. F. LUDER

In the course of an investigation of the conductivity of morpholine solutions, the following reactions were observed.

Morpholine, a weak base, reacts with the acidic stannic chloride[3,4] to give the expected addition compound $SnCl_4 \cdot 2C_4H_9NO$. It is similar to the compounds of morpholine prepared by Haendler and Smith.[5] Dilute solutions of morpholine and stannic chloride in carbon tetrachloride were mixed in a ratio of two moles of morpholine to one of stannic chloride. A white precipitate formed immediately. This product was washed in carbon tetrachloride, absolute alcohol and petroleum ether. It was insoluble in the common organic solvents, water and dilute acids, but it dissolved with decomposition in hot concentrated acids. It melted with decomposition between 215° and 235°. *Anal.* Calcd. for $SnCl_4 \cdot 2C_4H_9NO$: Sn, 27.3; Cl, 32.7. Found: Sn, 27.3; Cl, 32.0.

Morpholine also reacts with carbon tetrachloride and chloroform to give morpholinium chloride. Similar reactions have been observed previously with piperidine to form piperidinium chloride.[6] Because these reactions of morpholine with carbon tetrachloride and chloroform were of no concern to the investigation under way, no attempt was made to isolate other products in addition to morpholinium chloride. However, from the work of Powell and Dehn,[6] the principal ones may be N-trichloromethyl and N-dichloromethyl morpholine.

A 4.5% by weight solution of morpholine in carbon tetrachloride, made up for another purpose, contained a large quantity of needle-like crystals when noticed about four months later. The crystals melted at 177° and when dissolved in water gave a white precipitate with silver nitrate. Mixed melting points, using morpholinium chloride prepared by the reaction of dry hydrogen chloride with morpholine, confirmed the conclusion that the crystals were morpholinium chloride. When approximately equal volumes of morpholine and carbon tetrachloride were warmed to temperatures from 50 to 100°, the morpholinium chloride was formed in a few hours, and the remaining liquid became yellow or brown depending on time and temperature. Distillation of the colored liquid gave a colorless distillate which deposited more morpholinium chloride immediately upon cooling. The residue was viscous and dark brown. When mixed in a ratio of two moles of morpholine to one mole of carbon tetrachloride (both being dried over calcium chloride or calcium sulfate)

crystals formed within one day at room temperature leaving a colorless solution. The reaction took place even with calcium oxide present.

The behavior of morpholine with chloroform is similar. Morpholinium chloride was identified as the product by its melting point, by its reaction with aqueous silver nitrate, and by taking a mixed melting point with morpholinium chloride prepared from hydrogen chloride and from carbon tetrachloride.

Solubility of the Flavianates of Certain Organic Bases in Water, Ethanol, and *n*-Butanol at 3 and 30°

BY WILSON D. LANGLEY AND THOMAS R. NOONAN

The use of 2,4-dinitronaphthol-7-sulfonic acid (flavianic acid) for the purification and characterization of organic bases, first recommended by Kossel and Edlbacher, and Kossel and Gross,[1] has been extended by Sievers and Mueller[2] to include solubility data, and by Langley and Albrecht[3] to include crystallographic data. It has been our desire further to extend knowledge of the solubilities of the flavianates in certain solvents, so that flavianic acid may be more satisfactorily used for fractional precipitation of organic bases. Accordingly, we have determined the solubilities reported in the accompanying table. The solvents were selected as being suited for fractionation of extracts of tissues, and it was hoped that quantitative separations of bases could be accomplished readily once the components of mixtures were identified under the microscope. This work has been interrupted, and the prospects of it being resumed are remote.

The solvents used were purified by distillation just prior to use, and purity was established by constancy of boiling point, and by measurement of density (pycnometer). The flavianates used had been analyzed and reported upon previously.[3] Equilibrium was attained by frequent shaking of solvent in contact with solid for various lengths of time ranging from several days to several months. The saturated solutions were filtered, and were pipetted immediately by use of pipets which were calibrated at the temperatures used. Fifty-ml. portions (occasionally 20 ml.) of solutions were pipetted into weighed beakers, and the covered solutions were evaporated on a steam-bath. Final drying of the residue was done in an oven at 100°, constant weight being attained in each case.

1-Carbamyl-5-methylpyrazole-3-carboxylic Acid

BY ALBERT L. LEHNINGER

During the course of some work on the derivatives of acetopyruvic acid,[1] the reaction between semicarbazide and acetopyruvic acid became of interest as a means of identification of the latter compound. Von Auwers and Cauer[2] had reported that they were unable to obtain the expected product, 1-carbamyl-5-methylpyrazole-3-carboxylic acid (I), since the carbamyl group was apparently lost on ring closure, leading instead to 5-methylpyrazole-3-carboxylic acid (II).[3]

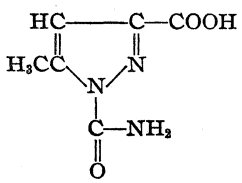
(1) Lehninger and Witzemann, THIS JOURNAL, **64**, 874 (1942).

(2) von Auwers and Cauer, *J. prakt. Chem.*, **126**, 146 (1930).

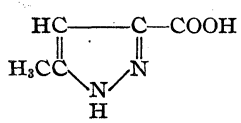
(3) Knorr and MacDonald, *Ann.*, **279**, 217 (1894).

By altering the conditions employed by von Auwers and Cauer, it was found that the expected carbamyl compound could be obtained easily and in large yields. Furthermore, the reason for their failure to obtain the compound became apparent on studying its properties.

This substance was found to hydrolyze readily to 5-methylpyrazole-3-carboxylic acid in water or in water–alcohol solutions on standing for several days at room temperature or on heating for short periods, with or without added acid. The long reaction periods employed by von Auwers and Cauer probably provided for the conversion of the primary product I into II.



I



II

The product of hydrolysis of the carbamyl compound was isolated and identified as 5-methylpyrazole-3-carboxylic acid.[3]

Experimental

1-Carbamyl-5-methylpyrazole-3-carboxylic Acid.—To a solution of 1.30 g. of acetopyruvic acid (prepared as previously described[1]) in 10 ml. of water was added 1.11 g. of semicarbazide hydrochloride dissolved in 10 ml. of water. The mixture was stirred and gently warmed. A white voluminous mass of microscopic needles immediately precipitated. The mixture was stirred for two minutes, filtered, washed copiously with cold water and dried over phosphorus pentoxide. The compound was thus obtained pure without recrystallization; yield, 80–85%; m. p. (dec. started at 155°, clear melt at 232–234° (cor.).

Anal. Calcd. for $C_6H_7O_3N_3$: C, 42.60; H, 4.17; N, 24.85. Found: C, 42.74; H, 4.13; N, 24.67. Amide N: Calcd. 8.28. Found (hydrolysis with H_2SO_4, followed by alkaline distillation of ammonia and titration), 8.12.

Hydrolysis to 5-Methylpyrazole-3-carboxylic Acid.—A suspension of 1.0 g. of the compound obtained above in 20 ml. of water was brought to the boiling point for one minute (evolution of carbon dioxide was apparent) and cooled. Crystals of 5-methylpyrazole-3-carboxylic acid separated. These were recrystallized from water; m. p. 236–236.5° (cor.); melting point of authentic sample (prepared according to Knorr and MacDonald[3]) 236–237°; a mixed melting point test showed no depression.

Anal. Calcd. for $C_5H_6O_2N_2$: C, 47.61; H, 4.80. Found: C, 47.42; H, 4.60. There was no detectable amide nitrogen.

The Polymerization of Styrene Catalyzed by *p*-Bromobenzenediazonium Hydroxide

BY CHARLES C. PRICE AND DOROTHY ANN DURHAM

The presence of fragments from the catalyst in polystyrene and polymethyl methacrylate prepared in the presence of substituted peroxides[1] has been interpreted as evidence strongly supporting the suggestion that such catalysts first dissociate into free radicals[2] which then initiate the polymerization process.[3]

Since the reaction of alkaline diazotized *p*-bromoaniline with benzene and its derivatives to form *p*-bromobiphenyl and the corresponding derivatives[4] has been ascribed to the decomposition of the diazonium hydroxide to a *p*-bromophenyl free radical,[2] the action of the diazonium hydroxide as a catalyst for the polymerization of styrene has been tested.

p-Bromobenzenediazonium hydroxide has indeed been found to catalyze the polymerization of styrene. The directions followed for carrying out the polymerization were those described for the preparation of *p*-bromobiphenyl[4] with the single exception that styrene replaced benzene. Alkali was added slowly to a vigorously-stirred suspension of 30 cc. of styrene in an aqueous solution of 11 g. of diazotized *p*-bromoaniline at 0°. After the addition of alkali was complete, the reaction mixture was allowed to warm up to room temperature. The aqueous layer was decanted and alcohol was added to the viscous organic layer. The polystyrene which precipitated was purified further by several reprecipitations from ether solution by pouring into ice-cold alcohol. The viscosity of a sample of this polymer in tetralin was measured at 20°; $\eta_{sp.}/C_{gm.} = 1.16$. Using the revised[5] value for the constant of the Staudinger equation relating this expression to molecular weight, the polymer contained an average of about twenty-two styrene units.

Anal. Calcd. for $BrC_6H_4(C_8H_8)_{30}C_6H_4Br$: C, 88.07; H, 7.27; Br, 4.65. Calcd. for BrC_6H_4-

$(C_8H_8)_{17}OH$: C, 87.75; H, 7.31; Br, 4.11. Found: C, 87.77; H, 7.24; Br, 4.2.[6]

Since no polystyrene was formed in a parallel experiment in which the diazonium salt was omitted, it appears that the *p*-bromophenyl radicals from the decomposition of *p*-bromobenzenediazonium hydroxide are capable of initiating the polymerization of styrene and are thereby incorporated in the polymer.

(6) This analysis was carried out by wet oxidation with silver and potassium dichromate in sulfuric acid. The halogen was absorbed in alkaline hydrogen peroxide according to Zacherl and Krainick (*Mikrochemie*, **11**, 61 (1932)) but analysis by titration of excess alkali was entirely unsatisfactory, evidently due to volatilization of organic acids. Volhard titration for bromide ion in the alkaline peroxide, however, proved very convenient and accurate.

The Composition of Alkylmagnesium Chloride Solutions in Ethyl Ether

BY C. R. NOLLER AND A. J. CASTRO

In previous work on the composition of *n*-butylmagnesium chloride solutions in ethyl ether,[1] it was thought that the values obtained were true equilibrium values expressing the relation between the amounts of *n*-butylmagnesium chloride, di-*n*-butylmagnesium and magnesium chloride as etherates in ether solution. On attempting to repeat, refine and extend this work, we have found that other factors seem to be involved. For example, in the original experiments it appeared that equilibrium was reached after fifty to one hundred and fifty hours. In the new series of experiments, at least in the higher concentrations, much less magnesium chloride had precipitated after seventy days than had been precipitated after 150 hours in the first series and did not reach the latter value until after 300 days. The only difference in procedure of which we are aware is that in the second series the solutions were kept in sealed glass tubes whereas in the first series the tubes were closed by stopcocks. It is possible, too, that in the second series somewhat more care may have been given to avoiding contact with air.

That exposure to air may be the cause of the discrepancy was indicated by a third series in which extreme care was taken to avoid contact with air by preparing the reagent and carrying out all transfers in an atmosphere of purified nitrogen. After 160 days practically no magnesium chloride had precipitated. In fact the chloride concentration of the solution was still greater than the alkylmagnesium concentration, a condition which had never been observed previously even in freshly prepared solutions of Grignard reagent. If no magnesium chloride precipitates, one should, of course, have an excess of chloride over alkylmagnesium because of side reactions which do not result in the formation of Grignard reagent. Similar but even more marked results were obtained with Grignard solutions from tertiary butyl chloride which after 150 days contained over 2.5 equivalents of chloride for each two equivalents of alkylmagnesium.

When increasing amounts of oxygen reacted with a 0.5 *N* solution of *n*-butylmagnesium chloride, the ratio of halogen to basic magnesium in the precipitate was about three to one for one-fourth oxidation, about one to one for the next fourth while complete oxidation caused removal of all of the halogen from the solution and all but a trace of basic magnesium. This indicates that if ROMgCl is the product of oxidation, it is capable of bringing down with it additional magnesium chloride, presumably by using the unshared electrons of the oxygen atom to form a complex with magnesium chloride much in the same way as dioxane forms an insoluble complex or as ether forms a soluble complex. If this is the case one might expect the precipitate to have ultimately the composition $ROMgCl \cdot 2MgCl_2$ in which the ratio of chloride to basic magnesium would be 5:1. To explain the behavior of the Grignard solutions on standing one might assume that, in the absence of oxygen, magnesium chloride is soluble in the Grignard solution either because the reagent is entirely in the form RMgCl or because the Grignard solution is a much better solvent for magnesium chloride than pure ether.[2] If oxygen is present, ROMgX, which itself is relatively insoluble, would be precipitated fairly rapidly, carrying down some magnesium chloride with it. This precipitate would then slowly go over to the still less soluble $ROMgCl \cdot 2MgCl_2$, causing slow precipitation of more magnesium chloride.

This picture, however, is incomplete because in the case of Grignard solutions from benzyl chloride, magnesium chloride precipitates fairly rapidly in spite of all precautions we have taken

(1) Noller and Raney, THIS JOURNAL, **62**, 1749 (1940).

(2) At present the latter seems to be the better explanation since we have obtained Grignard solutions from tertiary butyl chloride which contained as much as 0.3 mole of magnesium chloride per 1000 g. of solution above the 1:1 ratio while the solubility of magnesium chloride etherate in pure ether is of the order of 0.001 mole.

so far to exclude oxygen. Moreover, the precipitate contains as much as ten equivalents of chloride per equivalent of basic magnesium, which is much greater than the 5:1 ratio expected from the formula $ROMgCl \cdot 2MgCl_2$. Evidently, the effect of some Grignard solutions on the solubility of magnesium chloride is much less than others and magnesium chloride precipitates in addition to that brought down by the oxidized reagent.

Obviously this problem requires further study. It will be necessary to devise a technique for the preparation and sampling of the Grignard solutions entirely in the absence of oxygen. Moreover, the sampling will have to be done over a period of several years to ensure equilibrium conditions. We hope to initiate such experiments in the near future.

Preparation of Phenylpropiolic Acid

BY MARIE REIMER

Preparation of phenylpropiolic acid can be facilitated by a simple improvement in the preparation of cinnamic acid dibromide. The fact that the usual procedure for addition of bromine to the ethylenic linkage, using ice-cold solvents, is discouragingly slow in the case of cinnamic acid has led to the bromination of cinnamic ester.[1] The preparation of the ester can be eliminated, however, and a good grade of commercial cinnamic acid brominated quickly and in excellent yield by use of boiling carbon tetrachloride as solvent. A typical reaction is as follows: 74 g. (0.5 mole) of cinnamic acid and 500 ml. of carbon tetrachloride were placed in a three-necked flask fitted with an efficient stirrer, a reflux condenser and a separatory funnel. The mixture was heated to boiling, the stirrer started and the addition of 79.9 g. (0.5 mole) of bromine in 50 ml. of carbon tetrachloride begun. The color disappeared slowly at first, then so rapidly that all the bromine could be added in the course of forty-five minutes. Heating and stirring were carried on for an additional fifteen minutes and the stirring continued while the mixture cooled. The product, which began to separate from the solution when about two-thirds of the bromine had been added, consisted of fine colorless, shining needles, softening at 195° and melting with decomposition at 199–200°. This is sufficiently pure for subsequent use. The yield was 147 g. (95%) with an additional 2 g. of less pure material obtained by distilling the filtrate to 50-ml. volume. Repeated crystallization of the cinnamic acid dibromide from carbon tetrachloride did not improve the melting point appreciably, but after one crystallization from chloroform the compound separated in brilliantly shining needles, melting at 200–202°.

For obtaining phenylpropiolic acid in small amounts, a less elaborate procedure can be used than that recommended[2] for its preparation in larger quantity from the ester of cinnamic acid dibromide. Twenty-five grams of cinnamic acid dibromide was placed in an evaporating dish, 100 ml. of a 25% solution of potassium hydroxide in methanol added, and the mixture stirred over rapidly boiling water until nearly all the alcohol had evaporated. To the thick, pasty residue, 75 ml. of methanol was added and the procedure repeated to ensure complete reaction. The pale yellow granular product was cooled, subjected to strong suction to rid it of a small amount of residual liquid, washed with a few milliliters of chilled methanol and dissolved in 500 ml. of ice-water. To the solution, iced hydrochloric acid was added to faint acidity. As phenylpropiolic acid separates as an oil, the mixture was then seeded and the hydrochloric acid added slowly with vigorous stirring until the mixture was strongly acid. To make sure that all the oil had solidified, the mixture was left standing overnight in the ice-chest. The acid which had separated in 80% yield was pure white and melted at 128–136°. There was but slight loss on recrystallization from boiling carbon tetrachloride from which the acid separates in long, shining needles, melting at 136–138°.

Formation of Pro-carotenoids in "Monkey Flowers" under Some Conditions

BY W. A. SCHROEDER

An unpublished investigation, which has been carried out in these laboratories during the past year, has shown that the flowers of *Mimulus longiflorus* Grant (*Scrophulariaceae*), commonly termed "monkey flowers," contain no representative of the class of pro-carotenoids which possess

a partially *cis*-configuration.[1] This statement refers to flowers which have developed fully under natural conditions on the intact plant. In recent experiments it was found, however, that, if stems with buds were placed in water for several days and exposed only to diffuse light in the laboratory at room temperature, the flowers were noticeably different in tint and paler in color than flowers which developed on the intact plant in the open. Parallel chromatograms of extracts of the two materials established the fact that under these two sets of conditions, the polyene pigment mixtures differed both qualitatively and quantitatively with respect to the components found. The paler flowers contained a greater number of lycopene stereoisomers than the controls. The chromatogram of the paler flowers included considerable quantities of prolycopene, $C_{40}H_{56}$, and pro-γ-carotene, $C_{40}H_{56}$. The spectral maxima of these pigment fractions in petroleum ether (b. p. 60–70°) were 467, 440 mμ and 461, 431 mμ, respectively. Upon addition of iodine to the solutions, the bands showed the characteristic shift to 500.5, 469.5, 440 mμ and 494, 461 mμ. Both pro-carotenoids have been identified by mixed chromatograms with samples from other sources.

In the light of the above observation, it is possible that prolycopene and pro-γ-carotene are precursors of lycopene and γ-carotene in the biosynthesis of the *Mimulus* pigment.

Some Physical Constants of N-Octyl-, N-Dodecyl- and N-Cetyl-piperidine

BY F. H. STROSS AND R. J. EVANS

There exists little available information on the physical properties of the higher N-alkyl-piperidines. When, in the course of an investigation, it became necessary to prepare N-cetylpiperidine, only two references[1,2] were found which mentioned this compound. Its ionization constant was found to be surprisingly low in comparison with the known constants of the lower homologs, and, therefore, the N-dodecyl- and N-octyl-piperidines were also prepared and their characteristic properties measured. The results are given in Table I.

While the N-cetyl and N-dodecyl compounds are weak bases of a strength close to that of pyridine, N-octylpiperidine occupies a position intermediate between the higher homologs and the N-methyl- to butylpiperidines. The latter are almost as strong bases as the unsubstituted piperidine, which has a pK_H of 11.1 at 25°.

The bases were prepared by the method described by Magnusson and Schierz.[2] Aqueous piperidine was refluxed with a slight excess of the alkyl iodide, while an excess of potassium hydroxide was gradually added. The upper of the two layers formed during refluxing was fractionally distilled over solid potassium hydroxide at 2 mm. pressure, yielding a clear distillate. The cetylpiperidine was yellow, the dodecyl compound had a slight yellow tinge, and the octylpiperidine was colorless. The analyses were made and the constants determined after redistilling these products.

Empirical Heat Capacity Equations of Gases

BY HUGH M. SPENCER AND GORDON N. FLANNAGAN

Since the publication of empirical heat capacity equations of simple gases,[1] values of thermodynamic functions for many gases have been derived from spectroscopic data.[2] In the case of

(1) Hugh M. Spencer and John L. Justice, THIS JOURNAL, **56**, 2311 (1934). The heat capacities of bromine and equilibrium chlorine are better represented by equations of form (2). The constants a, $b \times 10^3$, $c' \times 10^{-5}$, maximum and average percentage deviations are 8.911, 0.140, −0.0298, 0.09, 0.02 and 8.764, 0.271, −0.656, 0.24 and −0.11, respectively.

Trichlorobromomethane	10	250–600	11.462	39.983	− 318.76			.57	.24
Water[v]	15, 20, 21	298.1–1500	7.219	2.374	+ 2.67			.96	.40

[a] For a number of gases the heat capacities cited in the references are incorrect at one or more temperatures. New values for these, based on the same wave numbers, have been calculated, and are indicated as in Note *b*. [b] Rotational distortion correction amounting to $0.058 \times 10^{-3}T$ has not been included. At 500°K. for $C_p^0 = 10.14$, read 9.92. [c] Percentage deviation tested with respect to mean heat capacity. [d] Several heat capacity measurements by K. S. Pitzer (THIS JOURNAL, **63**, 2413 (1941)) have caused him to doubt the correctness of the frequencies used in ref. 6. [e] At 250°K. for $C_p^0 = 20.11$, read 20.12. [f] At 450°K. for $C_p = 15.23$, read 15.24. [g] At 650°K. for $C_p^0 = 13.53$, read 13.48. [h] At 350, 550 and 600°K. for $C_p^0 = 10.22$, 14.93 and 15.66, read 11.22, 14.88 and 15.65, respectively. [i] The values of the mean heat capacity to 400, 700 and 1000° were neglected in setting up and testing the equation. [j] At 700°K. for $C_p^0 = 24.33$, read 24.05. [k] At 700°K. for $C_p^0 = 18.3$, read 18.83. The rotational distortion correction ($0.031 \times 10^{-3}T$) has not been included. [l] At 650 and 1200°K. for $C_p^0 = 12.07$ and 15.92, read 12.00 and 15.88, respectively. [m] Rotational distortion correction amounting to $0.064 \times 10^{-3}T$ has been included. [n] At 350°K. for $C_p^0 = 11.48$, read 11.47. [o] The rotational distortion correction ($0.068 \times 10^{-3}T$) has not been included. [p] Only three values of the mean heat capacity were available; these were solved simultaneously. [q] The mean heat capacity (298.1–350) was excluded. [r] Simultaneous solution at $T = 300$, 380 and 450°K. [s] Graphically extrapolated values of mean heat capacity at 400, 500 and 600 were used in setting up and testing the equation. [t] At 400 and 650°K. for $C_p^0 = 16.68$ and 18.45, read 16.78 and 18.38, respectively. [u] The two largest deviations are for temperatures for which the theoretical values do not fall on the curve. [v] Rotational distortion correction based on ref. 21, amounting to $0.092 \times 10^{-3}T$, has been included. The correction based on Wilson's[15] theoretical value derived from the force constants of the molecule would have been $0.081 \times 10^{-3}T$.

several triatomic gases more complete spectroscopic data have been treated by more satisfactory statistical mechanical methods. Though it is still necessary to consider the polyatomic (including some triatomic) molecules as harmonic oscillators, thermodynamic data based on this conception have proved to be of satisfactory, though not absolute, accuracy. Use of the normal coördinate analysis of vibrations, the assignment of potential barriers due to hindered rotations by reference to thermochemical data at one or more temperatures, and the methods of extrapolation to closely related molecules have further increased the useful applications of this method.

The same remarks concerning the usefulness of empirical heat capacity equations for these gases might be made as were made in the earlier paper.[1]

Table I presents the equations and the percentage deviations of such equations representing the heat capacities of the various gases in the forms

$$C_p^0 = a + bT + cT^2 \quad (1)$$

$$C_p^0 = a + bT + c'/T^2 \quad (2)$$

$$C_p^0 = a + bT + cT^2 + dT^3 \quad (3)$$

Except as indicated in the notes to Table I, equations of the forms (1) and (2) have been obtained as least square solutions of all the data in appropriate forms of heat capacity or mean heat capacity. Depending on the relative contributions of the various wave numbers over the range of temperatures concerned, one or the other of forms (1) and (2) are to be preferred. If the change of curvature with respect to the horizontal (T) axis is greater at the higher temperatures of a given range form (1) is preferable, and *vice versa*. In some instances the range of temperatures is relatively so great that comparatively large deviations from the most appropriate three-constant equation occur.[22] Adjusted simultaneous solutions of form (3) are offered for these. It should be noted that empirical equations are unreliable for extrapolation.

The original articles must be consulted to ascertain the bases of the theoretical values which the equations represent. As in most of the original publications constants of the "International Critical Tables" have been used.

(22) For one gas, carbon dioxide, a three-constant equation has been derived [R. L. Sweigert and M. W. Beardsley, Georgia School of Tech. State Eng. Expt. Sta. Bulletin No. 2 (1938)] involving T^0, T^{-1} and T^{-2} terms, which more accurately represents the values derived from spectroscopic data than do three-constant equations of forms (1) or (2).

Note on the Structures of the Gallium and Indium Trihalides

BY D. P. STEVENSON[1] AND VERNER SCHOMAKER

Brode[2] recently published the results of an electron-diffraction investigation of the structures of the so-called trihalides of aluminum, gallium and indium. We believe that the interatomic distances which he reported (given in row *a* of the table) have been falsified by his application of an unsuitable "correction,"[3] and that the values given below in rows *b* and *c* are significantly more reliable. Row *b* gives the values found by Brode with the use of the usual correlation method[4] (omitting the Wierl correction), while those of row *c* are the ones we have obtained by the application of the radial distribution method[5] to his data. These two sets of values agree reasonably well except in the case of Ga_2Br_6.

TABLE I

AVERAGE M–X BOND LENGTHS IN THE TRIHALIDES OF GALLIUM AND INDIUM

		Cl	Br	I
Ga	[a]	2.16	2.35	2.40[d]
	[b]	2.22	2.41	2.48
	[c]	2.22	2.34	2.50
In	[a]	2.39	2.49	2.67
	[b]	2.46	2.56	2.76
	[c]	2.46	2.58	2.76

[a] Brode's "corrected" value. [b] Brode's uncorrected value. [c] From the first peaks of the radial distribution functions. [d] GaI_3, coplanar equilateral triangle.

The bond angle values ($\angle$ XMX) indicated by the relative positions of the first and second maxima of the radial distribution functions substantiate Brode's conclusion that under the conditions of his experiments gallium tri-iodide is monomeric and coplanar, whereas the five other trihalides are dimeric. Inasmuch as we could not take account of the minima, for which Brode reported no measurements, the radial distribution functions tend to show spurious features, in these cases beyond the first two peaks, and we can draw no conclusions with regard to the conformation of the dimers.

RECEIVED JULY 13, 1942

(1) Present address, Shell Development Company, Emeryville, California.

(2) Brode, *Ann. Physik*, **37**, 344 (1940).

(3) The correction is one due to Wierl (*ibid.*, **8**, 521 (1931)), and implies a procedure of measurement different from that which has been found suitable by Pauling and his co-workers. Almost certainly this correction should not have been applied to Brode's measurements, for his measurements on aluminum chloride agree well with those reported by Palmer and Elliott (THIS JOURNAL, **60**, 1852 (1938)).

NEW COMPOUNDS

Some N-Aralkyl Barbituric Acids

The N-benzyl and N-phenethyl derivatives of amytal and neonal have been prepared by conventional methods from the corresponding malonic esters and benzyl and phenethyl ureas. They were crystallized from hexane. Data on these substances are presented in the table. The benzyl and phenethyl nembutals were also prepared, but, although general identity was shown by analysis, they were not obtained in a satisfactorily homogeneous condition.

Chaulmoogryl Quaternary Salts[1]

Since favorable bacteriological results have been obtained with methiodides and benzochlorides from mixtures of chaulmoogryl and hydnocarpyldimethylamines, it was decided to prepare some pure substances of this type.

Chaulmoogryl bromide[2] was heated in a bomb-tube at 105–110° with 33% methanolic dimethylamine in excess.

(1) Dittmar, *Z. Krebsforsch.*, **49**, 515 (1939), mentions a "Chaulmoogryl Zephirol." So far as the authors know these compounds have not been described.

(2) Sacks and Adams, THIS JOURNAL, **48**, 2397 (1926).

[a] From benzene. [b] From water.

The resulting tertiary amine boiled at 170° (0.5 mm.) and solidified in the refrigerator.

Chaulmoogryldimethylamine reacted with methyl iodide in absolute ether to form the methiodide, which is soluble in hot alcohol, sparingly soluble in cold alcohol, water, ethyl acetate and benzene, and insoluble in ether.

Attempts to prepare quaternary salts from the reaction of chaulmoogryldimethylamine with benzyl chloride, *p*-chlorobenzyl chloride and α-menaphthyl chloride resulted only in the formation of oils which presumably were in the main the desired quaternary salts but did not crystallize. Chaulmoogryldimethylbenzylammonium iodide, however, prepared from the chloride and sodium iodide, crystallized readily. It is soluble in alcohol, hot benzene, ethyl acetate and acetone, sparingly soluble in water and cold benzene, insoluble in ether and hexane.

For purposes of comparison octadecyltrimethylammonium iodide[3] and octadecyldimethylbenzylammonium iodide were prepared, the latter from the tertiary amine and benzyl iodide. Data on these and the preceding compounds are presented in Table I.

(3) Mentioned, but not described, by Shelton, Van Campen and Nisonger, at the Boston meeting of the Am. Chem. Soc., Sept., 1939.

1,1,1-Trichloro-2-hydroxy-3-nitroalkanes and their Reduction Products

The halogenated nitroalcohols were made by a procedure essentially the same as that described by Nicodemus and Wulff.[1] Four-tenths of a mole (66.2 g.) of chloral hydrate was dissolved in a mixture of 200 cc. of water and 15 cc. of concentrated hydrochloric acid, in a 500-cc. round-bottomed, three-necked flask equipped with a mechanical stirrer and a thermometer dipping below the surface of the solution. A slight excess of nitroparaffin was added and the stirrer was started. A saturated aqueous solution of potassium carbonate was added until the mixture was just alkaline to litmus. The mixture was heated in a water-bath at a temperature of 50–52° for two hours (six hours when 1-nitropropane was used), with constant stirring. The dark yellow lower layer was removed and fractionally distilled under reduced pressure. The results are summarized in Table I.

(1) Nicodemus and Wulff, U. S. Patent 2,123,556 (1938).

The halogenated nitroalcohols were reduced at room temperature using 0.1 mole of the nitro compound dissolved in 150 cc. of absolute ethyl alcohol, 9 g. of freshly prepared Raney nickel catalyst[2] and starting with an initial hydrogen pressure of about 55 pounds per square inch. The catalyst was removed by suction filtration and the dark green filtrate was concentrated by distilling the alcohol under reduced pressure. Attempts to remove the color by treatment with decolorizing carbon were unsuccessful. Consequently, the dark brown or black solids were treated with benzoyl chloride in alkaline solution. The benzoyl derivatives were washed well with water and recrystallized by dissolving in hot ethyl acetate and then adding ligroin to the cooled solution. The time required for practically complete reduction, the melting points and analyses of the benzoyl derivatives are also given in Table I.

In an attempt to obtain some pure 1,1,1-trichloro-2-hydroxy-3-aminopropane, it was found that the addition of acetone to a concentrated alcoholic solution of the amine resulted in the precipitation of an almost white solid. Repeated washing of the solid with acetone followed by recrystallization from a mixture of xylene and absolute alcohol and spontaneous evaporation of the solvent yielded white crystals which melted at 167.4–167.7° (cor.). The losses involved in this method of purification were enormous.

Substituted Sulfonamides

N¹-Chloroacetyl-*p*-nitrobenzenesulfonamide.—To 10 g. of *p*-nitrobenzenesulfonamide dissolved in 100 cc. of 4.4% sodium hydroxide was added, dropwise with stirring at 5°, 7 g. of chloroacetyl chloride (Eastman Kodak Co.). After fifteen minutes, the solution was neutralized with acetic acid and unchanged *p*-nitrobenzenesulfonamide separated by filtration. The filtrate was acidified to congo red with hydrochloric acid to precipitate the product, which was collected and dried at 60°. It was then recrystallized once from toluene (1 g. per 50 cc.); yield 5 g.

N¹-Chloroacetylsulfanilamide was prepared from 5 g. of finely divided nitro compound which was added at 35° to 12.25 g. of $SnCl_2 \cdot 2H_2O$ dissolved in 15 cc. of concentrated hydrochloric acid. Some cooling was necessary at first. After standing for eighteen hours, the solution was cooled and made alkaline with 10% sodium carbonate solution. The precipitate was removed and the filtrate clarified with activated carbon. The product was precipitated, after removal of the carbon, by acidifying the filtrate to congo red. It was dried at 60°, and purified by one recrystallization from benzene–alcohol; yield 1.5 g.

Benzenesulfonamido heterocycles were obtained by the reaction of benzenesulfonyl chloride with the appropriate amino heterocycle in dry pyridine. The general method has been described previously[1]; yields ranged from 75–90%.

COMMUNICATIONS TO THE EDITOR

BARBALOIN

Sir:

The recent note by Gardner and Campbell[1] on some reactions of the aloins emboldens us to place on record some experiments made in 1939. We can confirm Rosenthaler's statement[2] that barbaloin does not give methanol when hydrolyzed with borax and that Cahn and Simonsen's[3] observation is incorrect and we have observed also the formation of furfural under certain conditions. Our most fundamental result is however with reference to the empirical formula of barbaloin which was discussed at some length by Cahn and Simonsen.[3] Dr. E. G. Cox of the University of Birmingham has very kindly determined the molecular weight of barbaloin methyl ether by the X-ray crystal structure method and he finds it to be 521. There can therefore now no longer be any doubt that barbaloin methyl ether has the formula $C_{21}H_{17}O_2(OMe)_7$ from which it would apparently follow that barbaloin itself must be $C_{21}H_{17}O_2(OH)_7$. This formula for the methyl ether is in accord with the analytical data previously recorded (C, 64.5; H, 7.15; OMe, 40.7. Calcd. C, 64.8; H, 7.4; OMe, 41.9). We hope at some future date to be in a position to continue our experiments

THE TEMPERATURE COEFFICIENT OF THE CONDUCTANCE OF POTASSIUM CHLORIDE SOLUTIONS

Sir:

In THIS JOURNAL, **64,** 1544 (1942), Li and Fang give conductance data for aqueous solutions of potassium chloride at temperatures from 15 to 40°; they were apparently unaware, understandably enough, of our results both for potassium and sodium chloride solutions at temperatures from 15 to 45° (Gunning and Gordon, *J. Chem. Phys.* **10,** 126 (1942)). Their conductances at 25° are in moderate agreement with those of Shedlovsky, Brown and MacInnes [*Trans. Electrochem. Soc.*, **66,** 165 (1934)] and our own, and their 15° numbers are also in rough agreement with the measurements of Thompson and his associates [THIS JOURNAL, **59,** 2372 (1937); **61,** 1219 (1939)] and ourselves. For 15°, however, they employ a linear extrapolation of the Shedlovsky function Λ_0'; Shedlovsky, Brown and MacInnes showed that a $c \log c$ term was required for potassium chloride at 25°, and we showed that it was even more important for 15°. It is for this reason that the value Li and Fang give for Λ_0 at this temperature (120.88) is considerably less than the one we obtained by an extrapolation from much lower concentrations, *viz.*, 121.09.

The values of Λ_0 at 30° and 40° reported by Li and Fang are, however, about 0.25 and 1.1% less than those obtainable by interpolation in Gunning and Gordon's Table V. From LeRoy, Allgood and Gordon's transference data [*J. Chem. Phys.*, **8,** 418 (1940)] t^0_- is 0.5103 at 30° and 0.5120 at 40°; combining these with Li and Fang's values of Λ_0, one obtains 84.00 and 99.42 as the limiting mobility of chloride ion at these temperatures; Gunning and Gordon's Table VI, which resulted from a consideration of the transference and conductance measurements for *both* salts, gives 84.22 and 100.52. Interpolation of Owen and Sweeton's results for hydrochloric acid solutions [THIS JOURNAL, **63,** 2811 (1941)] gives 84.3 and 100.9; these are in agreement with Gunning and Gordon's values within the uncertainty of the transference numbers Owen and Sweeton were forced to employ.

If the discrepancy be ascribed to error in the temperature, this would correspond to a difference of 0.1° at 30° and to 0.6° at 40°; Li and Fang give no information about their temperature scale beyond stating that they used standard thermometers; our temperatures were determined by platinum resistance thermometer with N. B. S. certificate. It would therefore seem that Li and Fang's 30° and 40° data should be considered, for the moment at any rate, with reserve.

NEW BOOKS

Introduction to the Theory of Relativity. By PETER GABRIEL BERGMANN, Member, Institute for Advanced Study, 1936–1941; Assistant Professor of Physics, Black Mountain College. With a Foreword by Albert Einstein. Prentice-Hall, Inc., 70 Fifth Avenue, New York, N. Y., 1942. xvi + 287 pp. Illustrated. 15.5 × 23.5 cm. Price, $4.50.

This book not only appears with the *imprimatur* of Albert Einstein, but contains, p. 253, some hitherto unpublished work by Einstein and Bergmann. The proofreading has been astonishingly thorough: "mass" for "velocity" on p. 92, and superscript "s" for "5" in equation (18.24) on the very last page of the text, are the only errors the reviewer has found; he has, however, some differences of opinion with the author. The distinction between Riemannian and Lobachevskian spaces should be preserved, even if it is not of particular interest to the present discussion. The author recognizes, p. 60, that "only when n is 3 is the 'conjugate' tensor density to a tensor of rank 2 a vector density," but still adheres to Hamilton's definition of the vector product. (To one reader, at least, tensor densities seem "excess baggage.") The treatment of relativistic electrodynamics in Chapter VII is distinctly less elegant than that of E. B. Wilson and G. N. Lewis (1912), principally because the author has given the Cartesian interpretation of the derivation, step by step; to the reader who is not prepared to *think* in tensor terms this will not seem a defect.

The convention of calling tensors of negative rank "covariant" and those of positive rank "contravariant" is

not original with Dr. Bergmann, but that does not make it any less confusing.

In view of the use of subscript comma and semicolon to denote, respectively, ordinary and covariant differentiation, it is unfortunate that the equations have been punctuated. The hazards of combining punctuation with mathematical symbols are most amusingly illustrated by the caution on p. 239 "(do not sum over the index *rl*)."

"*The Euclidean character of a space depends only on the metric*," p. 162, seems a bit of an overstatement. An observer who found it possible, in a cylinder, to draw infinitely many geodesics between two given points, or who, in a cone of less than 60° vertex angle, found a geodesic intersecting itself, would have ground for questioning the Euclidean character of his space, in spite of the patently Cartesian metric tensor. Similarly on p. 74, "In . . . Riemannian spaces . . . there is, in general, a uniquely determined shortest connecting line between two points." This is certainly not the case for time-like intervals in *de Sitter* hyperspace.

In the matter of gravitational waves, p. 189, it might have been pointed out that in a gravitational collision, as in an electromagnetic collision between particles of like charge and equal mass, there is a first-order compensation of the components of the radiation field.

As for the "Schwarzschild singularity," p. 203, or the absence of plane-wave solutions of the *rigorous*, non-linear field equations, p. 189, what fails is, presumably, the fiction that either the field or the test particle can be unaffected by such extreme conditions.

It is refreshing that "from the point of view of . . . general formalism, there is no difference between the theories of Kaluza, Veblen and Hoffmann, and Pauli" (p. 268).

The book has both a synoptic table of contents and an index, and is so arranged as to suit readers of all grades of interest in the theory of relativity.

ELLIOT Q. ADAMS

Organic Analytical Reagents. By JOHN H. YOE, Ph.D., Professor of Chemistry, University of Virginia, and LANDON A. SARVER, Ph.D., Director of Research, Roanoke Plant Laboratory, American Viscose Corporation. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1941. ix + 339 pp. 2 figs. 15.5 × 23.5 cm. Price, $4.00.

Analytical Chemistry being a very old branch of the science, it would indeed be difficult to decide who first used an organic derivative or reagent to help identify or determine an element; the use of acetate, tartrate, citrate and other organic groups is far from new, as also are the ether extraction of iron and dimethylglyoxime for nickel. Modern pure analytical, industrial, biochemical and applied medical research, however, has vastly stimulated the application of organic compounds in analytical processes, and this book is an attempt to collect in one place the widely scattered literature dealing with this many-phased subject.

After an introductory Chapter (I), the authors proceed in Chapter II to group the compounds considered into a number of classes, according to their properties or functions: Solvents and Wash Liquids, Substances Used in Neutralizations, Organic Oxidizing Agents, Organic Reducing Agents, Indicators, Primary Standards (for volumetric analysis), Acidic Salinogenic Compounds, Basic Salinogenic Compounds, Photometric Acids and Substances for the Control of Adsorption, Diazotization and Coupling Agents (for nitrites), Alkaloids and Natural Products. In subsequent chapters are given more detailed theory and discussion of the major type groups of compounds, with many examples.

Organic solvents and wash liquids (Chapter III) may be used for washing and drying vessels and precipitates, lowering solubilities, extracting components of solid and liquid mixtures, displacing equilibria, aiding in distillation or other processes and serving as protective coatings. Most such compounds are hydrocarbons and their derivatives, such as thiols, halides, alcohols, glycols, ethers, aldehydes, ketones, esters, ester acids, amines (23 pp.). Chapter IV on organic acids and bases opens with a section on dissociation constants, lists typical acids and their properties, considers constants of bases and similarly lists a number of them. Organic oxidizing and reducing agents are taken up in six pages (V).

The subject of Indicators is discussed rather lengthily in Chapter VI, on the theory that these compounds are weak acids or bases and their salts, in colored or colorless form, containing chromophore groups which tautomerize or resonate. Many illustrative structural formulas are given, and tables of color changes and other properties, as well as numerous examples. Primary standards in volumetric analysis (Chapter VII) is an old field in which much profitable research has been done; the chapter is not long, since not many organic primary standards are in use. A number are described for alkaline and acid solutions, and a few for oxidimetry (for permanganate, iodine and thiosulfate).

Chapter VIII on valence and complex compounds seems to begin rather irrelevantly as one reads through a number of pages on the electronic theory of valence, types of linkage, Werner theory, complex compounds and their dissociation, and chelate groups, all this building up to a brief climax of compounds which form characteristic colored products with metals, such as various oximes, oxine, aurin, cupferron and nitrogen and sulfur compounds (with brief mention of isomerism of Werner complexes).

Salinogenic Reagents (Chapter IX) are defined as compounds capable of forming salts with metal or acid ions. The acidic ones are various types of ionizable —OH, —COOH, —NH and —SH compounds, while the basic ones are practically all trivalent nitrogen derivatives. Several pages are devoted to a discussion of ionization of the agents, the electronic and strain limitations on ring size and formation, covalent radii, planetary configuration of metal electrons and parachor; the remaining 40 pages list and describe the individual compounds in major and sub classes.

Chapter X (10 pp.) is entitled Photometric Aids: Colloids and Colorimetric Stabilizers, and deals briefly with protective colloids and their uses, the preparation, stabilization and precipitation of nephelometric suspensions. Miscellaneous Organic Reagents are grouped in Chapter XI (9 pp.), listing and describing compounds useful in electro-analysis, titration and a number of special analyses.

Part II consists of the Glossary and Bibliography. Chapter XII (22 pp.) is a listing of the reagents for various metals, ions and processes. Chapter XIII (53 pp.) is an alphabetical listing (with properties and uses) of the reagents considered. The book ends with a Bibliography of 2419 references, many of them as late as 1940, and a subject index. The descriptive theoretical parts of the book are neither extensive nor exhaustive; the rest of the work seems to succeed quite well in achieving its purpose. The typographical design and execution are good (except for a difficult block of matter in Chapter II), and obvious errors are scarce. The book should prove useful to a variety of readers and workers.

ALLEN D. BLISS

Chemical Dictionary. Compiled by F. H. CAMPBELL, D.Sc., F.A.C.I. Chemical Publishing Co., Inc., Brooklyn, N. Y., 1942. 85 pp. 15 × 22.5 cm. Price, $2.50.

In his introduction Dr. Campbell writes that terms which are known or can be found in textbooks are not included, while on the paper jacket the publishers state, "All chemical terms most commonly used are included." The compiler appears to have tried to effect a compromise between these two aims, for this list does indeed comprise many terms that perhaps should appear, but his obvious interest in physical chemistry has led to the retention of many also that should be replaced as being too rarely encountered to warrant inclusion in so small a volume. Thus enthalpy evacolation, Kurrol salts (but not Graham salt), liminal, and even some German terms are listed, while such new and important terms as co-polymer, chemurgy, precursor, molecular distillation and chemical warfare are omitted. The reference "Hydroxide, see Hydrate" does not conform with recommended practice. A valence table for pre-college students is included as a two-page appendix.

The definitions are often explanatory and informative. A student of chemistry in high school or college would be able to add considerably to his store of special knowledge by a careful study of this book page by page.

WILLIS A. BOUGHTON

War Gases. Their Identification and Decontamination. By MORRIS B. JACOBS, PH.D. Interscience Publishers, Inc., 215 Fourth Avenue, New York, N. Y., 1942. xiii + 180 pp. 8 illustrations. Cloth. 15.5 × 23.5 cm. Price, $3.00.

This book is a timely and concise compilation of the properties of chemical warfare agents and the methods for their analysis and destruction in areas and materials polluted by them. The subject matter is drawn from competent sources, including the most recent literature issued by American and British war and defense agencies. Many of the data are given in convenient tabular form.

Chapter I on Classification of the Chemical Agents gives a list of the war gases used or proposed in the last war and the recognized classifications of these gases based on their physiological action, their chemical composition, their physical properties or their tactical use.

Chapter II follows with a paragraph on the important physical and chemical properties and physiological action of each of the war gases arranged in order of their physiological classification. Further information on chemical properties is given in Chapter III which deals with their effect on water, food and other materials.

Chapter IV on Scheme of Analysis contains a useful table of data from several sources on the minimum detectable odor of war gases and the immediate physiological effect produced by them. The literature on field and laboratory tests appears to be well covered and procedures are concisely stated.

Chapter V (10 pages) is devoted to methods for the detection and estimation of arsenic, with special reference to foods suspected of contamination by Lewisite or other arsenical warfare agents.

Chapter VI gives the confirmatory tests for the identification of agents which have been chemically classified by the scheme of analysis given in Chapter IV. The qualitative procedures given are supplemented by reference to quantitative procedures in the literature.

Chapter VII is a well-arranged and concise description of methods for the decontamination of road surfaces, buildings, household articles, vehicles, clothing, water and food. Proper emphasis is given to the destruction of persistent gases such as mustard gas and the poisonous arsenicals. This chapter and the last one on the protection of foods are based on very recent publications issued by American and British defense agencies.

The book is well printed in legible type and should be very useful to anyone who has had some chemical education and has to deal with chemical warfare agents as an air warden, gas-identification officer or a decontamination officer. War gas chemists will find it a convenient manual for their work.

A. C. FIELDNER

The Physical Examination of Metals. Volume II. **Electrical Methods.** By BRUCE CHALMERS, D.Sc., Ph.D., F.Inst.P., Physicist, Tin Research Institute, and A. G. QUARRELL, A.R.C.S., Ph.D., F. Inst. O., Lecturer in Metallurgy, University of Sheffield. Longmans, Green and Co., Inc., 55 Fifth Avenue, New York, N. Y., 1941. viii + 280 pp. Illustrated. 14 × 22 cm. Price, $6.00.

The second volume of "The Physical Examination of Metals, Electrical Methods," carries forward the purpose set forth in "Volume I, Optical Methods." It presents a non-mathematical exposition and discussion of the techniques which have already proved of value to metallurgists or others to whom the examination of metals is important, as well as a discussion of new techniques which show promise. As a series, these volumes will form a convenient and valuable reference.

Under the general title of "Electrical Methods," the authors discuss magnetism, electrical measurements, X-ray diffraction, electron diffraction, the electron microscope and radiography. Each section presents a brief review of theory and general methods and then proceeds to discussion of the application of these methods to specific testing problems. Original references are given for the techniques discussed.

The section on magnetism and magnetic measurements is

introduced by a lucid and rapid review of magnetic theory followed by a description of precision apparatus for making magnetic measurements. Ballistic, oscillographic and general ferrometric methods are discussed. With respect to specific testing, the section on the Magnaflux method is particularly good, there being a detailed analysis of the applicability and limitations of Magnafluxing as well as of variations in technique. Of particular interest to metallurgists will be the sections on ferrographic metallography, the measurement of internal friction, the rapid determination of carbon content and the excellent section on thermomagnetic measurements which supplement routine metallography and are valuable in the identification of new phases. Measurement of the thickness of coatings and platings is also discussed.

In the section on electricity, the authors include a rather complete exposition of methods for making precision electrical measurements. These methods are applied to resistance thermometry, thermoelectricity, thermo-electric pyrometry, piezo-electricity, photo-electricity and electrical measurement of thickness from one side.

The longest and otherwise the most important section of the book is devoted to X-ray diffraction, but the treatment suffers from an attempt to present so much material in the space allotted. In the first place, the authors set up the diffraction problem with a non-vector formulation of the three Laue conditions—a procedure which is always somewhat involved and which, when treated in brief as it is here, adds nothing to the rigor or elegance of the presentation. The simpler Bragg formulation would perhaps have served the purpose better. On the other hand, many of the most important aspects of the diffraction technique are mentioned only in passing—particularly those aspects having to do with interpretation of diffraction patterns, the calculation of relative intensities of pattern lines, and other calculations of practical importance.

The experimental X-ray techniques are quite clearly presented, as are the various aspects of the particle size problem, and there is a very lucid treatment of the solid solution, superlattices and the order–disorder phenomena. Phase diagrams and intermetallic compounds are treated in a brief recapitulation of the work of Hume-Rothery and associates. There is also a short discussion of orientation effects and the effect of deformation upon diffraction patterns.

The section on electron diffraction is interesting and comprehensive. Principles, techniques, apparatus, particularly the Finch Diffraction Camera, are presented in detail. The application of electron diffraction to studies of basal-plane pseudomorphism, oxide layers, surface coatings, the Beilby layer and bearing surfaces is very enlightening. The discussion of the scope and limitations of the technique should be helpful.

Electron microscopy is a new technique which metallurgists are watching closely. Thus far it has proved difficult to adapt the microscope to metallographic use because reflection from a massive specimen has not been possible. The use of transparent surface replicas is at best a cumbersome and uncertain procedure. The authors present an account of the work that has been done in this field and give a detailed discussion of the construction of electron microscopes.

With respect to radiography the authors discuss the requirements for making satisfactory radiographs and the nature of flaws and defects which can be revealed.

The appendix contains data on electrolytic brightening, X-rays, crystal structure, spacing formulas, etc., and wave lengths associated with electrons. The index appears to be adequate.

J. N. HOBSTETTER

A Symposium on Respiratory Enzymes. Addresses given at an Institute held at the University of Wisconsin, September 11–17, 1941 (27 Contributors). The University of Wisconsin Press, Madison, Wisconsin, 1942. xii + 281 pp. Illustrated. 15.5 × 24 cm. Price, $3.00.

This book contains the following principal articles: Intermediate Carbohydrate Metabolism, O. Meyerhof; Oxidative Mechanisms in Animal Tissues, E. G. Ball; Pasteur Effect, F. Lipmann; Oxidases, Peroxidases and Catalase, K. G. Stern; Nicotinamide Nucleotide Enzymes, F. Schlenk; The Flavoproteins, T. R. Hogness; Cytochromes, E. Stotz; Phosphorylation of Carbohydrates, C. F. Cori; Metabolic Cycles and Decarboxylation, E. A. Evans, Jr.; and Transamination, P. P. Cohen. It also records discussions on hydrogen transport (Potter, Elliott, Ball and Lipmann, Stern and Haas, and Stotz), phosphorylation (Kalckar, Meyerhof, Johnson and Lipmann), tumor respiration (Baumann, Elliott, Potter, Burk and Kensler), bacterial respiration (Peterson, Wood and Burris, Werkman, Barron and Wilson, and Nord and Wilson), and animal tissue respiration (Elvehjem, Shorr, Elliott, Potter, Axelrod, Bernheim, Barron and Stare).

This symposium on respiratory enzymes fulfills the functions of a volume of this type. First, it reflects the best judgment of specialists in various branches of the subject in respect to the interpretation of data now available, and attempts to define the limits to which interpretations of physiological and pharmacological activities may safely be carried in terms of oxidative enzymes; secondly, it provides an up-to-date bibliography of the more important chemical, biochemical, and physiological literature in the field of biological oxidations and records, very satisfactorily in most instances, the advances which have been made in this field since the Cold Spring Harbor Symposium of 1939. During these three years there have been two major advances.

The first deals with the importance of phosphate transfer as a method of biological synthesis and has now reached the stage where phosphorylation can account for a number of chemical mechanisms underlying physiological activities. The paper by Cori and the discussion on phosphorylation supplement the earlier reviews of Kalckar and of Lipmann in bringing out the importance of phosphorylation in the control of carbohydrate metabolism.

The second major advance has been in the use of radioactive and other isotopes in tracing the chemical reactions concerned in the breakdown and utilization of carbohydrate, particularly the utilization of inorganic carbon dioxide by animal tissues to synthesize more complex carbon compounds. Various phases of this subject are here discussed by E. A. Evans, H. G. Wood and R. H. Burris.

The remarks of the latter two investigators should be particularly valuable to chemists and physicists desirous of applying such techniques to biological problems.

The article by F. Schlenk brings together a considerable amount of practical information regarding the properties of diphosphopyridine nucleotide and triphosphopyridine nucleotide which is not otherwise readily available in English.

The discussion on tumor metabolism will no doubt prove interesting to many, since it assembles for the first time much of the data currently available on the metabolism of butter yellow tumors and on the possible mechanism of formation of such tumors.

The book closes with a discussion of methods of handling tissue in metabolic experiments, including reference to certain techniques which have not been mentioned in earlier books on respiratory processes. The remarks of E. Shorr and K. A. C. Elliott on this subject should prove especially useful to chemists and physiologists who are anxious to study the relation of biological oxidations to their particular problems.

M. E. KRAHL

The Stone that Burns. By WILLIAMS HAYNES. D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, N. Y., 1942. xii + 345 pp. 14.5 × 22 cm. Illustrated. Price, $3.75.

This timely and readable book is a history of the American sulfur industry. Mostly, it is the story of one man's flash of genius; of Herman Frasch's idea that sulfur deep down in the earth could be melted by steam and while still molten brought to the surface by an air lift. The book covers in detail Frasch's long and almost vain struggle to make this idea work, of his final success and of the great development which this process has experienced in later years.

In the current textbooks of chemistry Frasch's process is presented as something simple and easy. Nothing could be further from the truth. This book is illuminating in making clear the difficulties which even an apparently simple idea encounters in actual large-scale operation.

The latter part of the book, dealing with the period of the first world war and thereafter, is particularly valuable from an historical point of view. It traces in detail the development of the European sulfur cartel, one of the first representatives of this phenomenon destined to play so great and ominous a role in the subsequent economic life of the world. Moreover, it records in detail with abundant documentation the steps in the creation and growth of the great American sulfur companies of today.

This book, however, is more than a monograph on a special chapter of chemical engineering. The story it tells illustrates in a striking way the functioning of our economic system based on the profit motive. Naïve persons are often impressed with the philosophical weakness of this motive and it is true that as society develops this motive requires control. However, the particularized information and factual account of the development of the sulfur industry as given in this book cannot but impress the thoughtful reader with the ceaseless, multifarious, indomitable and ultimately successful operation of the profit motive. So long as individual initiative can function, so long as men are free, the lure of profit, of useful gain, operates. Driven by it men are unabashed by the most formidable obstacle; they attack first here, then there, again and again and again until it is at last overcome!

ARTHUR B. LAMB

Advances in Colloid Science. Edited by ELMER O. KRAEMER, Ph.D., Biochemical Research Foundation of the Franklin Institute, Newark, Delaware, in Collaboration with FLOYD E. BARTELL, Ph.D., Professor of Chemistry, University of Michigan, Ann Arbor, Michigan, and S. S. KISTLER, Ph.D., Associate Director of Research, Norton Company, Worcester, Mass. Volume I. Interscience Publishers, Inc., 215 Fourth Avenue, New York, N. Y., 1942. xii + 434 pp. 161 figs. 15.5 × 23.5 cm. Price, $5.50.

Colloid science is not an isolated subdivision of science; rather it cuts across many sciences. The breadth and diversity of its applications are perhaps responsible for the large number of devotees and their almost evangelistic enthusiasm.

The present volume, an outgrowth of this enthusiasm, is the first of a series intended to present new discoveries in colloid science, either experimental or theoretical, in a more comprehensive and unified fashion than is possible in the regular technical periodicals. As to the manner of presentation, the editors say in the Preface, "Since in each instance the author (or authors) will have been closely identified with the development under discussion, it is to be expected that the contributions should have an individualistic point of view, and should show a definite emphasis upon the author's own part in the development in question. The contributions are thus not intended to be reviews or compilations from the literature in the usual sense, and the editors are willing to share any censure that readers may be inclined sometimes to level at an author because he has apparently failed to do adequate justice to other investigators in the field."

This volume contains twelve chapters, as follows:

"The Measurement of the Surface Areas of Finely Divided or Porous Solids by Low Temperature Adsorption Isotherms," by P. H. Emmett.

"The Permeability Method for Determining Specific Surface of Fibers and Powders," by R. R. Sullivan and K. L. Hertel.

"A New Method of Adsorption Analysis and Some of its Applications," by Arne Tiselius.

"Solubilization and Other Factors in Detergent Action," by James W. McBain.

"Recent Developments in Starch Chemistry," by Kurt H. Meyer.

"Frictional and Thermodynamic Properties of Large Molecules," by R. E. Powell and Henry Eyring.

"The Constitution of Inorganic Gels," by Harry B. Weiser and W. O. Milligan.

"The Creaming of Rubber Latex," by G. E. van Gils and G. M. Kraay.

"Streaming Birefringence and its Relation to Particle Size and Shape," by John T. Edsall.

"Synthetic-Resin Ion Exchangers," by Robert J. Myers.

"The Study of Colloids with the Electron Microscope," by Thomas F. Anderson.

"Anomalies in Surface Tensions of Solutions," by Ernst A. Hauser.

These chapters are all excellently done and are of the greatest interest. Indeed, it is stimulating to see what great progress has been registered recently in every one of the fields covered. Moreover, the fields are so diverse that any reader can be sure to find much that is novel and illuminating.

The editors and contributors are to be complimented on the success of this volume, and the promise that it affords of similar volumes in the future.

ARTHUR B. LAMB

A Course of Instruction in the Qualitative Chemical Analysis of Inorganic Substances. By ARTHUR A. NOYES, Late Professor of Chemistry, and ERNEST H. SWIFT, Associate Professor of Analytical Chemistry, California Institute of Technology. Tenth edition, Revised and Rewritten. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1942. xv + 418 pp. 13 figs. 14.5 × 22 cm. Price, $2.75.

Previous editions of this well known text by the late Professor Arthur A. Noyes have established a standard of excellence that has seldom been duplicated by other texts in the field of qualitative analysis, and in this new edition Professor Swift has wisely retained those features that have been responsible to such a great degree for the success of the previous editions. To quote from the Preface: "The division of the book into two main Parts, entitled The Course of Instruction and The System of Analysis has been retained, and as in the past the laboratory operations of the System of Analysis are described with as great definiteness as possible in short paragraphs entitled Procedures; and each of these is followed by Notes in which are given detailed facts regarding the operations, suggestions as to technique, the precautions necessary and the difficulties encountered in special cases, optional procedures for certain of these cases, and the indications frequently afforded of the presence of various constituents." "As a major change from previous editions, the treatment of the principles and more fundamental chemical facts connected with the procedure have been separated from the Notes and are given as Discussions immediately before the Procedure."

Although the revising author employs modern chemical principles liberally in the Discussions, and the method of treatment follows the best current usage, he has happily preserved a viewpoint that is realistic in its recognition of the complexity of many inorganic reactions and that thus avoids the pitfalls of too extensive and thoughtless application of hyper-simplified principles. For example, in his discussion of hydrogen sulfide separations the author quite correctly relegates to a minor role the dubious conclusions that so often result from the application of over-simplified solubility product reasoning, and stresses instead other important factors, such as complex ion formation, rate of precipitation, absorption and coprecipitation phenomena, which so frequently determine the success or failure of these separations.

Some noteworthy improvements in the Procedures include the use of potassium hydrogen sulfide for the separation of the Copper and Tin Groups, an improved scheme for the analysis of the Tin Group, the employment of isopropyl ether for the extraction of iron in the analysis of the Ammonium Sulfide Group, the complete precipitation of magnesium with the Alkaline Earth Group by means of solid ammonium carbonate, and the use of perchloric acid as a source of hydrogen ion in the Scheme of Analysis for Acidic Constituents, to mention only a very few. Considerable emphasis is placed on the analysis for acidic constituents, and provision is made for the detection of twenty-four anions (in addition to silicate, chromate, and permanganate) by a scheme whose degree of systematization approaches that of the scheme of analysis for the basic constituents, and which involves a minimal number of "side tests." An outstanding improvement in many of the Procedures has been attained by providing for the optional use of centrifugation to eliminate time-consuming filtrations.

During actual class use of this text for a semester the reviewer found only a surprisingly small number of errors, either typographical or otherwise, and only a few minor imperfections in procedural details. The book can be recommended to all those who believe that the primary purpose of a first course in qualitative analysis is to teach inorganic chemistry, rather than specialized techniques.

JAMES J. LINGANE

Annual Review of Biochemistry, Vol. XI. By JAMES MURRAY LUCK, Editor, and JAMES H. C. SMITH, Associate Editor. Annual Reviews, Inc., Stanford University P. O., California, 1942. ix + 736 pp. 16 × 23 cm. Price, $5.00.

With this volume, the Annual Reviews begins its second decade of a lifetime which has been of inestimable value to the biochemical research worker. The foresight of the original editorial committee is reflected in the unchanged editorial policy and subject matter of the series.

The present volume, in common with those earlier, deals with enzymes, vitamins, carbohydrates, proteins and various aspects of their metabolism. There are additional reviews of topics not so frequently considered. The following, which fall in this category, may be especially recommended: The Chemistry of Visual Substance, by S. Hecht; Avian Biochemistry, by T. H. Jukes and H. J. Almquist; Plant Tissue Cultures, by P. R. White; and Microbiology, by R. Dubos.

WILLIAM F. ROSS

Chemistry and Physiology of the Vitamins. By H. R. ROSENBERG, Sc.D. Interscience Publishers, Inc., 215 Fourth Avenue, New York, N. Y., 1942. xix + 674 pp. 25 figs. 15.5 × 23.5 cm. Price, $12.00.

This is the first attempt which has been made to cover the chemistry and physiology of all the vitamins in a single volume, and a very successful attempt it is, too. The book is beautifully arranged. There is first an introductory chapter on the vitamins in general, which contains precise

definitions of all of the terms to be used (although a definition of "enzyme" is, curiously enough, not given), a brief account of the history of the discovery of the vitamins, an explanation of nomenclature in this field, a list of the identified and unidentified vitamins and an outline of the methods of attack which various scientists, in their coöperative efforts, use to discover and elucidate the nature of a vitamin, together with the most important procedures that are employed. The specificity of the vitamins is here handled in a general way, along with the analytical methods which must be used, and then follows a brief discussion of the physiology and pathology which are connected with the vitamins. This first chapter is, in itself, an excellent general discussion of the whole subject of vitamins; with very minor changes it could be read with great profit by any individual who had no training in science but who wished to know something about what vitamins are, how they are discovered, how prepared, and how used, together with the "whys" of these questions.

Then follow separate chapters covering each of these vitamins: The A's, B_1, B_2, B_6, Nicotinic Acid, Pantothenic Acid, Inositol, *p*-Aminobenzoic Acid, C, the D's, the E's, H (Biotin), the K's, P, the non-identified Vitamins (the other B's, the L's, all the various factors such as T, U, Folic Acid, the Grass Juice Factor, etc.). Next come chapters on the Vitagens—Essential Fatty Acids, the Essential Amino-Acids, the Essential Carbohydrates and Choline, and the Essential, Transferable Methyl Group.

Within each major chapter, the material is systematically arranged into sub-topics, in general as follows: 1. Chronology, a brief table giving the "highlights" in connection with the development of the vitamin; 2. Occurrence; 3. Properties; 4. Isolation; 5. Chemical Structure; 6. Synthesis; 7. Industrial Methods of Preparation; 8. Biogenesis; 9. Determination; 10. Specificity; 11. Physiology; 12. Hypo- and Hyper-vitaminoses; and 13. Requirements. These topics are discussed in an authoritative and very entertaining manner. The citations are extremely numerous and are numbered by chapters, and there are over three thousand of them. The book closes with three very excellent indexes—patent, author, and subject—the preparation of which is a considerable achievement in itself.

It is possible that some specialists might consider their particular specialties to be treated in too elementary a manner, all the more so since books of approximately this same size could be written about almost any one vitamin, and have been written about some of them. But the reviewer found that those vitamins with which he is most familiar were treated comprehensively enough, and he thought these particular chapters were all the better for not having been written too exhaustively. It must be remembered that this is a book on "The Vitamins," and it is the first book of its kind to appear. Nowhere else is there, between the covers of one volume, so much information covering all the aspects of the whole field.

Dr. Rosenberg has worked in the laboratories of Ruzicka and of Reichstein; he was present in Zürich when Karrer announced the successful isolation of essentially pure vitamin A; and he has been, since 1936, engaged in researches on vitamins and hormones at the Jackson Laboratory of E. I. du Pont de Nemours and Company. Thus he has been active in this field for about fifteen years. It seems almost incredible, yet this short time has witnessed almost the whole of the development of the true chemistry of the vitamins. Although the pace is no longer quite as rapid as it was, yet it is still rapid enough, for almost literally while the ink was drying on the pages of this book, many important contributions in the field of the vitamins appeared. Thus, to mention only a few, it was shown that vitamin A_2 was definitely devoid of any activity and a new structure was proposed,[1] a new synthetic vitamin E factor was announced,[2] α-tocopheryl acetate was crystallized,[3] and new and accurate determinations of vitamin B_1[4] and of α-tocopherol[5] were published. One has to be daring, and to be possessed of a spirt of great eagerness, even to think of writing a book covering the whole of such an active field, and Dr. Rosenberg has done the job very well indeed. One could say, of course, that "this book fills a long-felt want," and he would be telling the truth—but it is even more than that. If the tired and busy chemist would like to have something he can read while relaxing and thoroughly enjoying himself; something authoritative and important, but which at the same time is easy to read and is exciting—this is it.

There are few errors in the book, and those few are, for the most part, rather obvious. Such things, for instance, as the use of "hydrocyanic" where "isocyanic" is meant on page 388; the use of "active" instead of "inactive" on page 409; and a few obvious mistakes in correcting the structural formulas. The printing and binding are excellent, and the only real criticism the reviewer has concerns the price of the book. Here is a book which merits a very wide circulation, but it is to be feared that the high price will effectively bar it from the libraries of the younger scientists and the general scientific reader, where it really belongs. This is a pity.

LEE IRVIN SMITH

The Dynamic State of Body Constituents. By RUDOLF SCHOENHEIMER, M.D., Late Associate Professor of Biological Chemistry, Columbia University. Harvard University Monograph in Medicine and Public Health, Number 3. Harvard University Press, Cambridge, Mass., 1942. x + 78 pp. 6 figs. 15.5 × 23.5 cm. Price, $1.75.

The death of a scientist at the height of his intellectual powers and while engaged upon a problem of great importance is a tragic thing. In the case of Rudolf Schoenheimer, it is especially tragic since the problem had been brought so far toward solution that the results he had attained have already modified the current course of biochemical thinking.

The use of isotopes in the study of intermediary metabolism will, of course, continue, and probably at a rapidly accelerating pace. The application of these new techniques is a matter of such fundamental importance as far

to transcend the fate of the individual, whatever this may be. Accordingly it is fortunate that an opportunity was presented to Schoenheimer, by the invitation of Harvard University to deliver the Edward K. Dunham Lectures in the autumn of 1941, to bring together the whole of his labors with deuterium and the heavy isotope of nitrogen into a brief and simple account, unobscured by technical details.

These lectures have now appeared in the present slim volume. The first deals with the reactions of the body fats, the second with the state of the body proteins, and the third with the role of structural elements in the formation of excretory products. The thesis is developed that all components of the tissues are in a dynamic state and are constantly involved in rapid chemical reactions. If suitable starting materials are provided, all chemical reactions which the animal is capable of performing are carried out continually. No other conclusion is possible from the evidence afforded by the behavior of the isotopes used to trace the fate of various compounds administered to animals maintained in a state of nutritional equilibrium.

A brief preface explains that the printed lectures represent revisions by his colleagues from drafts prepared by the author, and there is, in addition, a biographical note and appreciation of Schoenheimer by Professor Hans T. Clarke who delivered the lectures and edited the manuscript.

H. B. VICKERY

The Nature of Thermodynamics. By P. W. BRIDGMAN, Hollis Professor of Mathematics and Natural Philosophy in Harvard University. Harvard University Press, Cambridge, Mass., 1941. xii + 229 pp. Illustrated. 21 × 14 cm. Price, $3.50.

Fifteen years ago in "Logic of Modern Physics" Bridgman made a notable contribution to epistemology by emphasizing that physicists, and similar scientists, actually acquired knowledge by operational procedures. Philosophers have been too much impressed with the finished products of the older and more theoretical sciences and have given too little attention to the ways in which scientists actually learn. Thus he joined the group containing C. S. Peirce, Wm. James, H. Poincaré, and L. J. Henderson, of scientists who philosophize, who for the most part do not labor their philosophies so much as the professional philosophers, but who bring to them the new ideas suggested from actual acquaintance with concrete phenomena.

In "The Nature of Thermodynamics" the author applies his operational analysis in detail to this difficult field. One can hardly fail to gain the impression that the sledding is a bit harder, but he is making a further and very useful effort to make clear whether the operations involved are instrumental or "paper and pencil" procedures. Especially to be noted is the discussion of the light thrown on methods of treating some irreversible phenomena by Bridgman's own researches. Those looking for "finality" and "finish" will be disappointed at such a frank assertion as: "I believe that no epistemology can be logically rigorous, but between rival epistemologies it can only be a question of which is logically the most tolerable in a particular setting." This is, however, true pragmatism, it is the method of getting ahead with the business of acquiring science; everything breaks down if pushed too far and practically no theory, surely no working hypothesis, subsumes all the known facts of its subject matter but shuts its eyes to some which are too stubborn.

Whether agreeing with him or not, every student of thermodynamics, that perplexing subject where things may not be too large without failing to satisfy equilibrium conditions nor yet too small without revealing fluctuations, will profit by the study of Bridgman's treatment of its nature.

Ketene Acetals. XI. The Pyrolysis of Ketene Acetals and Orthoesters

BY S. M. MCELVAIN, HARRISON I. ANTHES AND SYDNEY H. SHAPIRO

The C-alkylation of α-methoxystyrene[1] and ketene acetal[1a] by means of certain reactive organic halides shows the similarity in behavior and the high reactivity of the heteroenoid systems that are present in these two structures. It seemed of interest, therefore, to undertake a study of the effect of heat on the ketene acetals to ascertain if they would undergo the same type of thermal rearrangement as the α-alkoxystyrenes which have long been known[2] to rearrange into phenyl alkyl ketones

$$C_6H_5C(OR)=CH_2 \longrightarrow C_6H_5COCH_2R$$

It previously has been reported[3] that ketene diethylacetal may be heated at 190–240° in *new* Pyrex tubes without any perceptible polymerization. In the work which is now reported, the effect of heat on ketene diethylacetal and its chloro and bromo derivatives has been studied. These ketene acetals have been heated under three different sets of conditions, *viz.*, (a) in glass tubes at 200° for six hours, (b) in a steel bomb at 150–200° for six to seventy-two hours, and (c) during rapid passage over a variety of surfaces in a furnace at 300–400°. Under all of these conditions the ketene acetals that were studied showed only one type of behavior, *viz.*, pyrolysis into ethylene and the acetic ester

$$XCH=C(OC_2H_5)_2 \longrightarrow XCH_2COOC_2H_5 + C_2H_4 \text{ (X is H, Cl or Br)}$$

There was no indication in any experiment that an ethyl group had rearranged from an oxygen to a carbon as it does in ethoxystyrene.[3]

Under the conditions (six hours at 200°) that caused complete pyrolysis of ketene diethylacetal in glass tubes, ketene dimethylacetal remained unaffected. Indeed, 95% of this dimethylacetal was recovered after twenty-four hours of heating at 200°.

The failure of ketene, chloroketene and bromoketene diethylacetals to undergo thermal rearrangement as do the alkoxystyrenes led to a study of the thermal behavior of ketene diallyl- and dibenzylacetals. These compounds contain the necessary structure, $>C=\underset{|}{C}-O-CH_2-\underset{|}{C}=C-$, for the well-known Claisen or allylic rearrangement and would be expected to rearrange quite readily. As a matter of fact, neither of these ketene acetals could be isolated from the products of the reaction of potassium *t*-butoxide in *t*-butyl alcohol with either diallylbromoacetal (I) or dibenzylbromoacetal (III); the only products that could be separated were allyl allylacetate (II) and benzyl *o*-tolylacetate (IV) which were obtained in yields of 43 and 46%, respectively.

$$BrCH_2CH(OCH_2CH=CH_2)_2 + KOBu(t) \longrightarrow$$

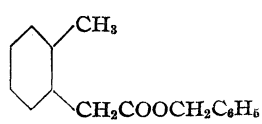
I

$$CH_2=CHCH_2CH_2COOCH_2CH=CH_2 + KBr + t\text{-BuOH}$$

II

$$BrCH_2CH(OCH_2C_6H_5)_2 + KOBu(t) \longrightarrow$$

III



$$+ KBr + t\text{-BuOH}$$

IV

(1) Mortenson and Spielman, THIS JOURNAL, **62**, 1609 (1940).

(2) Claisen, *Ber.*, **29**, 2931 (1896); Claisen and Haase, *ibid.*, **33**, 3778 (1900).
(3) Johnson, Barnes and McElvain, THIS JOURNAL, **62**, 964 (1940).

Undoubtedly the ketene acetal was the intermediate in each of these reactions, but it was so susceptible to rearrangement that it passed into the substituted acetic ester (II or IV) as rapidly as it was formed. It is interesting to note that these allylic rearrangements occur at or below the refluxing temperature (*ca.* 80°) of *t*-butyl alcohol which is an unusually low temperature for a rearrangement of this type. Also it should be noted that in the more widely studied rearrangements of the phenol ethers the allyl phenyl ethers generally rearrange with inversion of the allyl radical, while benzyl phenyl ether, in contrast to the allyl ethers and to the above benzylacetal, rearranges to the *o*- and *p*-benzyl phenols,[4] without any inversion of the benzyl radical.

Two reports of the pyrolysis of an orthoester into a ketene acetal and alcohol

$$RCH_2C(OEt)_3 \longrightarrow RCH{=}C(OEt)_2 + EtOH$$

have appeared in the literature. Reitter and Weindel[5] reported this pyrolysis for the compound in which R is carbethoxy and Staudinger and Rathsam[6] reported a similar behavior for the compound in which R is phenyl. These latter authors also reported that ethyl orthoacetate underwent a different type of pyrolysis, *viz.*, into ethyl acetate and ether, when passed over nickel on pumice at 250–260°.

Since, in some cases, orthoesters appear to pyrolyze into ketene acetals it seemed of interest to undertake a study of the pyrolysis of a variety of orthoesters and to determine, if possible, if there is any general tendency for them to pyrolyze into ketene acetals. In some preliminary experiments with ethyl orthoacetate it was found that this orthoester, when heated at 200° for twenty hours in a steel bomb with a glass liner, yielded alcohol, ethyl acetate and ethylene. These products could be the result of the pyrolysis of the orthoester into alcohol and ketene acetal followed by the pyrolysis of the acetal into ethylene and ethyl acetate. That this was actually the course which the pyrolysis took was shown by the products obtained when the orthoester was heated with an equivalent of phenol. It has been found in earlier work that the mixed orthoester obtained by the addition of phenol to ketene acetal decomposed on distillation into ethyl acetate and phenetole.[7] When ethyl orthoacetate was heated with phenol no ethylene was formed and practically quantitative yields of ethyl acetate and phenetole were obtained. The following sequence of reactions illustrates these transformations

$$CH_3C(OEt)_3 \xrightarrow{200°} CH_2{=}C(OEt)_2 + EtOH$$

$$CH_2{=}C(OEt)_2 + C_6H_5OH \longrightarrow CH_3C(OEt)_2OC_6H_5 \longrightarrow CH_3COOEt + C_6H_5OEt$$

The ability of phenol to divert the ketene acetal into phenetole as rapidly as it is formed and before it is pyrolyzed into ethylene and ethyl acetate made possible the study of the decomposition of a mixed orthoester of the type $CH_3C(OR)_2OR'$. Such an ester, on pyrolysis, could follow two reaction courses, A and B, and the extent of each reaction would be measured by the amount of each of the alcohols, ROH and R'OH, among the reaction products. An additional measure of the extent of reaction B would be given by the sum of the products, C_6H_5OR' and CH_3COOR', which result from the decomposition of the mixed orthoester (V) by reactions M and N.

$$CH_3C(OR)_2OR' \begin{cases} \xrightarrow{A} R'OH + CH_2{=}C(OR)_2 \xrightarrow{C_6H_5OH} CH_3C(OR)_2OC_6H_5 \longrightarrow CH_2COOR + C_6H_5OR \\ \xrightarrow{B} ROH + CH_2{=}C(OR)OR' \xrightarrow{C_6H_5OH} \underset{V}{CH_3C(OR')(OC_6H_5)_2} \begin{cases} \xrightarrow{M} CH_3COOR' + C_6H_5OR \\ \xrightarrow{N} CH_3COOR + C_6H_5OR' \end{cases} \end{cases}$$

Table I is a summary of the results obtained from the pyrolysis of a number of orthoesters. In general, the esters of the unsubstituted acetic acid (runs 1–9) were heated at 200° for twenty hours in order to insure complete pyrolysis. The esters of the substituted acetic acids were heated at the same temperature and, in some cases, for shorter periods of time in order to show roughly their relative tendency to pyrolysis. In the cases of the mixed orthoesters (runs 3–9) the total percentage of reaction (100% in all runs) is subdivided into the per cent. of each of the reactions A, B, M and N and the ratios of the pyrolysis products ROH to R'OH and CH_3COOR' to C_6H_5OR', *i. e.*, B/A and M/N is indicated. [a] In another run of this orthoester in which phenol was used, the total yield (97%) of the acetic ester in this run was composed of ethyl ethoxyacetate (47%) and phenyl ethoxyacetate (53%). [b] In this run 43% of the bromo-orthoester was recovered unchanged. [c] In this run no orthoester was recovered; in addition to the bromoacetic ester indicated above, 0.5 g. of acetaldehyde (identified as the 2,4-dinitrophenylhydrazone), 4 g. of ethyl bromide, 4.3 g. of ethyl acetate and a small amount of water (copper sulfate test) were obtained from a 30 g. run of the orthoester. [d] In this run 0.6 g. acetaldehyde, 11 g. of ethyl bromide, 2.9 g. of ethyl acetate, 10.8 g. of ethyl monobromoacetate and some water and alcohol were isolated from a 50 g. run of the orthoester.

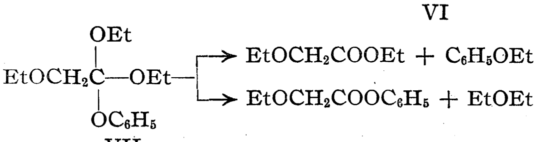
simple orthoesters (R = R′ = C_2H_5) in runs 10–16 were pyrolyzed without phenol and the total percentage of reaction is given in the sixth (reaction A) column of the table. These values were obtained from the amounts of acetic ester and unchanged orthoester that were present in the bomb after the heating period shown.

Runs 1 and 2 of Table I show that the time necessary for complete pyrolysis of ethyl orthoacetate at 200° is between ten to twenty hours. The behavior of the mixed orthoesters in runs, 3, 4, 6 and 9 show that the primary alkyl groups of either the normal or iso structure have practically the same tendency to be eliminated in the form of R′OH (reaction A). In each of these runs approximately one-third of the orthoester decomposes with the loss of the single alkyl group (R′) and two-thirds by the course in which one of the two like alkyl groups (R, reaction B) is lost. The neopentyl group (run 7) shows a noticeably greater tendency to be eliminated than do the other primary alkyl groups. The *s*-butyl group (run 5) and the benzyl group (run 8) are decidedly more resistant to elimination than are the ethyl and the other primary alkyl groups. Since the pyrolysis of an orthoester to a ketene acetal (reactions A and B) involves a rupture of the bond that holds the alkoxyl group in the orthoester, the behavior of the various alkyl groups in the mixed orthoesters is in line with the well-known fact that the oxygen–hydrogen bond is more reactive and the alkyl–oxygen bond less reactive in primary alcohols than in secondary (or benzyl) alcohols. In the decomposition of the mixed orthoester V it seems safe to assume that the phenyl ether is eliminated as C_6H_5O— and R (or R′) since in phenol the phenyl–oxygen bond is very stable as compared to the oxygen–hydrogen bond and also because of the high yields of the *s*-butylphenyl ether and benzylphenyl ether (reaction N, runs 5 and 8). It is interesting to note that reactions M and N take place to practically the same extent when R′ is *n*-butyl, isobutyl, isoamyl and ethyl (runs 3, 4, 6 and 9). This shows that these primary alkyl-oxygen bonds are, as are the bonds that hold the RO— and R′O groups in the orthoester, of the same order of strength. The failure of the mixed orthoester V, when R′ is neopentyl (run 7, Table I), to follow reaction N to any extent in its decomposition, together with the relatively high amount of reaction A in the run, shows the marked difference in the strength of a bond attached to a neopentyl group and one attached to a neopentoxy group.

In the group of ethyl esters of the substituted orthoacetic acids a number of interesting results

appear. Of all of the orthoesters that were studied the ethyl orthoethoxyacetate was pyrolyzed (runs 10 and 11) most readily. In one run (see footnote (a), Table I) in which the orthoester was pyrolyzed in the presence of phenol the resulting acetic ester was composed of about equal amounts of the phenyl and the ethyl esters. These products indicate that the mixed orthoester (VII), resulting from the addition of phenol to ethoxyketene acetal (VI), breaks down in two different ways, thus

$$EtOCH_2C(OEt)_3 \longrightarrow EtOH + \underset{VI}{EtOCH{=}C(OEt)_2} \xrightarrow{C_6H_5OH}$$



VII

The ethyl orthochloroacetate (runs 12 and 13) behaved as did the other orthoesters and, in contrast to the ethoxyacetate, is no more susceptible to pyrolysis than is ethyl orthoacetate. The bromo-substituted orthoesters, however, show a marked variation from the other orthoesters in the pyrolysis behavior. The yields of the corresponding bromo-acetic esters that were obtained from the pyrolyses that went to completion (runs 15 and 16) are quite low. Numerous other unexpected products (see footnotes *c* and *d*, Table I) were isolated from these pyrolyses. These products can best be explained upon the assumption that two competing modes of decomposition are followed by these esters. The one of these that occurs to the lesser extent, is the route (reactions A and B) that is followed by the other orthoesters.

The other, and main, reaction route appears to be connected with the positive character of the bromine of the mono and dibromo derivatives of ethyl orthoacetate[8] and to involve the loss of the elements of ethyl hypobromite from the orthoester. A ketene acetal with one less bromine than the original orthoester would be the result of this decomposition.[9] This ketene acetal would then pyrolyze into the corresponding acetic ester and ethylene or add hydrogen bromide (see below) to form the same acetic ester and ethyl bromide. Ethyl hypobromite does not appear to have been described in the literature, but if it were momentarily formed it would be expected to decompose into acetaldehyde and hydrogen bromide in a manner similar to that reported for ethyl hypochlorite.[10] The interaction of hydrogen bromide and alcohol to produce water explains the last of the various and unexpected products that were isolated from the pyrolyses of the orthobromoesters. The formation of these products from the pyrolysis of ethyl orthodibromoacetate is illustrated below.

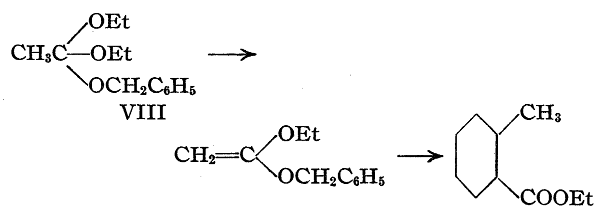
$$CHBr_2C(OEt)_3 \longrightarrow EtOH + Br_2C{=}C(OEt)_2 \longrightarrow Br_2CHCOOEt + C_2H_4$$

$$CHBr_2C(OEt)_3 \longrightarrow EtOBr + BrCH{=}C(OEt)_2 \longrightarrow BrCH_2COOEt + C_2H_4$$

$$Br_2C{=}C(OEt)_2 \text{ (or } BrCH{=}C(OEt)_2) + HBr \longrightarrow EtBr + Br_2CHCOOEt \text{ (or } BrCH_2COOEt).$$

$$CH_3CH_2OBr \longrightarrow CH_3CHO + HBr \xrightarrow{EtOH} EtBr + H_2O$$

The isolation of benzyl *o*-tolylacetate (IV) instead of the ketene acetal from the dehydrobromination of dibenzylbromoacetal (III) suggested the pyrolysis of benzyldiethyl orthoacetate (VIII) in the absence of phenol. This orthoester appears from run 8 of Table I to decompose to the extent of 84% into the mixed ketene acetal (IX) which, if not immediately diverted through reactions M and N by phenol, should rearrange into ethyl *o*-tolylacetate (X), thus



VIII IX X

When the orthoester VIII was heated alone at 200° for twenty-four hours there was considerable non-distillable tar produced, but from the volatile liquid portion of the pyrolysis mixture it was possible to isolate about 14% of the theoretical amount of X.

Finally an orthoester that has no α-hydrogen, and consequently cannot be converted into a ketene acetal, was pyrolyzed. Ethyl orthobenzoate, when refluxed gently under atmospheric pressure (b. p. 220–225°), slowly decomposed into the normal ester and diethyl ether.

$$C_6H_5C(OEt)_3 \longrightarrow C_6H_5COOEt + Et_2O$$

After six hours this decomposition amounted to 60%.

(8) McElvain and Walters, This Journal, **64**, 1963 (1942).

(9) The general method of preparation of ketene acetals involves the removal of the elements of ethyl hypohalite from α-halogenated orthoesters by means of sodium [Walters and McElvain, *ibid.*, **62**, 1482 (1940); McElvain, Clarke and Jones, *ibid.*, **64**, 1966 (1942)].

Experimental

The ketene diethylacetals that were used in the pyrolysis experiments and for the preparation of mixed orthoesters were prepared by procedures previously described.[3,11] In the pyrolysis experiments ketene, chloroketene and bromoketene diethylacetals were used.

Methyl Orthobromoacetate and Ketene Dimethylacetal.—This acetal could not be prepared from the bromodimethylacetal by the action of potassium *t*-butoxide in *t*-butyl alcohol because the ketene acetal boiled (89–91°) too near to the alcohol to allow them to be separated. Consequently, it had to be prepared from methyl orthobromoacetate by the action of metallic sodium.[12] This bromoester was obtained by the bromination of methyl orthoacetate, prepared by the method of McElvain and Nelson[13] from acetonitrile, according to the procedure described for the preparation of ethyl ortho-α-bromoisovalerate.[14] **Methyl orthobromoacetate,** b. p. 74–75° (17 mm.); d^{25}_4 1.4771; $n^{25}D$ 1.4501, was obtained in yields of 70% of the theoretical.

Anal. Calcd. for $C_5H_{11}O_3Br$: Br, 40.15. Found: Br, 40.33.

Ketene dimethylacetal, b. p. 89–91° (740 mm.); d^{25}_4 0.9274; $n^{25}D$ 1.3962, was obtained from the bromoester[12] in 65% yields.

Anal. Calcd. for $C_4H_8O_2$: C, 54.53; H, 8.93. Found: C, 54.31; H, 9.15.

The Pyrolysis of Ketene Diethylacetals

(a) **In Glass Tubes.**—Pyrex bomb tubes of 80-ml. capacity were washed with alcohol and ether and then filled with concentrated aqueous sodium hydroxide and allowed to stand for four hours. Then they were washed with distilled water, alcohol and ether. When rigorous anhydrous conditions were used the tubes were heated in a bunsen flame, stoppered with a calcium chloride tube, and allowed to cool. Approximately 5 g. of the ketene acetal was placed in the tube; when extreme precautions against moisture were used the acetal was distilled directly into the dried bomb tube. After sealing, the tube was heated in a bomb furnace at 200° for six hours, after which time it was cooled in an acetone–dry-ice mixture and opened. All tubes contained a high pressure of an inflammable gas (ethylene). The acetic ester remaining in the tube was distilled and weighed. When new, rigorously dried tubes were used the pyrolysis never amounted to more than 20% of the ketene acetal; in used tubes, similarly dried, the amount of pyrolysis rose to 50%; in air-dried, used tubes the pyrolysis was complete in six hours at 200°.

(b) **In a Steel Bomb.**—A solution of 20–30 g. of the ketene acetal in 40–60 ml. of cyclohexane (if a solvent is not used the reaction product is invariably a tar) was placed in a 500-ml. steel hydrogenation bomb that was fitted with a valve for the release of gas pressure and heated at 200° for six hours. Under these conditions the pyrolysis of the ketene acetals was complete. However, when a temperature of 150° was used there was no appreciable decomposition of the ketene acetal even after twenty-four hours. After cooling the ethylene was slowly released from the valve in the bomb, through two dry-ice traps, into an aspirator from which the ethylene determination was made. The yields of ethylene in these runs generally were 5–10% lower than those of the esters. The amounts of esters were determined in the case of ethyl acetate from the refractive index of the cyclohexane solution and, in the cases of the ethyl halogenocetates, by fractional distillation.

(c) **In Furnace.**—A 50-cm. Pyrex tube, loosely packed for a length of 17 cm. with either glass chips, manganese dioxide, aluminum oxide, zinc oxide or chromic oxide was heated in a short (35 cm.) electric furnace. The temperature was read from a pyrometer placed in the interior of the tube. The ketene acetal in 10–20 g. samples, was added dropwise into one end of the furnace from a dropping funnel protected with a calcium chloride tube and the gases from the furnace were conducted into a 50-ml. receiving flask that carried an efficient reflux condenser. The vapors that passed from the top of the reflux condenser were led through a cold trap surrounded by a dry-ice–acetone mixture and into a pair of 25-cm. test-tubes in series, each containing 50 g. of bromine. The last bromine tube was connected to an aspirator of about 8-liters capacity.

The acetic ester formed in the pyrolyses was determined by distillation of the material in the first receiving flask and the cold trap. The only contaminant of this ester was a small amount of unchanged ketene acetal. The amount of ethylene bromide in the two bromine tubes gave a measure of the ethylene (generally 10–25% below the yields of the esters) that was formed in the reaction. The yields of ester from all of the ketene acetals used, either through an unpacked tube or one packed with glass chips, were 80% or more at 400° and practically zero at 300°. With manganous oxide and aluminum oxide, however, ester yields of 80% and 60%, respectively, were obtained at 300°. Zinc and chromium oxides gave very little improvement in ester yield at this lower temperature over that obtained from an unpacked tube.

A 20-g. sample of ketene dimethylacetal was heated in a sealed glass tube at 200° for twenty-four hours as in procedure (a). When the tube was cooled, opened and the contents distilled, 95% of unchanged ketene dimethylacetal was recovered.

Diallylbromoacetal.—To 86.1 g. (1 mol) of freshly distilled vinyl acetate was added with stirring 60 g. (1 mol) of bromine over a period of two hours. The temperature was not allowed to go above 5°. The resulting mixture was added with stirring to 290 g. (5 ml.) of anhydrous allyl alcohol over a period of three hours. The reaction mixture then was allowed to come to room temperature slowly and stirred overnight. After this time 100 ml. of water was added to the vigorously stirred mixture, followed by small portions of potassium carbonate, until the solution was no longer acidic. The aqueous layer was removed and the remaining product dried over anhydrous potassium carbonate. On distillation the fraction boiling at 101–102° (20 mm.); $n^{25}D$ 1.4712[15] was collected. The yield amounted to 100 g. (45%); % Br, 35.9 (calcd. 36.0).

Allyl Allylacetate from Diallylbromoacetal.—To a solution of 39 g. (1 atom) of potassium in 550 g. of *t*-butyl

alcohol was added 220 g. (1 mol) of diallylbromoacetal. After refluxing for five hours the mixture was cooled to room temperature and the precipitated potassium bromide removed by centrifuging. It weighed 108 g. (90%). After removal of the *t*-butyl alcohol the reaction product was fractionated carefully through a 15-cm. Widmer column. After 7 fractionations 60 g. (43%) of allyl allylacetate was obtained; b. p. 48–50° (8 mm.) or 160–162° (740 mm.); $n^{25}D$ 1.4198; d^{25}_4 0.8808; sap. equiv., 141 (calcd. 140).

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.55; H, 8.63. Found: C, 68.71, 68.53; H, 8.97, 8.67.

Saponification of this ester yielded allyl alcohol, 3,5-dinitrobenzoate,[16] m. p., 47–48°, and allylacetic acid, the anilide of which melted at 92°.[17]

Dibenzylbromoacetal.—This compound was prepared in the same manner as the allyl acetal described above, except that benzyl alcohol instead of allyl alcohol was used. The yield of product when 1 mole each of vinyl acetate and bromine and 5 moles of benzyl alcohol were used amounted to 475 g. (75%); b. p. 190–195° (2 mm.); $n^{25}D$ 1.5620; d^{25}_4 1.2181.

Anal. Calcd. for $C_{16}H_{17}O_2Br$: Br, 28.8. Found: Br, 28.7.

Benzyl *o*-Tolylacetate from Dibenzylbromoacetal.—The dehydrobromination of this bromoacetal was carried out in the same manner as described above for the diallylbromoacetal. From 321 g. (1 mol) of the bromoacetal was obtained 146 g. of a distillate which after three fractionations gave 110 g. (46%) of benzyl *o*-tolylacetate; b. p. 158–162° (1.5 mm.); $n^{25}D$ 1.4575; d^{25}_4 1.0773.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71. Found: C, 80.01, 79.90; H, 6.81, 6.90.

This ester showed a saponification equivalent of 242 (calcd., 240) and from its saponification was isolated benzyl alcohol, the α-naphthylurethan of which[18] melted at 133–134°, and *o*-tolylacetic acid,[19] m. p. 89–90°.

Preparation of Orthoesters.—The mixed orthoesters were prepared by the addition of the alcohol, R'OH, to the ketene acetal, $CH_2{=}C(OR)_2$. Triethyl orthoethoxyacetate and triethyl orthochloroacetate were prepared from the corresponding nitriles.[8,13] The mono- and dibromo-orthoacetates were prepared by the bromination of ethyl orthoacetate.[8,20] Ethyl orthobenzoate was prepared in the following manner. To a cold (5°) solution of 69 g. (3 atoms) of sodium in 1200 ml. of absolute alcohol in a 2-liter, 3-neck flask, fitted with a reflux condenser, a stirrer and a dropping funnel, was added dropwise 195 g. (1 mol) of benzotrichloride, b. p. 85–87° (10 mm.). After the chloride had been added the ice-bath was removed and the solution stirred for five hours while it came to room temperature. The reaction mixture then was refluxed for eleven hours, after which time it was cooled and the salt filtered off. This salt was washed with ether and the ether washings added to the alcoholic filtrate. The yield of salt was 100 g. (58%). After distillation of the ether and alcohol the remaining orthoester was fractionated through a modified Widmer column. The yield of ester, b. p. 108–112 (13 mm.)[21] amounted to 50 g. (22%).

The properties and analyses of those orthoesters that have not been described previously are listed in Table II.

Pyrolysis of the Orthoesters.—A 0.1-mole sample of the ester and one equivalent of phenol (in runs 3–9) were placed in the glass liner (40-ml. capacity) of a steel bomb and the bomb electrically heated for the time indicated in Table I. After this time the bomb was cooled and opened and its contents fractionated through a 15-cm. modified Widmer column. In the cases of the mixed orthoesters (runs 3–9, Table I) the ROH and CH_3COOR were taken off as one fraction and R'OH and CH_3COOR' as another fraction under atmospheric pressure. The ester was determined in each of these fractions by saponification values and the remainder of the fractions calculated as the alcohol. The ethers, C_6H_5OR and C_6H_5OR', were removed from the remainder of the reaction mixture by fractionation under diminished pressure.

The properties of *n*-butyl-, isobutyl-, isoamyl- and benzyl phenyl ethers correspond to those previously reported in the literature.[22,23,24,25]

s-Butylphenyl ether appears not to have been previously described in the literature. The product isolated from run 5, Table I boiled at 184–185°; d^{25}_4 0.9210; $n^{25}D$ 1.4828.

Anal. Calcd. for $C_{10}H_{14}O$: C, 80.0; H, 9.4. Found: C, 79.9; H, 9.3.

In runs 10–16, Table I, the substituted acetic esters, $XCH_2COOC_2H_5$ and other pyrolysis products were separated by fractional distillation. In these runs no phenol was used. However, one run with ethyl orthoethoxyacetate was carried out in the presence of one equivalent of phenol and both the ethyl ethoxyacetate and the

phenyl ethoxyacetate[26] along with diethyl ether and phenetole were isolated (*cf.* footnote *a* Table I).

The pyrolyses of the halogen containing orthoesters were carried out in sealed glass tubes as these esters at the temperature of the reaction attacked the inside of the iron bomb. When the glass tube was opened after the pyrolysis there was a considerable release of pressure (ethylene). The remaining liquid material was fractionated. From the ethyl orthobromoacetate pyrolysis (run 15, Table I) the following fractions were collected (a) 0.5 g., b. p. about 20°; (b) 10 g., b. p. 37–38°; (c) 6.6 g., b. p. 61–73°; (d) 11.2 g., b. p. 55–60° (11 mm.). Fraction (a) was acetaldehyde, m. p. of 2,4-dinitrophenylhydrazone, 146–147°; fraction (b) after washing with concentrated sulfuric acid weighed 4 g., and had the density and index of refraction of ethyl bromide; fraction (c) was composed of ethyl alcohol, ethyl acetate and water and saponification indicated the presence of 4.3 g. of the ester; fraction (d) possessed the lachrymatory characteristics of ethyl bromoacetate and its bromine content indicated that it contained 7.7 g. of this ester.

The fractionation of the liquid portion of run 16, Table I, yielded the products listed in footnote (d) of the table, together with 5.8 g. (15%) of ethyl dibromoacetate, b. p. 38–45° (2 mm.).

Pyrolysis of Benzyldiethyl Orthoacetate in the Absence of Phenol.—A 34-g. (0.15 mole) sample of this orthoester was heated at 200° for twenty-four hours, after which time the bomb was opened and the products fractionated. There was the usual pressure of ethylene produced by the pyrolysis. In the first fractionation the following fractions were collected (a) 6.7 g., b. p. 73–78° (740 mm.); (b) 4 g., b. p. 190–210° (740 mm.); (c) 5.6 g., b. p. 104–120° (10 mm.); (d) 1.5 g., b. p. 120–160° (10 mm.). A considerable amount of tar remained after this distillation. Fraction (c) was refractionated and collected as the following fractions (c-1) 0.3 g., b. p. 60–71° (3 mm.); (c-2) 0.4 g., b. p. 72–74° (3 mm.); (c-3) 0.6 g., b. p. 74–75° (3 mm.); (c-4) 0.8 g., b. p. 76–77° (3 mm.); (c-5) 2.3 g., b. p. 78–83° (3 mm.). A 1-g. residue remained after this second fractionation. Fraction c-4 showed the correct carbon and hydrogen content for ethyl *o*-tolylacetate[27] and had $n^{25}D$ 1.4990; d^{25}_4 0.9988.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.1; H, 7.9. Found: C, 74.1; H, 7.8.

Fraction c-5 was saponified and the *o*-tolylacetic acid obtained was identified as its amide.[19] If fractions c-3, c-4 and c-5 are considered to be ethyl *o*-tolylacetate, the yield of this rearrangement product amounts to approximately 14% of the theoretical.

Pyrolysis of Ethyl Orthobenzoate.—A 10-g. sample of this orthoester was gently refluxed (b. p. 220–225°) for six hours under a 40-cm. air condenser, the top of which was connected to a cold trap. After this time 1.6 g. of ether, b. p. 35°, had collected in the cold trap. The ester in the flask was fractionated and separated into 4 g. (60%) of ethyl benzoate and 4 g. of unchanged ethyl orthobenzoate.

(26) Sommelet, *Bull. soc. chim.*, [4] **1**, 368 (1907).

(27) The use of ethyl *o*-tolylacetate has been mentioned in two instances in the literature [Ruzicka and Hosking, *Helv. Chim. Acta*, **13**, 1411 (1930); V. Braun and Zobel, *Ber.*, **56**, 2147 (1923)] but no reference to a description of its properties or to its analysis could be found.

Summary

Ketene diethylacetal and its halogenated derivatives have been found to undergo pyrolysis at 200° with the formation of ethylene and the corresponding ethyl acetate. Ketene dimethylacetal, however, is quite stable at this temperature.

Attempts to prepare ketene diallyl- and dibenzylacetal have resulted in the isolation of the respective rearrangment products, allyl allylacetate and benzyl *o*-tolylacetate.

Ketene acetals have been shown to be the intermediates in the pyrolysis of a variety of orthoesters that have a structure that permits the decomposition to take the course

$$R_2CHC(OR')_3 \longrightarrow R'OH + R_2C{=}C(OR')_2$$

The pyrolysis of mixed orthoesters of the type $CH_3C(OR)_2OR'$ has been studied and the relative tendencies of these esters to eliminate the OR and OR′ groups determined. Diethylbenzyl orthoacetate on pyrolysis yields some ethyl *o*-tolylacetate as the result of the rearrangement of the intermediate ketene ethylbenzylacetal.

While ethyl orthochloroacetate follows the course of the other orthoesters on pyrolysis, the ethyl orthobromo- and orthodibromoacetates give only a small amount of this type of decomposition. The main products that result from the pyrolysis of these bromoesters appear to be the result of an initial loss of the elements of ethyl hypobromite (instead of ethyl alcohol) from the bromoester with the formation of a ketene acetal that contains one less bromine than the original orthoester.

Ethyl orthobenzoate, which has no α-hydrogen, yields the normal ester and diethyl ether on pyrolysis.

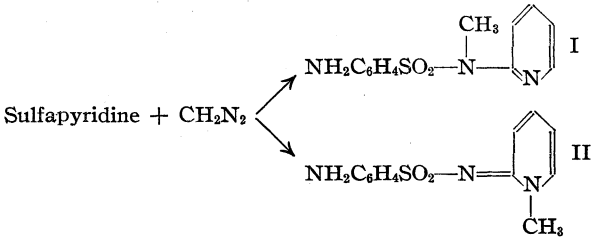
Properties of the Nitrogen–Carbon–Nitrogen System in N^1-Heterocyclic Sulfanilamides[1]

BY ROBERT G. SHEPHERD, A. CALVIN BRATTON[2] AND KENNETH C. BLANCHARD

Our chemotherapeutic studies led to the preparation of two types of isomeric derivatives of certain sulfanilamido heterocycles. The structures of these derivatives were determined[3] and direct evidence for the constitution of the parent sulfonamides was obtained by means of ultraviolet absorption measurements.

2-Sulfanilamidopyridine and 2-sulfanilamidothiazole[4] in absolute ether suspension both react rapidly with diazomethane at room temperature to give two methylated isomers. Although 2-(N^4-acetylsulfanilamido)-pyridine[5] under the same conditions reacts much more slowly, a mixture of two products likewise results. This reaction and others throughout this paper will be illustrated by sulfapyridine to represent the behavior of any of the three sulfonamides mentioned above. The



yield-ratio of I:II was 70:30 with the first two substances and 60:40 with the acetyl compound.

The structures of types I and II were determined by three methods. Hydrolysis of both types with 12 *N* hydrochloric acid gave sulfanilic acid and bases whose picrates or hydrochlorides were identified by mixed melting points with the same salts of bases of established structures. The preparation of the N^1-methyl[5] derivative (I) from N^1-methyl-N^4-acetylsulfanilamide and 2-bromopyridine[6] served as a check on the degradation procedure. Structures of type II were also obtained by synthesis from acetylsulfanilyl chloride and the corresponding base of known structure. The products of these two syntheses as well as the amines prepared by de-acetylation were compared by mixed melting points with the corresponding products from the diazomethane reaction.

Alkylation of the sodium salts of sulfapyridine, sulfathiazole and N^4-acetylsulfapyridine with dimethyl sulfate or various alkyl halides was found to produce compounds of type II. The structures of all the products were determined as described above in order to see if the product varied with the alkylating agent. Although our work does not eliminate the possibility of some N^1-alkylation, the main product in each case had structure II. Many of these substances have been erroneously assigned[7] structure I. Our structural conclusions are in direct opposition to the work of Ewins and Phillips, which presumably showed that alkylation of sodium 2-sulfanilamidopyridine produced N^1-alkyl derivatives. They reported the formation of N^1-methyl-2-(N^4-acetylsulfanilamido)-pyridine from condensation of N^1-methyl-N^4-acetylsulfanilamide and 2-bromopyridine by the Ullmann method and from coupling acetylsulfanilyl chloride with 2-methylaminopyridine. The products from both reactions melted at 231° and were de-acetylated to an amine melting at 225°. The corresponding substances from sodium salt methylation were found to have the same melting points and were therefore designated as N^1-methyl derivatives. The acetyl compound which we obtained from the Ullmann synthesis melted at 119.5–120.0° and gave on de-acetylation an amine melting at 86.5–87.0°. We were unable by exhaustive purification to raise these melting points to the values reported. Moreover, our results obtained from acid degradation and from unequivocal syntheses prove conclusively that these products are isomers of

(2) Lalor Foundation Fellow.

(3) After completion of the present work, the proof of structure of certain of the 2-sulfanilamidothiazole derivatives described herein was reported by Druey, *Helv. Chim. Acta*, **24**, 226E (1941), and Jensen, *ibid.*, **24**, 1249 (1941).

(4) The usual names for these substances have been retained although our results indicate that 2-sulfanilimido-1,2-dihydropyridine and 2-sulfanilimido-2,3-dihydrothiazole are perhaps just as correct. They are hereafter referred to as sulfapyridine and sulfathiazole.

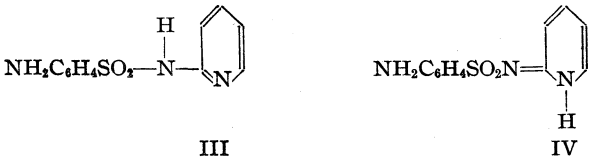
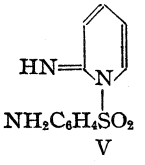
those resulting from sodium salt methylation. Contrary to the evidence of Phillips,[7] we have shown that reaction of sodium sulfapyridine with ethyl chloroacetate or chloroacetamide produces ring nitrogen substitution.

The sulfanilamido heterocycles prepared by coupling acetylsulfanilyl chloride with a heterocyclic amine may have the following three structures (illustrated by sulfapyridine)



III IV



V

Structure V is eliminated by the preparation from sulfapyridine and sulfathiazole of *two* isomeric methyl derivatives as well as by their proof of structure. Likewise, Phillips' synthesis[6] of sulfapyridine from sulfanilamide and 2-bromopyridine excludes V. Structure IV cannot be eliminated on the basis of the evidence proposed by Crossley, *et al.*[8] The same sodium salt would be expected from III and IV since the negative ion of the salt is capable of resonance. Furthermore, the stability of these sulfonamides to alkaline cleavage is not valid evidence against IV since substituted compounds of that structure (such as II) are very stable compared to the 1-alkyl-2-pyridone imines. A more fundamental objection to the proposed analogy between IV and the 1-alkyl-2-pyridone imines is the fact that a compound having structure IV would first be changed in alkaline solution to a salt of unknown bond structure. The sodium salt alkylation cannot be used as suggested by Druey[3] as evidence of IV in the sulfanilamido heterocycles since this reaction involves a salt whose properties need have no simple relation to the parent.

The results of the diazomethane alkylation may indicate the presence of both III and IV. However, diazomethane cannot be considered a reliable diagnostic reagent for tautomeric equilibria if the reaction mechanism is ionic. In the case of compounds such as the sulfanilamido heterocycles which are capable of yielding a resonating negative ion, an ionic mechanism would invalidate its diagnostic use since the products would be determined by the electronic nature of this ion, obtainable by dissociation of H^+ from both tautomers. Moreover, even if the reaction is non-ionic, the rates of reaction of the tautomers with diazomethane must be approximately equal and be very great compared to the rate of tautomeric rearrangement in order to get a mixture of methyl derivatives comparable to the original tautomeric mixture.

These considerations necessitate a more direct approach to the constitution of such sulfonamides. A distinct difference was observed in the ultraviolet absorption spectra of the methyl derivatives represented by structures I and II, and comparison was made with the spectra of the parent compounds.

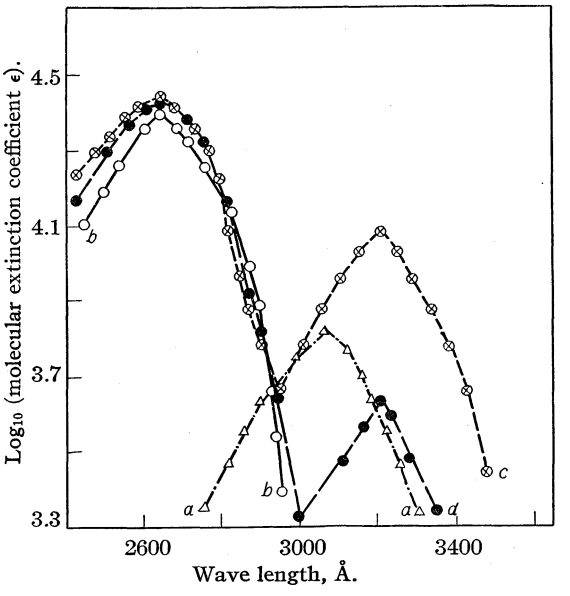


Fig. 1.—(a) △, 1-(β-Hydroxyethyl)-2-pyridone imine (Hilger-1 mg. %); (b) ○, N¹-methyl-2-(N⁴-acetylsulfanilamido)-pyridine (Hilger-0.5 mg. %); (c) ⊗, 1-methyl-2-(N⁴-acetylsulfanilimido)-1,2-dihydropyridine (Hilger-0.5 mg. %); (d) ●, 2-(N⁴-acetylsulfanilamido)-pyridine (Hilger-1 mg. %). The peaks at 3215 Å. in (c) and (d) had log ε = 3.98 (5.2 mg. %) and 3.7 (8.1 mg. %), respectively, when determined with the Beckman instrument.

The peak at 3215 Å. in Fig. 1 is assigned to the pyridone imine structure since it appears in (a) and (c) and not in (b). Likewise, the maximum at 2600 Å. in Fig. 2 is exhibited only by (a) and (d) which are known to contain the thiazolone imine structure and is not shown by the isomeric constitution (c). Qualitatively, the presence of structure IV in N⁴-acetylsulfapyridine, sulfapyri-

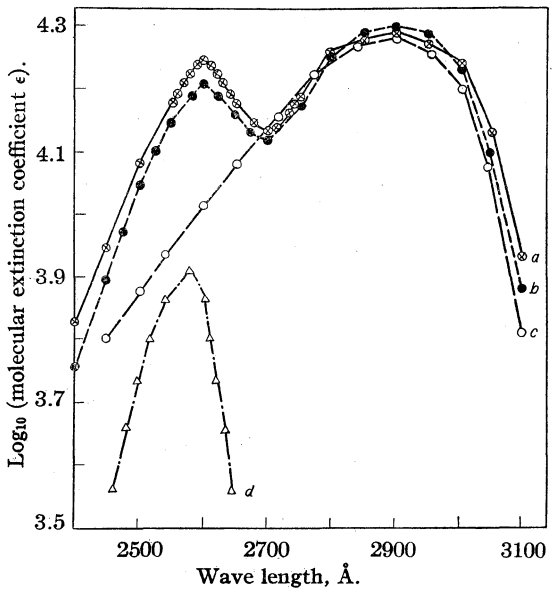

Fig. 2.—(a) ⊗, 3-Methyl-2-sulfanilimido-2,3-dihydrothiazole (Beckman-4.1 mg.%); (b) ●, 2-sulfanilamidothiazole (Beckman-2.6 mg. %); (c) O, N^1-methyl-2-sulfanilamidothiazole (Beckman-4.2 mg. %); (d) Δ, 3-methyl-2-thiazolone imine (Hilger-1 mg. %)—whole curve moved up 0.5 along ordinate axis.

dine and sulfathiazole is demonstrated by the observation of these maxima. The quantitative use of these results to determine the amount of this structure is based on the reasonable assumption that the extinction coefficients of the methyl derivatives are approximately the same as those of the corresponding hydrogen compounds. Therefore, the quantitative conclusions are not rigorous but are estimations subject to the limitations of this assumption.

On the basis of data obtained with the Beckman spectrophotometer, N^4-acetylsulfapyridine contains about 60% of structure IV. The spectra of sulfapyridine and its methyl derivatives show that this sulfonamide is similarly constituted. The maximum at 3215 Å. in 1-methyl-2-sulfanilimido-1,2-dihydropyridine has a slightly lower extinction coefficient ($\log_{10} \epsilon = 3.93$) than in its acetyl derivative. Although these measurements were made on absolute ethanol solutions, we observed the pyridone imine absorption in a few results on 95% ethanol or aqueous solutions. This is confirmed by Scudi's curve[9] for sulfapyridine in water which showed the characteristic pyridone imine maximum at about 3200 Å. The amount of this absorption indicates that a considerable proportion of tautomer IV is also present in aqueous solution. The absorption of sulfathiazole at 2600 Å. corresponds to the presence of about 90% of structure IV. The curve for this substance is the same as that found by Bergeim, *et al.*,[10] who also observed the 2600 Å. maximum in the 4-methyl and ethyl derivatives.

The region of absorption of the pyridine and thiazole rings has not been investigated at present. Observation of the absorptions of these rings in sulfapyridine and sulfathiazole would be necessary to prove the presence of structure III. The available data prove the presence of IV but do not permit one to decide whether these substances have that structure entirely or are tautomeric mixtures of both III and IV.

TABLE I

In Vitro ACTIVITY RATIOS, USING THE MACLEOD STRAIN OF *E. coli*

Compound		Activity ratio[a]
2-Sulfanilamidopyridine		1[b]

	3-(β-Hydroxyethyl)-	1/128

[a] Based on the relative minimal inhibitory concentrations using an end-point reading after forty-eight hours incubation at 37°. [b] Taken as unity; actual min. inhib. concn. = 0.16 mg.%. [c] Taken as unity; actual min. inhib. concn. = 0.04 mg.%.

Chemotherapeutic Activity.—Table I shows the *in vitro* activity of these sulfonamides tested against *E. coli* in a synthetic medium by the method described in detail elsewhere.[11]

The *in vivo* activity of the ring N-methyl derivatives of sulfapyridine and sulfathiazole was determined in mice infected with β-hemolytic streptococcus (strain C 203) using the drug-diet method.[12] On the basis of blood concentrations, both were about equal to sulfanilamide in activity. Since it has been shown[13] that sulfapyridine and sulfathiazole are about equal to sulfanilamide in this infection, the two ring N-methyl compounds are as active as the parents. The ring N-(β-hydroxyethyl) derivatives appear to be as active as the

unsubstituted sulfonamides against this streptococcus infection; the quantitative data have been reported elsewhere.[13]

When tested in a pneumococcus infection (Neufeld type I) of mice, both N^1-methyl derivatives (Table I) appeared to be practically inactive and quite toxic. On the other hand, the ring N-methyl isomers were active, less toxic than the N^1-methyl compounds and apparently less active than the parents. The inactivity of N^1-methyl-2-sulfanilamidothiazole with respect to its ring N isomer was also observed in duck malaria.[14]

Experimental Section[15]

Methylation of Sulfonamides with Diazomethane.—Sulfapyridine and sulfathiazole react rapidly enough with diazomethane to permit distillation of this reagent into a stirred mixture of the sulfonamide and ether. This continuous procedure avoids the danger of handling 10-g. quantities of diazomethane.

Diazomethane (7.5 g.) was distilled[16] into a stirred mixture of 0.25 mole of sulfonamide (200 mesh) and 75 cc. of absolute ether at 15–20°. The evolution of nitrogen proceeded during the addition of this reactant and the mixture was subsequently stirred until this evolution ceased. After warming to the boiling point, the reaction mixture was filtered and the insoluble material extracted twice with hot ether containing 3% ethanol. The residue from this extraction was shaken with 2 *N* sodium hydroxide to remove starting material, and the residual insoluble ring-nitrogen derivative was recrystallized from 6 *N* acetic acid. The original ether filtrate and the ether extracts were combined and evaporated to a sirup which crystallized after cooling and seeding. This was suction-filtered and carefully washed dropwise with methanol and absolute ether. Methanol was used for recrystallization of the N^1-methyl derivative thus obtained. The yield of methylated products was 50–80% of the sulfonamide, depending, primarily, on its state of subdivision. The yield-ratio of N^1-methyl to ring N-methyl derivative was about 70:30. This ratio was changed only slightly by methylation of 2-sulfanilamidopyridine immediately after liberation from its sodium salt at about −100°.

The lower order of reactivity of 2-(N^4-acetylsulfanilamido)-pyridine with diazomethane under these conditions necessitates using smaller quantities than above. Since the spontaneous inflammability of the vapors was regularly observed, the use of large quantities is somewhat dangerous. Isolation of the two products was carried out in essentially the same way as above. The yield-ratio of N^1-methyl to ring N-methyl derivative was about 60:40. N^1-methyl-2-(N^4-acetylsulfanilamido)-pyridine: m. p. 119.5–120.0°; *colorimetric factor*, calcd., 0.564, obs., 0.557. 1-Methyl-2-(N^4-acetylsulfanilimido)-1,2-dihydropyridine: m. p. 239–40°; *colorimetric factor*, calcd., 0.564, obs., 0.555.

The N^1-methyl derivatives of sulfapyridine, acetylsulfapyridine and sulfathiazole are all quite soluble in methanol, ethanol and ether containing 3% ethanol; their isomers are only slightly soluble.

Methylation of Sodium Sulfonamides with Dimethyl Sulfate.—Four-tenths of a mole of sulfonamide was alkylated in alkaline solution as described by Ewins and Phillips.[7] The product was recrystallized from 300–400 cc. of 6 *N* acetic acid with charcoal decolorization, washed with 20% ethanol and dried at 120°; yield 140–50%. Recrystallization from ethanol resulted in further purification.

Increasing the amount of dimethyl sulfate used in one step or re-treating the reaction filtrate did not increase the yield of desired product but increased the production of an alkali-insoluble gum. An important constituent of this gum was shown to be the result of methylation of the arylamine group as well as the heterocyclic nitrogen.

Preliminary tests demonstrated that these conditions do not give satisfactory methylation of certain sulfanilamido heterocycles derived from imidazole, pyrimidine and pyrazine.

Sodium Sulfonamide Benzylation.—The procedure of Ewins and Phillips[7] was modified slightly by the use of a 75% ethanol reaction mixture which resulted in an increased yield. 1-Benzyl-2-(N^4-acetylsulfanilimido)-1,2-dihydropyridine; m. p. 213–4°; *colorimetric factor*, calcd., 0.452, obs., 0.458.

Acetic Acid Derivatives of 2-Sulfanilamidopyridine.—To 48 g. of sodium 2-sulfanilamidopyridine in 55 cc. of 50% ethanol was added a solution of 40 cc. of ethyl chloroacetate in 95 cc. of 95% ethanol and the mixture refluxed for one hour, then cooled and precipitated with ice and water.

(14) Marshall, Litchfield and White, *J. Pharmacol.*, **75**, 89 (1942).
(15) All the melting points recorded are corrected.
(16) Hellerman and Newman, THIS JOURNAL, **54**, 2864 (1932).

After filtration the solid was shaken thoroughly with ether, then with 2 *N* sodium hydroxide and finally washed well with water. The yield of 1-carbethoxymethyl-2-sulfanilimido-1,2-dihydropyridine was 18 g; m. p. 200.5–201.0° after recrystallization from absolute ethanol or methanol. *Colorimetric factor:* calcd., 0.514; obs., 0.534. 1-Carbethoxymethyl - 2 - (N^4 - acetylsulfanilimido) - 1,2 - dihydropyridine obtained from a similar reaction melted at 212–3°; *colorimetric factor:* calcd., 0.457; obs., 0.463.

Five grams of the first ethyl ester and 8.9 cc. of 11% potassium hydroxide in 98% methanol were refluxed together for twenty minutes. After acidification with 1.1 cc. of 12 *N* hydrochloric acid, the potassium chloride was separated from the hot solution. The crystals of 1-carboxymethyl-2-sulfanilimido-1,2-dihydropyridine resulting from the cooled filtrate were suction-filtered and washed free of chloride ion with water. A monohydrate melting at 97–98° (sealed tube) was formed on recrystallization from water; *colorimetric factor:* calcd., 0.529; obs., 0.529.

1 - Carbamidomethyl - 2 - sulfanilimido - 1,2 - dihydropyridine was prepared by reaction of the sulfonamide in alkaline solution with chloroacetamide; m. p. 230° (dec.); *colorimetric factor:* calcd., 0.562; obs., 0.555. Alkaline hydrolysis of the amide group produced an acid identical to that obtained by the same treatment of the ester described above.

Reaction of Sodium Sulfonamides with Ethylene Chlorohydrin.—The anhydrous sodium salt of N^4-acetylsulfapyridine or N^4-acetylsulfathiazole was refluxed for thirty minutes in an oil-bath at 130° with five moles of ethylene chlorohydrin. The mass was then cooled, powdered, washed with ether, dried and washed with dilute sodium hydroxide, followed by water. The crude products were recrystallized from 6 *N* acetic acid with the addition of charcoal. 1-(β-Hydroxyethyl)-2-(N^4-acetylsulfanilimido)-1,2-dihydropyridine; m. p. 217–8°. *Anal.* Calcd. for $C_{15}H_{17}N_3O_4S$: C, 53.72; H, 5.11; N, 12.53. Obs.: C, 53.67; H, 5.26; N, 12.64. 3-(β-Hydroxyethyl)-2-(N^4-acetylsulfanilimido)-2,3-dihydrothiazole; m. p. 231–2° (dec).

The former substance was de-acetylated by refluxing for two hours with 2 moles of 1 *N* alcoholic sodium hydroxide. After concentrating on the steam-bath, the crystalline mass was washed with a little water and recrystallized from water. The latter compound was de-acetylated by boiling thirty minutes with 6 *N* hydrochloric acid (3 cc. per g.), precipitated by neutralization and recrystallized from alcohol with charcoal decolorization. The yield of both hydrolysis products was about 50%, based on the original sodium salts.

Structure Determination by Acid Degradation.—All of these sulfanilamide derivatives were hydrolyzed by heating one to two hours in a steam-bath with 10 moles of 12 *N* hydrochloric acid. After cooling, the precipitated sulfanilic acid was collected and recrystallized from dilute hydrochloric acid. It was identified by its decomposition point, strong acidity in the absence of chloride ion and quantitative diazotization. The acid filtrate from the hydrolysis was concentrated and the heterocyclic base was either allowed to crystallize as the hydrochloride or sodium acetate was added to *p*H 4 and the base precipitated as a picrate in 80–90% yield. The picrates were recrystallized from water or ethanol and then compared with the salts of bases whose structures had been established in the literature indicated. The melting points of the latter salts are recorded in Table III. These values are the same as those found for the picrates from hydrolysis and for the mixed melting points of the two groups.

[k] This base is more conveniently prepared using dimethyl sulfate rather than methyl iodide; *cf.* Näf, ref. *e*.

The bases necessary for this comparison were synthesized by available methods, with the exception of 2-imino-3-(β-hydroxyethyl)-2,3-dihydrothiazole which was prepared as follows: In a large test-tube, a mixture of 4 g. of 2-aminothiazole and 8.6 g. of iodoethyl acetate was heated gradually in an oil-bath to about 130°, stirring the mixture constantly with a thermometer. Suddenly the temperature began to rise and the tube was placed in a cold oil-bath to prevent the temperature from exceeding 180°. After the reaction had subsided, the mixture was heated for thirty minutes at 150°, cooled and taken up in 15 cc. of hot absolute ethanol. The crystalline 2-imino-3-acetoxyethyl-2,3-dihydrothiazole hydroiodide, obtained on chilling, was recrystallized several times from glacial acetic acid; yield, 1.9 g.; m. p. 153.5–154.5°. *Anal.* Calcd. for $C_7H_{11}N_2O_2SI$: C, 26.76; H, 3.53. Found: C, 26.91, H, 3.41; m. p. of picrate 164–165° (recryst. from glacial acetic acid).

After hydrolyzing the ester by refluxing for thirty minutes with 1 *N* hydrochloric acid, the picrate was formed by adding picric acid to the concentrated and buffered hydrolyzate; m. p. 159.5–161.0° (recryst. from methanol). *Anal.* Calcd. for $C_{11}H_{11}N_5O_9S$: C, 35.39, H, 2.97. Found: C, 35.66, H, 3.04.

Structure Determination by Alkaline Degradation.—When 1 - (β - hydroxyethyl) - 2 - sulfanilimido - 1,2 - dihydropyridine was hydrolyzed by boiling for five hours with 6 *N* sodium hydroxide (10 cc. per g.), sulfanilamide and 1-(β-hydroxyethyl)-2-pyridone were obtained. It was found that the latter is dimorphic: m. p. 84–85° by rapid crystallization of the fused substance; m. p. 93.5–95° by slow crystallization from dilute solution. This accounts for the discrepancies in melting point which have been reported.[17]

It was impossible to decompose sulfapyridine under similar alkaline hydrolytic conditions. In this connection, it should be pointed out that in the short time required to completely decompose the alkyl pyridone imines with alkali, no appreciable cleavage of the ring N derivatives (II) of sulfapyridine was observed.

Structure Determination by Synthesis.—Coupling acetylsulfanilyl chloride with the 1-alkyl-2-pyridone imines[18] and 3-alkyl-2-thiazolone imines yields sulfonamides whose point of substitution is definitely established. This is also true for the product obtained by reacting N^1-methyl-N^4-acetylsulfanilamide with 2-bromopyridine according to the method of Ewins and Phillips.[7] The acetyl compounds prepared by these routes and the corresponding amines resulting from de-acetylation were proved to be identical with those prepared by alkylation of the acetylsulfanilamido and sulfanilamido heterocycles. The melting points are recorded in Table III; the mixed melting points were identical.

1-Carboxymethyl-2-sulfanilimido-1,2-dihydropyridine.—Having proved the position of substitution, there still remain two possible structures differing in the position of a hydrogen atom. One would be a carboxymethylpyridone imine derivative; the other, an aminopyridine betaine derivative. On methylation, the former would presumably give a methyl ester; the latter, an N-methyl derivative. On treating the compound in question with diazomethane, there was obtained a neutral substance which without purification contained 99.2% of an alkali-labile ester. Repeated treatment of the acid with dimethyl sulfate in alkaline solution gave no evidence of N^1-methylation. Although these results are not entirely conclusive, they indicate that the carboxymethyl-pyridone imine structure is probably correct.

Ultraviolet Absorption Measurements.—These data were obtained on absolute ethanol solutions with the aid of two instruments: a medium Hilger "Spekker" spectrograph employing a tungsten-steel arc as the light source and a 4-cm. cell; a Beckman quartz spectrophotometer with a hydrogen-discharge tube as the light source and a 1-cm. cell.

(18) Polyakova and Kirsanov, *cf. C. A.*, **35**, 2146 (1941).

Acknowledgment.—We are indebted to Drs. E. K. Marshall, Jr., J. T. Litchfield, Jr., and H. J. White for the determination of the chemotherapeutic activity of these substances. The ultraviolet absorption measurements with the Beckman spectrophotometer were obtained through the courtesy of the Department of Physiological Chemistry of the Johns Hopkins University. We are grateful to the American Cyanamid Company for the sulfapyridine and 2-aminopyridine, and to E. R. Squibb and Sons for the sulfathiazole used in this investigation.

Summary

1. 2-Sulfanilamidopyridine, 2-sulfanilamidothiazole and 2-(N^4-acetylsulfanilamido)-pyridine react with diazomethane to give both N^1-methyl and ring N-methyl derivatives, the ratio of products being 70:30 for the first two compounds and 60:40 for the last.

2. Alkylation of the sodium salts of these sulfonamides is shown to produce ring N-alkyl derivatives in all the cases examined.

3. The structures of the products from these two reactions have been conclusively determined by both degradative and synthetic methods.

4. The dimorphism of 1-(β-hydroxyethyl)-2-pyridone is demonstrated.

5. A method is proposed for determination of the constitution of the sulfanilamido heterocycles based on the comparison of the ultraviolet absorption spectra of the parent sulfonamide with the spectra of its two isomeric N-methyl derivatives. The available data indicate the presence of large amounts of the pyridone imine structure in sulfapyridine and N^4-acetylsulfapyridine solutions and of the thiazolone imine structure in sulfathiazole solution.

6. Chemotherapeutic results show that the ring nitrogen derivatives of sulfapyridine and sulfathiazole are approximately as active as the parent sulfonamides, while the isomeric N^1 compounds are practically inactive.

Carvacrolphthalein

BY MAX H. HUBACHER

According to Curt Ehrlich,[1] carvacrolphthalein has a melting point of 246–247° and produces a prolonged purgative effect as compared with phenolphthalein. The compound obtained in this Laboratory was different in these properties. It melted at 294° and was devoid of laxative activity, showing a potency of under 0.05.[2]

It is believed that Ehrlich's compound of melting point 246–247° was thymolphthalein, the melting point of which is described as being 246–247°[3] and that he probably used impure carvacrol containing a substantial amount of thymol in the preparation of his compound. When a mixture of equal parts of carvacrol and thymol was condensed with phthalic anhydride and the crude product purified by crystallizations, then thymolphthalein was obtained.

Thymolphthalein was also prepared for comparison and likewise found to lack laxative activity,[2] though it is also stated to be a laxative compound.[1] It forms in much higher yields than carvacrolphthalein under the same experimental conditions. Thymolphthalein was found to have a melting point six degrees higher than the one given in the literature.[3]

The diacetate is described here because it has never been mentioned in the literature.

Experimental[4]

Carvacrolphthalein (I).—Zinc chloride as a condensing agent gave only traces of I. The yields on I when using stannic chloride were quite low and various changes such as quantities of condensing agent, temperature, etc., did not improve yields. Technical carvacrol of solidification point −11 to −10° gave the same yields as Eastman Kodak Co. carvacrol of crystallizing point −2°.

15.0 g. (0.1 mole) of carvacrol, 7.4 g. (0.05 mole) of phthalic anhydride and 15.0 g. of anhydrous stannic chloride were stirred for one hour at 100°. Unreacted carvacrol was steamed out and the residual phthalic acid was removed by extraction with hot water. The semi-solid brown crude I was crystallized directly from acetic acid (1 g. in 5 ml.) yielding 1.78 g. of m. p. 264–275° (8%). Further crystallizations from acetic acid (1 g. in 30 ml.) gave colorless crystals of m. p. 293.5–294.7°.

Anal. Calcd. for $C_{28}H_{30}O_4$: C, 78.11; H, 7.02; mol. wt., 430. Found: C, 78.30; H, 6.86; mol. wt., 415 ± 44 (Rast, in camphor).

Carvacrolphthalein turns from colorless to blue at a *p*H of 9.5 to 10.5. The solution of I in concd. sulfuric acid is purple-red. The crystals of I are not easily affected by 0.1 *N* sodium hydroxide, but after wetting them first with ethanol, they dissolve quite readily.

Diacetylcarvacrolphthalein (II).—This compound was prepared by refluxing for one hour 2.15 g. of I, 2.0 g. of acetic anhydride, 10 ml. of acetic acid and one drop of concd. sulfuric acid; 2.49 g. (96%) was obtained. The pure compound recrystallized from ethanol (1 g. in 33 ml.) formed cubes and melted at 217.8–219.7°.

Anal. Calcd. for $C_{32}H_{34}O_6$: C, 74.68; H, 6.66; mol. wt., 514. Found: C, 74.97; H, 6.82; mol. wt., 471 ± 13 (Rast, in camphor), 511 ± 40 (Signer method[5]).

Carvacrolphthalein Dimethyl Ether (III).—This compound was prepared by refluxing for ten hours 4.30 g. of I, 2.8 g. of potassium carbonate, 50 ml. of acetone and 3.7 ml. of methyl iodide. The crude was purified by crystallizations from ethanol as well as by sublimation at 180° and 50 microns. The pure III melts partially at 202°, then solidifies and melts again at 211.5–212.2°. III dissolves in concd. sulfuric acid with red color in transmitted light and violet in reflected light.

Anal. Calcd. for $C_{30}H_{34}O_4$: C, 78.57; H, 7.47; -OCH_3, 13.52. Found: C, 78.93; H, 7.77; -OCH_3, 13.29.

Thymolphthalein (IV).—30.0 grams (0.2 mole) of thymol and 14.8 g. (0.1 mole) of phthalic anhydride were heated to 95°. While stirring, 25 g. of anhydrous stannic chloride was then added over a period of thirty minutes. The reaction was continued for another thirty minutes at 96–103° (oil-bath temperature 99–104°). The reaction mass was taken up in hot 0.1 *N* hydrochloric acid, filtered and washed. The crude IV was finally dissolved in 700 ml. of acetic acid and 450 ml. distilled off from the filtrate: 26.6 to 30.1 g. (62–70% yield) of m. p. 247–252° was obtained. The pure IV obtained by recrystallization from acetic acid (1 g. in 9 ml.) melted at 252.4–253.1° (lit. 246–247°[3]).

When in place of pure thymol a mixture of 15.0 g. of technical carvacrol and 15.0 g. of pure thymol was used and the crude recrystallized twice from acetic acid, it melted at 243–245°. Further crystallization from the same solvent did not increase the melting point, but after two more crystallizations from ethanol, it melted at 251.8–252.4° (no depression when mixed with pure IV).

Thymolphthalein Diacetate (V).—A mixture of 2.15 g. of IV, 2.0 g. of acetic anhydride, 10 ml. of acetic acid and one drop of sulfuric acid was refluxed for one hour: 2.54 g. (99%) of m. p. 150–153° was obtained. Recrystallized twice from ethanol (1 g. in 8.5 ml.) it melted at 153.0–153.6°.

(4) All melting points are corrected.

(5) E. P. Clark, *Ind. Eng. Chem., Anal. Ed.*, **13**, 820 (1941). Acetone was used as a solvent and azobenzene as a standard.

Anal. Calcd. for $C_{32}H_{34}O_6$: C, 74.68; H, 6.66; -CO-CH_3, 16.71; mol. wt., 514. Found: C, 74.88; H, 6.71; -$COCH_3$, 16.43; mol. wt., 488 ± 7 (Rast, in camphor).

Thymolphthalein Dimethyl Ether (VI).—4.3 g. (0.01 mole) of IV, 3.73 ml. (0.06 mole) of methyl iodide, 50 ml. of acetone and 2.76 g. (0.02 mole) of potassium carbonate were refluxed for ten hours. The crude was recrystallized from ethanol (1 g. in 24 ml.) yielding 4.03 g. (88%) of m. p. 175–176°. After two more crystallizations, it melted at 175.9–176.7°.[6]

(6) Lin Che Kin, *Ann. chim.*, **13**, 344 (1940), reports m. p. 177°. He prepared VI by condensing the methyl ether of thymol with the methyl ether of the 2-thymoylbenzoic acid in the presence of aluminum chloride.

Summary

Carvacrolphthalein was shown to melt at 294° and to be devoid of laxative effect. The melting point of 247° given in the literature for this compound is wrong. Thymolphthalein was prepared with a melting point 6° higher than reported heretofore. The diacetyl derivative and the dimethyl ether of both compounds were prepared.

Isolation of Lupeol from the Osage Orange (*Maclura pomifera* Raf.)[1]

BY LYLE JAMES SWIFT AND E. D. WALTER

In the isolation of osajin by Walter, Wolfrom and Hess[2] the dried osage oranges were first extracted with petroleum ether to remove latex and other interfering substances. In this paper the isolation of lupeol from this extract is described, and its crystallographic optical properties recorded. A wax-like material, to be described later, was also obtained.

Lupeol was discovered by Schulze[3] and described by Likiernik[4] and has since been isolated from several latex bearing plants. Ruzicka[5] recently proposed a structure for lupeol.

A characteristic reaction of lupeol is the red color it gives with concentrated sulfuric acid and acetic anhydride when in chloroform solution. This test also is given by the dried latex of the osage orange.

Acknowledgment.—We are indebted to Dr. M. L. Wolfrom, Department of Chemistry, Ohio State University for some of the extract used in this work.

Experimental

Isolation of Lupeol. The dried, ground osage oranges were completely extracted with low boiling petroleum ether. The extract was concentrated and passed through an aluminum silicate adsorbent described by Kraybill, *et al.*,[6] which removed the wax-like material. The concentrated petroleum ether extract was saponified with twice its volume of 95% ethanol saturated with potassium hydroxide. The mixture was diluted with water and extracted with ether. The ether was evaporated and the residue was mixed with about an equal weight of Nuchar W. The mixture was extracted in a Soxhlet apparatus with ether which was subsequently evaporated. Repeated crystallizations from acetone and then from 85% ethanol gave a product melting at 208–211°. Final purification was effected through formation of the acetate and saponification of this to get lupeol melting at 214–215°; yield, 5.1 g. of crude lupeol or 2.3 g. of pure lupeol from 1 kg. of dried osage oranges.

Anal. of lupeol. Calcd. for $C_{30}H_{50}O$: C, 84.44; H, 11.81; mol. wt., 426.7. Found: C, 84.45; H, 11.88; mol. wt. (freezing point depression using stearic acid), 448, 458; $[\alpha]^{22}D$ +27.63° ($CHCl_3$, c = 3.926). Ruzicka (7) obtained +27.2°.

Lupeol acetate was prepared by the method of Ruzicka[7]; yield, 1.88 g. (from 2.16 g. of lupeol) m. p. 216–216.5°. Ruzicka[7] reported a m. p. of 215–217°.

Anal. of lupeol acetate. Calcd. for $C_{30}H_{49}(OCOCH_3)$: C, 81.99; H, 11.18; mol. wt., 46.78. Found: C, 81.79; H, 11.29; mol. wt. (saponification equivalent), 469.5; $[\alpha]^{25}D$ +41.95° ($CHCl_3$, c = 1.652). Ruzicka obtained +40.7°.

Lupeol benzoate was prepared by the method of Ruzicka.[7] Lupeol (1.8 g.) yielded 1.57 g. of the benzoate m. p. 263–265°.

Anal. of lupeol benzoate. Calcd. for $C_{30}H_{49}(OCOC_6H_5)$: C, 83.72; H, 10.25; mol. wt., 530.8. Found: C, 83.59; H, 9.80; mol. wt. (saponification equivalent), 543; $[\alpha]^{25}D$ +61.36° ($CHCl_3$, c = 0.9908). Ruzicka obtained +60.9°.

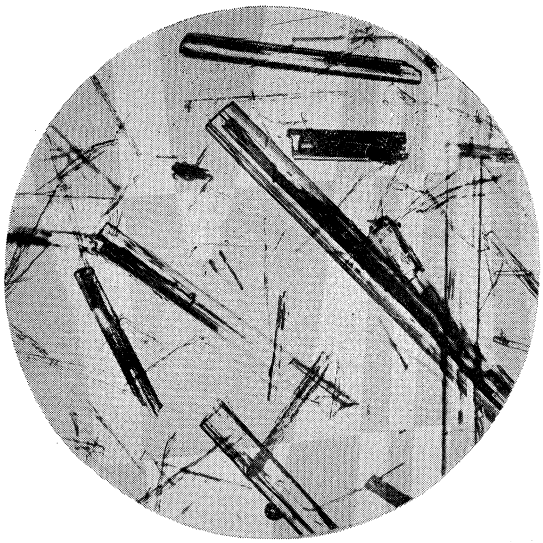

Fig. 1.—Lupeol (×60).

Crystallographic Optical Properties

Lupeol.—In parallel polarized light (crossed nicols), the extinction is parallel; the elongation is negative. In convergent polarized light (crossed nicols) an optic normal interference figure is found on faces showing brightest white color. Refractive indices: n_α = 1.551, found lengthwise; n_β = indet.; n_γ = 1.565, found crosswise (both values ±0.003) (see Fig. 1).

Lupeol Acetate.—In parallel polarized light (crossed nicols) many faces show practically no extinction, while a few show red and blue interference colors and parallel extinction. In convergent polarized light (crossed nicols) a biaxial, optic axis figure is common. The optic sign is negative. Refractive indices: n_α = 1.540; n_β = 1.567 (both ±0.003); n_γ = indet.

Lupeol Benzoate.—In parallel polarized light (crossed nicols) the extinction is parallel; the elongation is negative. Many of the rods show red, green and yellow interference colors. In convergent polarized light (crossed nicols) biaxial interference figures are common. The optic sign is positive. Refractive indices: n_α = 1.565 found lengthwise on rods with red and blue interference colors; n_β = 1.567 found on fragments showing an optic axis interference figure; n_γ = 1.634 found crosswise, all ±0.003.

Summary

1. Lupeol has been isolated from the osage orange. Apparently it is a constituent of the latex.

2. Some crystallographic optical properties are presented for lupeol, lupeol acetate and lupeol benzoate.

Surface Tensions, Densities and Parachors of the Aliphatic Nitroparaffins

BY G. E. BOYD AND L. E. COPELAND

Introduction

The synthesis and chemical properties of the aliphatic nitroparaffins previously have attracted considerable attention.[1-4] In view of the unusually high dipole moments shown (CH_3NO_2 = 3.13) by the molecules of these substances, it is of interest to determine the effect of this property upon the surface tension and the parachor. Since these liquids are extremely polar the possibility of two or more molecular species arises. Questions of this type sometimes may be settled by surface tension investigations.[5]

In the study reported, the variation of the surface tensions in the interval 25.0 to 60.0° of the first four members of the aliphatic nitroparaffins and their secondary isomers have been measured. Additionally, the variation of density with temperature, the total surface energies at 25°, the parachors and the critical temperatures have been obtained.

Apparatus, Chemicals and Methods

Reports of measurements of the variation of the surface tension with temperature are far less numerous in the literature than is to be desired. The variety of methods suitable is limited by a number of practical considerations. In these researches the ring method[3] was employed, and a clean liquid surface was insured by repeatedly overflowing the cup in which it was contained.

Although the question of technique and errors in the ring method has been discussed,[3,6] our experience has convinced us of the necessity of stressing certain vital points again.

If accurate results are to be obtained, it is essential that the ring be entirely in one plane, and that the stirrup supporting the ring be such that this plane be horizontal to a high degree of trueness. The effect of ring tilt has

TABLE I

SURFACE TENSION, DENSITY, AND MOLECULAR SURFACE ENERGY OF THE ALIPHATIC NITROPARAFFINS FROM 25.0 TO 60.0°

Compound	*a*	*b*	*c*	*d*	*e*	
Nitromethane	39.25	0.1387	1.16576	0.001383	992.7	1.610
Nitroethane	34.03	.1090	1.06823	.001202	996.6	1.520
1-Nitropropane	31.74	.0985	1.02300	.001093	1056.2	1.578
2-Nitropropane	30.78	.1084	1.01208	.001119	1104.2	1.805
1-Nitrobutane	31.65	.0979	0.99170	.000960	1193.2	1.801
2-Nitrobutane	31.32	.1067	.98455	.000963	1251.2	2.026

been studied.[3] However, warping of the plane of the ring is probably an error of a greater degree of seriousness. Although it is difficult to estimate quantitatively the error from this source, invariably low surface tension values are obtained unless precaution is taken.

It is desirable to carry out an analysis of errors in order that a precision measure of our results may be stated. The surface tension, γ, is given by the formula

$$\gamma = [Mg/4\pi R]F(R/r, R^3/V)$$

where M = maximum mass of the liquid column supported by the ring, g = gravitational constant, R = radius of ring (center of ring to center of wire), r = radius of wire. The maximum volume, V, of the liquid column elevated above the free surface of the liquid is given by

$$V = M/(D_L - D_v)$$

where D_L and D_v are, respectively, the densities of the liquid and of air saturated with the vapor of the liquid at the prevailing temperature and pressure. Evidently, the precision measure of the derived result (*i. e.*, the surface tension) is governed by the precision measure of components involving mass and length only.

Repeated experiments have shown that M can be determined to within ±0.1 mg., and R to within ±0.0005 cm. Harkins and Jordan[3] state that the values of F are accurate to 0.3%, with a probable error of less than 0.2% for rings whose R/r ratios lie between 30 and 80. Using these data, a numerical computation of the actual error in the derived surface tension due to the actual error in each component in the case of nitromethane at 25° gave 35.78 ± 0.12 dyne cm.$^{-1}$, or an accuracy of 0.33%.

The ring employed was made of platinum–iridium, and its mean radius was 0.6378 cm.; the value of R/r was 39.87. As a result of many observations, it was found that the precision of measurement was appreciably better than the 0.33% accuracy claimed. In the series of results being reported a reproducibility in a given surface tension value was observed to better than 0.20%.

Density determinations, performed simultaneously at the same temperatures as surface tension measurements, were carried out in conventional Ostwald pycnometers of approximately 18-ml. volume equipped with ground glass caps to check evaporation losses.

Temperatures were read to 0.05° on a totally immersed 0–50° thermometer graduated in tenths of a degree which had been compared with a calibrated Bureau of Standards thermometer.

Refractive indices were obtained with a Zeiss dipping refractometer maintained at 25.0° within 0.1°.

The compounds used throughout our researches were supplied through the generosity of the Commercial Solvents Corp. by Messrs. F. K. Hoover and E. B. Hodge, and were of a high degree of purity. Their physical constants are given in Table III. The liquids were stored in the dark away from air, and, with the exception of nitromethane, no decomposition occurred over a period of three months.

Results

The results of the measurements of density and surface tension when plotted in a large graph against the temperature indicated that within the range 25 to 60° these quantities may be represented by linear equations. Thus the surface tension equation is

$$\gamma = a - bt \qquad (1)$$

where a and b are constants independent of the temperature of the surface, t, in °C. Similar type equations for the density and molecular surface energy, $\gamma(Mv)^{2/3}$, can be written

$$\rho_4^t = c - dt \qquad (2)$$

and

$$\gamma(Mv)^{2/3} = e - fT \qquad (3)$$

where M is the molecular weight, v, specific volume and T the absolute temperature. The values for the constants in the least squares equations summarize the experimental results (Table I).

The least squares equations fit the experimental surface tension data with a precision of better than 0.13%, and the densities better than 0.018%, with the exception of nitromethane where the precision is 0.06%.

An attempt to evaluate our surface tension and density data in terms of individual values existing in the literature met with small success. With the exception of the first two members of the series, no values were found. In the example of nitromethane a satisfactory comparison can be made. Table II lists values for the densities and surface tensions chronologically.

From the results of Table II, it would appear that the density of nitromethane at 25° must lie within the range: 1.1307 to 1.1313. The agreement between our value for the surface tension

TABLE II

A COMPARISON OF DENSITIES AND SURFACE TENSION VALUES FOR THE ALIPHATIC NITROPARAFFINS AT 25°: NITROMETHANE

ρ^{25}_4	Year	Author[7]

and that of the "International Critical Tables" (I. C. T.) is within 0.3 dyne cm.$^{-1}$.

No comparison of the densities for the other members of the homologous series can be made owing to the complete absence of reports of such measurements on pure compounds in the literature. In the case of nitroethane a comparison of the surface tension values can be made. The value of 31.6 dyne cm.$^{-1}$ at 25° interpolated from the "I. C. T." values is comparable with our value of 31.30 at the same temperature. It is believed that the general self-consistency of the parachor values (see Table III) and their increments offer additional evidence of the accuracy of the surface tension and density values found in this study.

Discussion

The data of Table I permit the calculation of three additional quantities of importance. The total surface energy, E_l, at any one temperature may be obtained from the equation

$$E_l = \gamma_l - T\left(\frac{d\gamma_l}{dT}\right) \qquad (4)$$

and some values are given in Table III.

(7) Jaeger, *Z. anorg. Chem.*, **101**, 1 (1917); Williams, THIS JOURNAL, **47**, 2648 (1925); Mathews, *ibid.*, **48**, 562 (1926); Wright, Murray-Rust and Hartley, *J. Chem. Soc.*, 199 (1931); Timmermans and Hennaut-Roland, *J. Chim. Phys.*, **29**, 529 (1932); Walden and Birr, *Z. physik. Chem.*, **163A**, 263 (1933); Morgan and Stone, THIS JOURNAL, **35**, 1505 (1913).

Parachors were computed from Sugden's[8] formula

$$[P] = M\gamma^{1/4}/(D_l - D_v) \qquad (5)$$

where M is the molecular weight; γ the surface tension; D_l the density of the liquid; and D_v the density of the saturated vapor at the desired temperature. This latter quantity was computed by means of the equation

$$\log (D_v/D_b) = 5(T/T_b - 1) \qquad (6)$$

where D_b is the density of the vapor at the boiling point T_b, and was estimated, following Sugden, by the relation

$$D_b = 0.0122\, M/T_b \qquad (7)$$

The magnitude of the correction of the density of the saturated vapor to the liquid density, D_l, was less than 0.02%, and might have been neglected.

Molecular surface energies calculated in Table I are of use in the estimation of the critical temperatures, T_c, of these compounds. The equation of Ramsey and Shields

$$\gamma(Mv)^{2/3} = k(T_c - T - 6) \qquad (8)$$

was used in conjunction with equation (3) in the calculations summarized in the eighth column of Table III.

TABLE III

Compound	ρ^{25}_4	$\eta^{25}D$	T_b	γ_{25}	E_{25}	$[P]$	T_c	T_b/T_c
Nitromethane	1.13118	1.37872	375.0	35.78	77.11	132.7	622.7	0.60
Nitroethane	1.03819	1.39015	387.9	31.31	63.78	171.0	661.8	.59
1-Nitropropane	0.99569	1.39901	404.6	29.28	58.44	208.1	675.2	.60
2-Nitropropane	.98410	1.39206	393.1	28.07	60.38	208.3	617.9	.64
1-Nitrobutane	.96770	1.40851	426.7	29.20	58.39	247.6	668.5	.64
2-Nitrobutane	.96047	1.40222	413.1	28.65	60.46	248.3	623.7	.66

It is apparent that the well-known rule that secondary compounds show a lower surface tension than corresponding primary members of a series is obeyed by the nitroparaffins.

The value listed by Sugden[9] for the parachor of nitromethane is 132.0, in excellent agreement with Table III. The increment in the parachor per CH_2 group is 39 which compares favorably with the average of 38.3 from Table III. It is apparent also that the parachors of isomers are identical as is required by the principle of the additivity of atomic parachors.

The unusually high values for the critical temperatures of the nitroparaffins suggest that there may be considerable association in the liquid state. Thus, the compounds 1-nitrobutane, butyric acid, 1-amyl nitrile and butyl alcohol show values

(8) S. Sugden, *J. Chem. Soc.*, **127**, 1540 (1925).

(9) S. Sugden, "Parachor and Valency," p. 119.

of T_c equal to 669, 628, 602 and 560°K., respectively. However, allotropy of the liquid nitroparaffins, whether due to changes in molecular aggregation or to other causes, would probably affect surface tension. Within the temperature range here reported, such effects seem to be absent.

Summary

1. The surface tensions of the aliphatic nitroparaffins at 25.0° vary from 35.78 for nitromethane to 29.20 dyne cm.$^{-1}$ for 1-nitrobutane. The secondary isomers show characteristically lower free surface energies, with 2-nitrobutane giving 28.65 ergs cm.$^{-2}$.

2. The total surface energies of the nitroparaffins at 25.0° vary from 77.11 ergs cm.$^{-2}$ for nitromethane to 58.39 ergs cm.$^{-2}$ for 1-nitrobutane. The secondary isomers, however, exhibit a higher surface energy, with 2-nitrobutane giving 60.46 ergs cm.$^{-2}$.

3. The parachor values calculated from the measured surface tension and density are in good agreement with the predictions of Sugden.

4. Values of the critical temperatures calculated from the Ramsey–Shields equations are: nitromethane, 623°K.; nitroethane, 662°K.; 1-nitropropane, 675°K.; 2-nitropropane, 618°K.; 1-nitrobutane, 669°K.; and 2-nitrobutane, 624°K.

The Composition and Structure of Molybdenum Blue

BY F. B. SCHIRMER, JR., L. F. AUDRIETH, S. T. GROSS, D. S. MCCLELLAN AND L. J. SEPPI

The composition of molybdenum blue has been the subject of controversy ever since it was first discovered by Berzelius[1] in 1826. Even modern investigators are not yet in agreement as to its formula, the most recently reported values varying from Mo_5O_{14} to Mo_8O_{23}.[2,3,4] There is little doubt but that products of different composition are obtained when heteropoly acid formers such as phosphoric and arsenic acids are present, or when oxidizing agents such as nitric acid are used in acidifying solutions of molybdate. There is also the very good possibility that the common practice of "purifying" molybdenum blue by extraction from aqueous solution by means of organic solvents gives products which are different. For these reasons the authors undertook to develop methods of synthesis which would avoid these complicating factors.

Molybdenum blue has been prepared by a number of methods, carefully purified and analyzed. Samples were subjected to an X-ray examination and found to yield identical diffraction patterns. The colloidal nature of molybdenum blue was verified subsequently by a study of these products under the electron microscope.

Experimental

Preparation

(a) **Reduction of Molybdate with Trivalent Molybdenum.**—The recommended procedure, by which the majority of the samples were prepared, involves interaction of a solution of trivalent molybdenum, obtained by reduction of molybdate in a Jones reductor, with an acidified molybdate solution (*p*H 0.4). Specific directions follow: a receiver containing 500 ml. of 0.4 *M* sodium molybdate, $Na_2MoO_4 \cdot 2H_2O$, and 200 ml. of 6 *N* hydrochloric acid is attached to the reductor. A solution containing 40 ml. of 0.4 *M* sodium molybdate, 60 ml. of 6 *N* hydrochloric acid and 100 ml. of water is passed slowly through the column and the resulting olive-green solution of trivalent molybdenum is allowed to drop directly into the solution of hexavalent molybdenum. The last of the solution in the reductor is washed into the receiver with dilute hydrochloric acid. The precipitate of molybdenum blue forms in the flask.

The precipitate and the solution are separated by centrifugation and the slightly colored supernatant liquid, containing an excess of trivalent molybdenum, is either discarded or treated as in method (c). The precipitate is washed by centrifuging three to five times with a solution of 5 ml. of 6 *N* hydrochloric acid in 100 ml. of distilled water. This is followed by similar treatment of the precipitate with successive portions of distilled water until both the supernatant liquid and the precipitate are chloride free. After each washing the suspension is centrifuged and the supernatant liquid decanted.

During the washing with dilute hydrochloric acid very little of the product is lost. As the electrolyte is subsequently removed by washing with distilled water considerable peptization takes place with the result that the

supernatant solutions assume a deep blue color. While the yield of molybdenum blue is decreased by this final treatment, a purer product is obtained which more than compensates for this loss. The molybdenum blue is then dried and stored in a vacuum desiccator. Using the quantities specified above yields of 16 to 18 g. of purified molybdenum blue may be obtained. These yields correspond to about 45–55% calculated on the assumption that the hydrate obtained has the average composition $Mo_8O_{23}\cdot 10H_2O$.

(b) **Oxidation of Trivalent Molybdenum with Molybdate.**—This method is essentially similar to (a), but involves addition of acidified molybdate to an excess of a solution containing trivalent molybdenum prepared by reduction with zinc in a Jones reductor.

(c) **Oxidation of Lower Valent Molybdenum.**—The supernatant liquid which remains upon centrifugation of the reaction mixture in (a) above contains an excess of lower valent molybdenum. An additional yield of the blue can be obtained by passing oxygen through the solution for several days. The precipitated molybdenum blue is centrifuged, washed and dried as described under (a).

Analysis.—The water content was determined by heating gradually a weighed sample of the blue to a temperature of 500° in a stream of oxygen and absorbing the moisture in tared bulbs containing magnesium perchlorate. The residual molybdenum trioxide was either weighed directly or dissolved in dilute ammonium hydroxide and its molybdenum content determined volumetrically as outlined by Scott.[5] Samples of molybdenum blue were also analyzed directly for their molybdenum content. The oxygen content was calculated by difference.

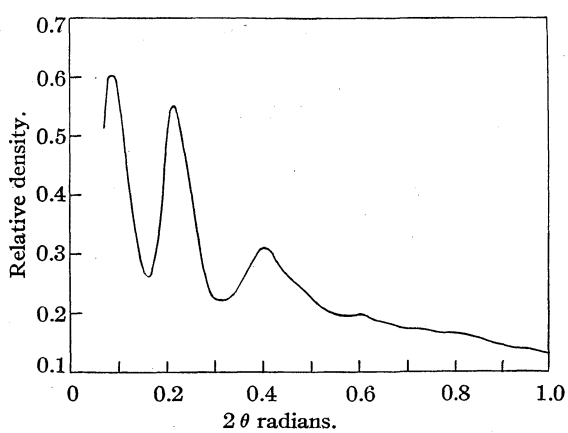

Fig. 1.—Relative density curve made from X-ray diagram of molybdenum blue using Leeds and Northrup microphotometer; filtered molybdenum radiation, circular camera (radius 6.4 cm.), wedge sample.

The analytical results presented in Table I indicate that the composition of molybdenum blue, prepared by four different methods and purified carefully, may be represented approximately by the empirical formula $Mo_8O_{23}\cdot xH_2O$, where x varies from six to fourteen depending upon how long the product has been dried.

TABLE I

COMPOSITION OF MOLYBDENUM BLUE

Method of prepn.	Samples analyzed	Value of x in Mo_8O_x
a	14	23.04 ± 0.12
		(extremes, 22.85–23.31)
b	2	23.31 ± 0.10
c	2	22.97 ± .06
d[6]	2	23.41 ± .06

X-Ray and Electron Microscope Study.—Molybdenum blue preparations were examined by the X-ray diffraction method using both filtered molybdenum and filtered copper radiation with the wedge technique. Three intense and four faint halos or diffuse bands were observed. The intense interferences correspond to the following "*d*" values.

Cu K-alpha, Å.	Mo K-alpha, Å.
8.43	8.57
3.28	3.25
1.79	1.76

Measurements of the remaining halos are uncertain, two of them partly overlapping more intense interferences, and the remaining two corresponding to very faint diffuse bands. A tracing of the microphotometer curve obtained for molybdenum blue from an X-ray pattern with molybdenum radiation is shown in Fig. 1. This pattern is apparently perfectly characteristic of the purified material regardless of the method of preparation.[7] It seems significant that this halo pattern shows little resemblance to the diffraction pattern of molybdenum trioxide, a fact which suggests the presence of a definite structure other than any known form of molybdenum trioxide.

In view of a question raised by one of the referees relative to the interpretation of the broad X-ray diffraction interferences obtained with molybdenum blue, it was suggested by Professor G. L. Clark that electron photomicrographs be made of these preparations.[8] The sample was

(6) Prepared by reduction of acidified molybdate with stannous chloride.

(7) Burgers and van Liempt, *Z. anorg. Chem.*, **202**, 325 (1931), examined qualitatively molybdenum bronzes by the X-ray method, but give no experimental details, measurements, calculations or interpretation. They reproduce photographs of patterns obtained (a) from a so-called molybdenum blue, (b) from an ignited product and (c) from a sample of sublimed molybdenum trioxide. They describe the first of these as different from the other two which are identical. All of their samples are crystalline materials. The patterns obtained consistently by the authors bear no resemblance to those published by Burgers and van Liempt.

(8) The R. C. A. instrument was employed by Dr. Martha Barnes Baylor at a magnification of 15,500 X and the photographs were then enlarged fourfold for a final magnification of 62,000 X.

shaken up with water, allowed to settle and a drop of the top of the aqueous suspension applied to the collodion film and dried. The remarkable dispersion of particles is shown in Fig. 2 (magnification 62,000 X). A fairly uniform distribution of single primary particles some of which are only 100 Å. in diameter, appears in the background. These particles are narrower in one dimension than the other and probably lie flat as still thinner flakes. As might be expected otherwise, these are too small to show definite crystalline faces. Some small flocs representing the first stages of agglomeration of the individual particles appear in the center of the photograph. Finally, there is a distribution of larger, darker and more nearly spherical particles which must represent larger primary particles of the order of several hundred Ångström units in size.

This proof of a typical colloidal structure, therefore, confirms the interpretation of the broad X-ray interferences by means of which calculations can be made of a particle size of the order of 100 Å., or somewhat less. It is not necessary to claim absolute crystalline perfections of these extremely small particles. That some lattice organization is present is indicated by the number of diffraction halos on the patterns—several more than for carbon black which is known to be built up into particles from crystalline layers which are stacked at random like a twisted deck of cards.

Fig. 2.—Electron photomicrograph of molybdenum blue (62,000 ×).

Summary

Molybdenum blue has been prepared by a number of new methods and purified carefully. Its composition may be represented by the empirical formula, $Mo_8O_{23}\cdot xH_2O$. Samples prepared under the prescribed conditions yield identical and characteristic diffraction patterns. Electron photomicrographs confirm the colloidal nature of molybdenum blue.

The Adsorption of Gases at Low Temperature and Pressure on Smooth Silver

BY MARION H. ARMBRUSTER

This paper reports the results of measurements of the adsorption of hydrogen, nitrogen, argon, carbon monoxide, carbon dioxide and oxygen at pressures up to 0.1 cm. on a substantially plane, reduced surface of silver over the temperature range −195 to 20°. The investigation was undertaken to determine the nature and properties of the smooth surface of a typical, pure, homogeneous metal as a first step toward a better understanding of the characteristics of the surface of a less pure or less homogeneous metal, such as steel. Silver was selected chiefly because it is readily obtainable in a high degree of purity in the form of foil, a form which provides a large, smooth and reproducible surface; it is also relatively inert so that, aside from the sorption of oxygen, there should, in the range of experimental conditions covered, be no complex chemisorption which might confuse interpretation of the results.

Materials and Apparatus.—The quality of the several gases used, the apparatus, and the experimental procedure already have been described.[1]

Silver Surface.—The silver used (99.98+ % Ag) was foil 0.021 cm. thick, cut into strips, 1.8 × 11.0 cm. to form a bundle weighing 846.5 g. and having a total geometric area of 8002 sq. cm. X-Ray diffraction patterns of the foil, obtained by D. S. Miller, indicated a fairly high degree of preferred orientation of the grains on the surface of the foil. The crystallographic plane in the surface was not one of simple indices, but appeared to be one which made an angle of 15° with the (110) plane. The strips were degreased with absolute alcohol and anhydrous ether, suitable precautions being taken to guard against subsequent contamination. Since oxygen sorbed on silver is not readily removed by baking in vacuum even at a temperature as high as 300°,[2,3] the surface was, before each run, freshly reduced for four to eight hours at 400° in a stream of purified hydrogen. The adsorption bulb was then sealed off in an atmosphere of hydrogen after which the sample was outgassed at 450° under a pressure of 10^{-6} mm. This pretreatment sufficed to give a surface on which the adsorption was reproducible within the precision of measurement, which is about 0.001 cc. As direct test showed that hydrogen is not measurably sorbed on smooth silver in the range of temperature and pressure covered, the sample was cooled in hydrogen to hasten equalization of temperature. At least two, and usually four, check runs were made with each gas at each temperature. After several measurements the surface of the silver developed an etched appearance, probably as a result of evaporation but this was not accompanied by any appreciable increase of surface area since the sorption was not measurably altered. The Pyrex bulb containing the silver also developed a slight brown discoloration, indicating probable contamination by silver.

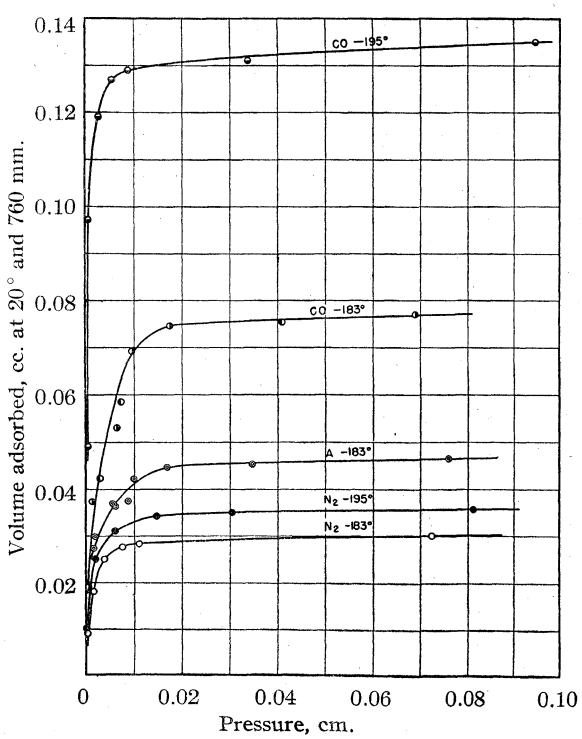

Fig. 1.—Isotherms for CO, A and N_2 at −183 and −195°.

Results.—Hydrogen was not measurably sorbed at any temperature investigated; argon, nitrogen and carbon monoxide were sorbed at −195° and −183° but not at −78° or 20°. Carbon dioxide was not sorbed at 20°, but at −78° was sorbed to the slight extent of 6 cu. mm. at a pressure of 0.02 cm. Typical isotherms for nitrogen, argon and carbon monoxide at −195° and −183°, selected as representative from among the several concordant runs made with each gas, are given in Fig. 1. For each gas, adsorption was instantaneous and completely reversible in the sense that measurements on desorption agreed with those for adsorption, and a surface pumped out at temperature gave results identical with those obtained on a baked out surface.

The sorption of oxygen is illustrated by the typical isotherms presented in Fig. 2. At −195° and −183° the adsorption was fairly rapid, being substantially complete within a few minutes.

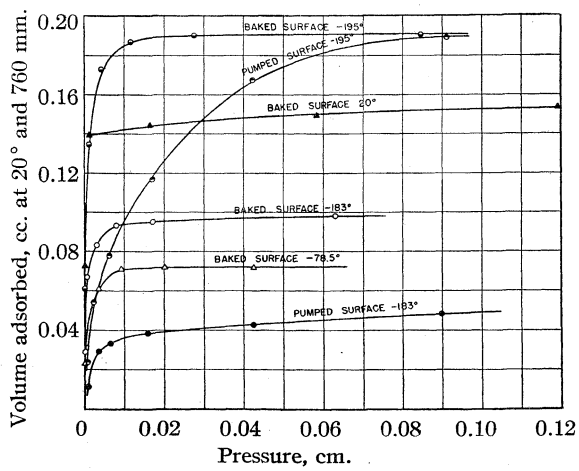

Fig. 2.—Isotherms for oxygen at −195, −183, −78.5 and 20°.

The adsorption was not, however, entirely reversible since the amount of gas sorbed was not the same on a surface which had been pumped out at temperature as on one which had been freshly reduced and baked out. Thus, at −183°, the sorption on the pumped out surface was markedly less than on the surface which had been reduced and baked, whereas at −195° it was less in the lower range of pressure but probably was greater

(1) Armbruster and Austin, THIS JOURNAL, **60**, 467 (1938); **61**, 1117 (1939).

(3) Benton and Drake, *ibid.*, **56**, 255 (1934).

at higher pressures. At −78° and 20°, on the other hand, the rate of adsorption was relatively slow; the first portion of oxygen admitted came to equilibrium only after an hour or more, as is illustrated by the typical rate curves shown in Fig. 3; subsequent additions attained equilibrium more rapidly. At these higher temperatures, the volume of oxygen sorbed was, over most of the range investigated, virtually independent of pressure. Moreover, at −78° and above, the sorbed oxygen could not be removed by pumping at temperature but was taken off by reduction and baking in vacuum at 400° or higher.

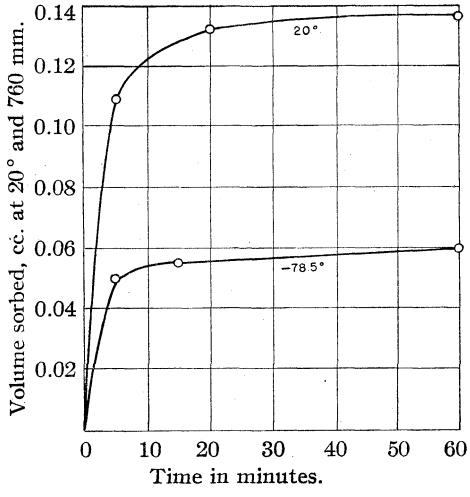

Fig. 3.—Rate of initial adsorption of oxygen at −78.5 and 20°.

Discussion of Results

Nature of the Adsorption.—The fact that nitrogen, argon, and carbon monoxide are adsorbed instantaneously and reversibly, together with the fact that the volume sorbed at a given pressure increases with decreasing temperature, indicates that the adsorption is of the van der Waals type. The sorption of oxygen at −195° and −183° is, in part, likewise of the van der Waals type but at least some portion of the sorbed film appears to be held to the surface more tightly than would be expected from the action of purely physical forces. Thus, at −183°, the sorption on the pumped out surface is less than on the freshly reduced and baked surface, which suggests that all the sorbed oxygen was not removed by evacuation. At −78° and 20°, the rate of adsorption of oxygen is slow and the sorbed gas is not removed from the surface by evacuation of the system, indicating that the sorption is of the activated type, a conclusion which is confirmed by the fact that the volume of gas sorbed at a given pressure increases with increasing temperature, as is illustrated by the typical isobar shown in Fig. 4.

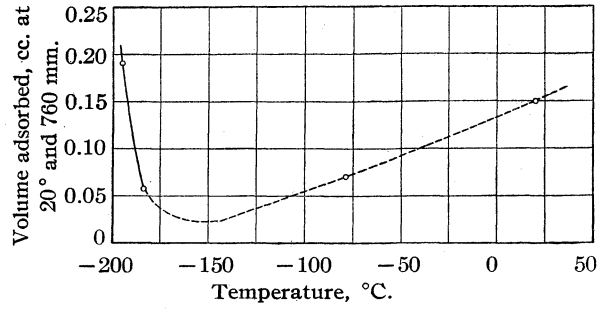

Fig. 4.—Isobar for oxygen at $P = 0.05$ cm.

Form of the Isotherms.—Since the curves in Figs. 1 and 2 appear to be of the Langmuir type, representative isotherms for the several gases have been replotted in Fig. 5 as p/v against p, a method which yields a straight line if the observations conform to either the Langmuir equation[4] or to the formally identical equation for monomolecular adsorption developed by Bru-

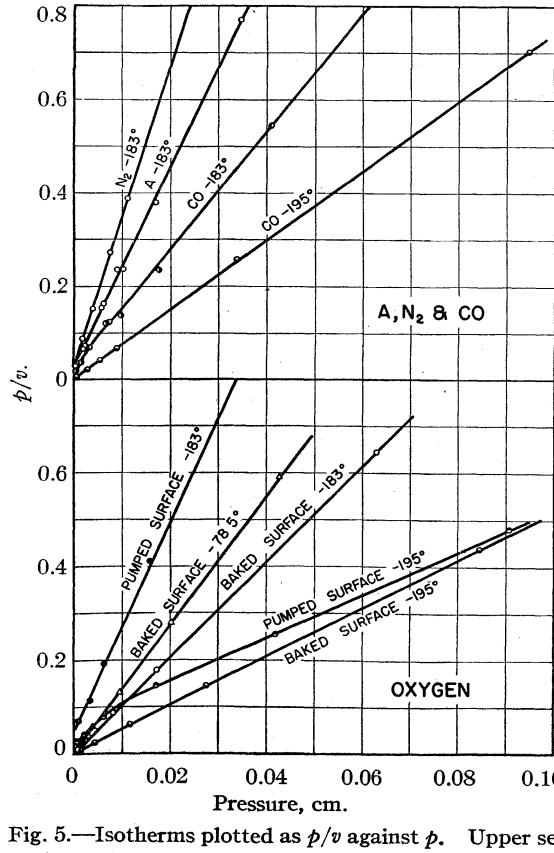

Fig. 5.—Isotherms plotted as p/v against p. Upper section shows data for N_2, A and CO; lower section shows data for O_2.

(4) Langmuir, THIS JOURNAL, **40**, 1361 (1918).

nauer, Emmett and Teller.[5] It is evident from this diagram that a linear relation is obtained except at the lowest pressures, hence, over virtually the entire range of pressure covered, the data are represented with satisfactory accuracy by either of these relations.[6] The greatest deviation from a straight line is in the isotherm for oxygen at −195° at pressures up to 0.010 cm.; another, less marked, departure occurs in the same range of pressure in the isotherm for carbon monoxide at −183°.

In Fig. 6 the isotherms for −183° are plotted in the form of v, the volume (reduced to 1 atm. and 20°) sorbed at pressure p, against the logarithm of the adsorption potential ϕ,[7] as suggested by Palmer and Clark.[8] This method of plotting is of interest in connection with the calculation of the force-area curve, since, if a straight line is obtained, as it frequently is,[8,9] the spreading force can be calculated by means of an equation derived by Palmer.[10]

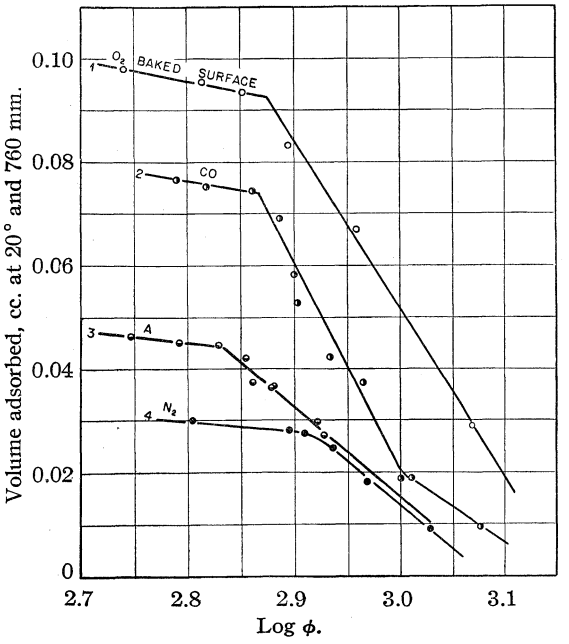

Fig. 6.—Isotherms at −183° plotted as volume sorbed against log ϕ.

All the isotherms in Fig. 6, except that for carbon monoxide, consist of two straight lines which intersect at a value of v approximately equal to that at which the corresponding curve in Figure 1 flattens off. The isotherm for carbon monoxide consists of three sections, two of which intersect at a value of v which, just as with the other gases, corresponds approximately to the value at which the isotherm in Fig. 1 flattens off; the other intersection occurs in the range of higher adsorption potentials, that is, at lower pressure, at a value of v which corresponds fairly well with the pressure at which deviation from linearity becomes evident in the isotherm shown in Fig. 5. The isotherms for the several gases at −195° fall so close to the corresponding curves for −183° that they have not been included in Fig. 6.

Fraction of Surface Covered.—The limiting volume, V_s,[11] for each gas at each temperature, as derived from the slope of the p/v–p isotherm, is given in Table I. On the assumptions that the geometric area of the foil represents the true area of the surface, and that the mean cross-section of a sorbed molecule is the same as that of a molecule in the liquid, the fraction of the surface covered, in the pressure range in which the isotherm is virtually horizontal, can be estimated from the value of V_s. The coverage derived on this basis is shown in the last column of Table I. In only one instance, the sorption of oxygen on a pumped out surface at −195°, is the coverage substantially complete; in every other, only from

TABLE I

V_s, VOLUME OF GAS SORBED AND FRACTION OF SURFACE COVERED AT SATURATION AS CALCULATED BY MEANS OF THE LANGMUIR EQUATION

Gas (surface)	Temp., °C.	V_s, cc. at 20° and 760 mm.	Molecules sorbed per sq. cm. as derived from V_s	Fraction of surface covered
A	−183	0.0486	0.153×10^{15}	0.20
N_2	−183	.0305	.096	.15
N_2	−195	.0355	.112	.17

O_2	−78.5	.0729	.230	.29
O_2 (Baked)	−183	.0980	.309	.40
O_2 (Pumped)	−183	.0450	.142	.18
O_2 (Baked)	−195	.1904	.560	.78
O_2 (Pumped)	−195	.2295	.722	.94

(5) Brunauer, Emmett and Teller, THIS JOURNAL, **60**, 309 (1938).

(6) This does not preclude the possibility that at higher pressures the isotherms might curve upwards to become convex to the pressure axis.

(7) The adsorption potential ϕ is equal to $RT \log p_0/p$, where p_0 is the vapor pressure of the adsorbate in the liquid phase at temperature T.

(8) Palmer and Clark, *Proc. Roy. Soc.* (London), **A149**, 360 (1935).

(9) Armbruster and Austin, THIS JOURNAL, **60**, 474 (1938).

(10) Palmer, *Proc. Roy. Soc.* (London), **A160**, 254 (1937).

(11) This is the volume which investigators of adsorption at low pressure on plane surfaces have commonly called the maximum volume sorbed, or the saturation maximum, and have designated b, c_1, x_s or v_m, (*cf.* Langmuir, ref. 4; Bawn, THIS JOURNAL, **54**, 81 (1932); Wilkins, *Proc. Roy. Soc.* (London), **A164**, 510 (1938)). It is to be distinguished from the volume v_m defined by Brunauer, Emmett and Teller (ref. 5) as the volume required to form a close-packed monolayer.

one-third to two-thirds of the surface is covered. Although it is customary to calculate coverage of the surface in this manner, it is entirely permissible, and in some ways preferable, to interpret the apparent saturation of the surface in terms of effective cross-section of the sorbed molecules, that is, in terms of the density of packing in the sorbed film. On this basis, the effective cross-section derived from V_s (Table I) is considerably greater than that of a molecule in a three-dimensional condensed phase.

Apparent saturation of the surface, as indicated by the flattening of the isotherm, at such a relatively low pressure is in marked contrast to the behavior of metal powders for which there is no comparable flattening even at a much higher pressure. Moreover, the relatively small estimated coverage of the smooth surface in the range of apparent saturation appears to be characteristic of a number of metals. For example, Langmuir[4] reports saturation of a surface of platinum foil with hydrogen, carbon monoxide and oxygen at a coverage not exceeding a few per cent. More recently, Wilkins[12] in more extensive measurements on platinum foil, observed saturation at −183° by argon, nitrogen and oxygen with a coverage of 34, 30 and 42%, respectively. With argon at −195° the surface appeared to be completely covered at saturation by a monomolecular layer. Wilkins found further that when his data were plotted as p/v against p, there were marked deviations from linearity at low pressures, the departures becoming more marked the lower the temperature. Finally, Smittenberg[13] reports that on a smooth surface of nickel at −183° the greatest adsorption of hydrogen or argon corresponded to a coverage which does not exceed 2 and 8%, respectively. It is evident, therefore, that the observed adsorption on the silver surface is typical of that on a smooth metallic surface.

The sorption of oxygen at −195° has another feature worthy of special mention in that V_s is greater for the pumped out surface than for a surface which has been freshly reduced and baked. This difference is reflected in a difference in the form of the isotherms (Figs. 2 and 5) which was confirmed by repeated measurements. The cause of the difference is not apparent for it is difficult to visualize a mechanism by which merely pumping the gas from the system should so condition the surface that it can subsequently adsorb a significantly greater volume of oxygen. The observations suggest, however, that at −195°, as at −183°, all the sorbed oxygen is not removed by pumping, and that the molecules remaining so alter the surface that it becomes virtually an oxide surface capable of forming a complete monolayer of the van der Waals type of adsorption. In line with this difference it should be noted that the calculated heat of sorption, as derived in a later section, is 2800 cal. for the pumped out surface, which is significantly less than the value 3400 cal. for the surface which has been reduced and baked.

Variation of V_s with Temperature.—As indicated in Table I, V_s increases markedly with decreasing temperature, a variation seemingly characteristic of adsorption in which there is an apparent saturation of the surface. Wilkins and Ward[14] have suggested that this temperature coefficient is due to some factor which alters the number of molecules which can be packed into the adsorbed phase, the volume of which is independent of temperature; that is, the temperature coefficient of V_s corresponds to the expansion coefficient of a gas at constant pressure. On this basis, $dV_s/V_s dT$ should have about the same value as dV/VdT for an ideal gas, which is equal to $1/T$. The value of $dV_s/V_s dT$ derived from the present measurements (Table II) is, for nitrogen, approximately that of an ideal gas but for carbon monoxide and oxygen it is very much greater, which suggests that the molecular interactions in the sorbed film are much greater for carbon monoxide and oxygen than for nitrogen. The value derived for nitrogen also agrees fairly well with that derived from Langmuir's measurements on mica. Thus, if the value of $dV_s/V_s dT$ is taken as 0.0145 at −150° and varies about 2% per degree, as given by Langmuir, the difference in V_s for nitrogen at −183° and −195° should be 7 cu. mm., which is in excellent agreement with the observed value of 6 cu. mm.

Heat of Sorption.—Of the several methods for calculating heat of sorption, that described by

(12) Wilkins, *Proc. Roy. Soc.* (London), **A164**, 510 (1938).

(13) Smittenberg, *Rec. trav. chim.*, **53**, 1065 (1934).

(14) Wilkins and Ward, *Z. physik. Chem.*, **144**, 259 (1929).

Brunauer, Emmett and Teller[5] appears to be the most reliable. This method, which yields the average heat of sorption, when applied to the present data for −195° and −183°, yields the heat effects shown in Table III, which includes, for comparison, the heat of liquefaction of each gas. In every case, the heat of adsorption lies in the range 2800 to 3600 calories and is about twice the heat of liquefaction, again indicating that the sorption is chiefly of the van der Waals type. The heats of sorption on silver are also virtually identical with those for adsorption of the same gases on platinum foil at −183° (last column Table III) as calculated by the same method from Wilkins' measurements.[12]

TABLE III

COMPARISON OF THE CALCULATED HEAT OF SORPTION ON SILVER FOIL WITH THE HEAT OF LIQUEFACTION AND WITH THE CALCULATED HEAT OF SORPTION ON PLATINUM FOIL

Gas (surface)	Temp., °C.	Heat of adsorption, (cal./mole) Silver	Platinum[b]	Heat of liquefaction at nominal boiling point, cal./mole

O_2 (Pumped)	−195	2800		1630

[a] Temperature −189.5°. [b] Calculated from data of Wilkins.

Force–Area Curves.—Two methods, both based upon the Gibbs adsorption equation, are available for deriving the force–area curve of a sorbed film. The first was devised by Palmer,[15] who suggests that if the observations yield a straight line when log ϕ is plotted against v (Fig. 6), that is, if the potential can be represented as a function of v by the relation $\phi = \phi_0 e^{-sv}$, then the spreading force, F, of the film when volume v is adsorbed is given by

$$F = f\phi_0\, e^{-sv}(v + 1/s) + I$$

where f is a constant for adjusting units, ϕ_0 is the extrapolated value of the adsorption potential at zero volume adsorbed, s is the slope of the log $\phi - v$ line, (d log ϕ/dv), and I is an integration constant which is evaluated on the assumption that F is zero when v is zero. In applying this equation to adsorption data which yield a plot with two linear portions (Fig. 6), the value of the integration constant of the section covering the range of higher volume sorbed has been adjusted so that the value of F agrees with that of the other linear section at the intersection. The value of A, the area occupied per molecule, corresponding to a given value of F is calculated by dividing the geometric area of the surface by the number of molecules contained in the volume of gas sorbed.

The force–area cuvres for the several gases at −183°, derived on this basis, are shown in Figs. 7 and 8, which also include the force–area curve for an ideal two-dimensional gas at the same temperature, calculated by means of the relation $FA = 1.372T$. In every case the spreading force calculated by Palmer's method is less than that for an ideal gas in the range of relatively large values of A but is greater in the range of small values of A. The curves for argon and nitrogen are, as might be expected, very similar (Fig. 7). The curve for carbon monoxide falls very close to the ideal curve over the major part of the range covered. In the case of oxygen the deviation from ideality in the region of the larger values of A is more marked than in the case of any other gas at −183°. The curve for oxygen on a pumped out surface has not been given since it lies very close to that for total oxygen.

The corresponding force–area curves for the several gases at −195° have not been included. However, it may be said that these bear similar relation to the ideal curve at −195° with two exceptions. The curve for carbon monoxide at −195° falls more markedly below the ideal curve in the region of the larger values of A; the curves for oxygen lie closer to the ideal curve, that for oxygen on a pumped out surface practically coinciding with it.

The resemblance of these curves to the corresponding P–V curve of a three-dimensional gas is striking, yet the data are not adequately represented by a two dimensional analog of van der Waals' equation of the form $(F + C/A^2)(A - A_0) = kT$, where C and A_0 are constants. The deviations from this relation are, however, of the same kind as are obtained when the van der Waals' equation is applied to a three dimensional gas.

The force–area curves bear an even stronger resemblance to those for certain insoluble films on water. Thus, in a number of them there is a rather sudden break in the curve in the range of lower values of A, indicating a much more marked

(15) Palmer, *Proc. Roy. Soc.* (London), **A160**, 254 (1937).

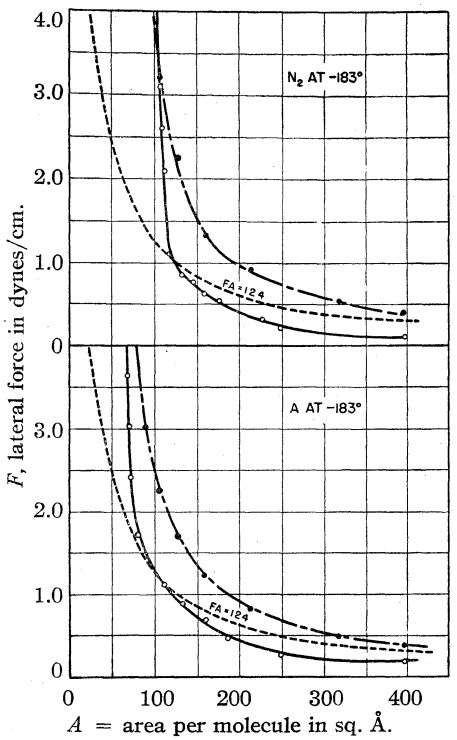

Fig. 7.—Variation of lateral force with surface area per molecule for N_2 and A sorbed at −183°. Full lines calculated by Palmer's method, dot-dash lines by method of Innes and Rowley. Dotted curve for an ideal two dimensional gas ($FA = 1.372T$).

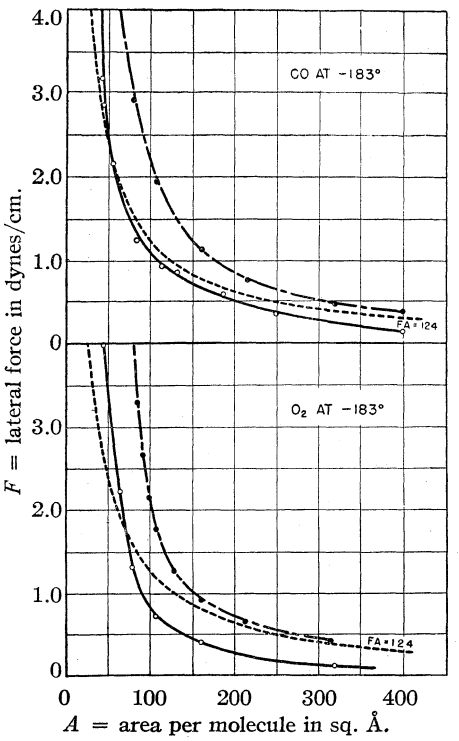

Fig. 8.—Variation of lateral force with surface area per molecule for CO and O_2 (baked surface) at −183°. (Curve for O_2 on pumped out surface lies close to that for the baked surface.) Full lines calculated by Palmer's method, dot-dash curves by method of Innes and Rowley. Dotted curve is for an ideal two dimensional gas ($FA = 1.372T$).

increase in spreading force with decrease in area. Too much emphasis should not be placed upon the significance of this break, however, since the occurrence of the break is in part probably a consequence of the assumption that the Palmer isotherm consists of two linear branches, that is, that there is, in effect a discontinuity on the isotherm. It is, nevertheless, interesting to compare the value of A obtained by extrapolating the steep part of the curve to $F = 0$ with the area per molecule as calculated from v_s. This comparison is made in Table IV. For argon and nitrogen at −183° and for carbon monoxide at −183 and −195°, the agreement is fairly good, but in the other cases the value of A obtained from the force–area curve is of the order of twice that calculated from v_s. This is the deviation which is to be expected, however, since the force–area curve indicates the area at which the virtual compressibility of the film becomes markedly less, whereas the other method gives the value in a much more highly compressed film. It should be noted that in every case the area per molecule is many times greater than the mean cross section of the molecule in liquid phase at this temperature; moreover, the area per molecule at saturation is less at −195° than at −183°.

TABLE IV

COMPARISON OF CROSS-SECTIONAL AREA/MOLECULE FROM FORCE–AREA CURVE AND LANGMUIR'S ISOTHERM

Gas (surface)	Temp., °C.	Area/molecule in sq. Å. at break in force–area curve	Area/molecule in sq. Å. at Langmuir saturation
A	−183	70	65.3
N_2	−183	128	104.1
N_2	−195	120	89.2
CO (Baked and	−183	44	41.3
pumped)	−195	27	23.4
O_2 (Baked)	−183	52	33.0
O_2 (Pumped)	−183	113	70.4
O_2 (Baked)	−195	37	17.9
O_2 (Pumped)	−195	25	13.9

The second method of calculating the force–area curve is a graphical one based on the following equation reported by Innes and Rowley[16]

$$FA = v_1 RT + RT \int_{p/v \text{ as } v \longrightarrow 0}^{p_1/v_1} v \, \mathrm{d} \ln \left(\frac{p}{v}\right)$$

(16) Innes and Rowley, *J. Phys. Chem.*, **45**, 158 (1941).

in which F is the spreading force in dynes/cm., and v and v_1 are the volumes of gas adsorbed at pressures p and p_1, respectively.[17] Hence, by plotting v against ln (p/v) and measuring the area under the curve between the desired limits, the value of FA may be readily computed. The extrapolation involved in this method introduces some uncertainty since reliable values of v and of p/v are difficult to obtain experimentally as v approaches zero. The several force–area curves derived by this method are shown by the dash-dot lines in Figs. 7 and 8. Without exception they lie above the curve for an ideal two-dimensional gas and they do not show the sharp break evident in the curves derived by Palmer's method.

The curves derived by the Innes–Rowley method indicate the existence of large repulsive forces acting between the sorbed molecules over the entire range of sorption covered, whereas, the curves derived by the Palmer method indicate that attractive forces predominate in the range of small volume sorbed but that repulsive forces predominate when the volume sorbed approaches saturation. This difference in the two methods is not easy to explain but is probably due in part to the extrapolations necessary in each case.

Comparison of Sorption of Oxygen on Foil and on Powder.—The sorption of oxygen on two samples of finely-divided silver at −183° and −78.5°, and at pressures up to one atmosphere, has been measured by Benton and Drake[18] with results which, though in many respects similar to those obtained with silver foil, are in others significantly different. Thus, on the powder, as on the foil, the sorption at −183° is chiefly of the van der Waals type with, however, an indication of a small amount of a somewhat stronger sorption characterized by a relatively slow rate of sorption for the initial additions of oxygen. At −78.5°, the sorption is in each case chiefly of the activated type; moreover, at this temperature the isotherm is in each case of the saturation type in which the amount of oxygen adsorbed is substantially independent of pressure over virtually the entire range of pressure studied, that is, up to 0.1 cm. on the foil and on the powder up to the dissociation pressure of silver oxide.

The chief point of difference is in the isotherms at −183°. On the foil there is a flattening of the curve at a pressure of less than 0.01 cm. and at a volume of gas sorbed corresponding to only a fraction of a close-packed monolayer, with no appreciable further sorption up to a pressure of about 0.15 cm. In contrast, the isotherm for the powder gives no indication of flattening of the curve at low pressures, although the data for this range are not very satisfactory, but has the S-shape characteristic of adsorption which is multimolecular at the higher pressures. On the basis that the beginning of the linear portion of the isotherm for the powder corresponds to the first appearance of a second layer, an assumption used to estimate the surface area of powders,[19] the first layer on the powder is complete at a pressure of approximately 10 cm. which is 1000 times greater than the pressure at which the surface of the foil appears to be saturated. It should also be noted that on the pumped out foil at −195° the sorbed oxygen forms a substantially complete monolayer, and that this apparent saturation is very nearly achieved at a pressure of the order of 0.1 cm. These facts indicate that although the forces involved may be basically the same they differ in degree between the surface of a powder and that of foil. This difference is further illustrated by a comparison of the heat of adsorption on the different surfaces. Thus the heat derived by means of the Brunauer–Emmett–Teller equation for powder II, used by Benton and Drake, is 2390 cal. which is significantly lower than the heat of 3560 cal. calculated for the foil by the same method. A difference such as this between the surfaces, also the fact that the range of pressure studied is considerably lower than is used for powders, may account for the apparent flattening of the curve at relatively lower pressures in the case of the foil.

Another interesting comparison is that the surface concentration of oxygen in the activated adsorption at −78.5° is the same on the foil as it is on the powder. Thus, on the foil, the concentration is 0.22×10^{15} molecules per sq. cm., as calculated from the value of V_s and the geometric surface area. The surface area of the powders used by Benton and Drake, as estimated by means of the Brunauer–Emmett–Teller equation, is 13 and

(17) The relation given by Innes and Rowley is

$$FA = RT \int_{v=0}^{v=v_1} \ln \frac{p_1}{p}\, dv$$

but in a personal communication they have suggested the alternative form above because it requires a less difficult extrapolation.

(18) Benton and Drake, THIS JOURNAL, **56**, 255 (1934).

(19) Emmett and Brunauer, *ibid.*, **59**, 1558 (1937).

26 sq. m., respectively,[20] for powders I and II. On the basis of these areas, the surface concentration of oxygen at −78.5° is 0.21×10^{15} and 0.16×10^{15} molecules per sq. cm. which is virtually identical with that on the foil. The fact that the oxygen held on the foil so strongly at −183° that it could not be pumped off at temperature was also present on the surface at a concentration of 0.16×10^{15} molecules per sq. cm. suggests, though it does not prove, that the sites which hold oxygen so strongly at −183° are the same upon which activated adsorption occurs at −78.5°.

It is interesting to note that if one assumes that the activated adsorption at −78° represents the formation of a silver oxide complex on the surface, the number of sites is about equal to the observed number of molecules sorbed. Thus, on this basis, each oxygen molecule would be associated with 4 atoms of the silver on the surface. The X-ray diffraction patterns indicate that as a first approximation the silver grains are so arranged that the (110) planes lie on the surface, and since, on this plane, four silver atoms occupy an area of about 46 sq. Å., the concentration of groups of sites of four silver atoms is about 0.22×10^{15} per sq. cm., which corresponds very well with the observed concentration of oxygen sorbed at −78°, and to the concentration of oxygen held so tightly at −183° that it cannot be removed by pumping at temperature.

(20) Assuming that the cross section of an oxygen molecule in a complete monolayer is 12 sq. Å.

Summary

The adsorption of hydrogen, nitrogen, argon, carbon monoxide, carbon dioxide and oxygen at pressures up to 0.1 cm. on a substantially plane, reduced surface of silver has been measured over the temperature range −195 to 20°. Hydrogen is not measurably sorbed at any temperature; argon, nitrogen and carbon monoxide are sorbed at −195 and −183° but not at −78 or 20°. Carbon dioxide is not sorbed at 20° but at −78° is sorbed to the slight extent of 6 cu. mm. at a pressure of 0.02 cm. The adsorption is in each case instantaneous and reversible. Oxygen is sorbed at −195 and −183° and although most of the gas appears to be held by van der Waals forces some part of it cannot be removed by pumping at temperature. At −78 and 20° there is activated adsorption of oxygen. All the isotherms are of the type observed in a plane surface of other metals, and are satisfactorily represented by the Langmuir equation. The values of V_s as derived from the slope of the $p/v - p$ isotherm, correspond to a surface only partially covered, the coverage varying from about 20 to 90% of a close-packed monolayer.

Force–area curves are derived by two different methods, with results which differ significantly. The adsorption of oxygen on smooth silver is compared with the adsorption of oxygen on finely-divided silver as reported by Benton and Drake.

The Attachment and Detachment of Dropping Mercury under Various Conditions

BY I. M. KOLTHOFF AND G. J. KAHAN

Although the mercury–water interfacial tension is little affected by dissolved non-capillary active electrolytes in the aqueous phase, it has been found by several workers that the drop time of mercury from a glass capillary into air-saturated water can be quite different from that into electrolyte solutions. For example, J. Heyrovský reports[1] that his capillary had a drop time of six to eight seconds in distilled water and of three seconds in electrolyte solutions. On the other hand, Kolthoff and Lingane[2] mention that with their capillary the drop times in water and in 0.1 *M* potassium chloride were hardly different. It is not stated whether the water used was air-free.

In our experiments we found that the drop time of an electrically disconnected capillary in air-containing water was badly reproducible and, as a rule, much larger than in 0.1 *M* salt solutions. Slight deviations from the vertical in the position of the capillary resulted in large variations of the drop time, whereas no such effect was found in not

Fig. 1.

too dilute electrolyte solutions. By slightly changing the angle of inclination it was sometimes possible to obtain the same drop time in air-containing water as in electrolyte solutions, the agreement being merely accidental and not readily reproducible. Moreover, it was found that the ratio $t_{H_2O}/t_{0.1\ M\ KCl}$ of an electrically disconnected capillary in air-saturated solutions depended greatly upon the properties of the capillary. A ratio of the order to 2 to 3 was found with capillaries of small diameter and small length, while wider capillaries with greater length gave ratios close to 1.

The present study attempted to find the reason for the large erratic drop time found in air-containing water when narrow, short capillaries were used. Microscopic observation of the drops revealed that in case of an abnormally large drop time the drop of mercury remained attached to the glass during its life-time (Fig. 1). Pictures 1 and 2 were obtained with capillary no. 1 which was short and had a small diameter. Picture 1 shows the drop of mercury in air-saturated water just before it fell. Picture 2 was made with the same capillary but in 0.1 *M* potassium chloride solution. In distilled water the drop touched the glass and it was larger than in 0.1 *M* potassium chloride solutions. In the electrolyte solution the drop did not touch the glass, but was suspended symmetrically from the bore of the capillary. In air-containing distilled water it hung sideways from the glass. The area of glass touched by the mercury depended upon the inclination of the capillary, and upon small irregularities of the glass surface. The short capillary (no. 1) delivered 1.62 mg. of mercury per second in 0.1 *M* potassium chloride solution without electrical connection. The drop time of this capillary was 2.5 seconds in 0.1 *M* potassium chloride solution and was of the order of three and one-half to four seconds in air-saturated distilled water.

In 0.1 *M* potassium chloride solution the drop time is approximately given by the equation

$$mgt = 2\pi r\sigma \qquad (1)$$

in which m is the mass of mercury that flows from the capillary per second, g is the acceleration due to gravity, t is the drop time, r is the radius of the bore of the capillary and σ is the interfacial tension between mercury and the solution. Experimental data which demonstrate the validity of the expression[1] are found in Kolthoff and Lingane.[3] When the drop is attached to the glass, this equation does not hold. Here not only the mercury-solution interfacial tension but also the mercury-

(3) I. M. Kolthoff and J. J. Lingane, "Polarography," Interscience Publishers, Inc., New York, N. Y., 1941, p. 68.

glass interfacial tension contribute to the support of the drop. The drop weight is greater under these conditions than when the drop is not attached to the glass.

Pictures 3, 4 and 5 were obtained with capillary no. 2, which had a wide bore, a length of 20 cm. and a drop time of three seconds in 0.1 *M* potassium chloride. The dropping mercury was always electrically disconnected unless otherwise stated. Picture 3 in Fig. 1 was taken when the mercury was dropping into air-saturated water. At the moment when the picture was taken the mercury was attached to the glass. At a later stage during the life of the drop the weight became large enough to detach it from the glass, but the force resulting from the interfacial tension between the mercury and the solution kept the drop suspended. Equation (1) was found to hold approximately, even though the drop was attached to the glass during part of the time. After the drop became detached from the glass its appearance and characteristics became closely similar to that of the drop formed in 0.1 *M* potassium chloride (pictures 4 and 5, Fig. 1). The ratio of the drop time in water and 0.1 *M* potassium chloride solution was close to unity.

In order to find the factors which are responsible for the attachment or detachment of the mercury to the glass experiments were carried out with water or aqueous solutions from which the air had been displaced by hydrogen. The capillary used (no. 3) had approximately the same characteristics as capillary no. 1. It was found that in the absence of oxygen the drop time of the electrically disconnected capillary in water was normal and close to the drop time in 0.1 *M* potassium chloride solutions. However, when connection was made with a pool of mercury in the bottom of the cell, the drop time in water became abnormally large and the drop became attached to the glass during its lifetime. When a positive potential was applied to the dropping mercury electrode, the drop time increased, whereas it decreased upon application of a negative potential. When the current became zero or cathodic, the drop time became normal. A normal drop time was accompanied by detachment of the drop from the glass. Some typical data are found in Table I.

In air-free 0.001 *M* potassium chloride solution, the results were qualitatively the same as in distilled water, but the drop times were smaller (see Fig. 2).

TABLE I

MERCURY DROPPING INTO AIR-FREE DISTILLED WATER SATURATED WITH HYDROGEN (CAPILLARY NO. 3)

E, applied volts	*i*, microamp.	*t*, seconds	Microscopic observation
Not connected	..	5.5	Detached
+0.8	−1.5	13.2	Attached
+ .5	−0.5	13.5	Attached

Discussion

From the fact that the drop time of the electrically disconnected mercury in air-free water was normal but became abnormal upon connection with the mercury pool, it was concluded that normal or abnormal drop time, accompanied by detachment or attachment of the drop of mercury to the glass depended upon the interaction of the double layers at the glass and mercury interfaces. Glass in contact with distilled water acquires a negative charge and the sign of its electrokinetic potential is negative. In distilled water the electric field of the electrokinetic potential extends relatively far beyond the layer of liquid firmly attached to the glass. Electrically disconnected mercury dropping into pure air-free water is uncharged and there is no electrokinetic potential at the mercury–water interface. However, when the dropping mercury is electrically connected with the mercury pool at the bottom of the cell, it acquires a positive charge and the electrokinetic potential is positive. Again the electrokinetic field at the mercury–water interface extends far beyond the liquid layer firmly attached to the mercury surface. Thus when the glass with its firmly adhering water layer and the mercury with its adhering water layer come together, the negative field around the glass attracts the positive field around the mercury, and the drop remains attached to the glass.

This explanation is substantiated by several of the experiments described. In 0.1 M or more concentrated electrolyte solutions the double layers are compressed and do not extend beyond the firmly adhering liquid films. Detachment results.

In 0.001 M potassium iodide solutions there is a strong adsorption of iodide ions on the mercury and a negative instead of a positive electrokinetic potential at the mercury results.[4] In this case the two double layers have the same sign; they repel one another and detachment results.

In 5×10^{-5} M thorium nitrate the electrokinetic potential of the glass is positive. At the positive side of the isoelectric point of the mercury the sign of the double layer is also positive. The double layers at the glass and mercury surfaces repel each other and the drop remains detached.

At first glance one might expect that on the negative side of its isoelectric point the mercury in the thorium nitrate solution would become attached to the glass. However, the tetravalent thorium ions compress the negative double layer around the mercury so much that the electric intensity outside the attached liquid film is zero.

Not explained are the facts that the drops of anodically polarized mercury become attached to the glass in 10^{-5} M lanthanum chloride and 10^{-5} M thorium nitrate.

In the experimental part it was shown that the electrically disconnected mercury becomes attached to the glass when it is dropping into air-saturated water. Under these conditions the mercury is no longer electrically neutral. By the adsorption of oxygen it acquires a positive charge. Hence, there again results interaction between the negative field close to the glass and the positive field close to the mercury, leading to attachment.

In the above we have considered the interaction between the two liquid films as the primary cause of the attachment. Whether there is an aqueous film between the attached mercury and the glass or whether the liquid is squeezed out cannot be answered on the basis of our experiments. In view of the experiments of Frumkin, *et al.*,[5] one could expect that such a film between the attached drop and the glass should exist.

In order to avoid the abnormal effects described in this paper it is recommended that the characteristics of a capillary—drop time and mass of mercury per second—always be determined in

0.1 *M* electrolyte solutions and not in distilled water.

Acknowledgment is made to the Graduate School of the University of Minnesota for a grant which enabled us to carry out this investigation.

Summary

1. When electrically disconnected mercury drops into air-saturated water or when mercury connected with a pool of mercury drops into air-free water an abnormally large drop time is found. The drop of mercury remains attached to the glass. The abnormal behavior becomes more pronounced the smaller is the bore of the capillary.

The results obtained with an abnormally dropping capillary are badly reproducible and depend greatly on the degree of inclination of the capillary.

2. The abnormal behavior has been interpreted on the basis of interaction between the electric double layers at the glass and at the mercury–aqueous phase interfaces.

Studies in Stereochemistry. II. Steric Strains as a Factor in the Relative Stability of Some Etherates of Boron Fluoride

BY HERBERT C. BROWN AND RICHARD M. ADAMS[1]

Modern physical techniques for studying gaseous molecules have contributed much information regarding molecular configurations.[2,3] In the main, these later results have confirmed those of the early workers in stereochemistry who drew their conclusions from isomer number and chemical reactions. In many instances, however, detailed data on atomic dimensions and valence angles and the careful study of small irregularities in the physical and chemical properties of substances has made possible some interesting extensions of the classical principles of stereochemistry.

One recent extension of this kind is based on evidence that steric interference between two groups may weaken considerably the bond joining the groups. To illustrate, the per cent. dissociation of the tetraaryldialkylethanes and the dixanthyldialkylethanes increases with increasing size of the alkyl group[4]; and the ortho methyl groups of sym-tetraphenyldi-*o*-tolylethane increase the dissociation into free radicals more than do the methyl groups of the corresponding meta or para derivatives (25% *vs.* 5%).[5]

Unfortunately, these examples are not entirely satisfactory. The molecules are large and complicated; moreover, interpretation of the results is made particularly hazardous by the fact that resonance plays an important part in the dissociation of such ethane derivatives. It would be highly desirable to have more substantial evidence of this same effect in simpler molecules in which resonance is not important. Recently, such examples of unmistakable weakening of bonds by steric strains have been found.[6] A study of the relative stability of some coördination compounds of borine, boron fluoride and trimethylboron with amines revealed that trimethylamine is a stronger base (in the generalized Lewis sense[7]) than pyridine toward the acids hydrogen chloride, borine and boron fluoride, but that the reverse is true when trimethylboron is used as the reference acid.

This "anomalous" result is apparently due to steric strains, for molecular models reveal that in the compounds studied considerable steric interference is to be expected only in trimethylamine-trimethylboron.[8,9]

There are reasons to believe that such steric strains are more common than has been supposed

(8) For a discussion of the nomenclature used for these coördination compounds, see Davidson and Brown, THIS JOURNAL, **64**, 316 (1942), footnote 11.

(9) It was pointed out that steric strains present in trimethylamine-trimethylboron must be duplicated in its isostere, hexamethylethane, since the dimensions and configurations of the two molecules are almost identical.[6] It is of considerable interest that in a recent electron-diffraction study of this hydrocarbon, Bauer and Beach [*ibid.*, **64**, 1142 (1942)] find evidence that the central C–C bond is stretched (1.58 *vs.* 1.54 Å.).

and that they play a far more important role in determining the physical and chemical properties of substances than has hitherto been realized. It appears highly desirable to obtain more information concerning the existence and magnitude of these effects. Accordingly, a study was made of the addition compounds between boron fluoride and some representative aliphatic ethers (methyl ether, ethyl ether, isopropyl ether and tetrahydrofuran). Particular attention was given to the effect of steric strains on the relative ease with which the addition compounds dissociate.

Experimental Part

Apparatus and Methods.—The high vacuum apparatus shown in Fig. 1 was constructed and used in the preparation and study of the etherates of boron fluoride. The materials were introduced into the apparatus through the tube opener, TO, and condensed in the desired section of the apparatus (*e. g.*, in the storage bulbs, SB) with aid of liquid nitrogen. The starting materials were purified by fractional distillation and fractional condensation in the fractionation system, FS. The homogeneity of the substances used in this investigation was usually established by vapor pressure measurements. (In some cases purification by distillation outside the vacuum system was relied upon.) The vapor pressure of the more volatile substances could be measured satisfactorily on the manometers, M_1 and M_2, in the fractionation system, FS. The vapor pressures of the less volatile substances were studied in the apparatus HTB (high temperature bulb).[10]

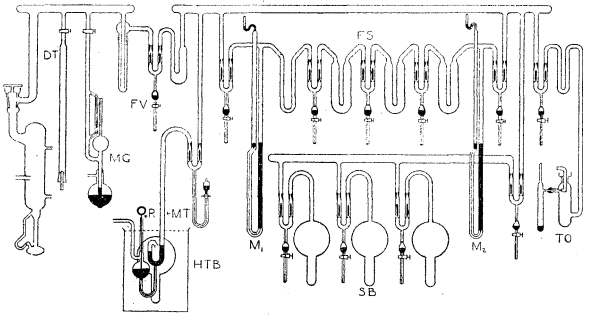

Fig. 1.—Diagram of apparatus.

This apparatus (HTB) was used as follows. The material was condensed in the apparatus with liquid nitrogen, the mercury was allowed to rise in the tube, MT, by raising the rod, R, thus shutting the flask off from the rest of the vacuum line. The entire apparatus was immersed in a heated bath and the pressures read with a cathetometer. The bath was constructed from a 3-liter beaker carefully selected for freedom from striations. The sides of this beaker were insulated with several layers of asbestos paper, but a narrow section opposite the manometer was left uncovered to serve as a window for observing the pressure. A close-fitting asbestos lid covered the beaker, which rested on a heavy copper plate heated with a gas flame. An air-driven stirrer kept the bath liquid (either water or paraffin oil) well stirred. With this bath the temperature could be maintained constant for periods of time more than sufficient for the purposes of the investigation.

Preparation and Study of the Etherates of Boron Fluoride.—The usual procedure for the preparation of the etherates of boron fluoride was to condense equal volumes (measured as gases under standard conditions)[11] of the ether and boron fluoride in the high temperature bulb, HTB. Very shortly after the liquid nitrogen was removed, the components reacted to form the addition compound.

The flask was heated by means of the bath previously described and the saturation pressures of the complex noted. After a series of measurements had been completed, a portion of the compound was removed to another part of the apparatus, and the observations were repeated on the portion remaining. The reproducibility of the values observed was taken as satisfactory evidence of the homogeneity of the products.

The degree of dissociation of the addition compounds ($R_2O:BF_3 \rightleftarrows R_2O + BF_3$) over a range of temperatures was studied in the same apparatus, HTB. Equal volumes of ether and boron fluoride were introduced into the flask and the pressures observed over a range of temperatures. Since the size of the samples introduced was selected so that the total pressure would be considerably below the saturation pressure of the complex, the degree of dissociation, α, could be calculated from the ratio of the observed pressure to the pressure calculated assuming no dissociation. The equilibrium constant at each temperature was then calculated from the value of α by the use of the equation

$$K_p = \alpha^2 P/(1 - \alpha^2)$$

The free energy change, ΔF, was calculated from the equilibrium constant

$$\Delta F = -RT \ln K$$

Finally, from the variation in K with temperature, ΔH could be calculated by the well-known thermodynamic equation

$$\Delta H = RT^2 \frac{\mathrm{d} \ln K}{\mathrm{d}T}$$

Since the etherates of boron fluoride dissociate almost completely at temperatures where the saturation pressures of the complexes are high, it was necessary to work at comparatively low pressures (10–30 mm.). Preliminary experiments indicated that it was possible to measure pressures over a considerable range of temperature to better than 0.1 mm. This accuracy was considered satisfactory. The observed readings were, of course, corrected for the density of mercury and its vapor pressure (the latter correction was necessary because one limb of the manometer was open to a high vacuum).

Results

Methyl Ether–Boron Fluoride, $(CH_3)_2O:BF_3$.—The addition compound, methyl ether–boron fluoride, was prepared by the reaction of 12.5 cc. of

(10) Burg and Schlesinger, THIS JOURNAL, **59**, 785 (1937).

(11) All volumes given in this paper refer to gases at standard conditions.

boron fluoride (p = 309 mm. at −111.6°)[12] and 12.4 cc. of methyl ether (p = 119.6 mm. at −60°)[13] at a low temperature. The product was a white solid which melted to a colorless liquid at −14 to −12°. The saturation pressure data of the complex are given in Table I and represented graphically in Fig. 2-A. It has been previously reported

that the "boiling point" of the complex is 126–8°.[14] Extrapolation of the saturation pressure curve to 760 mm. yields a value of 127° for the "boiling point." This is not a true "boiling point," since at this temperature the complex is practically completely dissociated into its components, methyl ether and boron fluoride.

The dissociation of the complex was studied over a range of temperatures in the manner previously described. Methyl ether, 5.83 cc., and 5.83 cc. of boron fluoride were condensed in the high temperature bulb (volume, 247.6 cc.) and permitted to react. The apparatus was then heated to a temperature at which the total pressure was below the saturation pressure of the complex and observations made over a range of temperatures. The results are summarized in

Isopropyl Ether–Boron Fluoride, $(i\text{-}C_3H_7)_2O$: BF_3.—A commercial sample of isopropyl ether was purified by distillation through a 16-plate column. The fraction boiling at 68° under 751 mm. with $n^{20}D$ 1.3682 was used. The addition compound, isopropyl ether–boron fluoride, was prepared by condensing together (in the high temperature bulb) 31.0 cc. of boron fluoride and 31.0 cc. of isopropyl ether at the temperature of liquid nitrogen. The addition compound is a white solid at room temperature; its melting point is above 68°, but quite indefinite, apparently because of rapid decomposition of the complex at these temperatures.[17] This instability was also evidenced by its behavior during preliminary studies of its saturation pressures. At temperatures up to 45–50°, the complex did not undergo any apparent change. Above 50°, however, a slow, irreversible change of some sort occurred, for the pressure began to increase slowly, although the temperature was maintained constant. At about 68°, decomposition was so rapid that within a few minutes, the pressure rose to 180 mm.—about twice 97.8 mm., the value at 61°. After reaching this maximum value, the pressure dropped, rapidly at first, then more slowly. By working fast, and using freshly prepared samples of the complex, it was found possible to obtain reproducible values of the saturation pressures at temperatures up to 61°. The data are listed in Table V and are represented graphically in Fig. 4-A.

TABLE V

SATURATION PRESSURES OF ISOPROPYL ETHER–BORON FLUORIDE

Temp., ° C.	23	30	40	50	61

Because of this instability of the complex its dissociation could be studied only over a relatively

(17) This decomposition was studied, but no definite conclusion was reached as to the reactions involved. It is probable that the first step is the splitting of the ether with the formation of isopropyl fluoride and isopropoxy boron fluoride, a reaction similar to the well-known reactions of boron chloride and boron bromide with ethers [Wiberg and Sütterlin, *Z. anorg. allgem. Chem.*, **202**, 22 (1931); Benton and Dillon, THIS JOURNAL, **64**, 1128 (1942)]. The isopropyl fluoride then probably reacts with the boron fluoride present [Burwell and Archer, *ibid.*, **64**, 1033 (1942)], forming polymeric materials of low volatility.

short temperature range. Boron fluoride, 3.10 cc., was condensed with 3.10 cc. of isopropyl ether in the high temperature bulb in the usual manner. (It was necessary to work with a small sample in order to volatilize completely the material at a temperature where the rate of decomposition was comparatively slow.) The small size of the sample and the necessity for making rapid measurements reduce the accuracy of the data. However, they clearly indicate that the complex is highly dissociated. The results of the dissociation studies are listed in Table VI and shown graphically in Fig. 4-B. Because of the low accuracy and short temperature range, no attempt has been made to draw a line through the points on the graph (4-B).

TABLE VI

DISSOCIATION PRESSURES OF ISOPROPYL ETHER–BORON FLUORIDE

Tetrahydrofuran–Boron Fluoride, $C_4H_8O:BF_3$. —Tetrahydrofuran was prepared by the decarboxylation of 2-furancarboxylic acid[18] followed by reduction of the resulting furan.[19] The product was distilled through a fractionating column with a rated efficiency of 16 theoretical plates, and a middle fraction (b. p. 65° at 747 mm.; $n^{20}D$ 1.4049) was taken for use in this investigation. The addition compound, tetrahydrofuran–boron fluoride, was prepared by the reaction of 35.0 cc. of tetrahydrofuran with 35.0 cc. of boron fluoride at the temperature of liquid nitrogen. The product was a white solid which melted to a colorless liquid at 8–10°. The saturation pressure data of the complex are given in Table VII and Fig. 5-A.

Discussion

It is a generally accepted postulate of modern electronic theories of organic chemistry that the substitution of an alkyl group for hydrogen in a molecule produces an electronic displacement away from the substituent.[20] The increase in

(20) Ingold, *Chem. Revs.*, **15**, 225 (1934).

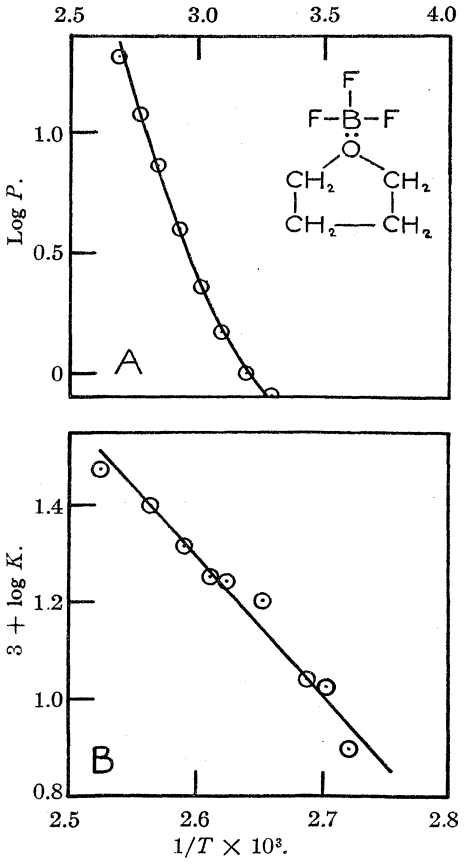

Fig. 5.—Tetrahydrofuran–boron fluoride: A, saturation pressure data; B, dissociation data.

basicity noted in the series[21] ammonia, methylamine and ethylamine is thus explained.

NH_3	$CH_3 \rightarrow NH_2$	$CH_3 \rightarrow CH_2 \rightarrow NH_2$
$K = 1.8 \times 10^{-5}$	5.0×10^{-4}	5.6×10^{-4}

The decrease in acidity in the series water,[21] methyl alcohol[22] and ethyl alcohol[23] is similarly interpreted.

HOH	$CH_3 \rightarrow OH$	$CH_3 \rightarrow CH_2 \rightarrow OH$
$K = 1 \times 10^{-16}$	7×10^{-18}	7×10^{-20}

It would, therefore, be predicted that ethyl ether should be a somewhat stronger base than methyl ether. However, if boron fluoride is used as the reference acid, the opposite is true. Under comparable conditions ethyl ether–boron fluoride is more highly dissociated than the corresponding methyl ether complex (Table IX).

It is suggested that this inversion is due to steric strains which are more important in the ethyl ether complex than in the corresponding methyl ether derivative. This conclusion is based on the following considerations. Three possible configurations of the ethyl ether molecule are shown in Fig. 6-B, D, F. The last of these may be immediately discarded because of the tremendous strains involved—the distance between the two methyl groups is only 1.7 Å. whereas the van der Waals radius of each methyl group is approximately 2.0 Å. It is more difficult to decide be-

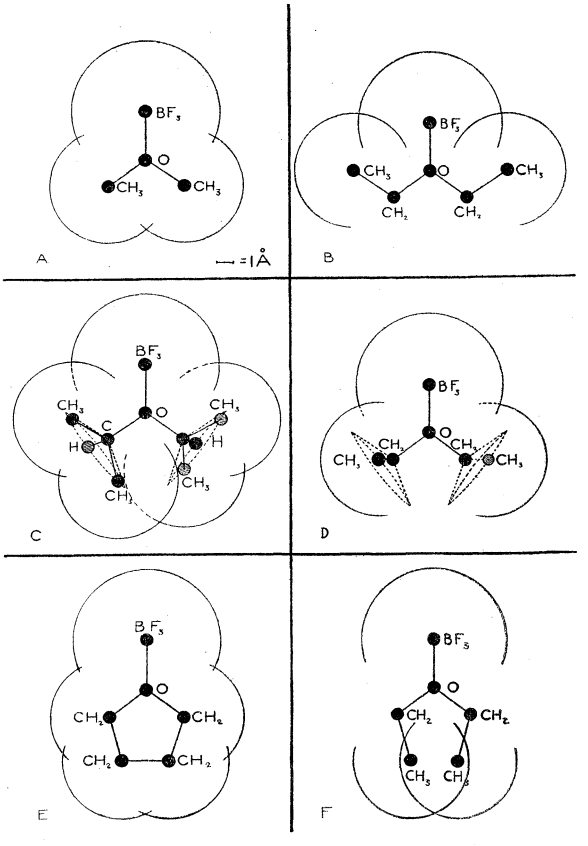

Fig. 6.—Molecular models: A, methyl ether–boron fluoride; B, D, F, ethyl ether–boron fluoride; C, isopropyl ether–boron fluoride; E, tetrahydrofuran–boron fluoride. These models are constructed using the bond distances and van der Waals radii given by Pauling.[3] The van der Waals radii are reduced somewhat (25%) to permit clearer visualization of the relative steric strains.

tween the other two possibilities (Fig. 6-B, D), but there are good reasons to believe that the arrangement shown in Fig. 6-B is the normal configuration of the ethyl ether molecule.[24]

The addition of boron fluoride to an ethyl ether molecule with this configuration must be markedly hindered as a result of the position of the end methyl groups and the size of the boron fluoride molecule (Fig. 6-B). In all probability, the addition of the boron fluoride group to the oxygen atom is accompanied by a rearrangement of the ethyl ether molecule into a configuration of somewhat higher energy, such as is shown in Fig. 6-D. As a result, the stability of the ethyl ether complex with respect to dissociation into its components is lowered relative to the corresponding methyl ether complex (Fig. 6-A).

The argument may be extended to the isopropyl ether–boron fluoride complex (a possible configuration for which is shown in Fig. 6-C), leading to the conclusion that the dissociation of this complex is also favored by the steric effects. Of the three ethers, isopropyl ether is the weakest base (Table IX), although from the inductive effect of the alkyl groups, it would have been predicted to be the strongest.

In order to test the hypothesis, the study of the dissociation of tetrahydrofuran–boron fluoride was undertaken. On the basis of the factors commonly believed to control base strength, it would be predicted that this cyclic ether would be approximately equal in strength to ethyl ether. If steric strains play the important role ascribed to them in this publication in altering the stability of addition compounds, it follows that the base strength of this cyclic ether should be markedly greater than that of ethyl ether, since the rigidity of the five-membered ring greatly reduces the possibility of steric strains (Fig. 6-E). The fact that tetrahydrofuran–boron fluoride is by far the most stable of the etherates studied (Table IX) lends considerable support to the hypothesis of steric strain.

(24) Stuart, *op. cit.*, pp. 101–102, 236; *Phys. Rev.*, **38**, 1372 (1931); *Z. Physik*, **63**, 533 (1930). Stuart bases his conclusion upon evidence from dipole moment studies, upon his investigations of the Kerr constant, and upon considerations of atomic dimensions and bond angles.

Summary

1. The boron fluoride addition compounds with methyl ether, ethyl ether, isopropyl ether and tetrahydrofuran have been prepared and characterized.

2. The dissociation of these compounds ($R_2O:BF_3 \rightleftarrows R_2O + BF_3$) was studied over a range of temperatures; and ΔH, ΔF and ΔS for the reaction were obtained.

3. The basic strength of the ethers decreases in the order: tetrahydrofuran, methyl ether, ethyl ether, isopropyl ether. This order is inexplicable on the basis of the factors generally believed to control base strength. The anomalies may be accounted for by taking into consideration the probable steric strains resulting from spatial limitations within the respective molecules.

Studies in Stereochemistry. III. The Preparation of *d*-1-Deutero-2-methylbutane and the Study of Its Optical Rotation

BY HERBERT C. BROWN AND CORNELIUS GROOT[1]

The discovery of isotopes has brought about far-reaching changes in the prevalent concepts and has opened up a wide variety of problems for investigation. One of these which is of considerable importance to stereochemistry has not yet been conclusively solved, in spite of numerous attempts. The point at issue is whether a substance such as

$$R'—\overset{\displaystyle R_1}{\overset{|}{\underset{\underset{\displaystyle R_2}{|}}{C}}}—R'',$$

in which the two atoms or groups R′ and R″ differ only in their isotopic composition, exhibits optical activity. At the present time, all attacks upon the problem have been restricted to the use of hydrogen and deuterium as the isotopic substituents. These two isotopes differ much more than others in their chemical and physical properties; moreover, until

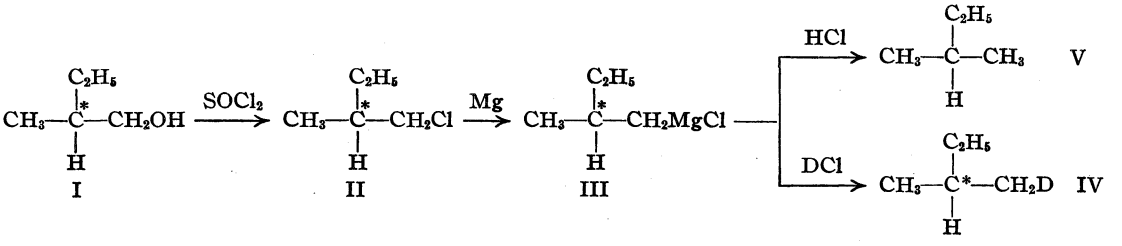
(1) This paper is taken from a dissertation submitted by Cornelius Groot to the Faculty of the Division of the Physical Sciences of the University of Chicago, in partial fulfillment of the requirements for the degree of Master of Science.

recently they have been the only isotopes available in large quantities.

The question whether the difference between hydrogen and deuterium may give rise to optical activity has been investigated mainly by three general methods: (1) resolution of a suitable hydrogen–deuterium compound by classical means; (2) introduction of deuterium into a compound containing one asymmetric center so as to induce a new asymmetric center (partial asymmetric synthesis); and (3) introduction of deuterium into a suitable active compound in such a way that two groups attached to the asymmetric center become structurally identical but isotopically distinct.

In spite of repeated investigations[2] involving each of the three general procedures, no definite decision to the question of isotopes as a source of optical activity can yet be made. It is evident that the first two methods (resolution and partial asymmetric synthesis) are less satisfactory than the third method mentioned. Failure to resolve a compound or failure to induce a new asymmetric center does not permit valid conclusions to be drawn with regard to the cause of the failure. This failure may be due to the experimental techniques, or to the insensitivity of the instruments used, or perhaps to the inherent nature of the substance. On the other hand, more definite information should be obtainable by suitable application of the third method. The compound formed will either be observed to be optically active or an upper limit will be put on the optical activity resulting in this instance from the hydrogen–deuterium asymmetry. To obtain such definite results, it is however essential that the starting material be optically active, easily obtained in moderately large quantities and easily purified; that it be readily transformed into the desired product by reactions which are very unlikely to affect the active center; and that the reaction product be one which can be rigorously purified.

These stringent conditions for the starting product are satisfactorily filled by *d*-2-methylbutanol-1 (I). Large quantities of this material can be isolated readily in a high state of purity from fusel oil[3]; moreover, the substance can be transformed by simple reactions (II, III) into the desired product, *d*-1-deutero-2-methylbutane (IV), which may be rigorously purified by distillation through an efficient column. The boiling point of isopentane (27.7°) or of its deuterium derivative is much lower than that of any probable optically active impurity.[4]



Accordingly, the preparation of *d*-1-deutero-2-methylbutane by these reactions was undertaken. A total of five preparations were carried out. In three of the preparations the Grignard reagent (III) was treated with deuterium chloride; in the other two, with hydrogen chloride. The product (IV or V) of each run was carefully fractionated in a column (rated efficiency: 100 theoretical plates) and 10 approximately equal fractions (10–12 cc.) collected. This material was then examined for possible activity in a sensitive polarimeter at the University of Illinois.[5]

The instrument, a Schmidt and Haensch (Berlin) product, was constructed to read rotations to a thousandth of a degree. Since for a colorless substance the magnitude of the rotation of plane polarized light is approximately inversely proportional to the square of the wave length, the mercury green line at 5461 Å. was utilized for the observations. After a number of preliminary experiments, the zero reading (the average of five consecutive determinations) could be reproduced with an average deviation of 0.001°.

(2) Previous work on the subject is reviewed by Buchanan, *J. Soc. Chem. Ind.*, **57**, 748 (1938).

(3) Brauns, *J. Research Natl. Bur. Stand.*, **18**, 315 (1937); Whitmore and Olewine, THIS JOURNAL, **60**, 2569 (1938).

(4) To illustrate this point, calculation reveals that the distillation of a 50:50 mixture of *d*-1-deutero-2-methylbutane and *d*-1-chloro-2-methylbutane through a column operating at an efficiency of 50 theoretical plates yields a product which, per mole, *contains less than* 10^{-30} *mole of the active chloride.*

(5) The authors wish to express their appreciation of the kindness of Professors Roger Adams and Duane T. Englis in placing this instrument at their disposal. They also wish to acknowledge the assistance given them by Professor Englis and numerous students in the Department of Chemistry of the University of Illinois during this phase of the investigation.

In each run, fractions 2 through 9 were examined in the polarimeter in a tube of 1 dm. in length (the end fractions 1 and 10 were not studied, since such impurities as may have been present in the crude product would have concentrated in these fractions). Five consecutive readings of each fraction were taken. The results for all eight fractions in a run were then averaged to obtain the value for the run. These values, with the average deviations, are listed in Table I.

TABLE I

SUMMARY OF OPTICAL ROTATION DATA (1-DM. TUBE) FOR *d*-1-DEUTERO-2-METHYLBUTANE AND ISOPENTANE

Run	Substituent	Rotation	Average deviation
A	Deuterium	0.002	0.003
B	Hydrogen	.003	.005
C	Deuterium	.000	.003
D	Hydrogen	— .001	.002
E	Deuterium	.001	.001
Average for deuterium runs		.001	.001
Average for hydrogen runs		.001	.002

In Table II the data for run E are expanded to illustrate the accuracy which was attained. It is concluded that the optical rotation (1-dm. tube) of *d*-1-deutero-2-methylbutane is definitely less than 0.005° and is probably less than 0.002°.[6]

TABLE II

EXPANDED DATA OF DISTILLATION AND OPTICAL ROTATION (1-DM. TUBE) OF *d*-1-DEUTERO-2-METHYLBUTANE (RUN E)

Fraction	Volume, cc.	Boiling point, °C.	Barometric pressure, mm.	Polarimeter readings	Average	Rotation[a]
1	11	19.2–26.8	746	.....	...	...
2	10	26.8–27.0	746	2.323, 2.324, 2.322, 2.325, 2.327	2.324	0.001

10	9	Holdup	...	.....	...	...

[a] Calculated using the zero value 2.323 (average of 2.327, 2.320, 2.321). [b] Large part of fraction lost by evaporation in course of making measurements—unable to repeat observations to check result. Value is not included in average.

Experimental Part

Fractionation Column. Isolation of *d*-2-Methylbutanol-1.—The column used for the isolation of *d*-2-methylbutanol-1 from fusel oil was packed with single-turn metal helices.[7] The dimensions of the packed section were 108 inches by 7/8 inch. For convenience in assembling and handling, the column was constructed in three sections of equal lengths which fitted together by means of standard ground glass joints. Each section was vacuum-jacketed and equipped with an individual heating jacket. Since these heating jackets offer some advantages over the more conventional designs, they will be described in some detail. Each jacket consists of a 36-inch length of 2-inch glass tubing, the ends of which fit into grooves cut into Transite plates. These plates are held against the glass tube by four 0.25 inch steel rods, threaded at the ends and fitted with nuts. (In later designs of this heating jacket used for other fractionating columns, the end plates are constructed of Bakelite and the supporting rods are included within the glass tube, making a very compact unit.) The heating element consists of 12 lengths of 24 gage (B. and S.) nichrome wire. These wires, encased in lengths of 4-mm. glass tubing, extend longitudinally through the jacket, and are joined in series by means of connections on the Transite ends. A thermometer is suspended in each jacket. Since the heat loss from the column is greatly reduced by the vacuum jacket, it is unnecessary to control the temperature of the heating jackets very closely. Usually the temperature was maintained at 2–5° below the boiling point of the material being distilled, but considerably greater variations (such as sometime occurred at night during continuous operation) did not noticeably affect the efficiency of the column.

The construction of the column in three individual sections permits compensation for the difference between floor and ceiling temperatures (often as high as 20°). The glass construction of the column and the jackets permits instantaneous observation of flooding and constant examination of the condition of the packing. The efficiency of a single section of the column was examined in considerable detail with a *n*-heptane-methylcyclohexane test mixture, using the convenient graph of Lecky and

(6) It had been hoped that a more definite answer to the problem under discussion could be obtained by the use of a meter-long tube for the measurements. However, a number of circumstances made this impossible. The present activities of the authors make it highly improbable that they will be able to carry this project out within the next few years. The preparations have been carefully preserved, and will be available to anyone with the time and means for making the measurements.

(7) Fenske, Tongberg and Quiggle, *Ind. Eng. Chem.*, **26**, 1169 1934); Fenske, Tongberg, Quiggle and Cryden, *ibid.*, **28**, 644 (1936).

Ewell.[8] This section reached equilibrium conditions in less than forty-five minutes. At this time the composition of the test mixture in the head indicated an efficiency of 17 theoretical plates; at the end of four hours, the indicated efficiency was but slightly higher, 18 theoretical plates. The efficiency is thus one theoretical plate for every two inches of column length—a result which corresponds fairly well with the value obtained by Fenske and his co-workers.[7]

The fusel oil, a product of the United States Industrial Alcohol Company, contained 15.6% of the active material. Roughly 17% of the material distilled below 126°; this portion consisted chiefly of isobutyl alcohol (*ca.* 60%) and *n*-butyl alcohol (*ca.* 20%). Two distillations of the 2-methylbutanol-1-isoamyl alcohol fraction raised the concentration of the active alcohol to 85–90%. This material was considered satisfactory for the purposes of the investigation.

Preparation of *d*-1-Chloro-2-methylbutane.—The active alcohol was transformed into the corresponding active chloride by treatment with thionyl chloride and pyridine, according to Darzens' procedure.[9]

Four moles each of the active amyl alcohol and pyridine were placed in a 2-liter flask cooled by an ice–salt mixture. An efficient reflux condenser was attached to the flask by a ground glass joint; to the top of the condenser was fixed a dropping funnel and a tube to carry away the evolved gases. Through the dropping funnel 6 moles of thionyl chloride was added, the first two moles slowly over a period of sixty minutes, the remainder rapidly. The mixture was allowed to stand overnight at room temperature, then heated on the steam-bath for twenty-four hours, and finally poured into a 2-liter separatory funnel. The lower layer was drained off. The upper layer was treated with ice (to decompose excess thionyl chloride) and then washed first with small portions of water, next with saturated sodium carbonate solution, and finally again with water. The crude product was dried with calcium chloride and distilled. The fraction taken boiled from 98–102°. The yield of this crude product was 87%. This product was carefully fractionated and the fraction boiling at 99.5° at 750 mm., with $n^{20}D$ 1.4126 and $\alpha^{25}D$ +1.33°, was used in the subsequent experiments.

Preparation of *d*-1-Deutero-2-methylbutane.—The Grignard reagent was prepared from the active chloride in *n*-butyl ether and treated with deuterium chloride, conveniently generated by the action of benzoyl chloride on "heavy water."[10]

A 2-liter 3-necked flask was fitted with a 500-cc. dropping funnel, a mercury-sealed stirrer, and a reflux condenser protected by a calcium chloride tube. In this flask were placed 36 g. (1.5 moles) of magnesium, 100 cc. of *n*-butyl ether, and a few drops of methyl iodide to catalyze the formation of the reagent. Active 1-chloro-2-methylbutane, 143 g. (1.33 moles), was placed in the dropping funnel, and a few cc. were run into the reaction flask. The flask was heated on the steam-bath until cloudiness of the liquid indicated that reaction had begun. The dropping funnel was then nearly filled with *n*-butyl ether (approximately 350 cc.), its contents stirred, and the mixture run into the flask, drop by drop. The reaction was kept under control by cooling the flask with a water-bath (20–25°). (A colder bath stopped the reaction completely, thus causing a dangerous accumulation of the active 1-chloro-2-methylbutane.) The mixture of *n*-butyl ether and 1-chloro-2-methylbutane was added over a period of two hours, after which the water-bath was removed and the reaction mixture allowed to stand. After another hour, heat was no longer evolved, and the reaction was assumed to be complete. The mixture was then diluted to a total volume of 1000 cc. with more *n*-butyl ether.

A 2-ml. sample was pipetted out, added to about 40 ml. of 0.1 *N* standard acid, heated to boiling, and back-titrated with standard base, using phenolphthalein as indicator. The yield of Grignard reagent was 1.16 moles, or 87% of the amount calculated.

The apparatus for generating deuterium chloride[10] was connected to the reaction flask in place of the dropping funnel and deuterium oxide, 11.7 g. (1.17 equiv.), was converted to deuterium chloride, which was passed into the solution, cooled by means of an ice-bath, over a period of two to three hours. The solution was agitated vigorously in order to prevent caking of the magnesium salt. When the reaction appeared complete, the contents of the dry-ice trap were returned to the reaction flask, the deuterium chloride apparatus was replaced by a Vigreux stillhead and condenser, and the reflux condenser was replaced by a cork holding a thermometer. The receiving flask, immersed in an ice-bath, was connected to the condenser by an adapter. The only air outlet was through a side-arm on the adapter; this outlet led through a dry-ice trap. The reaction flask was heated in an oil-bath (at *ca.* 150°) until the inside temperature was 142°, the boiling point of pure *n*-butyl ether. The receiving flask was removed and weighed: the yield of crude product was 79 g. (1.08 moles), 92% of the calculated quantity based on either the Grignard reagent or the deuterium oxide. The material was then carefully fractionated in a Podbielniak "Heli-Grid" column.[11]

Summary

The object of the investigation was to determine whether a compound of the type $R_H—\overset{R_1}{\underset{R_2}{C}}—R_D$ (where the groups R_H and R_D differ only in their hydrogen and deuterium composition), exhibits a measurable optical activity. *d*-1-Deutero-2-methylbutane was prepared from *d*-2-methylbutanol-1 and examined in a sensitive polarimeter. It is concluded that the optical activity of the pure hydrocarbon in a 1-dm. tube is definitely less than 0.005° and probably less than 0.002°.

(11) The column, somewhat modified from the standard design of the Podbielniak Centrifugal Super-Contactor Company, was constructed for use with a total reflux-partial takeoff head. Solid carbon dioxide was used as the refrigerant in the head to minimize losses of the volatile product. The rated efficiency of the column is 100 theoretical plates. Its holdup, approximately 15 cc., is remarkably small for a column of such high efficiency, and made the column particularly useful for the purpose.

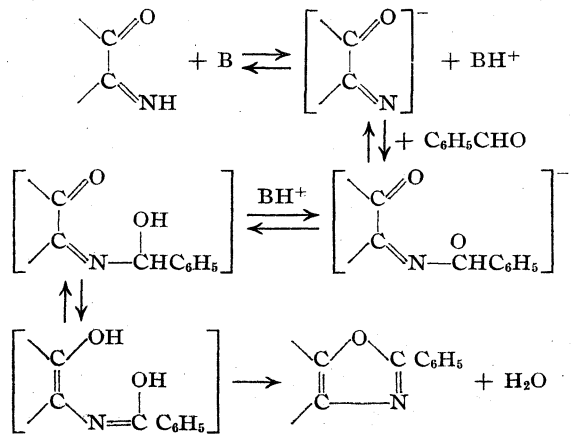
The Reactions of Retenequinonimine and Phenanthraquinonimine with Aldehydes. A New Example of an Aldol-Type of Condensation[1]

BY CHARLES W. C. STEIN[2] AND ALLAN R. DAY

In the course of the preliminary work leading to the present investigation, it was noted that the interaction of retenequinonimine, benzaldehyde, and *n*-butylamine gave excellent yields of 2-phenylretenoxazole. When aniline was substituted for the *n*-butylamine, a much lower yield of 2-phenylretenoxazole was obtained. The use of retenequinonimine, *n*-butyraldehyde, and *n*-butylamine produced 2-propylretenoxazole in excellent yields. Careful consideration of the components involved suggested two possible courses of reaction: (1) the aldehyde may undergo an aldol-type of condensation with retenequinonimine under the influence of the basic catalyst *n*-butylamine; and (2) the aldehyde and amine may react to form the Schiff base, benzal-*n*-butylamine, which then might condense with the quinonimine. It is possible that both courses of reaction could proceed simultaneously in the reactions noted above. Since the reactions of aldehydes with the quinonimine proved to be less complicated, they are presented first.

Several types of aldol condensations have been reported for compounds which contain the carbonyl group but apparently none have been reported where a quinonimine furnishes the labile hydrogen. To test the possibility of basic catalysis, amines were chosen which could not react with aldehydes to form Schiff bases. It was found that retenequinonimine and benzaldehyde reacted in the presence of triethylamine or piperidine to give excellent yields of 2-phenylretenoxazole. When the weaker base pyridine was used, however, no oxazole was formed. The above evidence indicates an aldol-type of condensation as the first step in the reaction. This is followed by an allylic-type shift of hydrogen and subsequently by the splitting out of water to form the oxazole. The course of the reaction may be represented as shown in the accompanying formulas. The last step, being irreversible, is an important determining factor in the reaction. In all of the reactions in which oxazole was formed, the solutions became dark red within a few minutes and then changed to yellow. Alcoholic potassium hydroxide can also be used to catalyze the reaction but the yields of oxazole (about 25%) were greatly reduced, due to side reactions between the quinonimine and potassium hydroxide. When sodium ethylate was employed, no oxazole was formed.



This reaction appears to be a general method for the preparation of 2-substituted retenoxazoles. For example, when *n*-butyraldehyde was used with triethylamine as the catalyst, a 92% yield of 2-propylretenoxazole was isolated. Even salicylaldehyde, which is known to produce a mixture of 2-(2′-hydroxyphenyl)-retenoxazole and 2-(2′-hydroxyphenyl)-retenimidazole when treated with retenequinone in the presence of ammonia, yields only the oxazole when treated with retenequinonimine and an amine.

The reactions of phenanthraquinonimine with aromatic aldehydes yielded similar results. The direct action of phenanthraquinonimine and benzaldehyde in the absence of basic reagents failed to produce 2-phenylphenanthroxazole. In the presence of piperidine and triethylamine good yields of the oxazole were obtained, but with the weaker base, aniline, lower yields were obtained. The reactions of *n*-butyraldehyde and phenanthraquinonimine gave similar results.

Experimental

All of the melting points given below are corrected values, and, unless otherwise stated, check the literature values.

(1) Presented at the Memphis Meeting of the American Chemical Society in April, 1942.

(2) Present Address, General Aniline Works, Grasselli, N. J.

Preparation of Retenequinone.—This compound was prepared by the method of Kreps and Day[3] from retene (Eastman Kodak Co. practical grade). It was recrystallized from chloroform; yield 50%; m. p. 197–199°.

Preparation of Retenequinonimine.—The quinonimine was prepared by the method of Bamberger and Hooker.[4] This preparation must be carried out in the absence of moist air. The crude product was recrystallized from absolute alcohol saturated with dry ammonia (below 55°), yield 60%, m. p. 107–108°.

Preparation of Phenanthraquinone.—In this preparation the directions of Graebe[5] for the oxidation of phenanthrene were modified, in that the purification was carried out according to Courtot[6]; m. p. 208–209.5°.

Phenanthraquinonimine.—The method of Pschorr[7] was used for preparing phenanthraquinonimine. The crude product was recrystallized from absolute alcohol saturated with ammonia. As in the case of retenequinonimine, the temperature should be kept below 55° and the time of heating should not exceed fifteen to twenty minutes; yield 75%; m. p. 156–157.5°.

Reactions of Retenequinonimine with Aldehydes and Amines.—In general the reactions were carried out by dissolving 2 g. (0.0076 mole) of retenequinonimine, 0.0076 mole of the aldehyde, and 0.0076 mole of the amine in 50 cc. of absolute alcohol and refluxing the solution on the water-bath.

(1) **With Benzaldehyde and *n*-Butylamine.**—The solution was refluxed for one hour. After cooling, the 2-phenylretenoxazole was removed by filtration and recrystallized from absolute alcohol; yield 68%; m. p. 174.5–175°.[8]

Anal. Calcd. for $C_{25}H_{21}NO$: N, 3.99. Found: N, 4.02.

(2) **With Benzaldehyde and Aniline.**—In this case the refluxing was continued for four hours. On cooling and diluting with water, a mixture of retenequinonimine and 2-phenylretenoxazole separated. Pure 2-phenylretenoxazole was obtained by recrystallization from 80% dioxane–water solution and subsequently from absolute alcohol; yield 9.7%; m. p. 174.5–176°.

(3) **With *n*-Butyraldehyde and *n*-Butylamine.**—After refluxing for four hours, the 2-*n*-propylretenoxazole was precipitated by the addition of water to the hot solution. The crude product was recrystallized from 60% dioxane–water and finally from dilute alcohol and obtained as colorless needles; yield 85%; m. p. 100.5–101.3°. This compound has not been reported previously.

Anal. Calcd. for $C_{22}H_{23}NO$: C, 83.17; H, 7.31; N, 4.42. Found: C, 82.99; H, 7.12; N, 4.26.

(4) **With Benzaldehyde and Triethylamine.**—The solution was refluxed for four hours. On cooling, an 84% yield of crude 2-phenylretenoxazole was obtained. It was recrystallized from absolute alcohol; yield 74%; m. p. 178.5–180°.

Anal. Calcd. for $C_{25}H_{21}NO$: N, 3.99. Found: N, 3.93.

(5) **With Benzaldehyde and One-half an Equivalent of Triethylamine.**—After refluxing for four hours, a 78% yield of 2-phenylretenoxazole was obtained. Recrystallization from absolute alcohol gave the characteristic white, fibrous needles, m. p. 177–178.5°.

(6) **With Benzaldehyde and Piperidine.**—After refluxing for four hours and cooling, a 92% yield of 2-phenylretenoxazole was obtained. It was recrystallized from absolute alcohol, m. p. 174.5–176°.

Anal. Calcd. for $C_{25}H_{21}NO$: N, 3.99. Found: N, 3.89.

(7) **With Benzaldehyde and Small Amounts of Alcoholic Potassium Hydroxide.**—One and one-half grams (0.0057 mole) of retenequinonimine, 0.59 g. (0.0056 mole) of benzaldehyde, and 10 drops of 10% alcoholic potassium hydroxide were mixed with 50 cc. of absolute alcohol and refluxed for four hours. On cooling, a mixture of orange and yellow solids separated. Recrystallization from 80% dioxane–water and finally from absolute alcohol gave a 25% yield of 2-phenylretenoxazole, m. p. 174–175.5°. Evaporation of the original filtrate produced a reddish-brown intractable gum. The substitution of one equivalent of sodium ethylate for the potassium hydroxide in the above reaction gave no observable yield of oxazole.

(8) **With *n*-Butyraldehyde and Triethylamine.**—After refluxing for sixteen hours, the solution was diluted with water and cooled. The 2-propylretenoxazole so obtained was washed with 50% alcohol and then recrystallized from 80% alcohol; yield 92%; m. p. 100–101°.

Anal. Calcd. for $C_{22}H_{23}NO$: N, 4.42. Found: N, 4.40.

(9) **With Salicylaldehyde and *n*-Butylamine.**—The solution was refluxed for thirty-five minutes. After cooling, the crude 2-(2′-hydroxyphenyl)-retenoxazole was removed by filtration. The filtrate was evaporated to dryness and the residue treated with hot 95% alcohol. The yellow solid remaining after this treatment was added to the first precipitate and recrystallized from a dioxane–water solution with the use of decolorizing carbon; yield 51%; m. p. 245.5–247°.

Anal. Calcd. for $C_{25}H_{21}NO_2$: N, 3.81. Found: N, 3.71.

Reactions of Phenanthraquinonimine.—In these reactions the same molar equivalents of reactants were used as in the reactions with retenequinonimine.

(1) **With Benzaldehyde.**—When an absolute alcohol solution of phenanthraquinonimine and benzaldehyde was refluxed, no reaction occurred and only unchanged quinonimine could be isolated.

(2) **With Benzaldehyde and Aniline.**—The solution was refluxed for four hours. After cooling for several hours, the crude product was removed and recrystallized from 80% dioxane–water until colorless needles of 2-phenylphenanthroxazole were obtained; yield 17.5%, m. p. 205–206°.

Anal. Calcd. for $C_{21}H_{13}NO$: N, 4.74. Found: N, 4.62.

(3) Kreps and Day, *J. Org. Chem.*, **6**, 140 (1941).
(4) Bamberger and Hooker, *Ann.*, **229**, 102 (1885).
(5) Graebe, *ibid.*, **167**, 140 (1873).
(6) Courtot, *Ann. chim.*, (10) **14**, 69 (1920).
(7) Pschorr, *Ber.*, **35**, 2739 (1902).
(8) The pure samples of 2-phenylretenoxazole obtained during the course of the work usually melted at 174–176°, but occasionally a higher melting sample (178–180°) was obtained. However, careful examination disclosed the fact that all the samples had the same crystal structure and mixed melting point determinations showed no appreciable depression.

(3) **With Benzaldehyde and Piperidine.**—The solution was refluxed for two hours. The 2-phenylphenanthroxazole, obtained after cooling the solution, was recrystallized from absolute alcohol; yield 97%; m. p. 204.5–205.5°.

Anal. Calcd. for $C_{21}H_{13}NO$: N, 4.74. Found: N, 4.58.

(4) **With Benzaldehyde and Triethylamine.**—In this reaction the solution was refluxed for only thirty minutes. The 2-phenylphenanthroxazole, obtained after cooling the solution, was recrystallized from absolute alcohol; yield 77%; m. p. 204–205.5°.

Anal. Calcd. for $C_{21}H_{13}NO$: N, 4.74. Found: N, 4.69.

(5) **With *n*-Butyraldehyde and Aniline.**—No oxazole was formed in this reaction even after long refluxing.

(6) **With *n*-Butyraldehyde and Two Equivalents of Triethylamine.**—After refluxing the solution for sixteen hours, it was evaporated and the gummy residue taken up in 10 cc. of methyl alcohol. On the addition of 2 cc. of water, a dark, viscous oil slowly separated. After four hours the supernatant liquid was decanted and let stand in the ice-box overnight. On standing, a small amount of 2-propylphenanthroxazole separated. The dark, viscous oil was stirred with 50% methyl alcohol and a few pellets of sodium hydroxide until it had entirely solidified. The combined solids were recrystallized from 80% alcohol, with the aid of decolorizing carbon, until colorless crystals were obtained; yield 50%; m. p. 84–86°. This compound has not been reported previously.

Anal. Calcd. for $C_{18}H_{15}NO$: C, 82.73; H, 5.79; N, 5.36. Found: C, 82.67; H, 5.74; N, 5.38.

Summary

1. Retenequinonimine and phenanthraquinonimine have been shown to react with aldehydes, in the presence of amines, to form 2-substituted retenoxazoles or phenanthroxazoles.

2. The first step in the reaction has been shown to consist of an aldol-type of condensation, with the quinonimine supplying the labile hydrogen.

3. The base-catalyzed reaction is a new and useful method of synthesis for 2-substituted retenoxazoles and phenanthroxazoles, giving high yields and products of excellent purity.

PHILADELPHIA, PA. RECEIVED JULY 14, 1942

The Reactions of Retenequinonimine and Phenanthraquinonimine with Schiff Bases. A New Example of an Aldol-Type of Condensation[1]

BY CHARLES W. C. STEIN[2] AND ALLAN R. DAY

It was noted in the previous paper in this series[3] that the interaction of retenequinonimine or phenanthraquinonimine with aldehydes, in the presence of amines, gave excellent yields of 2-substituted retenoxazoles or phenanthroxazoles. It was shown that where secondary or tertiary amines were used, the first step in the reaction consisted of a basically catalyzed aldol-type of condensation between the aldehyde and the quinonimine. However, where a primary amine such as *n*-butylamine was employed, it was realized that another possible course of reaction existed. The amine and aldehyde may react to form a Schiff base and the latter then might undergo an aldol-type of condensation with the quinonimine. Schiff bases are known to behave like aldehydes in many respects (the =NR acting as the carbonyl oxygen) and so it appeared to be quite reasonable to expect them to undergo a similar condensation with the quinonimine.

To test this possibility, benzal-*n*-butylamine was prepared and treated with retenequinonimine. A rapid reaction took place, with the formation of good yields of 2-phenylretenoxazole. Since these reactions were carried out under anhydrous conditions, the possibility that the benzal-*n*-butylamine underwent hydrolysis before reaction was practically excluded. Definite proof was obtained, however, by testing the benzal-*n*-butylamine for free aldehyde in dry toluene solution. Addition of phenylhydrazine to the solution of the Schiff base produced no precipitate of benzaldehyde phenylhydrazone, even when heated on the water-bath for thirty minutes, the approximate time of many of the reactions. A similar test carried out with a sample of freshly distilled benzaldehyde gave an immediate precipitate of phenylhydrazone. It was further noted that *n*-butylamine was evolved in nearly quantitative amounts when retenequinonimine and benzal-*n*-butylamine in equivalent quantities were heated at 100° in dry solvents.

A consideration of all the evidence available at

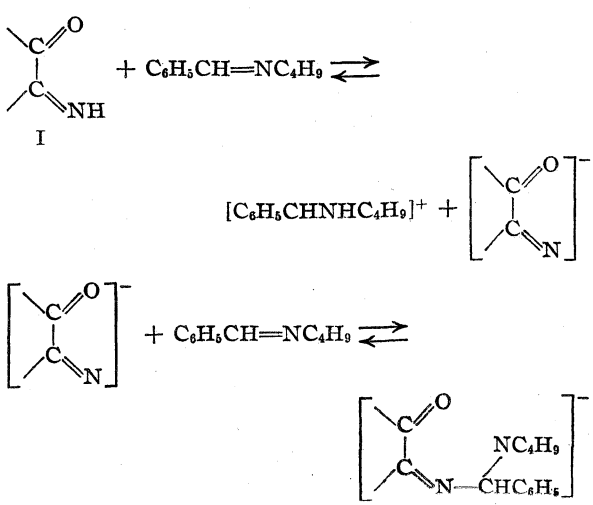
(1) Presented at the Memphis Meeting of the American Chemical Society in April, 1942.

(2) Present address, General Aniline Works, Grasselli, N. J.

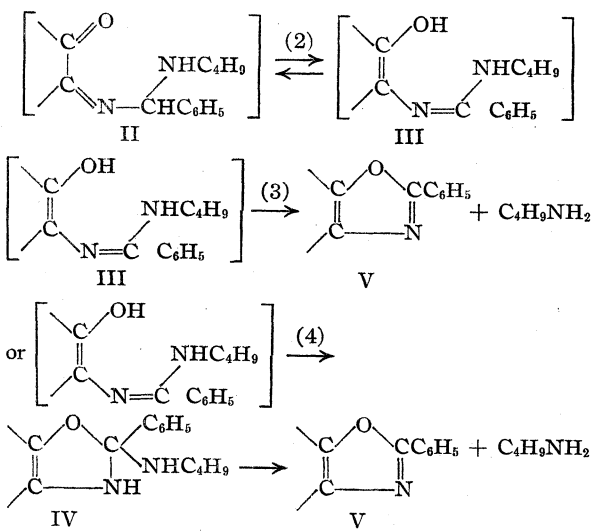
(3) Stein and Day, THIS JOURNAL, **64**, 2567 (1942).

this point showed that any suggested mechanism for this reaction must meet the following requirements. (1) The reaction between the quinonimine and benzal-*n*-butylamine must evolve *n*-butylamine, equivalent in quantity to the amine (present in combined form) in the Schiff base at the start of the reaction; and (2) the substituent in position two of the oxazole ring is derived from the aldehyde portion of the Schiff base.

In accord with these requirements, a mechanism is suggested which involves an aldol-type of condensation between the aldehyde and the quinonimine (step 1). Since the hydrogen of the imino group may be said to be an active hydrogen, it appears reasonable to believe that addition to the Schiff base occurs as the initial step. Indirect evidence for this may be deduced from the fact that when retenequinone is used in place of the quinonimine, no oxazole is formed. Hence the presence of the imino group is essential for the reaction. The addition of the quinonimine to the Schiff base involves an aldol-type condensation where the base acts as an aldehyde and the quinonimine supplies the active hydrogen. The Schiff base also acts as the basic catalyst for the reaction, at least in the case where benzal-*n*-butylamine was used. Such condensations are conditioned by the basic strength of the catalyst and it is interesting to note that when benzalaniline is substituted for the benzal-*n*-butylamine, the reaction is very slow and low yields of oxazole result, unless a more basic catalyst such as piperidine is added. The initial reaction between the quinonimine and benzal-*n*-butylamine, step (1), may be written as



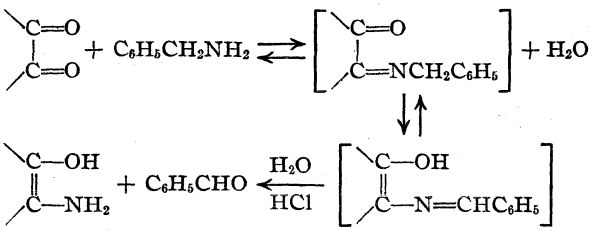
This is followed by two allylic-type shifts of hydrogen, step (2), and subsequently by the splitting out of *n*-butylamine to form the oxazole, step (3) or (4).



There is a considerable amount of information in the literature which may be offered in support of the above mechanism. The addition of various types of active hydrogen compounds to the double bond in Schiff bases has been reported by Mayer.[4] In all of the reactions reported by Mayer, the course of reaction involved addition of the active hydrogen to the nitrogen atom and addition of the other group to the unsaturated carbon atom of the Schiff base. These additions are undoubtedly basic catalyzed reactions for they occur under the influence of basic reagents.

Step (2) in the postulated mechanism also is quite reasonable, for allylic-type shifts of hydrogen would be expected in the type of structure shown. Direct evidence for this shift is difficult to obtain, but in closely related work McCoy[5] has been able to establish such a shift. The hydrolysis of the interaction products of retenequinone and benzylamine yields benzaldehyde. This can be explained only on the basis of a hydrogen shift.

(4) Mayer, *Bull. soc. chim.*, [3] **33**, 157, 395, 498 (1905).
(5) McCoy and Day, unpublished work.



In the final reaction (ring closure to form the oxazole), step (3) appears to be more reasonable in view of the close similarity between Schiff bases and aldehydes in addition reactions. Furthermore, the postulated intermediate III, being a substituted amidine, would be expected to undergo such a condensation.[6] However, step (4) cannot be ruled out. The addition of a hydroxyl group across a double bond with the formation of a heterocyclic ring has been reported in the synthesis of the tocopherols and related compounds.[7] The postulated intermediate (IV) resulting from such an addition would be a dihydroretenoxazole. Such a derivative would be expected to pass readily into the oxazole. A search of the literature disclosed the fact that in cases where 2,3-dihydro-oxazoles or 2,3-dihydroimidazoles might be expected to be the end-products, only the corresponding oxazoles or imidazoles were isolated. The last step, then, may represent spontaneous conversion (oxidation) of a dihydro-oxazole to the oxazole (with the elimination of an amine rather than hydrogen). This assumption is in agreement with the absence of 2,3-dihydro-oxazoles in the literature. Either course suggested for the last step in the reaction, (3) or (4), would explain the liberation of *n*-butylamine.

The use of different types of Schiff bases has yielded some interesting results: benzal-*n*-butylamine yielded up to 93% of 2-phenylretenoxazole; benzalaniline gave a 21% yield of 2-phenylretenoxazole; *n*-butylidene-*n*-butylamine gave only a 7% yield of 2-propylretenoxazole; and *n*-butylideneaniline gave no oxazole. In considering the variation in yields produced by the different types of Schiff bases, it was thought that a relationship might be shown between the yields of oxazole and the basic strength and (or) molecular aggregation of the Schiff bases. Since the initial reaction is a basically catalyzed condensation, the basic strength of the Schiff base should be an important factor. When retenequinonimine and benzalaniline were heated in dry alcohol solution in the presence of one equivalent of piperidine, a 90% yield of 2-phenylretenoxazole was obtained, as compared with a 21% yield in the absence of piperidine. This result agrees with the fact that benzalaniline is a weaker base than benzal-*n*-butylamine. When retenequinonimine and *n*-butylidene-*n*-butylamine were heated in dry alcohol with one equivalent of piperidine, the yield of 2-propylretenoxazole was raised from 7% to 23%. Under similar conditions *n*-butylideneaniline yielded no oxazole. In the last two cases, it is apparent that some other factor is important.

In the dimerization of certain Schiff bases[8] a hydrogen atom on the alpha carbon of the aldehyde part of the base adds to the nitrogen atom of another molecule of the Schiff base. Hence it may be assumed that alpha hydrogen is necessary for dimerization to occur. Since oxazole formation probably depends on the existence of the Schiff base monomer in the reaction mixture, lower yields or no yield of oxazole might be expected when alpha hydrogen is present in the Schiff base. As a check on this hypothesis, a qualitative study of the molecular weights of *n*-butylidene-*n*-butylamine, benzal-*n*-butylamine, and benzalaniline was made by the Rast method. *n*-Butylideneaniline has been shown previously to be a dimer.[8] Values were obtained which were sufficiently reproducible to indicate the probable state of molecular aggregation. With benzalaniline a value was obtained which indicated that the base was essentially monomeric. Benzal-*n*-butylamine gave a somewhat similar result. *n*-Butylidene-*n*-butylamine, however, proved to be trimeric. Since at temperatures of 80–100° the associations (monomer–polymer relationships) are probably reversible, the values cannot be used for a quantitative interpretation but may be used as suggestive evidence for the presence or absence of the monomeric forms at these temperatures.

These results confirm the supposition that the Schiff bases which yield appreciable quantities of oxazole exist preponderantly as the monomers, whereas those which yield little or no oxazole are mostly dimeric or more highly associated. The types $ArCH{=}NCH_2R$ and $ArCH{=}NAr$ are among the former, while the types $(RCH{=}NCH_2R)_n$ and $(RCH{=}NAr)_n$ are among the latter.

The use of phenanthraquinonimine in place of retenequinonimine gave similar results.

(8) Kharasch, Richlin and Mayo, THIS JOURNAL, **62**, 494 (1940); Emerson, Hess and Uhle, *ibid.*, **63**, 872 (1941).

Since the completion of the above work, a general study of basically catalyzed additions to Schiff bases has been started. It is believed that such an investigation will lead to a better understanding of the factors involved and in some cases lead to improved synthetic methods.

Experimental

Analyses and Melting Points.—See previous paper.[3]

Retenequinone, Retenequinonimine, Phenanthraquinone and Phenanthraquinonimine.—These compounds were prepared by the methods noted in the previous paper.

Benzal-*n*-butylamine.—This derivative apparently has not been reported previously. Twenty-five grams (0.236 mole) of freshly distilled benzaldehyde was dissolved in 25 cc. of absolute alcohol and 19 g. (0.26 mole) of *n*-butylamine added gradually with cooling. The solution was allowed to stand over anhydrous potassium carbonate for two days. The alcohol was removed by distillation and the crude benzal-*n*-butylamine was distilled under reduced pressure, b. p. 112–113° at 14 mm., yield 34%, d^{24}_4 0.906, $n^{24}D$ 1.5229. The addition of phenylhydrazine to a solution of the benzal-*n*-butylamine in dry toluene gave no precipitate of benzaldehyde phenylhydrazone, even when heated on the water-bath for thirty minutes. A similar test carried out with freshly distilled benzaldehyde gave an immediate precipitate of the phenylhydrazone. *Anal.* Calcd. for $C_{11}H_{15}N$: N, 8.70; mol. wt. calcd. for monomer, 161, dimer 322. Found: N, 8.64; mol. wt., 220 (in naphthalene), 227 (in triphenylmethane).

Preparation of Benzalaniline.—This was prepared by the procedure described by Bigelow and Eatough.[9] It was recrystallized from 85% alcohol; yield, 84%; m. p. 51°. *Mol. wt.* Calcd.: monomer 181, dimer 362. Found: mol. wt., 216 (in naphthalene).

Preparation of *n*-Butylidene-*n*-butylamine.—At the time this work was undertaken, this compound had not been reported, but it was reported about one month later by Emerson, Hess and Uhle.[8] The method used here is a modification of the method of Chancel.[10] *n*-Butyraldehyde (21.6 g., 0.30 mole) was slowly added to 21.9 g. (0.30 mole) of cooled *n*-butylamine. After standing for one hour, the layers were separated and the upper layer dried over potassium hydroxide. The dried product was distilled at atmospheric pressure, b. p. 141–145°. *Mol. wt.* Calcd. for trimer: 383. Found: 383 and 414 (13% solution in naphthalene).

Preparation of *n*-Butylideneaniline.—This was prepared by the method of Kharasch, Richlin and Mayo;[8] yield 32%. It was reported to be a dimer.

Reactions of Retenequinonimine with Schiff Bases.—In general 2 g. (0.0076 mole) of the quinonimine and one equivalent of the Schiff base were added to 50–100 cc. of dry alcohol and refluxed for a suitable length of time on the water-bath. In most cases the solution was then cooled and the product removed by filtration.

Reaction of Retenequinonimine with Benzal-*n*-butylamine.—The solution was refluxed for nineteen minutes. The crude 2-phenylretenoxazole was recrystallized from absolute alcohol; yield 78%; m. p. 174–175°. *Anal.* Calcd. for $C_{25}H_{21}NO$: N, 3.99. Found: N, 3.96.

Reaction of Retenequinonimine with Two Equivalents of Benzal-*n*-butylamine.—The solution was refluxed for ninety minutes. The product was purified as described above; yield 93.5%; m. p. 175–177°.

Reaction of Retenequinonimine with Benzal-*n*-butylamine in Dry Toluene. (a) Test for *n*-Butylamine as a Reaction Product.—The solution was heated on the water-bath for three hours. After cooling the mixture, the 2-phenylretenoxazole was removed by filtration. The filtrate was distilled and the distillate collected in hydrochloric acid. The acid solution was evaporated to about 20 cc., made alkaline with sodium hydroxide and treated with *m*-nitrobenzenesulfonyl chloride. The filtrate on acidification yielded N-butyl-*m*-nitrobenzenesulfonamide which was recrystallized from alcohol and water; m. p. 67°. A mixed m. p. with an authentic sample showed no depression. **(b) Determination of the Amount of *n*-Butylamine Liberated.**—A run similar to the one described above was carried out in dry alcohol. At the end of the heating period the mixture was steam distilled and the distillate collected in 4% boric acid solution containing methyl red. The boric acid solution was then titrated with standard hydrochloric acid. The volume of the acid used corresponded to 96.58% of the *n*-butylamine originally held in the benzal-*n*-butylamine. In this particular experiment an 82% yield of 2-phenylretenoxazole was obtained.

Reaction of Retenequinone with Benzal-*n*-butylamine.—The solution was refluxed for one hour. No oxazole formation was observed.

Reaction of Retenequinonimine with Benzalaniline.—After refluxing for four hours, the mixture was cooled and the orange-yellow solid removed by filtration. The crude product was recrystallized from 80% dioxane–water to separate the 2-phenylretenoxazole from retenequinone. Final purification was effected from dry alcohol with the use of decolorizing carbon; yield 21.6%; m. p. 177–178.5°. *Anal.* Calcd. for $C_{25}H_{21}NO$: N, 3.99. Found: N, 3.95.

Reaction of Retenequinonimine with *n*-Butylidene-*n*-butylamine.—After refluxing for two hours, the solution was evaporated to a small volume and cooled. The crude 2-propylretenoxazole, so obtained, was recrystallized from 80% dioxane–water, with the aid of decolorizing carbon, until colorless; yield 7%; m. p. 98.5–100.5°. *Anal.* Calcd. for $C_{22}H_{23}NO$: N, 4.42. Found: N, 4.43.

Reaction of Retenequinonimine with *n*-Butylidene-aniline.—No oxazole could be isolated from the reaction mixture after refluxing for four hours.

Reaction of Retenequinonimine with Benzalaniline in the Presence of One Equivalent of Piperidine.—The solution was refluxed for four hours and the crude 2-phenylretenoxazole was recrystallized from dioxane and water; yield 90.5%; m. p. 178–180°.

Reaction of Retenequinonimine with *n*-Butylidene-*n*-butylamine in the Presence of One Equivalent of Piperidine.—After refluxing for four hours, the solution was evaporated to dryness and the gummy residue extracted with a small amount of methyl alcohol, leaving 0.65 g. of a yellow solid. Recrystallization from 80% alcohol, with

(10) Chancel, *Bull. soc. chim.*, [3] **11**, 933 (1894).

the use of decolorizing carbon, gave white, fluffy needles of 2-propylretenoxazole; yield 23%; m. p. 100–100.5°.

Reaction of Retenequinonimine with *n*-Butylideneaniline in the Presence of One Equivalent of Piperidine.—No oxazole could be isolated from this reaction mixture after refluxing for fourteen hours.

Reaction of Phenanthraquinonimine with Benzal-*n*-butylamine.—The solution was refluxed for forty-five minutes and the crude 2-phenylphenanthroxazole recrystallized from 80% dioxane–water using decolorizing carbon and finally alcohol; yield 79%; m. p. 205–205.8°. *Anal.* Calcd. for $C_{21}H_{13}NO$: N, 4.74. Found: N, 4.57.

Reaction of Phenanthraquinonimine with Benzalaniline.—The 2-phenylphenanthroxazole obtained after refluxing the solution for four hours was recrystallized from 80% dioxane–water with the use of decolorizing carbon; yield 21.7%; m. p. 206–207°. *Anal.* Calcd. for $C_{21}H_{13}NO$: N, 4.74. Found: N, 4.72.

Reaction of Phenanthraquinonimine with Benzalaniline in the Presence of One Equivalent of Piperidine.—In the presence of piperidine, the yield of 2-phenylphenanthroxazole increased from the 21.7% noted above to 85%, after only two hours of refluxing.

Reaction of Phenanthraquinonimine with *n*-Butylidene-*n*-butylamine.—The solution was refluxed for four hours. After three weeks of standing in the cold, a small amount of yellowish-brown solid separated and was removed. Evaporation of the filtrate yielded only an intractable gum. The crude 2-propylphenanthroxazole was recrystallized from 80% alcohol and finally from 50% alcohol and obtained as colorless needles; yield 0.8%; m. p. 84.3–86.2°. Several runs were necessary to obtain sufficient material for the analyses. *Anal.* Calcd. for $C_{18}H_{15}NO$: C, 82.73; H 5.79; N, 5.36. Found: C, 82.56; H, 5.71; N, 5.30.

Reaction of Phenanthraquinonimine with *n*-Butylidene-*n*-butylamine in the Presence of One Equivalent of Piperidine.—After refluxing for four hours, the solution was evaporated and the viscous residue stirred with 50% methyl alcohol and a few pellets of sodium hydroxide until it had solidified. The 2-propylphenanthroxazole was then recrystallized from 80% alcohol, with the aid of decolorizing carbon; yield 30%; m. p. 85–86°. *Anal.* Calcd. for $C_{18}H_{15}NO$: N, 5.36. Found: N, 5.27.

Reaction of Phenanthraquinonimine with *n*-Butylideneaniline.—No 2-propylphenanthroxazole could be isolated in the absence or the presence of piperidine, after four hours of refluxing.

Summary

1. Retenequinonimine and phenanthraquinonimine have been shown to react with most types of Schiff bases to form 2-substituted retenoxazoles or phenanthroxazoles.

2. The first step in the reaction has been shown to consist of an aldol-type of condensation, with the quinonimine supplying the labile hydrogen. Some Schiff bases are sufficiently basic to catalyze the condensation.

3. This base-catalyzed reaction is a new and useful method for the synthesis of 2-substituted retenoxazoles and phenanthroxazoles.

Para Acylation of Polyalkylbenzophenones by Aryl 2,4,6-Trialkylbenzoates

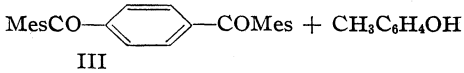
BY REYNOLD C. FUSON, E. M. BOTTORFF, R. E. FOSTER AND S. B. SPECK

Alkylmagnesium halides and arylmagnesium halides that carry a substituent in the para position have been shown to condense with aryl mesitoates to produce ketones.[1] A much more remarkable result was obtained with arylmagnesium halides that had no substituent in the para position. *p*-Tolyl mesitoate and phenylmagnesium bromide, for example, yielded *p*-cresol and a substance that proved to be *p*-dimesitoylbenzene (III). The structure of this compound was proved by synthesizing it from terephthalyl chloride and mesitylene by the Friedel–Crafts method.

The first step in this transformation appeared to be the formation of benzoylmesitylene, which then condensed with unchanged mesitoic ester to produce the diketone (III). In confirmation of this hypothesis, it was discovered that the diketone could be made also by condensing benzoylmesitylene with *p*-tolyl mesitoate.

$$MesCO_2C_6H_4CH_3 \xrightarrow{C_6H_5MgBr} MesCOC_6H_5 \text{ and } CH_3C_6H_4OH$$

$$MesCO_2C_6H_4CH_3 + MesCOC_6H_5 \longrightarrow$$



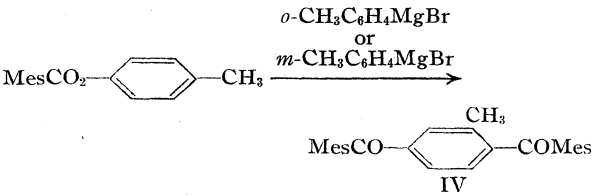
III

This condensation is without parallel. The net result is the acylation, under the influence of the Grignard reagent, of a benzene ring in the position *which is para to the meta-directing carbonyl group*. The condensation can be formulated as a Claisen reaction in which a nuclear hydrogen atom is replaced by an acyl group. This point of view is supported by the fact that the condensation between the ketone and the ester can be effected with the aid of a number of alkaline cata-

(1) Fuson, Bottorff and Speck, THIS JOURNAL, **64**, 1450 (1942).

lysts. Among these are sodium, ethylmagnesium bromide, mesitylmagnesium bromide and the binary mixture, Mg–MgI_2.[2] The binary mixture afforded the best yields, but usually gave less than 50% of the theoretical amount.

Under the influence of this reagent *p*-tolyl mesitoate condensed with *m*-toluylmesitylene, *m*-methoxybenzoylmesitylene, dibromomesityl phenyl ketone and α-naphthoylmesitylene to yield the expected diketones. It is interesting that *o*- and *m*-tolylmagnesium bromide reacted with *p*-tolyl mesitoate to yield the same diketone–1,4-dimesitoyl-2-methylbenzene (IV).



IV

The formation of 1,4-diaroylbenzenes appears to be general for highly hindered ketones. Aryl esters of 2,4,6-triethylbenzoic, 2,4,6-triisopropylbenzoic and 2,3,5,6-tetramethylbenzoic acids were found to condense with the corresponding aryl phenyl ketones to yield, respectively, 1,4-di-(2,4,6-triethylbenzoyl)-benzene, 1,4-di-(2,4,6-triisopropylbenzoyl)-benzene and 1,4-di-(2,3,5,6-tetramethylbenzoyl)-benzene.

Experimental

Synthesis of Ketones.—The ketones prepared in this work are listed in Table I, which indicates also melting points, yields, solvents and analytical data. All except the last four in the table were prepared by the condensation of the corresponding acid chloride with the appropriate hydrocarbon by the Friedel–Crafts method. A description of the preparation of *p*-dimesitoylbenzene will illustrate the procedure.

***p*-Dimesitoylbenzene.**[3]—A solution of 15 g. of terephthalyl chloride,[4] 40 cc. of carbon disulfide and 10 cc. of mesitylene was added dropwise, with stirring, at room temperature to a mixture of 26 g. of mesitylene, 28 g. of aluminum chloride and 50 cc. of carbon disulfide. The solution was refluxed gently and stirred for six hours. The dark-red reaction mixture was poured into an ice–hydrochloric acid mixture. The carbon disulfide was evaporated and the solution extracted with three portions of hot benzene. The benzene extracts were washed with hot water, hot 5% sodium hydroxide solution and again with water. A portion of the benzene was removed by distillation, and the remaining solution was allowed to cool; 12 g. of *p*-dimesitoylbenzene crystallized. The melting point after two recrystallizations from benzene was 244–246°.

Dibromomesityl Phenyl Ketone.—This compound was prepared by direct bromination of benzoylmesitylene in carbon tetrachloride.

2,4,6-Tribromophenyl Mesitoate.—This compound was prepared in 84% yield by condensing 2,4,6-tribromophenol with mesitoyl chloride. It crystallized from alcohol in colorless needles melting at 86°.

Anal.[5] Calcd. for $C_{16}H_{13}O_2Br_2$: C, 40.26; H, 2.74. Found: C, 40.56; H, 2.89.

Condensation of Hindered Esters with Aryl Grignard Reagents.—The reactions of a few hindered esters with certain aryl Grignard reagents have been studied. The arylmagnesium halides selected were those having no substituents in the para position. The results of this work are shown in Table II. Since the experimental details were very similar for all of these reactions, the procedure will be described only for one, *viz.*, that between *p*-tolyl mesitoate and phenylmagnesium bromide.

***p*-Tolyl Mesitoate and Phenylmagnesium Bromide.**—The reagent was prepared from 5 g. of magnesium and 28.2 g. of bromobenzene in 50 cc. of *n*-butyl ether. A solution of 20.4 g. of *p*-tolyl mesitoate in 60 cc. of *n*-butyl ether was added, with stirring. The clear solution slowly became a deep wine color. The mixture was heated at 100° for two hours in an atmosphere of nitrogen.

The reaction mixture was decomposed with cold dilute hydrochloric acid and the aqueous layer extracted twice with ether. The ether solution was washed once with water, then with three 100-cc. portions of 10% sodium hydroxide. The sodium hydroxide solution was washed twice with ether, acidified with hydrochloric acid and extracted with ether. The ether solution was washed with water, dried over magnesium sulfate, and freed of solvent by evaporation. The residual *p*-cresol weighed 6.4 g.

The solvent was removed from the ether solution and the oil treated with alcohol. The *p*-dimesitoylbenzene which separated was collected on a filter and washed with alcohol; yield 5 g. The filtrate was distilled under reduced pressure and small amounts of biphenyl and *p*-tolyl mesitoate were obtained.

Many of the products shown in Table II could be isolated only by distillation of the neutral portion of the reaction mixture under reduced pressure. The fractions obtained were then taken up in ethanol, and crystallization was induced.

Condensation of Hindered Esters with Diaryl Ketones.—The condensation reactions are listed in Table III. The starting materials, reaction temperatures, reagent, products and yields are given. Since the procedures used for these reactions are very similar, only two will be described in detail.

Benzoylmesitylene and *p*-Tolyl Mesitoate.—A solution of 11.2 g. of benzoylmesitylene and 12.7 g. of *p*-tolyl mesitoate in 60 cc. of 1:1 toluene–*n*-butyl ether mixture was added slowly to a solution of the binary mixture, Mg–MgI_2, prepared from 2.5 g. of magnesium and 12.7 g. of iodine in 60 cc. of 1:1 ethyl ether–*n*-butyl ether mixture. The reaction mixture was stirred in an atmosphere of nitrogen at

TepCO$_2$Tol(*p*)[d]	C_6H_5MgBr	*p*-Cresol	*p*-TepCOC_6H_4COTep[a]

[a] A mixed melting point with an authentic specimen prepared by the Friedel–Crafts method gave no depression. [b] This ester was made by the method[1] described earlier for the para isomer; m. p. 38–39°. *Anal.* Calcd. for $C_{17}H_{18}O_2$: C, 80.30; H, 7.10. Found: C, 80.22; H, 7.37. [c] Identified by a mixed melting point with an authentic specimen.[6] [d] This ester was made by the method[1] described earlier for *p*-tolyl mesitoate; b. p. 170–171° (3 mm.); d^{20}_{20} 1.035; $n^{20}D$ 1.5435. *Anal.* Calcd. for $C_{20}H_{24}O_2$: C, 81.04; H, 8.10. Found: C, 81.14; H, 7.85.

115° for five hours. The color gradually became a very deep red.

The reaction mixture was decomposed with cold dilute hydrochloric acid and the aqueous layer extracted twice with ether. The ether solution was washed once with water, then with three 100-cc. portions of 10% sodium hydroxide. The sodium hydroxide solution was washed twice with ether, acidified with hydrochloric acid and extracted with ether. The ether solution was washed with water, dried over magnesium sulfate, and freed from ether by evaporation. The residual *p*-cresol weighed 4.3 g.

The solvent was removed from the original ether solution and the oil taken up in alcohol. *p*-Dimesitoylbenzene separated and was collected on a filter and washed with alcohol; yield 7.4 g. A small amount (0.45 g.) of a bright yellow compound, m. p. 189°, was isolated. It was not identified.

The filtrate was distilled under reduced pressure; 2 g. of benzoylmesitylene and 3.4 g. of *p*-tolyl mesitoate were recovered.

α-Naphthoylmesitylene and *p*-Tolyl Mesitoate.—A solution of the binary mixture, Mg–MgI_2, was prepared from 2.5 g. of magnesium and 12.7 g. of iodine in 50 cc. of 1:1 toluene–*n*-butyl ether. A solution of 13.7 g. of α-naphthoylmesitylene and 12.7 g. of *p*-tolyl mesitoate in 40 cc. of the solvent was added slowly. The mixture was stirred at 115° for three hours under an atmosphere of nitrogen. It was then treated with dilute hydrochloric acid and washed as described in the preceding experiment. *p*-Cresol was obtained from the alkaline extract.

After the solvent was removed from the neutral portion, a solid separated. The mixture was treated with alcohol, and the solid material collected on a filter and washed with alcohol. The yield was 5.7 g. of 1,4-dimesitoylnaphthalene, which melted at 171°, after many recrystallizations from an alcohol–benzene mixture, and was yellow in color.

The alcohol filtrate was distilled under reduced pressure,

[a] All reactions involving esters of p-cresol yielded p-cresol as one of the products. [b] Propiomesitylene was also produced. [c] A trace of 2-mesitoylbiphenyl was formed also. [d] Mesitoic acid was formed in 13% yield. [e] p-Cresol and mesitoic acid were the only products isolated. The yields were very low. [f] A 58% yield of mesitoic acid was obtained. [g] 2,4,6-Tribromophenol was also a product. [h] This compound was prepared by B. C. McKusick from the acid chloride and p-cresol; m. p. 138°, from alcohol. *Anal.* Calcd. for $C_{18}H_{20}O_2$: C, 80.55; H, 7.47. Found: C, 80.02; H, 7.41.

and the following substances were isolated from the distillate; 3.2 g. of p-tolyl mesitoate, 2.0 g. of α-naphthoylmesitylene and 0.75 g. of 1,4-dimesitoylnaphthalene.

The 1,4-dimesitoylnaphthalene was found to have two crystalline forms. When the yellow compound was heated above its melting point (171°) for a few minutes or was treated with chromic acid in glacial acetic acid and then recrystallized from alcohol, colorless needles were obtained. This colorless form showed a definite softening point at 171° and melted sharply at 193.5° to a bright yellow liquid, which when cooled rapidly gave the yellow solid.

This compound was synthesized from 1,4-dicyanonaphthalene[7] by way of the dicarboxylic acid and the acid chloride. Hydrolysis of the dinitrile by the method of Scholl and Neumann,[8] gave a 76% yield of the crude acid. The acid was converted to the acid chloride by the method of Beund and Herms.[4] The condensation of the impure acid chloride with mesitylene produced a mixture from which the diketone melting at 193.5° could be isolated.

A by-product, melting at 134° (cor.), was found to contain nitrogen and is believed to be 1-mesitoyl-4-cyanonaphthalene. Its origin may be traced to incomplete hydrolysis of the dinitrile giving rise to 4-cyanonaphthoic acid and eventually to the cyano ketone. It was purified by recrystallization from methanol and petroleum ether. It had a bright yellow color.

Anal. Calcd. for $C_{21}H_{17}ON$: C, 84.22; H, 5.75. Found: C, 84.36; H, 5.85.

Note on Invertase Activity in Identical Mixtures in the Liquid and Frozen State[1]

BY Z. I. KERTESZ

The publication of the following experiment was prompted by a recent article by Sizer and Josephson dealing with enzyme[2] kinetics as a function of temperature. These authors confirm the well-known fact that low temperatures do not inactivate the enzymes, lipase, trypsin and invertase, and state that "a sharp break in the relationship of rate to temperature appears at 0 to $-2°$." This observation is in harmony with and an extension of the writer's findings with invertase activity measured between $+40$ and $-40°$ and part of which was reported in an article[3] dealing with the velocity of the reaction in undercooled solutions. In connection with this latter work some measurements were performed in identical reaction mixtures of the rate of invertase action in the liquid and solid (frozen) state at the same temperature. These data, heretofore unpublished, gain additional interest by the observations of Sizer and Josephson and throw light on the suspected effect of change of physical state on the velocity of the reaction.

There is little to be added to the experimental technique described in my above article.[3] If reaction mixtures containing sucrose, invertase and buffer in water solution are quickly cooled, temperatures as low as $-9°$ may be reached without freezing the mixture. On the other hand, shaking of the test-tubes during cooling (or sometimes even moving them) is sufficient to cause a rapid solidification of the mixture. Single observations in liquid and frozen mixtures were performed at various temperatures between -2 and $-8°$ but it was at $-6.8°$ that the measurement of the two whole sets of determinations was most successful. These results and a few others indicating the rate of reaction at 20° and at a lower freezing temperature ($-17.8°$) are given in Table I.

The hydrolysis appears to be much slower in the frozen mixture than in the liquid one. The high value for the first monomolecular constant "k" in the frozen mixture at $-6.8°$ is believed to be caused by the higher velocity of the reaction while the mixture was cooled and until it was frozen. The great difference in the velocity in the liquid and frozen state confirms the statement of Sizer and Josephson that the change in phase may be the cause of the break in the rate of enzyme action. It is also apparent that no predictions concerning the rate of a reaction in the frozen state can be made from determinations in liquid mixtures although it is not impossible that in the future some predictable relation may be found between the two factors.

The difference between the rate of hydrolysis in the liquid and frozen mixtures is also apparent in most samples of the lipase series of Sizer and Josephson, although this is not emphasized by these authors.

The reason for the drop in the velocity upon freezing may be the restricted availability of water for the hydrolysis. This may well be the case because previous observations indicated[4] that the amount of water available in invertase reaction mixtures has more effect on the velocity of the reaction than physical conditions as changes in the viscosity, for instance. The possibility of an effect of the freezing on the enzyme itself cannot be disregarded. This effect, if any, must be temporary because when frozen reaction mixtures were melted, they exhibited a normal velocity of hydrolysis.

There is some uncertainty about the significance of results obtained in enzyme reaction mixtures in the presence of glycerol, ethanol and other chemicals used in order to lower the freezing point. In the writer's work difficulties were experienced with these materials in the study of invertase action. They exerted considerable effect on the reaction above the freezing point, as is observable in the lipase hydrolysis data of Sizer and Josephson. The use of these materials would open easy avenues of approach to the problem but their effect on the reaction is definite but not constant (see the lipase table of Sizer and Josephson) and thus there is an element of unreliability about results obtained by their use. The effect of these compounds seems to be again in changing the proportion of water available for the hydroly-

Av.	253.0		38.5		10.49		.321

sis rather than by altering the physical characteristics of the solutions.

Summary

The velocity of invertase action in a frozen mixture at −6.8° was only 27% of that in a like mixture in the liquid state. The diminished availability of water may be responsible for this phenomenon.

Some Derivatives of 2-Propionyl-1-naphthol

BY C. M. BREWSTER AND G. G. WATTERS

Since the substitution of acyl and alkyl groups for nuclear hydrogen in phenols has given compounds with marked germicidal properties, we have extended our study in this field by preparing some derivatives of 2-propionyl-1-naphthol, with changes in side chain and nucleus.

We have compared methods of preparation of 2-propionyl-1-naphthol[1] and found little difference in yield, whether the process is carried out directly with α-naphthol or by intra-molecular rearrangement of the ester first formed through the action of the anhydride. However, the direct method requires fewer steps and we have been able to minimize the formation of purple by-products by the procedure given in the experimental part.

In attempting to prepare a di-acyl naphthol from 2-acetyl-1-naphthol by condensation with propionic acid, using zinc chloride as condensing agent, we obtained 2-propionyl-1-naphthol in good yield, the larger acyl group replacing the smaller. A similar replacement occurred when benzoic acid reacted with 2-acetyl-1-naphthol; however, the yield was very small. This replacement recalls the method of preparation of higher members of the salol series, by heating salol with eugenol or other phenols; the higher phenol replaces the lower.[2]

When examining some crystals of 2-propionyl-1-naphthol in subdued light, it was accidentally discovered that the compound shows marked triboluminescence, and this phenomenon persists whether the compound is dry or moistened with water or ethanol, even after removal of traces of impurities.

Reduction of acyl naphthols replaced the carbonyl oxygen by hydrogen and resulted in alkyl naphthols which showed an increase in germicidal activity. However, the pure reduced compounds on standing in the air slowly turned to brown oils and their preservation was difficult. It was anticipated that modification of the acyl side-chain might give compounds of greater stability, and such compounds have been made by condensation of the acyl group with aldehydes.[3] While there was marked reactivity with 2-propionyl-1-naphthol, we have been able to isolate only two derivatives in pure form. Acid condensing agents such as zinc chloride, aluminum chloride, or concentrated sulfuric acid produced marked color

changes and complex products, while potassium hydroxide in aqueous or alcoholic solution caused less polymerization. The lower temperatures tended to inhibit the Cannizzaro reaction, and also decreased the tendency to polymerization.

The ethers of acyl and alkyl naphthols which are reported were somewhat difficult to prepare, which is characteristic of ortho substituted naphthols. They are more stable than the naphthols when heated or exposed to air.

Experimental

2-Propionyl-1-naphthol.—We have carried out numerous trials of the methods reported by Goldzweig and Kaiser,[4] by Hantzsch[5] and by Stoughton[6] and obtained best yields from the following shortened modification of Hantzsch's method. Two hundred grams of fused zinc chloride was crushed and warmed with 300 g. of propionic acid until dissolved. To the warm solution was added 300 g. of α-naphthol and the mixture heated under reflux in an oil-bath to gentle boiling (145–150°) for forty to fifty minutes. The solution became orange, then bright red; if allowed to become deep red, an undue proportion of tar is formed. The mixture was allowed to cool slowly and to stand overnight, then gently warmed to 60° and diluted with an equal volume of warm glacial acetic acid. On standing overnight large yellow-green crystals separated from the purple solution, and were filtered with suction, rinsed by suspension in 200 g. of 85% acetic acid, filtered and recrystallized from hot ethanol. A second crop of crystals was obtained from the purple mother liquor by warming with activated carbon. The hot filtrate was cooled and diluted, and the crystalline product recrystallized from ethanol. The compound may be purified by solution in ethanol and 2% sodium hydroxide, which is then warmed with activated carbon, filtered and precipitated by neutralization with hydrochloric acid. The compound may also be purified by distillation *in vacuo*. A total yield of 200 g. was obtained; m. p. 81–82°.[7]

Crystals which were formed after melting and slowly cooling the dry compound gave the greatest brilliance of luminescence; when ground to a powder no further luminescence was observed.

2-Propionyl-1-ethoxynaphthalene.—Fifteen grams of 2-propionyl-1-naphthol and 75 ml. of ethanol were heated with a solution of 3 g. of sodium hydroxide in 10 ml. of water. This mixture was heated to gentle boiling under reflux and 8 g. of ethyl bromide was added drop by drop. After six hours of heating, 6 g. more of ethyl bromide was added and heating continued for six hours more. When a test with ferric chloride showed no coloration, the solution was cooled, neutralized and the brown oily product separated with ether, dried, and distilled *in vacuo*, giving a yellow viscous oil, b. p. 175–180° (15 mm.); yield, 13 g.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.85; H, 6.9. Found: C, 78.9; H, 7.0.

2-Propionyl-1-naphthol Phenylhydrazone.—Yellow plates from acetic acid, m. p. 136°.

Anal. Calcd. for $C_{19}H_{18}ON_2$: N, 9.65. Found: N, 9.36.

2-Propyl-1-naphthol.—Preparation by the Clemmensen reduction method as given in detail by Coulthard, Marshall and Pyman[9] and reported by Stoughton[10] required heating under reflux for twelve hours. The pale yellow oil, obtained by distillation *in vacuo*, solidified on standing and gradually turned brown; m. p. 48–50°. The germicidal activity of this compound has been tested recently and reported to be superior to that of 2-propionyl-1-naphthol.[11]

2-Propyl-1-ethoxynaphthalene.—Ten grams of 2-propyl-1-naphthol and 50 ml. of methyl ethyl ketone with 2 g. of sodium hydroxide were warmed, giving a brown solution. Fifteen g. of ethyl iodide was added in small portions and heating under reflux continued for a total of fifteen hours. The solvent was distilled off, the brown oil dissolved in ether, washed with 2% sodium hydroxide, and the ether layer separated, dried and distilled. The opaque red-brown liquid was distilled twice *in vacuo*, giving a pale yellow oil, b. p. 294–296° (690 mm.).

Anal. Calcd. for $C_{15}H_{18}O$: C, 84.11; H, 8.41. Found: C, 83.9; H. 8.5.

2-Propyl-1-*n*-butyloxynaphthalene.—Ten grams of 2-propyl-1-naphthol was dissolved in 50 ml. of methyl ethyl ketone, and warmed with a solution of 2.1 g. of sodium hydroxide in 5 ml. of ethanol and 5 ml. of water. The solution turned deep green. Powdered copper, 0.1 g., was added as catalyst, and 10 g. of *n*-butyl bromide added in small portions. The solution was boiled under reflux for twenty-four hours, the solvents removed by distillation, and the brown oily residue was washed with 2% sodium hydroxide, extracted with ether, and the ether extract dried. Distillation *in vacuo* gave a pale yellow oil, b. p. 304–306° (692 mm.).

Anal. Calcd. for $C_{17}H_{22}O$: C, 84.3; H, 9.01. Found: C, 84.0; H, 9.1.

4-Bromo-2-propionyl-1-naphthol.—Fifty grams of 2-propionyl-1-naphthol was dissolved in 125 ml. of chloroform; to this was added slowly and with vigorous stirring a solution of 50 g. of bromine in 125 ml. of chloroform. Large volumes of hydrobromic acid were given off. After standing for thirty minutes, the solution was washed with water by decantation until no longer acid. The chloroform layer was separated, the chloroform distilled off, and the yellow mass crystallized from ethanol. Yellow needles were obtained in nearly quantitative yield; m. p. and

(7) On cooling an alcoholic solution of the compound, a crust of large transparent yellow-green plates formed. In dislodging these with a stirring rod, in a dark room, flashes of blue light were seen as the rod broke the mass of crystals beneath the mother liquor. This triboluminescence appeared when the compound was subjected to friction or to percussion, even after repeated recrystallization. The phenomenon persisted whether the crystals were dry or suspended in water or ethanol, and seemed to be an inherent property of the compound.[8]

m. p. when mixed with a sample prepared by Hantzsch's method,[12] 98–99°.

4-Bromo-2-propionyl-1-ethoxynaphthalene.—A mixture of 5.6 g. of 4-bromo-2-propionyl-1-naphthol with 0.8 g. of sodium hydroxide in 4 ml. of water and 50 ml. of methyl ethyl ketone was heated, and 5 g. of ethyl bromide slowly added. After eight hours of heating under reflux, 3.0 g. more of ethyl bromide was added, and heating continued for a total of sixteen hours. The solvent was then distilled off, the residue washed and crystallized from ethanol, giving a yield of 3.8 g. of pale yellow needles, m. p. 68–69°.

Anal. Calcd. for $C_{15}H_{15}O_2Br$: Br, 26.03. Found: Br, 26.10.

4-Bromo-2-propionyl-1-*n*-propyloxynaphthalene.—A mixture of 15 g. of 4-bromo-2-propionyl-1-naphthol, 50 ml. of methyl ethyl ketone, and a solution of 2.2 g. of sodium hydroxide in 10 ml. of ethanol and 10 ml. of water was heated under reflux, and 12 g. of *n*-propyl bromide was added in small portions. After forty-eight hours of heating the solvent was distilled off, the oily layer taken up in ether and washed with 2% aqueous sodium hydroxide. The ethereal layer was separated, dried and distilled *in vacuo*. The light yellow oil had a slightly sweet odor; b. p. 298–303° (690 mm.).

Anal. Calcd. for $C_{16}H_{17}O_2Br$: Br, 24.90. Found: Br, 25.23.

4-Nitro-2-propionyl-1-naphthol.—Ten grams of 2-propionyl-1-naphthol was powdered and suspended in 200 ml. of 50% acetic acid. Ten ml. of concentrated nitric acid was diluted with 30 ml. of glacial acetic acid and added slowly to the vigorously stirred suspension. After five hours the mixture was diluted, filtered, and the solid crystallized from ethanol giving fine yellow needles, m. p. 162–163°.

Anal. Calcd. for $C_{13}H_{11}O_4N$: N, 5.7. Found: N, 5.5.

The phenylhydrazone crystallized from ethanol in pale brown crystals which melted at 199–200°.

Anal. Calcd. for $C_{19}H_{17}O_3N_3$: N, 12.53. Found: N, 12.02.

2-Propionyl-β-(2-chlorobenzylidene)-1-naphthol.—Five grams of 2-propionyl-1-naphthol and 5 g. of *o*-chlorobenzaldehyde were suspended in 25 ml. of ethanol, cooled to 0°, and vigorously stirred. A solution of 50 g. of potassium hydroxide in 35 ml. of water was added slowly during a period of one hour, and stirring at 0° continued for two hours, after which the mixture was allowed to stand at room temperature out of contact with air for two days. The dark red alcoholic solution was poured into 200 ml. of ice-water and neutralized with dilute hydrochloric acid. The yellow precipitate was filtered off and crystallized from hot ethanol. Long yellow needles were obtained which melted at 93–94°.

Anal. Calcd. for $C_{20}H_{15}O_2Cl$: Cl, 11.01. Found: Cl, 11.06.

(12) Hantzsch, *Ber.*, **39**, 3097 (1906).

4-Bromo-2-propionyl-β-(2-chlorobenzylidene)-1-naphthol.—Three grams of 4-bromo-2-propionyl-1-naphthol and 1.5 g. of *o*-chlorobenzaldehyde were dissolved in 25 ml. of 1,4-dioxane, cooled to 0°, and a solution of 30 g. of potassium hydroxide in 20 ml. of water, also cooled to 0°, was added slowly over a period of two hours, with vigorous mechanical stirring. The solution turned dark red and a precipitate formed. The mixture was allowed to stand for two days out of contact with air and at room temperature, then poured into 100 ml. of ice-water and neutralized with dilute hydrochloric acid. The yellow precipitate was filtered and crystallized from ethanol, giving light yellow needles which melted at 129°.

Anal. Calcd. for $C_{20}H_{14}O_2ClBr$: Cl and Br, 28.76. Found: Cl and Br, 28.5.

As typical of the reactivity of aromatic aldehydes in the presence of condensing agents, when 10 g. of 2-propionyl-1-naphthol and 5 g. of benzaldehyde were warmed with 5 g. of fused zinc chloride the viscous mass became yellow-brown at 70°, deepening in color as the temperature rose, until at 170° there was slight effervescence and the color changed to deep crimson. The temperature was held at 170° for about ten minutes or until effervescence ceased. Upon dilution a gray-blue granular precipitate separated which was dissolved in acetic acid giving a red solution. Fractional precipitation by dilution with water gave successive portions of the gray-blue precipitate; none of the fractions contained unchanged starting material, and all sintered with decomposition when heated to 175–180°.

When concentrated sulfuric acid was used as condensing agent, a red-brown solution was obtained which on dilution with water gave a flocculent cream-colored compound, which sintered when heated to 105°. With aqueous sodium hydroxide solutions at room temperature or below, less tar was formed than when solutions were heated. On dilution and neutralization, red viscous products were obtained. The three condensing agents have been used with hydroxy and halogenated aldehydes with formation of deeply colored products, and we have been able to characterize two which were formed from *o*-chlorobenzaldehyde as described above.

Summary

1. A simplified method of preparation and purification of 2-propionyl-1-naphthol is reported. The compound shows marked triboluminescence.

2. A method of preparation involving direct replacement of a smaller by a larger acyl group is reported.

3. Ten new derivatives have been characterized, some of which are more stable than the parent acyl and alkyl naphthols.

Saponins and Sapogenins. XX. Bethogenin and Trillogenin, New Sapogenins from *Trillium Erectum*

BY S. LIEBERMAN,[1] F. C. CHANG, M. R. BARUSCH AND C. R. NOLLER

During the course of the isolation of diosgenin from commercial powdered beth root (*Trillium erectum*) by the procedure of Marker, Turner and Ulshafer[2] we have obtained a second sapogenin in an amount at least as great as the amount of diosgenin. This compound, which we have named "bethogenin," has the molecular formula $C_{27}H_{40}O_4$. It gives a yellow color with tetranitromethane and is precipitated by digitonin, suggesting that it is an unsaturated steroid sapogenin. Reaction with acetic anhydride in pyridine gave only a monoacetate, while benzoyl chloride and pyridine gave a monobenzoate. Two oxygen atoms tentatively may be assumed to be the inert oxygen atoms in the side chain characteristic of steroid sapogenins. This makes it still necessary to account for one more oxygen atom.

Attempts to dehydrate bethogenin failed, indicating that this oxygen atom is not a tertiary hydroxyl group. This was confirmed by a Zerewitinow determination which showed only one active hydrogen. On catalytic reduction in neutral alcohol solution with hydrogen and palladium catalyst, two moles of hydrogen were absorbed per mole of bethogenin. While isolation of a pure hydrogenated bethogenin has not yet been successful, acetylation of the reduction product gave a readily crystallized compound which proved to be a diacetate. From this it appears that bethogenin contains a carbonyl group.

In order to confirm this view, attempts were made to prepare a carbonyl derivative. It was found that bethogenin reacted with hydroxylamine in pyridine to give a new compound but analyses indicated that this was a dioxime. At present such behavior is difficult to explain. One possibility is that bethogenin is a diketone with one very readily enolizable carbonyl group so that it gives the reactions both of a carbonyl group and of a double bond and hydroxyl group. However, all of the usual tests for an enol group gave negative results. Another possibility is that the second molecule of hydroxylamine reacted with the side chain. Indication that the side chain of bethogenin behaves differently from that of other steroid sapogenins was obtained when it was found that bethogenin could not be converted into a pseudosapogenin.[3] Heating with acetic anhydride at 200° gave only uncrystallizable gums.

A third sapogenin has been isolated in small amount which appears to be unique among the known steroid sapogenins in that the two characteristic inert oxygen atoms are lacking. This compound has the empirical formula $C_{27}H_{48}O_4$ and yields a tetraacetate, $C_{35}H_{56}O_8$. Nothing further has been done with this compound because of the small amount of material that has been available. One is inclined to speculate that the customary side chain has been reduced with the formation of an open chain and two free hydroxyl groups. For this substance we suggest the name "trillogenin."

A very small amount of a fourth sapogenin, which appears to be identical with chlorogenin, also has been isolated.

The authors are indebted to Dr. L. F. Fieser for his interest in this problem and for permitting one of us (F. C. C.) to spend some time in this Laboratory working on the problem.

Experimental

Diosgenin and Trillin.—Ten pounds of powdered beth root[4] was extracted and hydrolyzed according to the procedure of Marker, Turner and Ulshafer.[2] The crude diosgenin was filtered from the second hydrolysis mixture and weighed only 15 g. It could not be purified readily by crystallization but on extraction in a Soxhlet apparatus with 60–70° ligroin, the diosgenin was removed and then readily purified by crystallization from acetone.

The unextracted residue amounting to 2.7 g. was purified by crystallization from glacial acetic acid and melted at 269.5°–271° when the capillary tube was placed in a preheated bath; $[\alpha]^{26}D$ −103.4°, $[\alpha]^{26}Hg$ −127.2° in dioxane. This substance is the "trillin" of Marker and Krueger[5] as shown by analysis, conversion to the acetate, and further hydrolysis to diosgenin. Our analysis checks better for the anhydrous compound than for the hemihydrate of Marker and Krueger.

Anal. Calcd. for $C_{33}H_{52}O_8$: C, 68.7; H, 9.1. Found: C, 69.3; H, 9.0.

(3) Marker and co-workers, *ibid.*, **62**, 518, 648, 898 (1940).

(4) Purchased from S. B. Penick and Company and described in their price list as "*Trillium erectum* and species."

(5) Marker and Krueger, THIS JOURNAL, **62**, 2548 (1940).

The **acetate**, m. p. 204–205°, has a rotation of $[\alpha]^{30}D$ −71.4°; $[\alpha]^{30}Hg$ −80.2° in dioxane.

Chlorogenin.—The aqueous alcoholic acid filtrate and washings from the crude diosgenin after standing for several days deposited about 0.2 g. of material which, after several recrystallizations from methyl alcohol, melted at 262–272° and did not depress the melting point of chlorogenin, m. p. 270–274°, but depressed the melting point of gitogenin and of trillin. Conversion to the acetate did not give enough product to purify to a melting point above 130°.

Bethogenin.—When the above alcoholic filtrates were poured into a large volume of water, a black tar precipitated. This was dissolved in 500 cc. of alcohol, just sufficient water added to prevent miscibility with 60–70° ligroin and the solution exhaustively extracted in a continuous liquid extractor with 60–70° ligroin. The ligroin extract on concentration left a yellow semi-solid residue weighing 20 g. which on repeated crystallization from methyl alcohol gave long white needles with a maximum melting point of 182–185°. Purification takes place more readily from a diluted rather than from a hot saturated solution. If the bethogenin was prepared by hydrolysis of the acetate with methyl alcoholic potassium hydroxide solution or by recrystallization from alcohol containing potassium hydroxide, a product was obtained melting at 193–194°. When this was recrystallized from pure methyl alcohol, the melting point dropped to 184–186° and on a second recrystallization to 163–182°. A sample which melted at 180–184° when first prepared melted at 160–173° after standing two weeks. The first two analyses given below are on material which had been purified by crystallization from methyl alcohol alone, while the second two are on samples that had been crystallized from alkaline alcohol. Bethogenin as obtained by crystallization from methyl alcohol contains solvent of crystallization. All samples were dried for analysis at 110° and 20 mm. to constant weight.

Anal. Calcd. for $C_{27}H_{40}O_4$: C, 75.67; H, 9.40; one OH, 3.97; mol. wt., 428.6. Found: C, 75.60, 75.06, 75.55, 75.60; H, 9.70, 9.87, 9.50, 9.96; OH (Zerewitinow), 3.84; mol. wt. (Rast), 442; $[\alpha]^{24}D$ −98.4° in dioxane.

Bethogenin gives a yellow color with tetranitromethane and is precipitated from alcoholic solution with digitonin. The ferric chloride test for enols, the Legal test, the Rosenheim test and the Zimmermann–Jaffee reaction were all negative. In the Lieberman test, a red color was formed which slowly darkened to a deep green.

The **acetate** was prepared by adding 12 cc. of acetic anhydride to 1.97 g. of bethogenin dissolved in 20 cc. of pyridine and allowing the solution to stand for one hour. The product crystallized and was filtered, washed with water and crystallized twice from a mixture of four parts ethyl alcohol and one part benzene. It melted at 230–232° and gave a yellow color with tetranitromethane.

Anal. Calcd. for $C_{29}H_{42}O_5$: C, 74.01; H, 8.99. Found: C, 73.50, 74.00, 74.62; H, 9.70, 9.89, 9.00; $[\alpha]^{24}D$ −94.4° in dioxane.

When 1 g. of bethogenin in 6 cc. of acetic anhydride and 6 cc. of pyridine was heated in a sealed tube at 100° for twenty hours,[6] a brownish colored solution resulted from which only the monoacetate could be isolated.

(6) Steiger and Reichstein, *Helv. Chim. Acta*, **20**, 823 (1937).

A solution of 0.24 g. of bethogenin in 10 cc. of dry pyridine was treated with 3 cc. of benzoyl chloride and allowed to stand overnight. After removing the pyridine under reduced pressure, water was added and the precipitate washed with hot water to remove benzoic acid. The residue was crystallized from methyl alcohol and gave 0.15 g. of the **benzoate** as needles, m. p. 190–191. Three more crystallizations from 1:4 benzene–methyl alcohol mixture raised the melting point to 212–215°.

Anal. Calcd. for $C_{34}H_{44}O_5$: C, 76.65; H, 8.33. Found: C, 76.97; H, 9.10; $[\alpha]^{24}D$ −65.1° in dioxane.

Tetrahydrobethogenin Diacetate.—A mixture of 1.5 g. of bethogenin, 0.3 g. of palladium oxide and 200 cc. of ethyl alcohol was shaken overnight under hydrogen at a pressure of 30 pounds per square inch. The mixture was filtered to remove the palladium and the filtrate evaporated to dryness. This product could not be crystallized readily from any of the common organic solvents. Crystallization did take place from 75% aqueous methyl alcohol but constant melting material could not be obtained even after thirteen crystallizations.

Acetylation of 0.86 g. of the crude product with 5 cc. of acetic anhydride in 7 cc. of pyridine gave 0.77 g., m. p. 126–129°. After fourteen crystallizations from ligroin (60–70°) the melting point was constant at 141–144°. It gave a negative test for unsaturation with tetranitromethane.

Anal. Calcd. for $C_{31}H_{48}O_6$: C, 72.05; H, 9.37. Found: C, 71.87, 72.30; H, 9.25, 9.66; $[\alpha]^{24}D$ −156° in dioxane.

A smaller sample of bethogenin in a semi-micro apparatus showed absorption of four atoms of hydrogen per mole.

Reaction of Bethogenin with Hydroxylamine.—A solution of 0.5 g. of bethogenin and 0.4 g. of hydroxylamine hydrochloride in 4 cc. of pyridine and 4 cc. of absolute alcohol was heated on the steam-bath for one hour and the flask allowed to stand overnight. The precipitate was filtered, washed with 95% alcohol and crystallized from absolute alcohol to a constant melting point of 241–243°.

Anal. Calcd. for $C_{27}H_{42}O_4N_2$: C, 70.72; H, 9.22; N, 6.11. Found: C, 70.42, 70.40; H, 9.54, 9.96; N, 5.94, 5.92.

Attempts to hydrolyze the reaction product to the original compound were unsuccessful.

Attempts to Prepare a Pseudobethogenin.—Three attempts were made to convert bethogenin into a pseudobethogenin. In the first bethogenin was heated with acetic anhydride at 200°, in the second bethogenin acetate was heated with acetic anhydride at 165° and in the third run bethogenin acetate and acetic anhydride were heated at 200°. Only unchanged acetate or resinous products could be isolated.

Trillogenin.—After standing for several months, the methyl alcohol solution which had been extracted with ligroin deposited a few tenths of a gram of precipitate which, after several crystallizations from methyl alcohol, melted at 206–210°; $[\alpha]^{24}D$ −41.6; $[\alpha]^{24}Hg$ −54.3 in dioxane. The substance does not give a color with tetranitromethane and gives marked depressions in melting point when mixed with diosgenin or tigogenin.

Anal. Calcd. for $C_{27}H_{48}O_4$: C, 74.26; H, 11.08. Found: C, 73.74, 74.17; H, 11.05, 11.08.

The compound was recovered unchanged after several hours of refluxing with alcoholic hydrochloric acid, proving that it is not a prosapogenin. When refluxed with acetic anhydride and sodium acetate, an acetate was obtained which, after several crystallizations from aqueous methyl alcohol, melted at 102–103°; $[\alpha]^{24}D$ 0°; $[\alpha]^{24}Hg$ −3.5° in dioxane.

Anal. Calcd. for $C_{27}H_{44}O_4(CH_3CO)_4$: C, 69.51; H, 9.33; acetyl, 28.48. Found: C, 69.97; H, 9.28; acetyl, 29.86, 29.52.

Summary

Bethogenin, a new sapogenin having the empirical formula $C_{27}H_{40}O_4$, has been isolated from the hydrolysis products of extracts of powdered beth root (*Trillium erectum*). It appears to be an unsaturated steroid sapogenin with one hydroxyl group and one carbonyl group.

Another new sapogenin, trillogenin, having the empirical formula $C_{27}H_{48}O_4$, has been obtained in very small amount. This compound is saturated and is unique among the known steroid sapogenins because it lacks the two characteristic inert oxygen atoms, all four oxygen atoms being accounted for by hydroxyl groups.

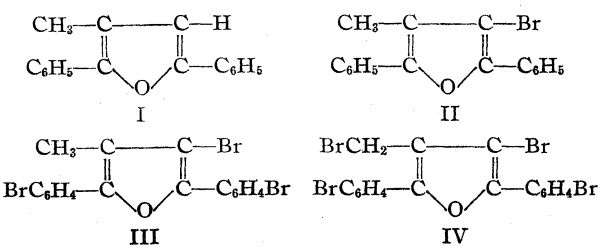
Halogen Compounds Derived from 4-Methyl-2,5-diphenylfuran

BY ROBERT E. LUTZ AND C. EDWARD MCGINN[1]

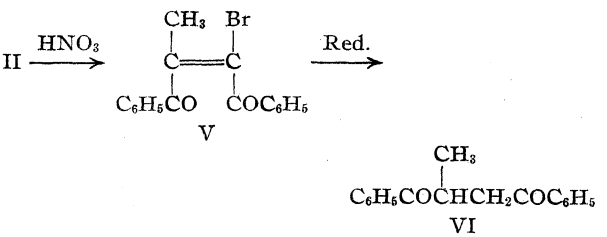
The bromination of this furan was of interest in connection with orientation[2] and the synthesis of certain brominated *cis* unsaturated diketones which could not easily be made otherwise.

The bromination of methyldiphenylfuran (I) proceeded stepwise with the formation successively of the mono,[3] tri and tetrabromo derivatives (II, III and IV).



I II III IV

Zinc and acetic acid reduced only the tetrabromo derivative and eliminated but one bromine to give the tribromo compound. The last bromine introduced therefore must have been aliphatic and located on the methyl group; and the three bromines of the tribromo compound must be aromatic. The tribromo compound on oxidation first with nitric acid and then with potassium permanganate gave more than one molecule of *p*-bromobenzoic acid, showing that two of the halogens occupied the two phenyl para positions. The remaining bromine atom, evidently the first introduced, must, therefore, be in the furan β-position (*cf.* II). This was confirmed by nitric acid oxidation of the monobromo derivative (II) to the unsaturated bromo 1,4-diketone[3] (V) and reduction of this to the saturated diketone (VI) with loss of the bromine. The structures of the three bromination products therefore are as represented in formulas II, III and IV.



II V VI

Each of the three brominated furans (II, III and IV) could be oxidized by the nitric–acetic acid reagent to the corresponding unsaturated 1,4-diketones (V, VII and IX) which are presumed to be *cis* from the mode of formation. The first of these oxidation products (V) already has been reported.[3] The other two (VII and IX) could be converted into the saturated diketone (VIII) by reduction with zinc and acetic acid and into the furan (X) by reduction under dehydrating conditions.

The *cis*-di-[bromobenzoyl]-propylene (XI) has become available through oxidation of the corresponding furan (X). This new unsaturated diketone in turn was reduced to the saturated diketone (VIII) and to the furan (X).

Unfortunately, it has not yet been possible to

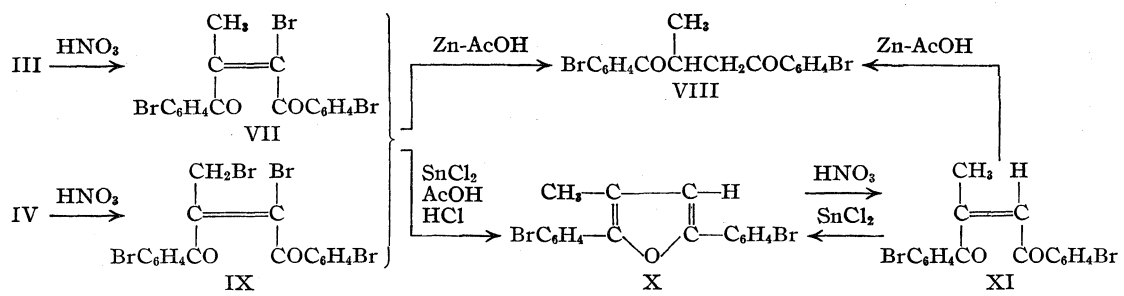
(3) Lutz and Stuart, *ibid.*, **59**, 2316 (1937).



make any of the corresponding *trans*-compounds in this series. One important approach which should have led directly to the *trans*-isomer of XI was blocked by the failure of the Friedel–Crafts reaction between bromobenzene and mesaconyl chloride to go beyond the first stage, namely, the formation of β-bromobenzoyl-β-methylacrylic acid.[4]

Experimental

3-Methyl-2,5-di(*p*-bromophenyl)-furan (X).—This furan was obtained in excellent yields by the stannous chloride reduction of 1-bromo-1,2-di-(*p*-bromobenzoyl)-propylene (VII), 1,2-di-(*p*-bromobenzoyl)-propylene (XI), and 1,3-dibromo-1,2-di-(*p*-bromobenzoyl)-propylene (IX). The following procedure is general.

A mixture of 30 ml. of concd. acetic acid, 25 ml. of concd. hydrochloric acid and 18 g. of stannous chloride was heated to boiling under mechanical stirring; 5 g. of (XI) in 15 ml. of concd. acetic acid was added; heating was continued for five minutes; and cooling and dilution with water gave a crystalline product. Recrystallizations from ethyl acetate raised the melting point to 158–159°. The yield of nearly pure product was 3.1 g.

Anal. Calcd. for $C_{17}H_{12}Br_2O$: C, 52.07; H, 3.09. Found: C, 52.12; H, 3.87.

3-Bromo-2,5-di-(*p*-bromophenyl)-4-methyl-furan (III). This compound was obtained directly by bromination of 3-methyl-2,5-diphenylfuran (I) by the calculated amount of bromine in chloroform solution but the method was impractical because of the difficultly separable mixture of bromination products which was obtained. The preparation is as follows:

A mixture of 2 g. of 3-bromo-4-bromomethyl-2,5-di-(*p*-bromophenyl)-furan and 2 g. of zinc dust in 70 ml. of concd. acetic acid was refluxed for five minutes and filtered. Upon dilution with water and crystallizing the resulting precipitate from a chloroform–ethanol mixture, 1.6 g. of nearly pure product (III) was obtained. Repeated crystallizations from chloroform–ethanol mixtures raised the melting point to 168–169°.

Anal. Calcd. for $C_{17}H_{11}Br_3O$: C, 43.35; H, 2.36. Found: C, 43.04, 43.03; H, 2.66, 2.66.

Zinc dust and boiling concd. acetic acid was without action on this compound.

3-Bromo-4-bromomethyl-2,5-di-(*p*-bromophenyl)-furan (IV).—A solution of 30 g. (4.1 moles) of bromine in 50 ml. of chloroform was added to 10 g. of methyldiphenylfuran (I) in 100 ml. of chloroform. The mixture was allowed to stand for twenty hours at room temperature, during which time hydrogen bromide was evolved, and a colorless crystalline product separated. Filtration, evaporation and finally dilution with ethanol gave successive crops totalling 17.9 g. (75%). After repeated crystallization it melted at 212–213°.

Anal. Calcd. for $C_{17}H_{10}Br_4O$: Br, 58.15. Found: Br, 58.33.

***cis*-1,4-Di-(*p*-bromophenyl)-2-methyl-2-butenedione-1,4 (XI).**—A mixture of 5 ml. of concd. nitric acid and 15 ml. of concd. acetic acid was added to a suspension of 2,5-di-(*p*-bromophenyl)-3-methylfuran (X) in 20 ml. of concd. acetic acid. After one hour at room temperature the mixture was diluted with water and the product crystallized from ethanol (yield 1.8 g.). Repeated crystallization from this solvent brought the melting point to 115–116°.

Anal. Calcd. for $C_{17}H_{12}Br_2O_2$: C, 50.0; H, 2.96. Found: C, 49.71; H, 3.08.

Sunlight was without action on a chloroform–iodine solution of this compound.

***cis*-1-Bromo-1,4-di-(*p*-bromophenyl)-2-methyl-2-butenedione-1,4 (VII).**—A mixture of 5 ml. of concd. nitric acid and 15 ml. of concd. acetic acid was added to a suspension of 5 g. of the furan (III) in 25 ml. of concd. acetic acid. After heating for one hour at 50°, diluting with ice-water and crystallizing the product from ethanol, 4.7 g. (91%) of VII was obtained. Recrystallization from ethanol brought the melting point to 119.5–120°.

Anal. Calcd. for $C_{17}H_{11}Br_3O_2$: C, 41.90; H, 2.28; Br, 49.23. Found: C, 41.46; H, 2.40; Br, 48.83.

***cis*-1-Bromo-2-(bromomethyl)-1,4-di-(*p*-bromophenyl)-2-butenedione-1,4 (IX).**—A mixture of 10 ml. of concd. nitric and 30 ml. of concd. acetic acids added to a suspension of 5 g. of IV, was heated for one hour at 50° and diluted with water. The product was crystallized from ethanol (4.5 g., 90%), and after further crystallization it melted at 117–117.5°.

Anal. Calcd. for $C_{17}H_{10}Br_4O_2$: C, 36.1; H, 1.78; Br, 56.40. Found: C, 35.77; H, 2.13; Br, 56.83.

Sunlight was without action on a chloroform–iodine solution.

1,4-Di-(*p*-bromophenyl)-2-methylbutanedione-1,4 (VIII).—The following procedure was employed using at will, VII, IX or XI.

A mixture of 5 g. of VII, 5 g. of zinc dust and 100 ml. of concd. acetic acid was refluxed for fifteen minutes, filtered and diluted with water. Extraction with ether, washing

(4) Lutz and Taylor, THIS JOURNAL, **55**, 1168 (1933).

the extract with water, evaporation and crystallization of the residue gave 3 g. of colorless prisms which after repeated crystallizations from ethanol melted at 120–120.5°.

Anal. Calcd. for $C_{17}H_{14}Br_2O_2$: Br, 39.0. Found: Br, 38.93.

Summary

Bromination of 3-methyl-2,5-diphenylfuran involves successive substitutions in the furan β-position, the phenyl para positions and in the methyl group.

The various brominated furans of this series have been oxidized to *cis* unsaturated diketones and these in turn have been reduced. The diketones of the di-*p*-bromophenyl series have become available through these reactions.

CHARLOTTESVILLE, VA. RECEIVED JULY 16, 1942

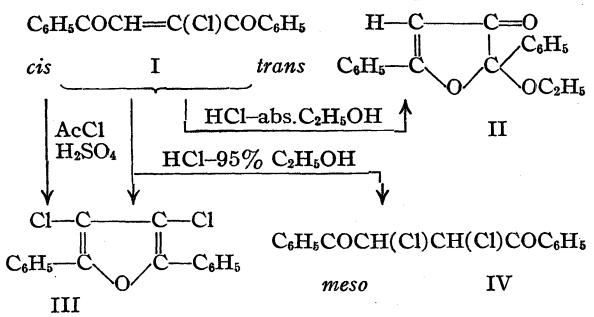
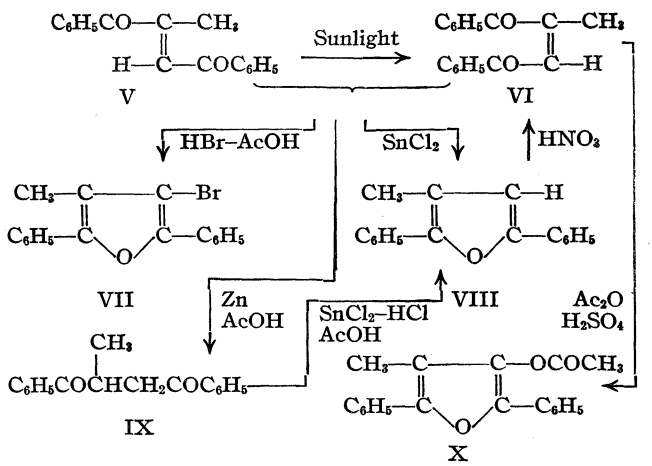
The Conversion of Unsaturated 1,4-Diketones into Furans and Hydroxyfuranones

BY ROBERT E. LUTZ AND C. EDWARD MCGINN[1]

It would be expected that *cis* unsaturated 1,4-diketones would be somewhat more reactive than *trans*. This is the case with the stereoisomeric dibenzoylchloroethylenes (I) where only the *cis*-isomer reacts under the usual conditions with acetic anhydride and with acetyl chloride (with sulfuric acid as catalyst) to give, respectively, the acetoxychlorodiphenylfuran and dichlorodiphenylfuran (III).[2] However, both the *cis*- and *trans*-dibenzoylchloroethylenes react easily with hydrogen chloride in 95% ethanol to give the same mixture of dichlorodiketone (IV) and furan (III)[3], and in absolute ethanol to give the ethoxyfuranone (II).[4] This report deals with more reactions of these types.

Certain of the *cis* unsaturated diketones which have been difficult if not impossible to make from the *trans*-isomers by the sunlight inversion can now be made in good yield through the corresponding furan by oxidation by means of nitric acid. This method has been applied successfully in the preparation in quantity of *cis*-dibenzoylmethylethylene (VI) as is outlined in the diagram.





The *cis*- and *trans*-dibenzoylmethylethylenes (VI and V) are converted readily into the bromofuran (VII) by hydrogen bromide in acetic acid, but it has not been possible under the experimental conditions to determine the relative ease of reaction in the two cases. In the reaction with acetic anhydride and sulfuric acid at room temperature, on the other hand, the *trans*-compound did not react whereas the *cis*-isomer was converted in good yield into the acetoxyfuran (X). Similarly the *trans*-compound did not react with benzoic anhydride and sulfuric acid whereas the *cis*-isomer did (although, unfortunately, not to give a crystalline product). Incidentally, it has since been found that in the medium acetic anhydride, acetic acid and zinc chloride, *trans*-dimesitoylethylene is reduced catalytically to the saturated diketone in the normal fashion whereas the *cis*-isomer in-

(1) Present location, National Aniline Division, Allied Chemical and Dye Corp., Buffalo.

(2) Lutz, Stuart, Wilder and Connor, THIS JOURNAL, **59**, 2314 (1937).

(3) Lutz and Wilder, *ibid.*, **56**, 1193 (1934).

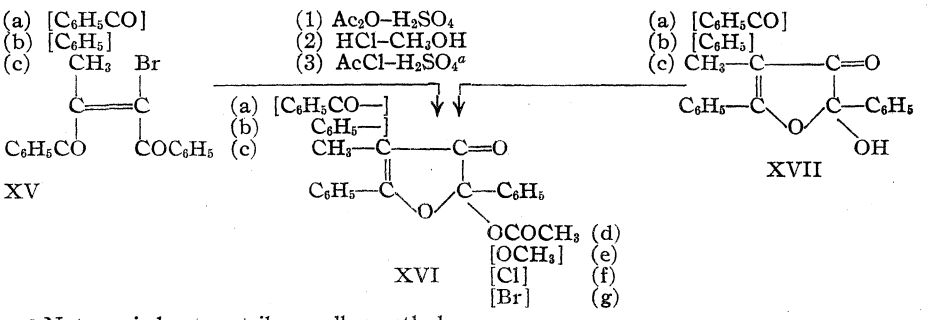
(4) Lutz, Wilder and Parrish, *ibid.*, **56**, 1980 (1934).

stead is converted into the acetoxyfuran by addition and dehydration.[5]

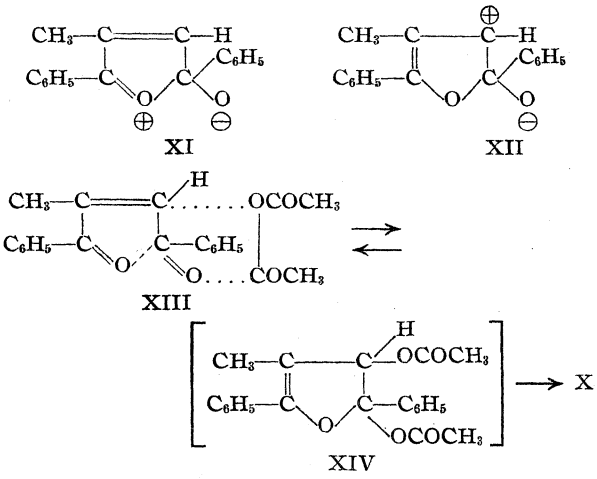
There probably is some special reason, other than the slightly higher energy content, for the greater reactivity of the *cis* as compared with the *trans* unsaturated 1,4-diketone. Possibly actual interaction of the two spatially proximate carbonyl groups is involved to give resonance hybrids such as XI and XII, which might facilitate the reaction with acetic anhydride or combination with the catalyst (*cf.* XIII, XIV).[6]

Each of the compounds discussed above carries in the chain position a hydrogen atom which makes possible elimination of an acid molecule or its equivalent to form the double bond needed to complete the conjugated system of the furan nucleus (*cf.* XIV). If this chain hydrogen were not available, as is the case with completely substituted unsaturated diketones such as XV, the formation of a furan would be impossible. However, with an oxygen or halogen atom at one of these chain positions, a reaction still could proceed by a mechanism similar to that suggested above but with the formation in the end of a 2,3-hydroxyfuranone derivative of the type XVI or XVII. This latter type of reaction has in fact been observed even when a chain hydrogen is available and where both the furan and the hydroxyfuranone theoretically might result [*cf.* the conversion of the *cis*- and *trans*-dibenzoylchloroethylenes (I) into the ethoxyfuranone (II[3,4])].

The formation of hydroxyfuranone types from suitably substituted unsaturated 1,4-diketones has already been utilized in a method of synthesis of 4-benzoyl-2-hydroxy-2,5-diphenylfuranone-3.[7] Other examples of this type of reaction have been sought and found; these reactions, including both old and new ones, are illustrated in the following diagram.



[a] Not carried out on tribenzoylbromethylene.



The *trans* unsaturated diketones corresponding to XV-b and c are not known and work is being undertaken to complete some suitably substituted *cis–trans* pairs for comparison with respect to relative facility of this type of reaction.

Experimental

trans-2-Methyl-1,4-diphenyl-2-butenedione-1,4 (V).—Earlier preparations[8] were not satisfactory. From a long series of experiments carried out under varied conditions, it was found that temperature control and rapid working-up of the product were very important factors. The directions finally evolved were practically identical with those which have since been published.[9]

cis-2-Methyl-1,4-diphenyl-2-butenedione-1,4 (VI).—A mixture of 10 ml. of concd. nitric and 30 ml. of concd. acetic acids at 10° was added to a solution of 10 g. of the furan (VIII) in 50 ml. of concd. acetic acid (also at 10°). Immediate reaction occurred with evolution of oxides of nitrogen, and after standing for five minutes 200 ml. of water was added. The viscous resinous precipitate was isolated by extraction with ether and evaporating. The product crystallized from ethanol; 8.7 g. (81%). It was identified by mixture melting point with a sample made by the sunlight inversion method.[10] The yields were lowered when the reactions were carried out at higher temperatures or over longer periods of time.

Reduction with zinc dust and concd. acetic acid at 100° gave the saturated diketone (IX) in excellent yields.

(5) Lutz, Reveley and Mattox, THIS JOURNAL, **63**, 3171 (1941).

(6) The idea of interaction of the two carbonyls to give a ring form in an equilibrium or oscillating system is not new [*cf.* the peroxide formula for *cis*-dibenzoylethylene suggested by Smedley [*J. Chem. Soc.*, **75**, 219 (1909)].

(10) Lutz and Taylor, *ibid.*, **55**, 1168 (1933).

Attempts to obtain a crystalline ethylene oxide from the *cis*-compound (VI) by the action of hydrogen peroxide were unsuccessful and only non-crystalline products were obtained.

3-Methyl-2,5-diphenylfuran (VIII).—A mixture of 250 ml. of concd. acetic acid and 200 ml. of concd. hydrochloric acid was heated to boiling, and 128 g. of stannous chloride was added, followed by 35 g. of *trans*-dibenzoylmethylethylene (V) in 100 ml. of concd. acetic acid. Heating was continued for five minutes during which time an oil separated. Upon cooling and diluting with 700 ml. of water and crystallizing the product once from ethanol, 31.3 g. (96%) of nearly pure furan was obtained (m. p. 58–59°). This melting point corresponds with that given in the literature.[11]

Equally good results were obtained using the *cis* unsaturated diketone (VI).

3-Bromo-2,5-diphenyl-4-methylfuran (VII).[12]—A solution of 1 g. of the furan (VIII) in 20 ml. of chloroform was treated with 0.8 ml. of bromine. The bromine color was discharged and hydrogen bromide was evolved. Evaporation and crystallization of the residue from ethanol gave 1.1 g. of the bromofuran (VII).

In another experiment, 5 g. of the *cis* unsaturated diketone (VI) was suspended in 50 ml. of acetic anhydride and treated with 10 ml. of 30% hydrogen bromide in concd. acetic acid at 0°. Three drops of concd. sulfuric acid were added and after fifteen minutes the mixture was hydrolyzed with water. The product was crystallized from ethanol and identified as the bromofuran (VII) (yield 5.1 g.).

3-Acetoxy-4-methyl-2,5-diphenylfuran (X).—A solution of 5 g. of the *cis* unsaturated diketone (VI) in 20 ml. of acetic anhydride was cooled to −5° and three drops of concd. sulfuric acid were added. The temperature was not allowed to rise above −1°. After standing for five minutes the solution was poured into 200 ml. of water. When crystallization was complete the product was recrystallized from isopropanol (yield 3.7 g. or 68%).

In a similar experiment on a larger scale in which the temperature was allowed to rise to 25° the yield was lower (about 50%).

The compound crystallizes as yellowish needles but undergoes vacuum evaporation onto a cold-finger condenser as colorless needles of m. p. 94–95°.

Anal. Calcd. for $C_{19}H_{16}O_3$: C, 78.06; H, 5.52. Found: C, 78.18; H, 5.58.

Attempts to obtain a chlorofuranone from this compound by means of phosphorus pentachloride, thionyl chloride and phenyliodochloride produced only non-crystalline materials. In the case of thionyl chloride a small yield (5%) of the dimolecular oxidation product, 2-bis-(4-methyl-2,5-diphenylfuranone-3), was obtained and identified by mixture m. p.[12]

2-Bromo-4-methyl-2,5-diphenylfuranone-3 (*cf.* XVI-c,g).—A solution of 0.8 g. of bromine in 8 ml. of carbon tetrachloride was added to a solution of 1.0 g. of the acetoxyfuran (X) in 15 ml. of the same solvent. The color was discharged by refluxing for a short time. Evaporation and crystallization of the residue from ligroin gave 1 g. of colorless prisms which after repeated crystallizations from ligroin melted at 88–89°.

Anal. Calcd. for $C_{17}H_{13}BrO_2$: C, 62.02; H, 3.98. Found: C, 62.98, 62.67; H, 4.22, 4.33. (The high values for carbon and hydrogen are accounted for by the instability of the compound and evident loss of some of the bromine through hydrolysis.)

When treated immediately with ethanol under refluxing for five minutes, the ethoxyfuranone was obtained in good yield and identified by mixture melting point.

***cis*-2-Bromo-3-methyl-1,4-diphenyl-2-butenedione-1,4**[12] **(XV-c).**—A mixture of 5 ml. of concd. nitric and 15 ml. of concd. acetic acid was added to a solution of 5.1 g. of the bromofuran (VII) in 25 ml. of concd. acetic acid with heating at 80° for one hour. Dilution with water gave 4.2 g. of nearly pure *cis* unsaturated diketone (XV-c).

A suspension of 1 g. of (XV-c) in 10 ml. of acetic anhydride at 0° was treated with two drops of concd. sulfuric acid. After fifteen minutes at this temperature, the solution was hydrolyzed with a large volume of water. The resulting oil was crystallized from ethanol (0.5 g.) and identified as the acetoxyfuranone (XVI-c,d).

A drop of concd. sulfuric acid was added to a suspension of 1 g. of (XV-c) in 10 ml. of acetyl chloride at 0° and the mixture was allowed to stand at this temperature for fifteen minutes and hydrolyzed in an excess of water. The resulting yellow solid was crystallized from ligroin (0.2 g.) and identified as the chlorofuranone (XVI-c,f).

A solution of 1 g. of the bromo unsaturated diketone (XV-c) in 20 ml. of 99% of methanol saturated with dry hydrogen chloride was allowed to stand at room temperature for twenty hours in a glass-stoppered flask. Upon cooling 0.6 g. of the methoxyfuranone (XVI-c,e) crystallized and was identified.

3-Bromo-2,4,5-triphenylfuran[13] was prepared in excellent yield by the action of 30% hydrogen bromide in concd. acetic acid on dibenzoylphenylethylene. The reaction was complete within two to three minutes at room temperature and the product crystallized on cooling.

***cis*-2-Bromo-1,2,4-triphenyl-2-butenedione-1,4**[14] **(XV-b)** was prepared by adding a mixture of 50 ml. of concd. nitric and 30 ml. of concd. acetic acids to a solution of 10 g. of 3-bromotriphenylfuran in 50 ml. of concd. acetic acid. The mixture was heated for fifteen minutes at 100° and poured into cold water. The product was crystallized from ethanol (7.2 g.).

Two drops of concd. sulfuric acid were added to a solution of 1 g. of (XV-b) in 10 cc. of acetic anhydride. The mixture was allowed to stand for fifteen minutes at room temperature and was hydrolyzed in an excess of water. Crystallization of the product from isopropanol gave 0.73 g. of the acetoxyfuranone (XVI-b,d).

In a similar experiment, using acetyl chloride instead of acetic anhydride, the chlorofuranone (XVI-b,f) was obtained in 85% yield.

A solution of 0.5 g. of (XV-b) in 10 ml. of methanol saturated with hydrogen chloride was allowed to stand for eighteen hours in a glass-stoppered flask; 0.3 g. of methoxyfuranone (XVI-b,e) was obtained.

Summary

Several *cis* unsaturated 1,4-diketones are shown to be much more susceptible than the *trans* isomers toward furanization through addition and dehydration. A mechanism is suggested to account for this.

The analogy between these furanizations and the formation of 2,3-hydroxyfuranones is considered and new examples of the latter reaction are described.

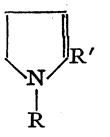
Basicity Studies of Tertiary Vinyl Amines

BY ROGER ADAMS AND J. E. MAHAN

The introduction of a double bond into a primary or secondary amine lowers the basic strength constant, that is, decreases the degree of ionization.[1] Hixon and co-workers[2] measured the ionization constants of several 2-alkyl substituted 4,5-dihydropyrroles (2-ethyl, 2-benzyl, 2-phenyl, and 2-cyclohexyl-Δ^2-pyrrolines) and of the corresponding saturated compounds (pyrrolidines). The saturated molecules were, in all cases, stronger bases than the unsaturated by 2.4 to 3.3 pK_H units.[2a] In the case of tertiary amines the same general effect as for primary and secondary amines might be expected but no examples were found in the literature. Vinyl tertiary amines, excluding the pseudo bases or anhydro bases formed from pyridinium type salts which are not entirely comparable have also, with one exception, not been studied. The normal assumption would be that they are weaker bases than the corresponding saturated amines.

An attempt to locate the relative position of a double bond to the nitrogen atom in retronecine, a base from the plants of the genera *Crotalaria*, *Senecio* and *Trichodesma*, was initiated by comparative basicity studies[3] of retronecine, desoxyretronecine and their reduction products. These substances were all tertiary amines containing pyrrolizidine rings. For purposes of comparison, a variety of tertiary vinyl amines and the corresponding reduced compounds have been synthesized and their relative basicity measurements made.

A series of 1,2-dialkyl-Δ^2-pyrrolines (I–IV) was first investigated, since such molecules are very closely related in structure to the products under



I. R = CH_3; R′ = CH_3
II. R = CH_3; R′ = C_4H_9
III. R = C_2H_5; R′ = CH_3
IV. R = C_4H_9; R′ = CH_3

study. The basic strengths of these pyrrolines and the analogous pyrrolidines are shown in Table I. It is to be noticed that in every case the unsaturated compound is more basic than the saturated. This interesting observation stimulated us to study analogous 6-membered ring compounds, namely, 1,2-dialkyl-Δ^2-tetrahydropyridines and the corresponding piperidines.

TABLE I

Name	Obs. pK_H	T, °C.	pK_H (25°)[4]	Diff.	Lit.

(2) Craig and Hixon, *ibid.*, **53**, 4367 (1931); Starr, Bulbrook and Hixon, *ibid.*, **54**, 3971 (1932).

(2a) The constant pK_H will be used in this paper to indicate the basic strengths. It is related to the more usual constant K_{ion}, by the expression $pK_H = pK_w - pK_{ion}$, where K_w is the ion product for water.

(3) Adams, Carmack, and Mahan, *ibid.*, **64**, 2593 (1942).

(4) Corrected to 25° employing the negative temperature coefficient of the constant as given by Hall and Sprinkle, *ibid.*, **54**, 3469 (1932), for amines of various basicity. Since these data are valid only for aqueous solutions the pK_H constants measured in aqueous methanol were not corrected to 25°.

(5) Craig, *ibid.*, **55**, 2543 (1933).

The results are shown in Table II. Here again the unsaturated tertiary amines are more basic than the saturated.

TABLE II

Name	Obs. pK_H	T, °C.	pK_H (25°)[4]	Lit.
1,2-Dimethyl-Δ^2-tetrahydropyridine	11.42	25.5	11.43	
1,2-Dimethylpiperidine	10.26	25	10.26	
1-Ethyl-2-methyl-Δ^2-tetrahydropyridine	11.57	25	11.57	
1-Ethyl-2-methylpiperidine	10.70	25	10.70	10.68[4]
ω-Dimethylamino-n-butyl methyl ketone	9.66	24.5	9.67	

A similar comparison has been carried to 1-propenylpiperidine and 1-n-propylpiperidine, as well as to a pair of straight chain compounds, 1-diethylamino-n-heptene-1 and 1-diethylamino-n-heptane (Table III). The basic strength determinations of these two sets of molecules were carried out in the former case in 25% methanol and in the latter in 50% methanol because of the fact that the unsaturated molecules are not sufficiently soluble in water. The phenomenon still holds that the unsaturated molecules are more basic than the saturated, though to a lesser degree than in the Δ^2-pyrroline and Δ^2-tetrahydropyridine series.

TABLE III

Name	Obs. pK_H	T, °C.	Diff.
1-Propenylpiperidine	10.66[a]	28	
1-Propylpiperidine	10.23[a]	25	0.43
1-Diethylamino-n-heptene-1	10.38[b]	28

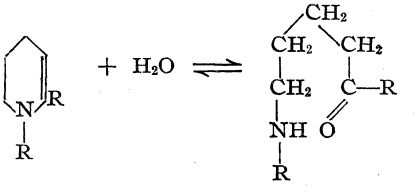
Piperidine (in 25% methanol which contained over an equivalent of propionaldehyde)	10.77	27	
Diethylamine (in 50% methanol which contained over an equivalent of heptaldehyde)	10.50	27	

[a] In 25% aqueous methanol. [b] In 50% aqueous methanol.

In experiments of this kind the question may be raised in the case of the pyrrolines and tetrahydropyridines whether the basic strength as determined is a measure of the molecules in cyclic form or whether of possible open chain hydrolytic products; in the case of the 1-propenylpiperidine and 1-diethylamino-n-heptene-1, whether the basic strength is that of the original molecules or of a mixture of the secondary amine and corresponding aldehyde. The smooth titration curves, described in the experimental part, support the supposition that only a single basic molecule is being titrated in each instance. Lipp and Widnmann[6] reported that when a Δ^2-tetrahydropyridine (V) (Table II) is dissolved in water, it is immediately hydrolyzed to some extent to give an open chain secondary amino ketone (VI). This was based



V VI

on immediate reaction of the compounds with carbonyl reagents to give derivatives of the open chain amine.

The basic strength of ω-dimethylamino-n-butyl methyl ketone, which is a tertiary amino ketone and thus cannot ring close to a Δ^2-tetrahydropyridine, gave a pK_H value of 9.68, which is relatively low and which led to the deduction that the strong basicity of aqueous solutions of the Δ^2-tetrahydropyridines is not due to the open-chain form of the equilibrium mixture.

Marz[7] observed that 2-methyl-Δ^2-pyrroline would react with hydroxylamine, semicarbazide and phenylhydrazine in aqueous solution, and hence concluded that a similar equilibrium existed in the Δ^2-pyrroline series. Craig,[8] however, prepared and studied several 1-methyl-2-alkyl-Δ^2-pyrrolines and because of their apparent non-reactivity with semicarbazide or phenylhydrazine assumed that hydrolysis did not occur to any great extent in aqueous solution.

Mannich and Davidsen[9] pointed out that vinyl tertiary amines in which the double bond is not a part of a ring are readily hydrolyzed in the presence of mineral acids to the corresponding aldehyde and secondary amine. If rapid hydrolysis occurs during the titration in the present basic strength studies, the resulting curve and pK_H value should be that of piperidine in the case of 1-propenylpiperidine, and that of diethylamine in the case of 1-diethylamino-n-heptene-1. Piperidine and diethylamine were titrated (Table III) in aqueous methanol in the presence of slightly over an equivalent of the appropriate aldehyde, approximating as nearly as possible those conditions used in the titration of the 1-propenylpiperi-

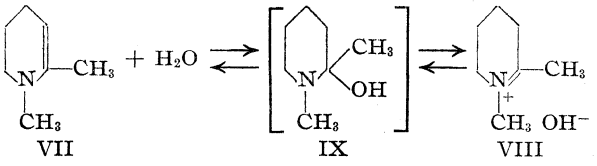
dine and the 1-diethylamino-heptene-1. The mixture of the aldehyde and base gave a slightly higher basicity than the molecules which were prepared from them, though the difference was far less than expected.

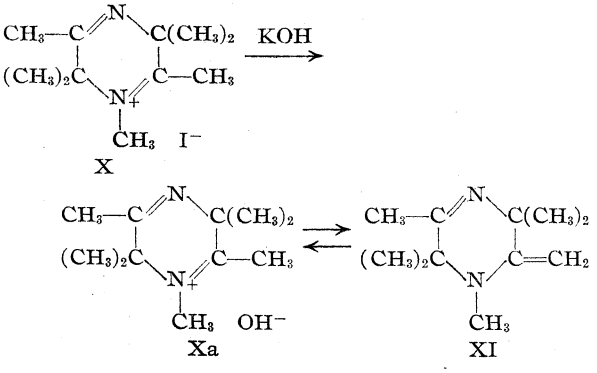
A possible explanation of the increased basicity of the vinyl tertiary amines compared with their saturated homologs lies in the assumption that an equilibrium exists in aqueous solution between the vinyl amine and a hydration product, the corresponding quaternary hydroxide as shown in formulas VII and VIII for 1,2-dimethyl-Δ^2-tetrahydropyridine as a representative of all the vinyl amines studied. The quaternary ammonium



VII IX VIII

hydroxides are known to be strong bases which exceed in basicity all the tertiary amines. Since pseudo bases in general are weak, no appreciable amount of pseudo base (IX) can be present in the solution when titrated.

Aston[10] studied the action of alkali on 1,2,3,-5,5,6-heptamethyldihydropyrazinium iodide (X) and obtained a strong base (Xa) (pK_H at 25°, 11.6) of a quaternary ammonium type which is in equilibrium in aqueous solution with the tertiary base XI. This coincides with the explanation offered for the basicity of the simple vinyl tertiary amines studied in this investigation.



X Xa XI

Vinyl primary or secondary amines if they undergo a similar rearrangement would form ammonium bases, not quaternary ammonium bases. Hence a lower basicity of the vinyl primary or secondary amines as compared with the corresponding saturated compounds would be expected and this agrees with the experimental facts. In Table IV, it may be noted that 2-methyl-Δ^2-tetrahydropyridine, a secondary vinyl amine, is less basic than 2-methylpiperidine, a fact which is in harmony with the above statement and the observations of Hixon and co-workers[2] on 2-alkyl-Δ^2-pyrrolines.

TABLE IV

Name	Obs. pK_H	T, °C.	pK_H (25°)[4]	Lit.
2-Methylpiperidine	10.99	25	10.99	10.98[4]
2-Methyl-Δ^2-tetrahydropyridine	9.57	24	9.55	

Although it has been generally assumed that unsaturated tertiary amines with the double bond not in the vinyl position are less basic than the corresponding saturated, it was deemed advisable to test two pairs of such molecules which are related to the amines under investigation. These are shown (Table V) by a comparison of 1-methyl-Δ^3-pyrroline with 1-methylpyrrolidine and 1-allylpiperidine with 1-*n*-propylpiperidine. The saturated molecules are more basic than the unsaturated.

TABLE V

Name	Obs. pK_H	T, °C.	pK_H (25°)[4]	Diff.	Lit.
1-Methylpyrrolidine	10.36	25	10.36		10.18[5]
1-Methyl-Δ^3-pyrroline	9.92	25	9.92	0.44	
Propylpiperidine	10.45	26.5	10.48		
Allylpiperidine	9.65	27	9.69	.89	

A few effects of substitution were noted in this work which have not been previously mentioned in the literature. When an N-methyl group is replaced by an N-ethyl group on the pyrrolidine or piperidine ring there is an increase in basicity of about 0.4 unit. This effect is exemplified in Table VI; compare 2 with 4, and 8 with 9. However, increasing the size of the alkyl group from ethyl to butyl has little effect on the pK_H value of the resulting base; compare 1 with 2, 7 with 8, 11 with 12 and 13. The close parallel of pK_H values of compounds of the pyrrolidine series with analogous substituted compounds of the piperidine series may be worthy of note; compare 1 with 9, 2 with 10, 4 with 11, and 8 with 16.

Craig, Shedlovsky, Gould and Jacobs[11] assigned the double bond in lysergic acid (XII) to the 5,10-position because this acid and ergome-

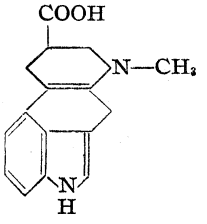
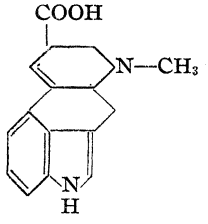
trine, a parent alkaloid, exhibited weaker basic properties than *iso*-lysergic acid (XIII) and ergometrinine. The double bond in *iso*-lysergic acid was then assigned to the 9,10-position. In view of the results obtained on the basic strengths of vinyl tertiary amines, it appears questionable whether the deductions of the authors were justified and whether the assignment of the formulas should not possibly be reversed.



XII



XIII

Experimental

Determination of Basic Strength Constants.—A sample of the base calculated to require between 20 to 30 cc. of 0.10 *N* hydrochloric acid was dissolved in 90 cc. of conductivity water. While the solution was continuously stirred by means of a small air-driven stirrer, the base was titrated by adding appropriate increments of standard 0.1 *N* hydrochloric acid. After each addition of acid the *p*H was carefully measured with a Hellige glass electrode *p*H meter (no. 7040). The *p*H of the solution when exactly half of the base had been neutralized (pK_H value) was read from the titration curve (*p*H *vs.* cc. of acid). Duplicate or triplicate measurements were made in all cases. The curves obtained were smooth and showed only the characteristic sharp break at the end-point. For compounds not sufficiently soluble in water, 90 cc. of an aqueous solution was used which contained the calculated amount of methanol to make a 25 or 50% solution just at the point when half the titer had been added. All of the amines studied were carefully fractionated in a carbon dioxide-free atmosphere immediately before use, and all boiled within a range of 1° or less.

Basicity measurements were made on several compounds for which values have been recorded in the literature by Hall and Sprinkle[4] who used a hydrogen electrode in their *p*H determinations. The close agreement (see tables) in all cases with their values indicates that no great error has been introduced by the use of a glass electrode in the basicity studies.[12] Before each titration the electrodes were washed, the half-cell tip flushed with fresh saturated potassium chloride solution, and the meter standardized with 0.05 *M* potassium acid phthalate. Each day that the *p*H meter was put in service it was further checked by titration of ammonia (pK_H (25°) 9.27).[4]

Δ^2-Pyrrolines.—1,2-Dimethyl-Δ^2-pyrroline and 1-methyl-2-*n*-butyl-Δ^2-pyrroline were prepared according to the method of Craig.[8] The reaction of methylmagnesium iodide on N-methylpyrrolidone-2 led apparently only to the formation of 1,2-dimethyl-Δ^2-pyrroline, as none of the 1,2,2-trimethylpyrrolidine reported by Lukeš[13] could be found. However, the reversible dimerization mentioned by Craig[8] was encountered. In the synthesis of 1-methyl-2-*n*-butyl-Δ^2-pyrroline by an analogous reaction using butylmagnesium bromide, 1-methyl-2,2-di-*n*-butylpyrrolidine was isolated from the mixture of by-products in 14% yield. In preliminary attempts to prepare 1-*n*-butyl-2-methyl-Δ^2-pyrroline, it was found that the reaction of methylmagnesium iodide on N-*n*-butylpyrrolidone-2 was incomplete and did not lead to the formation of any appreciable quantity of the desired pyrroline.

A second procedure proved to be more satisfactory for the general preparation of pyrrolines in which alkyl groups larger than methyl were attached to the nitrogen. This consisted in treatment of 3-bromo-*n*-propyl methyl ketone with the appropriate primary amine[14,15] in aqueous solution. If ethanol instead of water is used as a solvent, the resulting homogeneous mixture undergoes reaction rapidly at room temperature, thus eliminating the necessity of longer periods of agitation. The yields in the case of 1-*n*-butyl and 1-ethyl-2-methyl-Δ^2-pyrroline were increased from 15% to 40–50% by this modification.

1-Methyl-2-*n*-butyl-Δ^2-pyrroline and 1-Methyl-2,2-*n*-dibutylpyrrolidine.—To the Grignard reagent, prepared

(12) It is only in the presence of certain metallic ions that there is a serious error introduced by the use of a glass electrode in alkaline solutions. See Dole, "The Glass Electrode," John Wiley and Sons, Inc., New York, N. Y., 1941, Chapter 7.

from 31.6 g. (1.30 moles) of magnesium, 1200 cc. of dry ether, and 185 g. (1.34 moles) of *n*-butyl bromide, was added with stirring under nitrogen 63.5 g. (0.642 mole) of N-methylpyrrolidone-2[16] over a period of three hours. The mixture was stirred at room temperature for five hours when it became necessary to stop the stirrer due to the formation of a solid complex. After standing for twenty hours the mixture was hydrolyzed with an excess of 3 *N* hydrochloric acid. The aqueous layer was separated, made alkaline with 30% aqueous sodium hydroxide and steam distilled. The steam distillate (600–700 cc.) was neutralized with dilute hydrochloric acid, the solvent removed *in vacuo* on a water-bath and the residual sirup taken up in 60 cc. of water. This solution was made basic with sodium hydroxide, extracted with ether, and the ethereal extract dried over anhydrous magnesium sulfate. After removal of ether the product was fractionated. The main portion consisted of 1-methyl-2-*n*-butyl-Δ^2-pyrroline,[8] b. p. 88.5° (30 mm.); yield 48 g. (54%).

A second smaller fraction, 1-methyl-2,2-*n*-dibutylpyrrolidine, boiled at 122° (18 mm.); $n^{20}D$ 1.4567; d^{20}_4 0.846; yield 18 g. (14%). This substance, a colorless liquid, is only slightly soluble in water, but is readily soluble in all common organic solvents.

Anal. Calcd. for $C_{13}H_{27}N$: C, 79.12; H, 13.79. Found: C, 79.53; H, 13.69.

1-Methyl-2,2-dibutylpyrrolidine Methiodide.—This substance was prepared by treating a dry ether solution of the base with the calculated amount of methyl iodide. It was purified by recrystallization from ethanol–ether; white plates, m. p. 211° (cor.), unchanged on further recrystallization from methanol–ether.

Anal. Calcd. for $C_{13}H_{27}N\cdot CH_3I$: C, 49.55; H, 8.91; N, 4.13. Found: C, 49.67; H, 9.09; N, 4.22.

1-Ethyl-2-methyl-Δ^2-pyrroline.—To a solution cooled to 0° of 44 g. (0.68 mole) of 70% ethylamine in 110 cc. of absolute ethanol contained in a pressure bottle was added 55.9 g. (0.34 mole) of ω-bromo-*n*-propyl methyl ketone. The bottle was tightly stoppered and the contents permitted to warm up gradually; at 15° reaction set in and cooling was again necessary as the temperature rose quickly to 50–60°. When the reaction had subsided, as judged by a decrease in temperature, the mixture was shaken for fifteen to twenty minutes and then acidified with dilute hydrochloric acid. The solvent was removed *in vacuo* on a water-bath and the resulting sirup taken up in 100 cc. of water, made strongly alkaline with sodium hydroxide, and steam distilled. A part of the amine fraction would not steam distil as in all runs there was several cc. of very high boiling, brown, viscous oil which remained behind. The clear steam distillate (300–400 cc.) was made more strongly alkaline with 50% sodium hydroxide solution and the pyrroline extracted with ether. After drying and removal of ether the product was fractionated; b. p. 73.5–74.5° (55 mm.); $n^{20}D$ 1.4945; d^{20}_4 0.896; yield 19.5 g. (52%). When water was used as the reaction solvent and the mixture allowed to stand (occasional shaking) for twenty-four to forty-eight hours, the yields were decreased to 10–15%. 1-Ethyl-2-methyl-Δ^2-pyrroline is a colorless liquid which turns yellow and deposits an insoluble red viscous oil when exposed to the air. However, when sealed under nitrogen it will remain colorless indefinitely.

Anal. Calcd. for $C_7H_{13}N$: C, 75.62; H, 11.78. Found: C, 75.54; H, 11.80.

1-*n*-Butyl-2-methyl-Δ^2-pyrroline.—The procedure employed was that as described above for 1-ethyl-2-methyl-Δ^2-pyrroline. From 55.3 g. (0.335 mole) of ω-bromo-*n*-propyl methyl ketone and 49.5 g. (0.68 mole) of *n*-butyl amine was obtained 18.3 g. (39%) of product; b. p. 82–83.5° (16 mm.); $n^{20}D$ 1.4865; d^{20}_4 0.904. 1-Butyl-2-methyl-Δ^2-pyrroline is a colorless liquid which, like all vinyl tertiary amines, soon colors up when exposed to the air. It is only slightly soluble in water (1 part in 300–400 parts water), but is readily miscible with the common organic solvents.

Anal. Calcd. for $C_9H_{17}N$: C, 77.63; H, 12.31. Found: C, 77.50; H, 12.37.

1-Methyl-Δ^3-pyrroline.—This was prepared in 80% yield by the partial reduction[17] of 1-methylpyrrole.

Pyrrolidines.—All of the disubstituted pyrrolidines were synthesized by catalytic reduction of the corresponding unsaturated Δ^2-pyrrolines in ethanol with Raney nickel and hydrogen at two to three atmospheres pressure. The constants agreed essentially with those in the literature: 1,2-dimethylpyrrolidine,[5] b. p. 98–99°; 1-methyl-2-butylpyrrolidine,[5] b. p. 170.5°; 1-ethyl-2-methylpyrrolidine,[18] b. p. 118.5–119.5°; 1-*n*-butyl-2-methylpyrrolidine,[19] b. p. 86–86.5° (57 mm.). 1-Methylpyrrolidine was obtained by catalytic reduction of 1-methylpyrrole with platinum oxide.[20]

Δ^2-Tetrahydropyridines.—The Δ^2-tetrahydropyridines and ω-dimethylamino-*n*-butyl methyl ketone were synthesized from ω-bromo-*n*-butyl methyl ketone and the appropriate amine according to the directions of Lipp[6,21] and of Ladenburg.[22] Considerable decomposition occurs when ω-bromo-*n*-butyl methyl ketone is distilled at atmospheric pressure. By distilling under reduced pressure, b. p. 104–106° (17 mm.), this decomposition can be avoided.

1,2-Dialkylpiperidines.—These compounds were prepared by reduction of the corresponding tetrahydropyridines in ethanol with Raney nickel at two to three atmospheres of hydrogen.

1-Propenylpiperidine and 1-Diethylamino-*n*-heptene-1.—These vinyl tertiary amines were prepared according to the directions of Mannich and Davidsen.[9] 1-Propenylpiperidine was found to boil at 51–53° (10 mm.) instead of 61–63° (10 mm.) as previously reported.

1-Propylpiperidine and 1-Diethylamino-*n*-heptane.—These substances resulted when the corresponding vinyl amines were reduced in ethanol with Raney nickel and hydrogen at two to three atmospheres pressure.

1-Allylpiperidine[23] and 1-*n*-Butylpiperidine.—Refluxing one mole of bromide with two moles of piperidine in benzene solution resulted in good yields of the products.

N-*n*-Butylpyrrolidone-2.—This substance was prepared by the general method of Späth and Lintner.[16] A mixture of 50 g. (0.58 mole) of butyrolactone and 46 g. (0.64 mole) of *n*-butylamine was heated at 280° for four hours. After cooling, the reaction mixture was dissolved in 50 cc. of 6 *N* hydrochloric acid and the aqueous solution continuously extracted with ether for fifteen hours to remove the N-*n*-butylpyrrolidone-2, which is exceedingly soluble in water. After drying and removal of the ether the product was distilled; b. p. 121° (16 mm.); $n^{20}D$ 1.4650; d^{20}_4 0.964; yield 78 g. (95%).

Anal. Calcd. for $C_8H_{15}ON$: C, 68.04; H, 10.71; N, 9.92. Found: C, 68.03; H, 10.75; N, 10.18.

Summary

1. A variety of cyclic and straight chained vinyl tertiary amines have been synthesized as well as the corresponding saturated molecules.

2. Comparative basicity studies demonstrated that the vinyl tertiary amines were in all cases more basic than the corresponding saturated compounds.

3. This is explained by assuming hydration and rearrangement to a quaternary ammonium base.

URBANA, ILLINOIS RECEIVED JULY 30, 1942

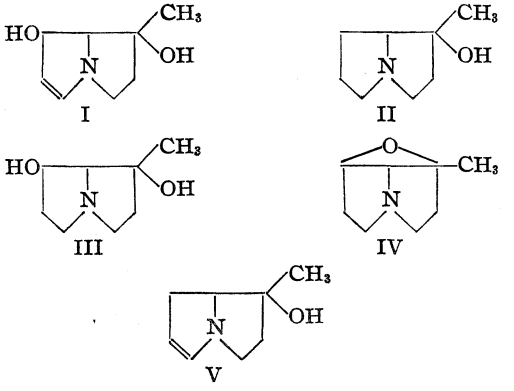
Structure of Monocrotaline. VII.[1] Structure of Retronecine and Related Bases

BY ROGER ADAMS, MARVIN CARMACK AND J. E. MAHAN

Structure I, previously suggested for retronecine, was deduced on the basis of (a) the validity of structure II for oxyheliotridane, a stereoisomer[2] of retronecanol, as proposed by Menshikov,[3] and (b) the reduction characteristics of retronecine and the reactivity of the hydroxyls in retronecine and related molecules. No structure other than I will explain as satisfactorily all the available experimental facts. The formulation of platynecine as III, anhydroplatynecine as IV, and desoxyretronecine as V will then result.



The most objectionable feature to structure I for retronecine, as pointed out in a previous paper, lies in the results obtained upon esterification. One hydroxyl in retronecine esterifies very readily, more readily than would be anticipated from the usual secondary alcohol, and the other esterifies with difficulty, but with more facility than is observed with any ordinary tertiary alcohol. Moreover, retronecanol (II) dehydrates more sluggishly than would be expected on the basis of a tertiary hydroxyl group.

Direct chemical proof for the positions of the hydroxyls and double bond in retronecine (I) was undertaken. The evidence for a pyrrolizidine nucleus and for a methyl group in the 1-position is indisputable. A complete assembly of the facts concerning known vinyl tertiary amines revealed that in no instance where the vinyl amine structure was established unequivocally was the molecule stable both to alkali and acid; hydrolysis occurs with one or the other especially when warmed with the reagent. Retronecine is stable to both even on boiling. Further evidence that the presence of a vinyl amine structure is unlikely was obtained through basicity studies. The following table gives the pK_H values for retronecine and its related compounds.

TABLE I

BASICITY OF RETRONECINE AND RELATED COMPOUNDS

Name	pK_H	*T*, °C.	pK_H (25°)
Retronecine	8.92	26	8.94
Platynecine	10.24	24	10.22
Desoxyretronecine	9.55	25	9.55
Retronecanol	10.92	24.5	10.91
Anhydroplatynecine	9.44	24	9.42
Heliotridane	11.44	27	11.48
Heliotridene	10.59	25.5	10.60
Isoretronecanol[5]	10.87	25.5	10.88

It is to be noted that the saturated molecules on the basis of the postulated structures (I–V)

(1) VI, Adams and Rogers, THIS JOURNAL, **63**, 537 (1941).

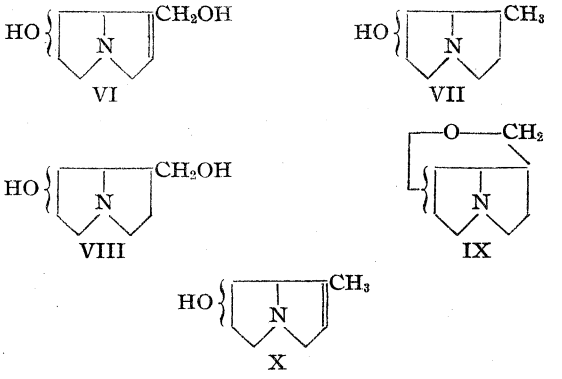
(2) Konovalova and Orekhov, *Bull. soc. chim.*, [5] **4**, 1285 (1937); *Ber.*, **69B**, 1908 (1936).

(3) Menshikov, *Bull. acad. sci. U. S. S. R.*, Classe sci. math., Ser. chim., 978 (1936).

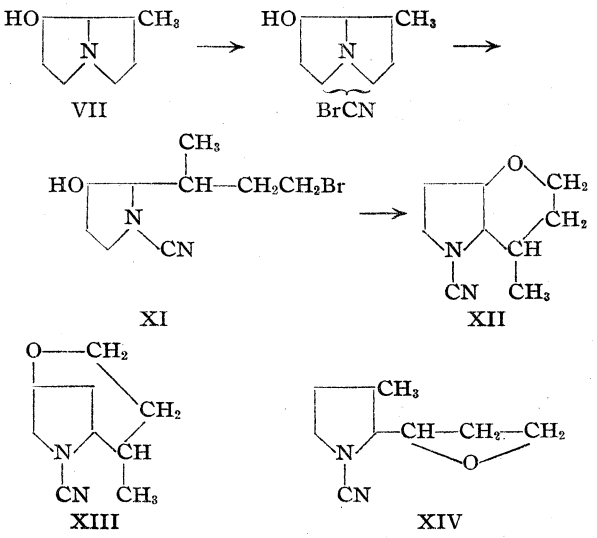
are more basic than the unsaturated—platynecine (III) is more basic than retronecine (I) and retronecanol (II) is more basic than desoxyretronecine (V). These results are in direct contradiction to what would be expected. Vinyl tertiary amines are more basic than the corresponding saturated molecules.[4]

The weight of this evidence and that derived from the stability experiments was sufficient to warrant the assumption that the vinyl amine structures for retronecine and desoxyretronecine were very probably incorrect. Assignment of the double bond in retronecine to any other non-vinyl position and retention at the same time of the positions shown in formula I for the hydroxyls gives molecular structures which will explain almost none of the important reactions of the molecule. It was thus obvious that a complete revision of the orientation of the double bond and hydroxyl groups in retronecine was necessary.

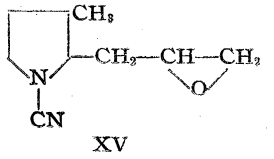
The experiments of Menshikov on oxyheliotridane, from which he deduced structure II, leave much to be desired. He performed a series of exhaustive methylations and reductions until a nitrogen-free compound was obtained. The final product was described[3] as a tertiary octanol. However, in this degradation no intermediates were isolated or purified, the characterization of the tertiary octanol was doubtful and no detailed description of his procedure was published. In view of this, the oxyheliotridane (stereoisomeric with retronecanol) structure reported by Menshikov was disregarded and a new set of structures for retronecine and its related compounds was formulated. The two hydroxyls and the double bond were introduced into the 1-methylpyrrolizidine nucleus in such a way that the following established experimental facts were satisfied: (a) difference in the rate of esterification of the two hydroxyls, which would more nearly agree with one secondary and one primary hydroxyl than with one secondary and one tertiary; (b) the ease of hydrogenolysis of one hydroxyl under very mild conditions; (c) the relative difficulty in dehydration of retronecanol which resembles more a secondary than a tertiary hydroxyl; (d) the resistance to hydrogenolysis of either hydroxyl in platynecine; (e) the ease of dehydration of platynecine to anhydroplatynecine; and (f) the absence of a vinyl amine linkage. The postulation of a primary hydroxyl limits its position to a substitution of a hydrogen atom on the methyl group of the 1-methylpyrrolizidine nucleus and this automatically, when the other conditions are fulfilled, establishes retronecine as having one of two structures (VI). Retronecanol would then be assigned structures VII, platynecine VIII, anhydroplatynecine IX, and desoxyretronecine X.



The readily hydrogenolyzed hydroxyl, the primary one, is shown as an allylic type. Construction of models indicates the structures represented by IX to involve very little strain whether the secondary hydroxyl is in the 6- or 7-position. The 7-position is favored on the basis of experiments involving the degradation of retronecanol (VII) by bromocyanogen. An addition compound is formed with this reagent which on rearrangement and treatment with alkali yields a halogen-free compound postulated as an ether (XII). Only the cyanide group is removed on hydrolysis with hot sulfuric acid; there is no cleavage of the cyclic ether. The mechanism of formation is postulated as follows



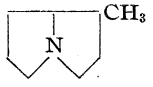
(4) Adams and Mahan, THIS JOURNAL, 64, 2588 (1942).



XV

The cleavage is believed to take place in the ring containing the methyl group; assuming the 7-position for the hydroxyl group a six-membered ether (XII) is produced, or assuming the 6-position a much less likely structure (XIII) would result. Cleavage of the unmethylated ring in VII would yield an ether of structure XIV or XV, depending on the position of the hydroxyl group. Either of these would be expected to hydrolyze upon treatment with hot sulfuric acid.

The changes in basicity of retronecine and related compounds, as influenced by the presence or absence of an hydroxyl group or double bond, are surprisingly parallel. These are shown in Table II. The structure of heliotridane is XVI, and the structure of isoretronecanol is XVII.



XVI

XVII

TABLE II

BASICITY COMPARISONS OF RETRONECINE AND RELATED COMPOUNDS; pK_H VALUES

(a) Effect of removal of primary hydroxyl	
Desoxyretronecine (X)	9.6
Retronecine (VI)	8.9
	0.7
Retronecanol (VII)	10.9
Platynecine (VIII)	10.2
	0.7
Heliotridane (XVI)	11.5
Isoretronecanol (XVII)[5]	10.9
	0.6

	0.6
(c) Effect of removal of double bond	
Platynecine (VIII)	10.2
Retronecine (VI)	8.9
	1.3
Retronecanol (VII)	10.9
Desoxyretronecine (X)	9.6
	1.3

(5) Adams and Hamlin, THIS JOURNAL, 64, 2597 (1942).

As shown in Table II, the removal of the primary or secondary hydroxyl results in an increase in basicity of about 0.7 pK_H unit; the removal of the double bond in an increase in basicity of 1.3 pK_H unit.

Experiments to establish whether the structures in series VI–X are correct are now under way and the first results are reported in this communication. A comparison of structures I–V and VI–X reveals that I–V all contain C–CH_3 groups, whereas such groups exist in the series VI–X only in structures VII and X. The determination of C–CH_3 in each of these molecules was undertaken and none could be found in retronecine (VI), platynecine (VIII), or anhydroplatynecine (X), but one was present in both retronecanol (VII) and desoxyretronecine (IX). As observed by those who have studied extensively this quantitative method, the amount of acetic acid produced upon oxidation of a molecule with a C–CH_3 group is never quantitative but varies in degree with the character of the molecule as a whole and especially on the substituents present on the carbon holding the methyl groups. The results are shown in Table III.

TABLE III

ACETIC ACID BY OXIDATION OF RETRONECINE AND RELATED BASES

Substance	Moles HOAc per mole of substance
Retronecine	None
Platynecine	None
Anhydroplatynecine	None
Retronecanol	0.69
Desoxyretronecine	.66
Heliotridane	.58
Heliotridene	.40
Isoretronecanol	None

These analytical data conform to the new structures VI–X which may be accepted provisionally in place of those previously proposed (I–V). None of the known experimental facts are in disagreement with present postulated formulas.

Experimental

Determination of Basic Strength Constants.—The procedure employed for the determination of the pK_H values was that previously described.[3] All solid amines were recrystallized to constant melting point, and the three liquid amines were freshly distilled in a carbon dioxide-free atmosphere immediately before use. The basicity measurements were taken at temperatures within the range 23 to 27° and the observed constant corrected to 25° employing the value of the negative temperature coefficient of the constant as given by Hall and Sprinkle.[6] Duplicate meas-

(6) Hall and Sprinkle, *ibid.*, 54, 3469 (1932).

urements were made on all of the substances listed in Tables I and II.

Carbon–Methyl Analysis.—The procedure used for carbon–methyl determinations was a macro modification adapted from the micro procedure of Kuhn and Roth,[7] and the macro method of Kuhn and L'Orsa.[8] That the acidity of the distillate after chromic acid oxidation was due to acetic acid was shown by conversion of the acid component to its *p*-bromophenacyl ester, m. p. 85°. The reported melting point of *p*-bromophenacyl acetate is 85°.[9]

Thymol was used as a control and gave 1.31 moles of acetic acid per mole of substance. Kuhn and L'Orsa[8] reported a value of 1.40.

Conversion of Retronecanol to the Cyanamide Ether (XII).—A solution of 8 g. of cyanogen bromide in 60 cc. of dry ether was cooled in a dry-ice–acetone mixture. To this was added slowly and with constant swirling a solution of 10 g. of retronecanol in 140 cc. of dry ether. A voluminous white precipitate separated instantly. The reaction mixture was allowed to warm up gradually (constant swirling) and at a point just below room temperature the white solid changed into a viscous oil. When the mixture had reached room temperature, 15 cc. of water was added to dissolve the sirup, the ether layer was then separated and washed once with very dilute hydrochloric acid to remove any unreacted retronecanol. The aqueous layer and acid washings were both extracted with ether and the ether washings combined with the ether layer from the original reaction mixture. The ethereal solution was dried over anhydrous magnesium sulfate and the solvent removed by distillation. The pale yellow viscous oil which remained was heated on the water-bath under reduced pressure to remove remaining solvent and any excess of cyanogen bromide; yield 11.3 g. All attempts to crystallize the sirup failed. It is probable that this product consisted of a mixture of bromocyanamides.

A sample of the bromocyanamide oil which had stood at 2° for several days deposited a small amount of crystalline material. A further quantity of this substance was obtained by dissolving the viscous residue in methanol, cooling in a dry-ice–acetone bath, seeding, and filtering rapidly through a precooled funnel. Pure material was obtained by recrystallization from water; m. p. 94.5–95° (cor.). Qualitative tests showed the absence of halogen. A solution in carbon tetrachloride did not decolorize bromine, and a solution in acetone–water did not decolorize 1% potassium permanganate solution.

Anal. Calcd. for $C_9H_{14}ON_2$: C, 65.03; H, 8.49; N, 16.86. Found: C, 65.14; H, 8.37; N, 16.89.

Rotation. 53.7 mg. made up to 2.50 cc. with absolute ethanol at 28° gave $\alpha^{31}D$ −4.63°; *l*, 2; $[\alpha]^{31}D$ −107.6°.

This substance was obtained in better yields as follows. A sample of 5.8 g. of the crude liquid bromocyanamide dissolved in 20 cc. of dry pyridine was refluxed for thirty minutes. The solution, which had turned deep red in color, was cooled, diluted with an equal volume of water, treated with Norite, and the solvent removed by distillation *in vacuo*. The residual brown viscous oil was diluted with a little water and on seeding crystallization ensued. Thus in two crops 1.08 g. was obtained; m. p. 92–94° (18% from retronecanol, or 28% from the crude bromocyanamide). Refluxing in pyridine for longer periods of time than thirty minutes did not increase the yield. The cyanamide ether could also be formed in approximately the same yield by warming the crude bromocyanamide with methanolic potassium hydroxide.

Hydrolysis of the Cyanamide Ether to a Secondary Amine.—A mixture of 0.88 g. of the cyanamide ether and 15 cc. of 15% sulfuric acid was refluxed for fifty-five hours. The solution was decolorized with Norite, cooled, made strongly alkaline with potassium hydroxide and the precipitated salts removed by filtration through glass wool. The filtrate was extracted thoroughly with ether and the ether extract dried over sodium carbonate. After removal of solvent the residue was distilled at 20 mm. and a bath temperature of 110–120°; yield 0.64 g. of colorless liquid. Although this product was not analyzed as such its identity as a secondary amine was shown by conversion to the following three analyzed derivatives.

Reconversion to Cyanamide Ether.—A sample of 68 mg. of the liquid amine was warmed with excess cyanogen bromide in ether for ten minutes. After evaporation of the solvent the residue was taken up in warm water and the solution seeded; yield 20 mg.; m. p. 92–93°, mixed melting point with an authentic sample of cyanamide ether produced no depression.

Picrate.—A sample of 68 mg. of liquid amine from the acid hydrolysis of the cyanamide ether was treated with 130 mg. of picric acid containing 15% water dissolved in 1 cc. of hot ethanol. After cooling in the ice-bath for fifteen minutes, 141 mg. of picrate was filtered; glistening yellow plates, m. p. 121.5–122.5° (cor.). Further recrystallization did not raise the melting point.

Anal. Calcd. for $C_8H_{15}ON \cdot C_6H_3O_7N_3$: C, 45.41; H, 4.90; N, 15.13. Found: C, 45.36; H, 5.01; N, 15.07.

N-Methyl Hydroiodide.—To a solution of 0.64 g. of the liquid amine in a mixture of 1 cc. of dry acetone and 1 cc. of dry ether was added gradually 1 cc. of methyl iodide. After the original vigorous reaction had subsided the mixture was refluxed on the steam-bath for ten minutes. On cooling crystallization occurred; yield 0.44 g. (in two crops). Two recrystallizations from acetone yielded pure material; long fine prisms, m. p. 195–196° (cor.).

Anal. Calcd. for $C_9H_{18}ONI$: C, 38.17; H, 6.41; N, 4.95. Found: C, 38.29; H, 6.54; N, 4.69.

Rotation. 15.7 mg. made up to 0.500 cc. with absolute ethanol at 33° gave $\alpha^{33}D$ −0.54°; *l*, 1; $[\alpha]^{33}D$ −17.2°.

Although this substance has the same molecular formula as retronecanol methiodide (m. p. 193°) a mixed melting point between the two gave a depression to 145–148°.

Summary

1. New structures are proposed for retronecine, retronecanol, platynecine and desoxyretronecine which agree with all the pertinent experimental data.

2. Basic strength constants and carbon–

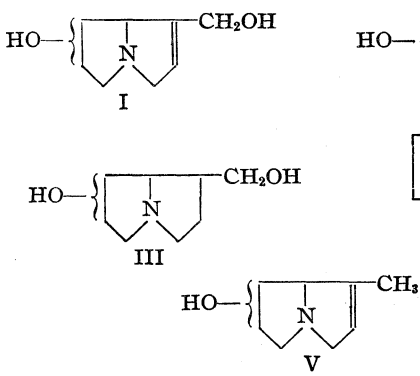
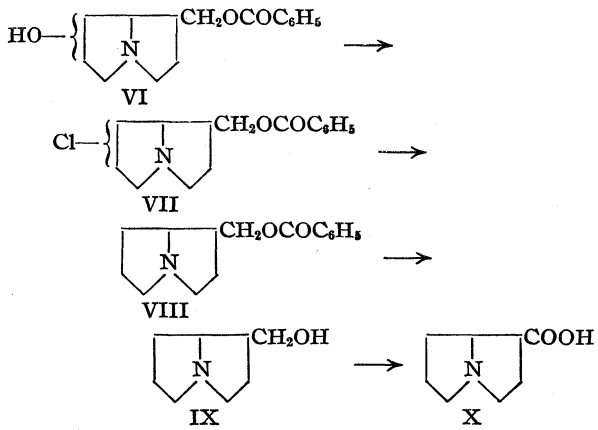
Structure of Monocrotaline. VIII. The Proof of Primary and Secondary Hydroxyl Groups in Retronecine[1]

BY ROGER ADAMS AND K. E. HAMLIN, JR.

Direct experimental evidence for the structures postulated for retronecine (I), retronecanol (II) platynecine (III), anhydroplatynecine (IV) and desoxyretronecine (V) is being investigated. This



communication describes work which has served to establish beyond dispute (1) the presence of a CH_2OH group in compound I and in its reduction product (III), and (2) the presence of a secondary hydroxyl group in retronecanol (II). Since all attempts to obtain tractable oxidation products from retronecine and its associated molecules have failed, it was concluded that the molecules probably were rendered sensitive to oxidation by the presence of an hydroxyl group substituted in the nucleus. Platynecine (III), synthesized from retronecine (I), was selected for study and the monobenzoate (VI) was prepared. This was converted to the corresponding chloride (VII) according to the directions of Konovalova and Orekhov.[2] These investigators reported failure in attempts to replace the chlorine by hydrogen in this molecule but in our experiments no difficulty was encountered by the use of Raney nickel and hydrogen in ethanol solution. Thus, a molecule (VIII) was produced which was the benzoate of a



new base, herein designated as isoretronecanol (IX). Upon hydrolysis, isoretronecanol (IX) was obtained. Structurally this resembles lupinine and differs from it merely in that the CH_2OH group is attached to a pyrrolizidine nucleus, a fusion of two five-membered rings, rather than to a norlupinane nucleus, consisting of two analogously fused six-membered rings. The procedure described for oxidizing lupinine to lupininic acid[3] was followed for the conversion of isoretronecanol (IX) to 1-carboxypyrrolizidine (X) and proved to be entirely satisfactory. The oily degradation products encountered in the oxidation of retronecine, *et al.*, were absent and a readily purified derivative with the properties of an amino acid was isolated. Analyses of the pure compound, its picrate and derivatives of the betaine, prepared from the reaction of diazomethane on the amino acid, were used for identification.

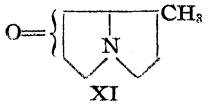
On the basis of structure II, retronecanol contains a secondary hydroxyl group. It has now been found that aluminum *t*-butoxide in the presence of cyclohexanone oxidizes the molecule without degradation and with the formation of the corresponding ketone, retronecanone (XI). The

(1) For previous paper see Adams, Carmack and Mahan, THIS JOURNAL, **64**, 2593 (1942).

(2) Konovalova and Orekhov, *Ber.*, **69**, 1908 (1936).

(3) Willstätter and Fourneau, *ibid.*, **35**, 1917 (1902).

ketone group was identified through its semicarbazone and its oxime.



XI

By these experiments the presence of a CH_2OH group and a secondary hydroxyl have been established directly in retronecine. The results serve to support the structures I–V postulated on the C–CH_3 determinations and the chemical properties of these molecules.

Experimental

Monobenzoylplatynecine (VI).—This was prepared from platynecine as described by Orekhov, Konovalova and Tiedebel.[4] It crystallized from ether–petroleum ether (b. p. 30–60°) in colorless prisms m. p. 118–119° (cor.). The reported melting point is 119–120°.

Rotation. 0.4081 g. made up to 15 cc. with absolute ethanol at 29° gave α_D −2.41; *l*, 1; $[\alpha]^{29}D$ −88.6°. The reported value is $[\alpha]_D$ −87.9° in ethanol.

Monobenzoylplatynecine Chloride (VII).—This was prepared as described by Konovalova and Orekhov.[2] Recrystallization from petroleum ether (b. p. 30–60°) gave colorless tufts of needles, m. p. 72–73° (cor.). The reported melting point is 73–74°.

Rotation. 0.6092 g. made up to 15 cc. with absolute ethanol at 29° gave α_D −0.59; *l*, 1; $[\alpha]^{29}D$ −14.5°.

Benzoylisoretronecanol Hydrochloride.—A solution of 7 g. of monobenzoylplatynecine chloride in 100 cc. of ethanol, to which was added about 4 g. of Raney nickel, was hydrogenated at 2–3 atm. pressure. Hydrogen was absorbed to the theoretical end-point in four and one-half hours. After filtration, the solution was made just acid to congo and the solvent removed *in vacuo*. The highly colored crystalline residue was taken up in chloroform, boiled with Darco, and the solution filtered. The colorless chloroform solution was treated with anhydrous ether until it became cloudy. The hydrochloride separated as fine colorless needles; recrystallized from chloroform–ether, m. p. 181–182° (cor.); yield, 6.02 g. (86%).

Anal. Calcd. for $C_{15}H_{19}O_2N \cdot HCl$: C, 63.91; H, 7.16; N, 4.97. Found: C, 63.84; H, 7.12; N, 4.80.

Rotation. 0.5056 g. made up to 15 cc. with absolute ethanol at 28° gave α_D −1.62; *l*, 1; $[\alpha]^{28}D$ −48.6°.

Benzoylisoretronecanol (VIII).—A solution of the base hydrochloride in water was treated with one equivalent of *N* aqueous sodium hydroxide. The mixture was thoroughly extracted with ether and the ethereal solution dried over anhydrous potassium carbonate. After carefully distilling off the ether, the residue was distilled *in vacuo*, b. p. 161.5–162.5° (1–2 mm.). The colorless, mobile distillate readily crystallized on cooling in a dry-ice–acetone bath. The crystalline product could be recrystallized from petroleum ether (b. p. 30–60°); large prisms, m. p. 56–57° (cor.).

Anal. Calcd. for $C_{15}H_{19}O_2N$: C, 73.42; H, 7.81; N, 5.71. Found: C, 73.51; H, 7.86; N, 5.70.

(4) Orekhov, Konovalova and Tiedebel, *Ber.*, **68**, 1886 (1935).

Rotation. 0.1578 g. made up to 5 cc. with absolute ethanol at 28° gave α_D −1.92; *l*, 1; $[\alpha]^{28}D$ −60.8°.

Benzoylisoretronecanol Picrate.—Prepared in and recrystallized from ethanol, the picrate formed yellow needles, m. p. 130–131° (cor.) with decomposition.

Anal. Calcd. for $C_{21}H_{22}O_9N_4$: C, 53.14; H, 4.67; N, 11.81. Found: C, 53.32; H, 4.82; N, 11.81.

Isoretronecanol (IX).—An aqueous solution of 4.4 g. of benzoylisoretronecanol hydrochloride was refluxed for three hours with 100 cc. of 10% aqueous sodium hydroxide. The alkaline solution thus obtained was extracted continuously with ether for twenty-four hours. On acidification of the residual alkaline layer, white crystals were obtained which were identified by melting point as benzoic acid.

The ethereal extract was dried well over anhydrous sodium carbonate and the ether removed by distillation. The oily residue was distilled *in vacuo*, b. p. 115–116° (1–2 mm.); yield 1.62 g. (74%). The colorless viscous distillate crystallized readily on cooling in dry-ice–acetone bath; m. p. 39–40° (cor.).

Anal. Calcd. for $C_8H_{15}ON$: C, 68.02; H, 10.71; N, 9.93. Found: C, 68.11; H, 10.69; N, 10.07.

Rotation. 0.1407 g. made up to 5 cc. with absolute ethanol at 27° gave α_D −2.20; *l*, 1; $[\alpha]^{27}D$ −78.2°.

Isoretronecanol Methiodide.—This product was prepared by treating a dry ether solution of isoretronecanol with an excess of methyl iodide. It was purified from methanol–ether; white needles, m. p. 281–282° (cor.) with decomposition.

Anal. Calcd. for $C_8H_{15}ON \cdot CH_3I$: C, 38.14; H, 6.41; N, 4.95. Found: C, 38.21; H, 6.50; N, 4.78.

Rotation. 0.0725 g. made up to 5 cc. with absolute ethanol at 26° gave α_D −0.44; *l*, 1; $[\alpha]^{26}D$ −31.0°.

Isoretronecanol Picrate.—Prepared in and recrystallized from ethanol, the picrate formed yellow needles, m. p. 194–195° (cor.) with decomposition.

Anal. Calcd. for $C_{14}H_{18}O_8N_4$: C, 45.34; H, 4.90; N, 15.12. Found: C, 45.51; H, 5.00; N, 15.02.

1-Carboxypyrrolizidine (X).—Following the procedure described by Willstätter and Fourneau[3] for oxidizing lupinine to lupininic acid, 0.5 g. of isoretronecanol was dissolved in a solution of 0.15 g. of sulfuric acid (sp. gr. 1.84) in 2 cc. of water. This mixture was added carefully to a cooled solution of 0.3 g. of chromic anhydride in 0.35 g. of sulfuric acid and 4 cc. of water. After warming this mixture a few minutes on a steam-cone until reduction of the chromic anhydride was complete, a second charge of the oxidizing mixture described above was added. The solution was now heated on a steam-cone for one and one-half hours. From this point the degradation product was worked up as described for lupininic acid. Before recrystallization, 0.22 g. of 1-carboxypyrrolizidine was isolated. After dissolving in absolute ethanol, boiling with a Darco–Norite mixture and filtering, excess dry acetone was added. At this point white flat plates crystallized, m. p. 228–229° (cor.) with decomposition.

Anal. Calcd. for $C_8H_{13}O_2N$: C, 61.91; H, 8.45; N, 9.03. Found: C, 62.06; H, 8.66; N, 9.13.

Rotation. 0.0996 g. made up to 5 cc. with absolute ethanol at 28° gave α_D −1.31; *l*, 1; $[\alpha]^{28}D$ −65.8°.

The amino acid was very soluble in water, fairly soluble in ethanol but insoluble in acetone, ether, and chloroform.

1-Carboxypyrrolizidine Picrate.—Prepared in and recrystallized from ethanol, the picrate formed beautiful yellow needles, m. p. 220–221° (cor.) with decomposition.

Anal. Calcd. for $C_{14}H_{16}O_9N_4$: C, 43.75; H, 4.20; N, 14.58. Found: C, 44.02; H, 4.25; N, 14.54.

Action of Diazomethane on 1-Carboxypyrrolizidine.—Following the procedure of Kuhn and Brydowna,[5] 0.1 g. of the 1-carboxypyrrolizidine was treated with a large excess of a moist ethereal solution of diazomethane. An immediate evolution of nitrogen took place which continued until the solid amino acid disappeared. After standing overnight, the ether was decanted from the small aqueous layer which appeared. The latter was diluted to about 1 cc. with water. The product was found to be predominantly in this aqueous portion. Identification of the compound as the betaine of the amino acid was made by analyses of the chloroaurate and the picrate.

Chloroaurate of the Betaine.—The gold salt was prepared from 10% aqueous auric chloride and an acidified (with hydrochloric acid) portion of the above aqueous solution of the betaine. Recrystallized from water, the yellow crystalline chloroaurate melted at 224–225° (cor.) with decomposition.

Anal. Calcd. for $C_9H_{16}O_2NAuCl_4$: C, 21.23; H, 3.17; Au, 38.73. Found: C, 21.72; H, 3.38; Au, 39.30.

Picrate of the Betaine.—The yellow crystalline picrate was prepared by adding a saturated ethanolic solution of picric acid to the aqueous solution of the betaine. After recrystallization from ethanol, the product melted at 194–195° (cor.) with decomposition.

Anal. Calcd. for $C_{15}H_{18}O_9N_4$: N, 14.06. Found: N, 13.81.

Retronecanone (XI).—A mixture of 5 g. of retronecanol, 15 g. of aluminum *t*-butoxide, 200 cc. of dry cyclohexanone and 700 cc. of dry toluene was refluxed for six hours. After cooling, the orange suspension was carefully extracted with 10% sulfuric acid. The acid extract, after washing well with ether to remove unchanged cyclohexanone, was treated with an excess of 50% sodium hydroxide. The basic solution was extracted continuously with ether for twenty-four hours and the ethereal extract dried over anhydrous magnesium sulfate. After carefully removing the ether, the residue was distilled *in vacuo;* the fraction boiling between 94 and 100° (15 mm.) was collected, yield 1.5 g. (30%). The pure amino ketone is a colorless, mobile liquid, distilling at 95–96° (15 mm.); $n^{20}D$ 1.4818; d^{20}_4 1.030.

Anal. Calcd. for $C_8H_{13}ON$: C, 69.03; H, 9.41; N, 10.06. Found: C, 68.76; H, 9.46; N, 10.14.

Rotation. 0.1127 g. made up to 5 cc. with absolute ethanol at 30° gave αD −2.18; *l*, 1; $[\alpha]^{30}D$ −96.7°.

Retronecanone is not stable and tends to decompose readily even when kept at 0°, protected from light and moisture.

(5) Kuhn and Brydowna, *Ber.*, **70B**, 1333 (1937).

Retronecanone Picrate.—Prepared in and recrystallized from ethanol, the picrate formed fine yellow needles, m. p. 195° (cor.) with decomposition.

Anal. Calcd. for $C_8H_{13}ON \cdot C_6H_3O_7N_3$: C, 45.65; H, 4.38; N, 15.21. Found: C, 45.99; H, 4.36; N, 15.34.

A mixed melting point with an authentic sample of retronecanol picrate (m. p. 214°) gave a depression to 182–183°.

Retronecanone Semicarbazone.—A solution of 0.7 g. of semicarbazide hydrochloride and 1.5 g. of sodium acetate in 10 cc. of water was added to 0.5 g. of retronecanone. After heating in a water-bath for one hour and then cooling, the solution was made alkaline to litmus. On further cooling and scratching, the crystalline derivative precipitated. After recrystallization from a mixture of chloroform–petroleum ether, the semicarbazone was obtained as white platelets, m. p. 209–210° (cor.) with decomposition.

Anal. Calcd. for $C_9H_{16}ON_4$: C, 55.08; H, 8.22; N, 28.55. Found: C, 55.01; H, 8.23; N, 28.31.

Retronecanone Oxime—To a solution of 1 g. of hydroxylamine hydrochloride in 6 cc. of 10% aqueous sodium hydroxide was added 0.6 g. of retronecanone. After heating twenty minutes on a steam-cone, the solution was cooled and the *p*H adjusted to about 8.5. The oxime was removed from the mixture by continuous ether extraction for twenty-four hours. After drying the ethereal extract and removing the solvent, a yield of 0.5 g. (75%) of the oxime was obtained. The most practical means of purification was found to be vacuum sublimation; small, white needles, m. p. 167–168° (cor.).

Anal. Calcd. for $C_8H_{14}ON_2$: C, 62.31; H, 9.15; N, 18.17. Found: C, 62.59; H, 9.16; N, 18.36.

Rotation. 0.0204 g. made up to 5 cc. with absolute ethanol at 26° gave αD −0.31; *l*, 1; $[\alpha]^{26}D$ −76.0°.

Summary

1. The base, isoretronecanol, has been prepared by the removal of the stable hydroxyl from platynecine. It has the formula $C_8H_{15}ON$. Isoretronecanol undergoes chromic acid oxidation to yield an optically active amino acid. Since there is no loss of carbon atoms, this product has been designated as 1-carboxypyrrolizidine (X) and thus establishes beyond doubt the presence of a CH_2OH group in retronecine (I) and platynecine (III).

2. Retronecanol by oxidation with aluminum *t*-butoxide and cyclohexanone gives retronecanone from which typical ketone reagent derivatives were prepared.

3. These experiments confirm the presence of a primary and a secondary hydroxyl group in retronecine.

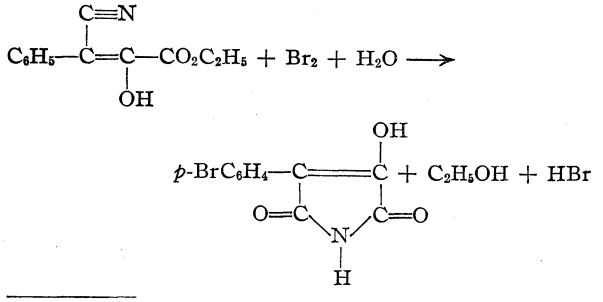
p-Bromophenylhydroxymaleic Imide

BY GLENN S. SKINNER, C. A. COGHLAN AND A. S. BERLIN

Bromine reacts with ethyl cyanophenylpyruvate in chloroform solution to give a colorless unstable addition product. The initial reaction is followed by the loss of hydrogen bromide. The products then undergo a series of reactions to yield *p*-bromophenylhydroxymaleic imide. This is a lemon-yellow crystalline substance whose brick-red sodium salt reacts with benzyl chloride in alcohol to give a benzyl derivative. The silver salt reacts with ethyl iodide in absolute ether to give an ethyl derivative. The nature of the reaction product is further attested by its oxidation to *p*-bromobenzoic acid and its alkaline hydrolysis to *p*-bromophenylacetic acid.

As to the mechanism of its formation, the first step in the breakdown of the addition product involves the loss of hydrogen bromide and the formation of the amide. The tertiary bromine atom then rearranges to the ring at this point or during cyclization. It is significant that this bromine atom appears exclusively in the para position since this is typical of the rearrangement of many similarly placed atoms or groups in the aromatic series. Ring formation takes place through the loss of alcohol. In the case of ethyl cyanomethylpyruvate[1] ethyl alcohol is not lost and the final product is ethyl β-bromo-β-carbamido-α-ketobutyrate. The last two steps are similar to the formation of phenylhydroxymaleic imide from the unbrominated ester by the action of cold concentrated sulfuric acid in alcohol.[2] The cyclization and bromination may also proceed partly in the reverse order as the same product is obtained by bromination of phenylhydroxymaleic imide. The reaction may be formulated as follows



(1) Wislicenus and Silberstein, *Ber.*, **43**, 1834 (1910).
(2) Bougault, *J. Pharm. Chem.*, **10**, 297 (1914).

Experimental

Bromination of Ethyl Cyanophenylpyruvate.—A hot solution of 21.7 g. of the ester in 80 cc. of dry chloroform contained in a 250-cc. bulb connected to a condenser by a glass joint was rapidly cooled to 45–50° in a water-bath. Water (1.8 cc.) and dry bromine (5.3 cc.) were added simultaneously with good mixing in the course of a few minutes. The reaction was rapid with the evolution of hydrogen bromide and initially a colorless almost entirely liquid layer may separate at the bottom in the absence of continued agitation. The mixture was kept at approximately 50° for six hours and then allowed to stand for two days at room temperature. A slight excess of bromine remained at the end of the reaction. The chloroform was decanted and the crystalline product was crystallized from boiling alcohol. The yield of lemon-yellow crystals was 22 g.; m. p. 239–240°.

Anal. Calcd. for $C_{10}H_6O_3NBr$: N, 5.22. Found: N, 5.15.

There was no lachrymatory effect of bromobenzyl cyanide from the residues in the mother liquor when the experiment was conducted in the above manner. The yield dropped to about 9 g. when the added water was omitted. In this case the residues had a powerful lachrymatory effect. Small amounts of ammonium bromide were always formed. The product was obtained in approximately the same yield from the methyl and *n*-butyl esters. An equivalent amount of the alcohol was isolated by extraction of the chloroform with water followed by salting out with potassium carbonate. Ethyl alcohol was further identified as a reaction product of the ethyl ester by conversion to the 3,5-dinitrobenzoate; m. p. 78–79°. No *o*-bromophenylhydroxymaleic imide could be isolated from the combined mother liquors.

Characterization of *p*-Bromophenylhydroxymaleic Imide.—The imide is slowly soluble in cold sodium bicarbonate solution and very soluble in ether. It is stable to cold dilute permanganate and to bromine water. The sodium salt was obtained in 88% yield by the following procedure: *p*-bromophenylhydroxymaleic imide (53.6 g.) was dissolved in a hot solution of 12.4 g. of sodium carbonate in 150 cc. of water. The solution was filtered hot and allowed to crystallize. The brick-red crystals were filtered with suction and washed with a 1:2 alcohol–ether mixture. The product was recrystallized from an alcohol–water mixture. The salt decomposes at 321°. For the analysis it was dried to constant weight at 110°.

Anal. Calcd. for $C_{10}H_5O_3NBrNa$: Na, 7.93. Found: Na, 7.92.

The brick-red gelatinous silver salt was precipitated quantitatively from an aqueous solution of the sodium salt. It was dried in a vacuum desiccator protected from light under the influence of which its color changes to chocolate-brown.

The N-ethyl derivative was made by gently refluxing for three days a mixture of 6.7 g. of the dry silver salt, 3.7 g. of ethyl iodide and 50 cc. of absolute ether. The unchanged imide was removed by extraction with sodium bicarbonate solution. The insoluble portion was dissolved in ether, 10 cc. of alcohol was added and the product was crystallized repeatedly by evaporation of the ether; yield, 1.4 g.; m. p. 191–192°.

The N-benzyl derivative was made by refluxing overnight a solution of 5.8 g. of the sodium salt and 2.53 g. of benzyl chloride in 25 cc. of alcohol. Crystallized from alcohol it melts at 169–170°; yield, 5.6 g.

Anal. Calcd. for $C_{17}H_{12}O_3NBr$: N, 3.91. Found: N, 3.89.

A sample of the imide (1.34 g.) oxidized by a boiling mixture of 5 cc. of nitric acid (1.42) and 5 cc. of water gave 0.8 g. of *p*-bromobenzoic acid which after crystallization from alcohol melted at 254°. The same acid was obtained by refluxing a solution of the imide (0.67 g.) prepared from 0.21 g. of sodium bicarbonate and 10 cc. of water, while 200 cc. of a 1% solution of potassium permanganate was added during a period of 2.5 hours.

To an ice-cold solution of 1.2 g. of sodium hydroxide in 10 cc. of water was added 2.68 g. of *p*-bromophenylhydroxymaleic imide. As it was stirred the red solution became colorless. The mixture was allowed to stand for one day. The products were ammonia, sodium oxalate and *p*-bromophenylacetic acid; m. p. 113–114°.

Phenylhydroxymaleic imide prepared by the method of Bougault was dissolved in 75 cc. of nitrobenzene. To this solution was added 1.8 cc. of bromine. After heating a short time the mixture was allowed to stand for three days at room temperature. The crystals were separated from the mother liquor by decantation and recrystallized from alcohol; yield, 4.3 g.; m. p. 239–240°.

Summary

The action of bromine on ethyl cyanophenylpyruvate leads to the formation of *p*-bromophenylhydroxymaleic imide. The identity of the product has been established by its hydrolysis to *p*-bromophenylacetic acid, its oxidation to *p*-bromobenzoic acid and its formation by the action of bromine on phenylhydroxymaleic imide.

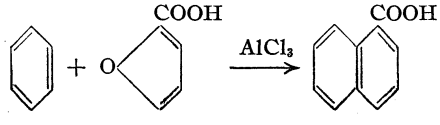
The Reaction of Furoic Acid with Tetralin

BY CHARLES C. PRICE AND NORMAN C. DENO

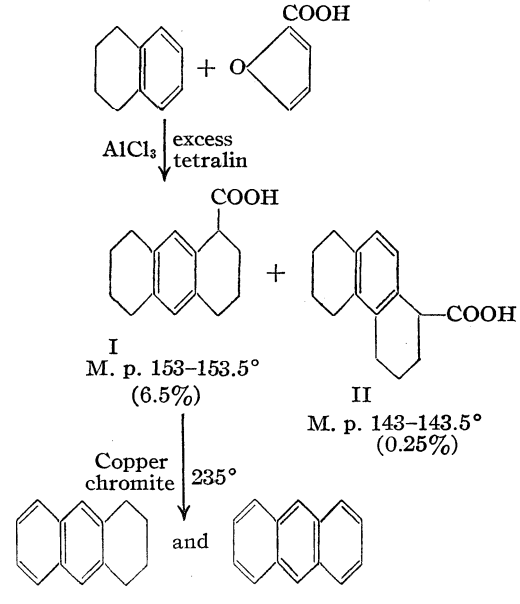
Since the reaction of furoic acid and aluminum chloride with various aromatic compounds of the benzene series was found to produce naphthoic acids,[1] the reaction has been extended to the



naphthalene series, in the expectation of obtaining phenanthroic or anthroic acids.

From naphthalene, furoic acid and aluminum chloride, the only product obtained was an intractable amorphous, neutral black powder, but from the condensation of tetralin and furoic acid it was possible to isolate two isomeric crystalline acids. These acids had four more hydrogen atoms than the expected tetrahydroanthroic or phenanthroic acids. Evidently, disproportionation of hydrogen occurred with the excess tetralin used as solvent for the condensation.

The crystalline product obtained in greater yield (6.5%), shiny white plates melting at 153–153.5°, has been shown by simultaneous decarboxylation and dehydrogenation with copper chromite catalyst to contain an anthracene nucleus and thus appears to be *sym*-octahydro-1-anthroic acid (I). The most likely structure for the isomeric product, slender needles melting at



(1) Gilman, McCorkle and Calloway, THIS JOURNAL, **56**, 745 (1934); McCorkle and Turck, *Proc. Iowa Acad. Sci.*, **43**, 205 (1936); Price, Chapin, Goldman, Krebs and Shafer, THIS JOURNAL, **63**, 1857 (1941).

143–143.5°, would appear to be that of *sym*-octahydro-1-phenanthroic acid (II).

Although the crystalline acids isolated represented only about one-tenth of the total acidic product formed in the reaction, no other crystalline material could be isolated from the residue.

Experimental[2]

***sym*-Octahydro-1-anthroic Acid (I).**—A suspension of 48 g. (0.43 mole) of furoic acid in 400 cc. of tetralin was stirred in an ice-bath while 120 g. (0.90 mole) of aluminum chloride was added in small portions. After the aluminum chloride had been added, the deep red-black viscous reaction mixture was stirred at 50–60° for twelve hours or at room temperature for forty hours. The reaction mixture was poured into 400 cc. of hydrochloric acid and 400 g. of ice and was stirred at 50–60° for six hours to complete hydrolysis. One liter of benzene was added and the deep red, green-fluorescent solution was extracted with sodium bicarbonate solution; 0.3 g. of *sym*-octahydro-1-anthroic acid was recovered from this extract by acidification. The benzene was then extracted with three 200-cc. portions of 2% sodium hydroxide and the red, blue-fluorescent extract was acidified; 68 g. of a pale tan tacky solid precipitated. This material, which had a neutral equivalent of 335, was redissolved in alkali and fractionally precipitated, either with hydrochloric acid or carbon dioxide. The brown gum first precipitated was removed by filtration. Further acidification gave about 10 g. of white solid which was recrystallized three times from 50% ethyl alcohol, yield, 6.2 g. (6.3%) of shiny white plates of ***sym*-octahydro-1-anthroic acid (I)**, m. p. 153–153.5°.

Anal. Calcd. for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24; neut. eq., 226. Calcd. for $C_{15}H_{18}O_2$: C, 78.23; H, 7.87; neut. eq., 230. Found: C, 78.31; H, 8.01; neut. eq., 230.

Treatment of this acid (I) by the procedure used for the dinitration of durene[3] gave an acid melting from 230 to 235° with a neutral equivalent of 333. The neutral equivalent for 9,10-dinitro-octahydro-1-anthroic acid should be 320.

Decarboxylation.—A solution of 0.5 g. of the anthroic acid (I) in 5 cc. of quinoline was heated for eighteen hours at 235° in the presence of 0.2 g. of copper chromite catalyst. The mixture was cooled, ether was added and the solution washed with several portions of dilute hydrochloric acid and sodium hydroxide. The ether was dried, treated with Norite, which removed most of the color, and then evaporated. The **tetrahydroanthracene**, 0.2 g., was recrystallized from 70% alcohol as white plates, m. p. 102–104°.[4] Because of the similarity of melting point and appearance, a mixture of the decarboxylation product and phenanthrene, m. p. 101–102°, was prepared; it melted at 84–99°. A second decarboxylation, apparently identical with that described above, gave some anthracene, identified by melting point and mixed melting point.

When one gram of the anthroic acid was heated with 0.56 g. of sulfur at 180–190° for ten hours, hydrogen sulfide was evolved copiously. The residue was dissolved in 50 cc. of benzene and the solution was filtered and extracted with sodium bicarbonate. Acidification of this extract precipitated 0.4 g. of orange-yellow powder, m. p. 216–226°. Purification of this material could not be effected by crystallization from alcohol, acetic acid or benzene. Sublimation at 205–210° yielded beautiful long, slender, clear-yellow needles,[5] but the melting point was the same as that of the crude product. Qualitative tests for sulfur by sodium fusion were negative.

***sym*-Octahydro-1-phenanthroic Acid (II).**—When the mother liquor from the first recrystallizaton of the octahydroanthroic acid (I) was allowed to evaporate slowly clusters of needles separated among the plates. After mechanical separation and six recrystallizations from 50% alcohol, the slender shiny needles obtained (0.25 g. or 0.25%) melted at 143–143.5°.

Anal. Calcd. for $C_{15}H_{18}O_2$: C, 78.23; H, 7.87; neut. eq., 230. Found: C, 78.46; H, 7.56; neut. eq., 233.

Summary

The reaction of furoic acid with tetralin in the presence of aluminum chloride gave a considerable amount of acidic product from which two isomeric crystalline acids were obtained in small yield. These acids contained four more hydrogen atoms than had been expected and are believed to be *sym*-octahydro-1-anthroic and 1-phenanthroic acids.

The Carotenoids of Yellow Corn Grain[1]

BY JONATHAN W. WHITE, JR., F. P. ZSCHEILE AND ARTHUR M. BRUNSON

It has only recently been recognized that the following carotenoids, other than "carotene" and "xanthophyll," often occur in the grain of yellow corn (*Zea mays L.*): zeaxanthol,[2] cryptoxanthol[3] β-carotene, α-carotene, K carotene and neocryptoxanthol.[4] It has been shown that the isomerization products neo-β-carotene,[5,6] neocryptoxanthol,[6] and neozeaxanthols A, B and C[7,8] are present under ordinary conditions in solutions containing β-carotene, cryptoxanthol, and zeaxanthol, respectively. Nagy[9] recently studied the carotenoid pigments of corn gluten meal and noted the formation of numerous isomeric forms, particularly of zeaxanthol, under acid conditions. The degree of isomerization of carotenoids during and after extraction from natural sources will depend upon experimental conditions. In quantitative analysis of corn grain pigments, Fraps and Kemmerer[4] considered the presence of neocryptoxanthol. Beadle and Zscheile[10] showed the necessity for inclusion of neo-β-carotene in the analysis of vegetable carotenoids.

In order to analyze solutions containing these neo-type pigments by spectroscopic methods, it is necessary that their identity and quantitative absorption spectra be known. Data given in this paper form the foundation for such a system of analysis which will be presented later.

During an investigation of the carotenoids of corn grain, several pigments were separated that had not previously been observed there.

Luteol.—Chromatography from ether on MgO–Supercel[11] of the saponified carotenol fraction of yellow corn showed in every case the presence of a zone immediately below the zeaxanthol zone. An ethanolic solution of the pigment from this zone had a characteristic absorption spectrum identical with that of luteol. Absorption spectra were determined on a photoelectric spectrophotometer previously employed for pigment studies.[10,11,12] The only other known carotenoid (except luteol esters) with an absorption spectrum of this type is α-carotene. When α-carotene and this pigment from corn grain were mixed in ether and adsorbed on magnesia, two zones were formed, indicating that the corn pigment was not α-carotene. From the above considerations it is concluded that this pigment is luteol.

Unnamed Carotene 1.—A spectrophotometric study was made of the carotene fraction of corn carotenoids, prepared from an extract by partition between hexane and 78.5% diacetone alcohol [which removed the carotenols, except cryptoxanthol] followed by partition between hexane and 92% 2-methyl-2,4-pentanediol as recommended by White and Zscheile.[13] In addition to other deviations from the absorption spectra of the pure pigments believed to be present, it was noted that a shelf [in some preparations a maximum] was present at 4250 Å. Chromatography on magnesia (three times), followed successively by adsorption on calcium hydroxide and on Brockmann's alumina gave a product with the absorption spectrum shown in Fig. 1 as curve I. A short heating of the[14] solution had no effect on the spectrum. The quantity of the compound was too small to permit the establishment of quantitative values for absorption coefficients or to permit chemical analysis. Strain[15] described a carotenoid from carrots with absorption maxima at 4250 and 4000 Å. A preparation of this carotenoid was made from carrots following Strain's directions. Its absorption spectrum had maxima at 4250, 4000, 3790, and 3600 Å. and a pronounced minimum at 4150 Å.

γ-Carotene.—Investigation of the cause in corn carotene fractions of relatively high absorption on the long wave length side of the 4780 Å. maximum of β-carotene resulted in the separation of a pigment with absorption maxima [4900, 4600, and 4300 Å. in hexane] in good agreement with those of γ-carotene.[16] It was adsorbed from hexane solution on magnesia above β-carotene. Quantities were too small to permit the most accurate determination of absorption values. The characteristic spectrum in hexane solution is shown in Fig. 1 as curve II.

Carotenoid with Properties Expected of a Monohydroxy-α-carotene.—The cryptoxanthol fraction of several inbred lines of yellow corn was found to produce from four to eight distinct zones on a magnesia adsorption column when absorbed from hexane and washed with ether.

In all cases but one, the zones other than those due to cryptoxanthol and to small amounts of β-carotene (not removed by the partition process) were too small to be isolated. In the case of inbred M4B[17] a buff zone was found immediately below the cryptoxanthol layer. These two zones were of approximately equal thickness. After washing with ether and elution with ethanolic hexane, the characteristic absorption spectrum of the pigment in this lower zone was determined in hexane. It agreed well with that of α-carotene, having maxima at 4740, 4450 and 4250 Å., and a deep minimum at 4625 Å.

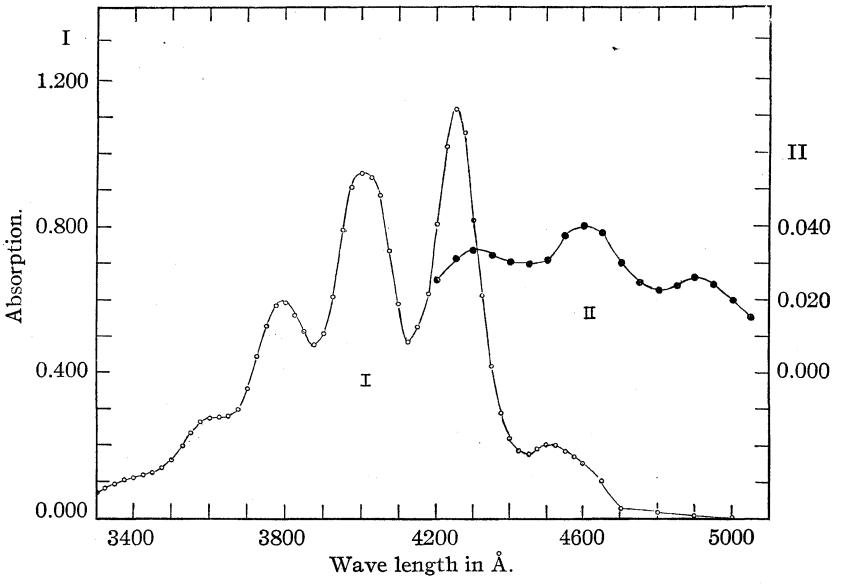

Fig. 1.—Absorption spectra in hexane: I, unnamed carotene 1; II, γ-carotene preparation from corn. Absorption = $\log_{10}(I_0/I)/l$.[14]

Portions of the solution were mixed with solutions of α-carotene in hexane and with luteol in ether. The resulting solutions each produced two zones when adsorbed on magnesia. The same results were obtained after the unknown compound was boiled for twenty minutes with alcoholic alkali, which indicated that it was not an ester of luteol. The mixed chromatograms showed that the compound was neither α-carotene nor luteol. In view of its occurrence in the cryptoxanthol fraction, its position of adsorption immediately below cryptoxanthol (α-carotene is adsorbed immediately below β-carotene), and its nonidentity with α-carotene and luteol, it is suggested that the compound may be a monohydroxy-α-carotene. Quantities available were too small for chemical analysis.

Neocryptoxanthol.—A hexane solution of pure cryptoxanthol was heated in an amber glass flask under reflux for twenty-four hours, cooled, and adsorbed on $Ca(OH)_2$-Supercel (1:1). After washing with 20% ether in hexane, two zones were found. No oxidation products were evident. The upper one contained cryptoxanthol, the lower neocryptoxanthol. After elution the latter was readsorbed, eluted, and made to volume. Its absorption spectrum was determined. An aliquot of this neocryptoxanthol solution was evaporated to dryness *in vacuo*, made to the original volume, and its spectrum redetermined. As shown in Fig. 2, the absorption of a solution of the material after drying decreased over the range from 3800 to 4157 and increased over the range from 4157 to 5000 Å. It is well known that the change cryptoxanthol-to-neocryptoxanthol is reversible.[6] The absorption coefficient at 4157 Å. did not change, indicating that the absorption coefficients of cryptoxanthol and of neocryptoxanthol are identical at this wave length. This makes it possible to establish the absorption spectrum of neocryptoxanthol on a quantitative basis.[18] It was necessary that the above procedure be used because the quantities of neocryptoxanthol available were too small to be weighed accurately. Also plotted in Fig. 2 is the characteristic spectrum of cryptoxanthol, recalculated from earlier data,[10] placed to intersect the other two curves at 4157 Å. It will be noted that the curve of the dried preparation falls at a proportional distance between the other two curves over the entire range. Determinations of the intersection point with several preparations (intersection points, 4137, 4157, and 4177 Å. gave the quantitative absorption spectrum of neocryptoxanthol shown in Fig. 3. The maximum deviation from this curve of absorption values of six preparations is ±3%. This curve bears a relation to cryptoxanthol which is strikingly similar to that between neo-β- and

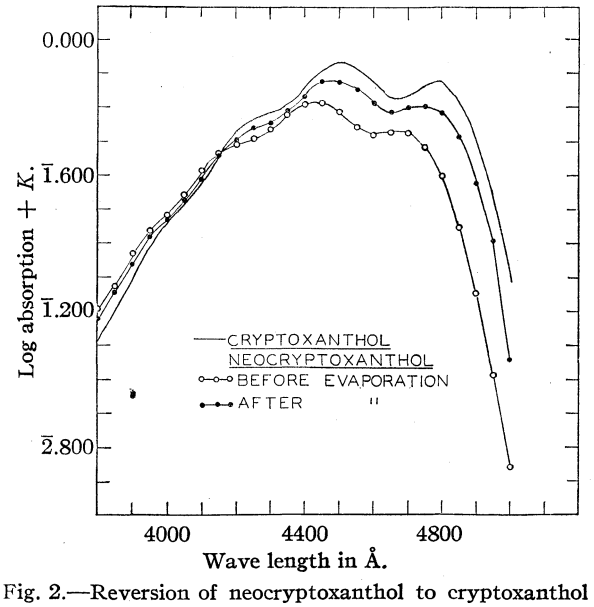

Fig. 2.—Reversion of neocryptoxanthol to cryptoxanthol in hexane solution.

(17) The designation of the various inbred lines is purely arbitrary and has no significance as to type of plant or chemical composition.

(18) In the case of neo-β-carotene, this method gave results which agreed with data obtained with weighed samples.[9]

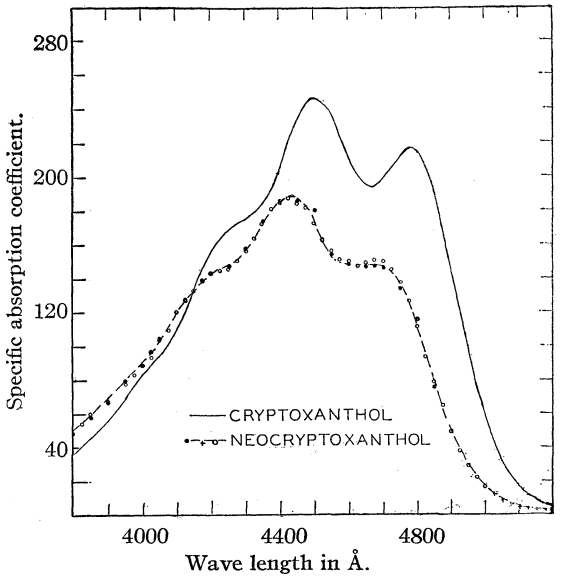

Fig. 3.—Absorption spectra of neocryptoxanthol and cryptoxanthol[11] in hexane.

β-carotenes.[10] Table I presents absorption values for two preparations of neocryptoxanthol in hexane solution.

TABLE I

ABSORPTION VALUES OF NEOCRYPTOXANTHOL IN HEXANE SOLUTION

Wave length, Å.	Specific absorption coefficient, liters/g. cm. 1	2
4650 Shelf	147	148
4425 Maximum	185	187
4150–4160 Region of intersection	133–135	133–135

Neozeaxanthols.—An ethanol solution of pure zeaxanthol was heated in an amber glass flask under reflux for twenty-four hours, the pigment transferred to a 50% solution of ether in hexane, and adsorbed on $Ca(OH)_2$–Supercel as before. Three zones were found. Spectra of the eluted pigments were determined, and the pigment from zone 2 was identified as zeaxanthol. The other two curves had maxima shifted toward shorter wave lengths than those of zeaxanthol. Since the relation of these two neo- pigments to neozeaxanthols A, B, and C of Zechmeister and Tuzson[7,8] was not clear, they were named neozeaxanthol I (more strongly adsorbed) and neozeaxanthol II (less strongly adsorbed). The neo-isomers were purified by further adsorption and attempts were made to apply the intersection-point method used with neocryptoxanthol. A short heating of the solutions was used instead of evaporation to dryness. When compared to the absorption curve before heating, the curve of the solution of neozeaxanthol I after heating decreased over the range 4350 to 5000 Å., increased over the range 3800 to 4200 Å., and did not change over the range 4200 to 4350 Å. Under similar treatment the absorption spectrum of neozeaxanthol II changed as follows: it increased over the range 4407 to 5000 Å., decreased over the range 3800 to 4407 Å., and did not change at 4250 Å. Adsorption showed three compounds in the solution.

In order to obtain a provisional value for the absorption spectra of these two compounds, it was assumed that the isomerization of neozeaxanthol I was to neozeaxanthol II and that of neozeaxanthol II was to zeaxanthol. It is on these assumptions that the absorption spectra of the neozeaxanthols shown in Fig. 4 were determined. These curves are only first approximations.

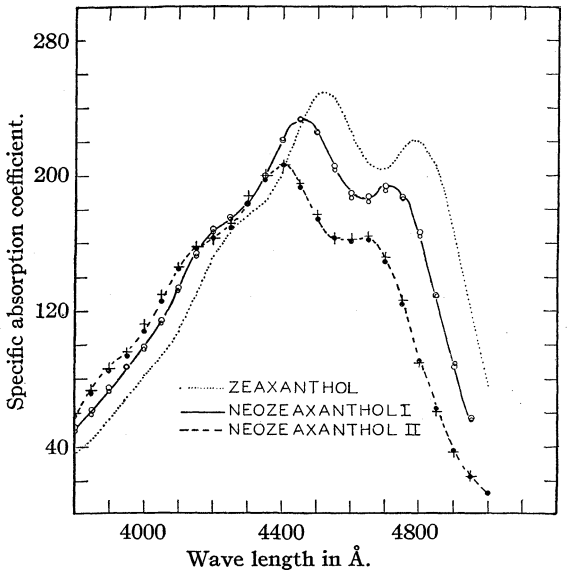

Fig. 4.—Absorption spectra of neozeaxanthols I and II in ethanol; spectrum of zeaxanthol in ethanol from earlier data.[11]

Discussion

If the method of measurement of pigment concentration used for the determination of the carotenoids of corn is sensitive enough to detect the presence of the neocarotenoids, it is necessary that proper account be taken of their possible presence. Likewise, if the other pigments reported here are present in high enough concentation, they must be considered. Determination of the carotenoids of corn is usually made for estimation of provitamin A potency. From this point of view the provitamin A potency of neocryptoxanthol and of the carotenoid with maxima at 4250 and 4000 Å. must be determined. Fraps and Kemmerer[4] reported neocryptoxanthol to be nearly as potent as cryptoxanthol.

In the same paper, Fraps and Kemmerer reported the presence in corn of a compound which they call K carotene and to which they assign provitamin A activity. They presented a qualitative absorption spectrum for the pigment with maxima at 4250 and 3970 Å. and a prominent shelf at 4450 to 4500 Å. Strain[15] reported the isolation of a pigment from carrot roots which he termed "flavoxanthin-like carotene." Its spec-

trum had maxima at 4250 and at 4000 Å. He also noted that his product was apparently identical with a pigment isolated by van Stolk, Guilbert, and Penau in 1932. In the spectrum of this compound as separated in this Laboratory, there was no trace of a shelf or maximum at 4500 Å. The spectrum was quite similar to that of unnamed carotene 1 as shown in Fig. 1, except for the absence of the maximum at 4500 Å. This maximum is not due to contamination of unnamed carotene 1 by β-carotene since absorption at 4800 Å. is too low. No preparation of unnamed carotene 1 from corn failed to show a maximum at 4500 Å. Since Fraps and Kemmerer's[4] curve for K carotene shows neither the 3790 Å. maximum nor the 3600 Å. shelf, it is possible that K carotene and un-named carotene 1 may not be identical.

Fraps and Kemmerer also stated that α-carotene was found in all but one of twenty-two corn varieties. The authors have never observed α-carotene in corn (six inbreds, several sweet corn varieties, and two hybrids were studied). The adsorbent used by Fraps and Kemmerer was capable of separating cryptoxanthol from neocryptoxanthol and might be expected to separate β-carotene from neo-β-carotene. However, they did not report neo-β-carotene in their corn extracts. They identified their α-carotene spectrophotometrically and by mixed chromatography. In this connection, it should be pointed out that Gillam and El Ridi[5] were unable to distinguish spectroscopically between α-carotene and neo-β-carotene. They found that α-carotene and neo-β-carotene formed a single zone when adsorbed on alumina from the carotene fraction of butter.[19] Examination of the spectra of α-carotene and neo-β-carotene by a very sensitive photoelectric spectrophotometer[10,11] shows that they can be differentiated spectroscopically with an instrument of sufficient accuracy. The experience of Gillam and El Ridi illustrates that failure of a mixture of two compounds to form two zones on a given adsorbent does not necessarily indicate that the compounds are identical. The writers consider it possible that the pigment identified by Fraps and Kemmerer as α-carotene might have been neo-β-carotene.

Summary

1. Luteol, γ-carotene and a compound tentatively identified as a hydroxy-α-carotene were found in yellow corn grain for the first time.

2. A compound having some properties like Fraps and Kemmerer's K carotene was also separated from yellow corn grain.

3. Preliminary quantitative absorption spectra of neocryptoxanthol and two neozeaxanthol isomers are presented.

The Malonic Ester Synthesis and Walden Inversion

BY WILLIAM E. GRIGSBY,[1] JOHN HIND, JACOB CHANLEY AND F. H. WESTHEIMER

It has been suggested recently that the reaction of alkyl halides and olefin oxides with the sodium salt of malonic ester is an example of the normal displacement reaction.[2,3] If this is the case, the reaction should proceed with Walden inversion about the carbon atom to which the halogen (or oxygen) atom is attached. An experimental demonstration of this inversion has now been established for the reaction of cyclopentene oxide with sodium malonic ester.

In all the previously known reactions of sodium malonic ester with an oxide—ethylene oxide,[4] epichlorhydrin,[4] cyclohexene oxide[5] and others[6]—the reaction product is a lactone. With ethylene oxide, for example, the product is α-carbethoxy-γ-butyrolactone. If the reaction with cyclopentene oxide had proceeded without inversion, the product would have been the lactone of the mono-

The reactions recorded in the literature were carried out between equimolar quantities of oxide, malonic ester, and sodium ethylate. However, repetition of the work of Traube and Lehmann, using two moles of malonic ester for each mole of sodium ethylate, showed that, in this case, excess malonic ester is without effect on the composition of the product obtained.

ethyl ester of *cis*-cyclopentanol-2-malonic acid (VI). In actual fact, inversion occurred and the product proved to be the diethyl ester of *trans*-cyclopentanol-2-malonic acid (II). Lactone formation in this case was precluded, since it would involve fusing two five-membered rings together in the *trans*-positions. Such a configuration involves a great deal of strain, and has been accomplished only once, and then with a carbocyclic compound.[7]

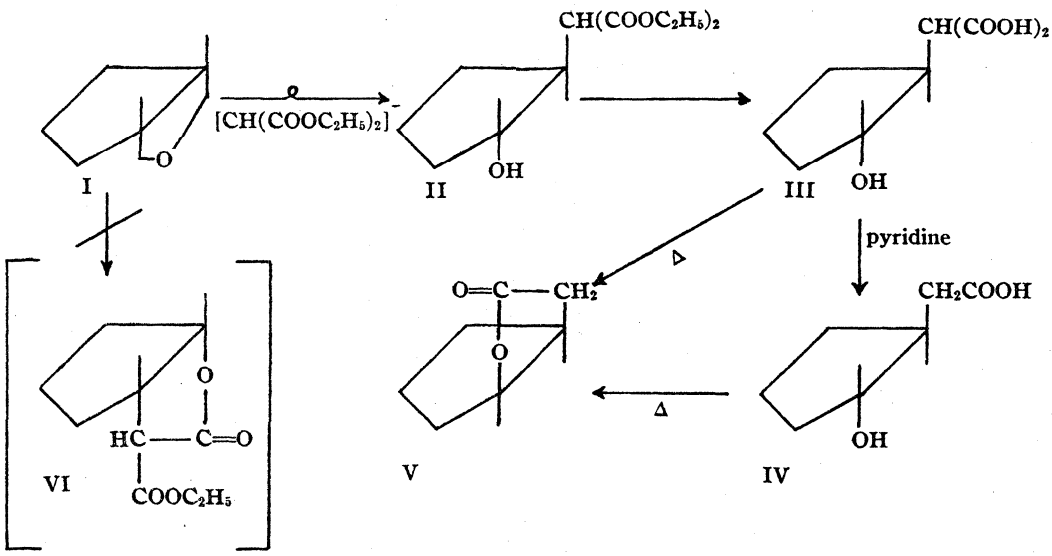
It is interesting to contrast the behavior of cyclopentene oxide with that of cyclohexene oxide. When cyclohexene oxide reacts with equivalent quantities of malonic ester and sodium ethylate, a lactone is formed.[5] No stereochemical conclusion can, however, be drawn from this fact. Many examples are known in which a six and a five membered ring are fused together in the *trans* positions.[8] As a matter of fact, lactones of both the *cis*- and the *trans*-cyclohexanol-2-acetic acids are known.[9]

Under favorable experimental conditions, the reaction between cyclopentene oxide and sodium malonic ester gave a 70–75% yield of the *trans*-diester. The ester was a liquid which could be purified by molecular distillation; saponification equivalent, and carbon, hydrogen and ethoxyl analyses all clearly showed that the compound was the *trans*-diester, II, not the *cis*-lactone, VI.

The fact that the liquid ester was *trans* was confirmed by transforming it to a derivative the structure and configuration of which are known. On refluxing with dilute alkali, the ester was converted into the salt of a diacid. The acid was obtained in 80–90% yield as a crystalline solid which evidently did not contain water of crystallization. The analytical data agree with those calculated for *trans*-cyclopentanol-2-malonic acid (III), but are not in agreement with those for the corresponding *cis*-lactone. It seems improbable that the saponification altered the configuration of the molecule, since there was no asymmetric carbon atom in a position alpha to a carbonyl group; inversion by enolization is therefore ruled out.[10]

The *trans*-diacid was decarboxylated by refluxing for ten minutes in pyridine solution; carbon dioxide and *trans*-cyclopentanol-2-acetic acid (IV) were obtained in excellent yields. By neutral equivalent, melting point, solubility behavior and analysis, the compound was shown to be identical with that previously prepared by an entirely independent method by Hückel and Gelmroth.[11] The configuration of this acid is not in doubt; the corresponding *cis*-compound exists only in the form of a lactone (V), melting at −14°.[12]

Evidence that the decarboxylation does not involve a change in configuration is offered by the fact that the lactone (V) of *cis*-cyclopentanol-2-acetic acid can be heated with pyridine and subsequently recovered unchanged.



While the reactions outlined above almost cer-

(12) Only in the case of a beta lactone has ring opening accompanied by Walden inversion been observed; Olson and Miller, THIS JOURNAL, **60**, 2687 (1938); see also Day and Ingold, *Trans. Faraday Soc.*, **37**, 686 (1941).

tainly did not involve a change in configuration, it is possible by more drastic means to rearrange the *trans*-compounds to the *cis*. Prolonged pyrolysis of the *trans*-diacid (fifty hours at 160°) was necessary to cause decarboxylation in the absence of pyridine and the product obtained was V, the lactone of *cis*-cyclopentanol-2-acetic acid. Under similar conditions, *trans*-cyclopentanol-2-acetic acid (IV) rearranged to the *cis*-lactone (V). The mechanism of this rearrangement may involve the acid-catalyzed dehydration of an hydroxy acid, followed by lactonization of the olefinic acid; it is possible, however, that the isomerization occurred without the actual formation of the unsaturated compound.

The series of reactions outlined above clearly shows that the reaction between cyclopentene oxide and sodium malonic ester occurs with Walden inversion. The facts are, therefore, consistent with the hypothesis that the reaction is a nucleophilic displacement on carbon involving the malonic ester anion $(C_2H_5O_2CCHCO_2C_2H_5)^-$. This general theory is also supported by the older observation of Wislicenus[13] that sodium malonic ester reacts much more readily with primary than with secondary halides.[14]

While the results of the present investigation were quite satisfactory, some experimental difficulties encountered during the research are worth discussing.

An interesting phenomenon was noticed regarding the saponification of the diester, II. The saponification took place more readily with dilute than with concentrated alkali, although of course complete saponification always led to the formation of the *trans*-diacid (III). Michael[15] noted a similar peculiarity in the saponification of some other mono substituted malonic esters, and Goldschmidt and Oslan[16] successfully explained why the rate of saponification of acetoacetic ester is independent of the alkali concentration.

It is also necessary to call attention to the fact that, in the reaction between sodium malonic ester and cyclopentene oxide, good yields were obtained only in alcoholic solution and in the presence of excess malonic ester. When benzene was used as a solvent, the yield fell to 30%. Furthermore, unless two molar equivalents of malonic ester were used, none of the pure *trans*-diester could be isolated, and neither the configuration nor the structure of the products obtained has yet been established.

It is a fact, however, that reactions of sodium malonic ester are frequently improved by the addition of malonic ester. In the condensations with either halides or oxides, excess malonic ester greatly increases the yield of monosubstitution product,[17] while the abnormal Michael[18] reaction occurs only when the amount of sodium present is equivalent to the malonic ester used. It seems probable that the malonic ester functions as an acid, and removes the reactive anion of the substituted malonic ester from solution. This explanation seems reasonable in the present case, since experiments showed that the anion of *trans*-cyclopentanol-2-malonic ester decomposed on refluxing in alcohol. Although its decomposition did not give the same products as were obtained from the cyclopentene oxide reaction without excess malonic ester, the instability of the anion was evident.

Experimental

Reaction of Sodium Malonic Ester with Cyclopentene Oxide.—About 125 cc. of absolute ethanol and 2.3 g. (0.1 mole) of sodium were placed in a 500-cc. three-necked flask, to which were attached a dropping funnel and a reflux condenser fitted with a calcium chloride tube. When all the metal had reacted, 31.5 g. (0.2 mole) of malonic ester was added. The solution was refluxed, 8.4 g. (0.1 mole) of cyclopentene oxide[19] was added over a period of an hour, and the solution refluxed for an additional three hours. The ethanol was removed by distillation, and a quantity of 10% sulfuric acid was added which was equivalent to the sodium used. The sodium sulfate was filtered and washed with ether, and the filtrate was extracted three times with ether. The combined ether extracts were washed, the ether distilled, and the excess malonic ester removed by vacuum distillation. The residue of pale yellow, crude *trans*-cyclopentanol-2-malonic ester corresponded to a yield of 70–75% and had a saponification equivalent of 110–115.[20] For identification and characterization, it was purified by molecular distillation in a Hickman still. At a pressure of 10^{-4} mm., a colorless oil came over at 75°; if the pressure rose to 10^{-2} mm., the product passed over at 150–160° with slight decomposition.

120, 122; $n^{20}D$ 1.4564; $d^{4}_{21.5}$, 1.109. The micro Zeisel analysis was performed by Dr. J. A. Alicino, Fordham University, New York, N. Y.

A similar reaction, carried out with benzene as solvent, gave a 27% yield of diester (II), identified by saponification, and isolation of the diacid, (III).

Saponification of the Diester, II.—The diester was saponified by refluxing the crude, undistilled ester for four hours with twice the calculated amount of 1.0 *N* sodium hydroxide. An amount of hydrochloric acid exactly equivalent to the sodium hydroxide was then added to this solution. Since it was impossible to extract the acid, because of its great solubility in water, the solution was evaporated to dryness *in vacuo* at room temperature. Unless solutions of the free acid were kept cool, they showed a marked tendency to precipitate out an insoluble polymer. The dry salt-cake was extracted with acetone and the acetone evaporated *in vacuo* at room temperature, leaving a 95% yield of a colorless oil. On stirring with benzene, this oil solidified (yields of 90% were obtained using only 1 g. of ester). The crude powder melted 20–30° lower than the best material finally obtained. The compound was difficult to recrystallize because it was extremely soluble in water, methanol, ethanol, acetone, ether and dioxane, was insoluble in benzene, chloroform, and ligroin, and precipitated as an oil from mixed solvents. However, it was possible to effect a purification by dissolving the compound in the minimum quantity of ethyl acetate or amyl alcohol, centrifuging to remove insoluble matter, and then removing most of the solvent with a stream of dry air. After a few days, the crystals were centrifuged, rapidly washed several times with ethyl acetate, and dried *in vacuo*. The melting point, after several recrystallizations from ethyl acetate, was 118.4–118.7° (with dec., cor.). Before analysis, the purified crystals were dried for a week in a vacuum desiccator over phosphorus pentoxide or over sulfuric acid. In no case did drying affect the melting point or neutral equivalent.

The yield on the recrystallization of the crude diacid was only about 50%; it seems reasonable to assume, however, that the crude material was essentially pure. The crude acid had a neutral equivalent which did not change on recrystallization and which was close to the theoretical value. Furthermore, subsequent decarboxylation gave yields of 80% of pure *trans*-cyclopentanol-2-acetic acid.

Anal. Calcd. for $C_8H_{12}O_5$ (III): C, 51.04; H, 6.39; neut. eq., 94.0. Found: C, 51.27; H, 6.49; neut. eq. (semi-micro), 94.9, 95.0.

Saponification with Concentrated Alkali.—About 1.2 g. of *trans*-cyclopentanol-2-malonic ester (II) was refluxed for nine hours with twice the calculated amount of 5.5 *N* sodium hydroxide. The acid recovered from this treatment had a neutral equivalent of 136, and a saponification equivalent of 99. Further saponification with 1.0 *N* alkali gave an 85% yield of solid *trans*-diacid, (III).

Decarboxylation.—One gram of crude diacid was dissolved in 10 cc. of pyridine, refluxed for ten minutes, and then poured into slightly more 1 *N* sodium hydroxide than the amount calculated for the neutralization of the resulting acid. The pyridine and water were removed at room temperature, and the residue acidified with an amount of 1 *N* hydrochloric acid which was exactly equivalent to the alkali previously added. The water was removed *in vacuo*, and the residue extracted with acetone. The extract was filtered, and the acetone removed at reduced pressure, to avoid polymerization of the acid.[11] This gave an 80% yield of an oil which solidified on scratching. The reported melting point for the *trans*-acid (IV) is 52.5–53.5°. The observed melting point of the recrystallized acid was 53.3–54.3° (cor.).

Anal. Calcd. for $C_7H_{12}O_3$ (IV): C, 58.29; H, 8.40; neut. eq., 144.1 (calcd. for $C_7H_{10}O_2$ (VI): C, 66.67; H, 7.94; neut. eq., 126). Found: C, 58.30; H, 8.00; neut. eq. (semi-micro), 145.9, 145.6.

Treatment of *cis*-Cyclopentanol-2-acetic Acid Lactone with Pyridine.—A solution of 0.5 g. of the lactone in several cc. of pyridine was refluxed for fifteen minutes. Five cc. of 1 *N* sodium hydroxide was added, and the refluxing continued for another fifteen minutes. After evaporation to dryness, acid was added and the lactone recovered unchanged.

Thermal *trans–cis* Isomerization.—Two grams of crude *trans*-cyclopentanol-2-malonic acid was heated for fifty hours at 160°. After two vacuum distillations, 0.6 g. of *cis*-cyclopentanol-2-acetic acid lactone was obtained. The material melted at −14°, while Hückel and Gelmroth[11] reported −17°. When 1.5 g. of *trans*-cyclopentanol-2-acetic acid was heated in a similar fashion and distilled twice, the resulting product, in 40% yield, was the same lactone. These samples of lactone were further identified by boiling point, saponification equivalent, analysis, and by determining the melting point of a mixture of the compound with a sample prepared according to Hückel and Gelmroth.[11]

Reaction without Excess Malonic Ester.—The reaction was carried out as previously described, except that two molar proportions of sodium and malonic ester were used for one of cyclopentene oxide, or else equal proportions of all reactants were used. The product in this case was obtained in only 20–40% yields, and had a saponification equivalent of 165. After prolonged saponification, the resulting acid was partitioned between benzene and water. The water layer contained an acid of neutral equivalent 120–140, while the benzene soluble portion of the mixture had a neutral equivalent of about 200. Clearly, the saponification product was a mixture. The products obtained here have not yet been identified.

Stability of the Anion of the Diester (II).—A gram of *trans*-cyclopentanol-2-malonic ester was dissolved in absolute alcohol, 0.1 g. of sodium added, and the solution refluxed for two hours. At the end of this period of time, only 25% of the *trans* diester could be recovered; the rest had been converted into water soluble compounds. If the solution was refluxed for seven hours, the recovery was only 8%.

Summary

1. A stereochemical study of the reaction of sodium malonic ester with cyclopentene oxide in the presence of excess malonic ester has shown that the reaction involves Walden inversion about one of the carbon atoms of the oxide ring.

2. This is the result which would be anticipated if the reaction proceeded by the usual mechanism for displacement reactions.

The Sorption of Carbon Monoxide by Metals. Temperature Variation Experiments

BY CARROLL W. GRIFFIN

Introduction

The identification of two types of adsorption, namely, physical and activated, has been definitely established for gases on many solids. The existence of a third sorptive force has long been suspected and that this might be solution was mentioned by the author in the case of hydrogen and massive copper.[1] Further evidence to support this belief was obtained in studies of the sorption of hydrogen on supported copper,[2] on massive nickel,[3] on supported nickel,[4] and particularly by the "experiments with temperature variation."[5] In the last two studies the attack has consisted of bringing the gas into sorptive equilibrium with the metal at −78.5°, raising the temperature to 0° and, after measuring the equilibrium conditions, returning the temperature to −78.5°. In this manner it was revealed that the sorption at −78.5° is followed first by a rapid desorption at 0° and then by a slower process (solution) at 0°. Upon cooling again to −78.5° the sorption is found to be greater than the original sorption at this temperature to an extent equal to the volume slowly taken up at 0°.

The success of this method of study of course depends upon selecting two temperatures, one at which the secondary sorptive force, thought to be solution, is absent or is at a minimum, and the other at which it manifests itself distinctly. The amount of solution, and not simply its rate, will be greater at the higher temperature and also at higher pressures. These facts hold for the studies already cited.

It is obvious that −78.5 and 0° might not always be the temperature at which the two sorptive forces would distinguish themselves best. Thus, although Benton and White do not specifically so label the experiment immediately under their Table IV,[6] this is really a run "with temperature variation," the variation here being from 110 to 210°. In connection with their study of carbon monoxide on massive copper it might be emphasized that the authors did not find, after noting the desorption coming with the elevated temperature, any resorption (solution) as evidenced by a drop in pressure. Yet, when the temperature was again brought to 110°, the sorption of carbon monoxide amounted to 15.00 ml. as compared with an original 14.43 ml. It therefore seems, in the writer's opinion, since 0.57 ml. is more than ten times their experimental error, that actually solution of over half a milliliter did take place at 210°, in excess of any dissolved at 110°, but it occurred simultaneously with the desorption of the activated carbon monoxide molecules and *was overshadowed by the desorption.* For as long as both processes are taking place and the rate of desorption exceeds the rate of solution there can be no observable evidence of the latter, save the greater total sorption when return is made to the lower temperature. Only when the desorption at the higher temperature is completed quickly or is relatively small may one observe the pressure reversal which indicates that solution is taking place.

Sorption studies with temperature variation have been confined to hydrogen on metals with the exception that Benton and White have shown the general behavior of carbon monoxide on massive copper. Therefore, the present work was undertaken to learn whether or not the effects observed with hydrogen are common also to other gases. Platinum and copper were the metals selected and, since little or no solution can be expected with supported metals, both forms have been employed with platinum. With copper only the supported metal was used. Since it has already been shown that solution of carbon monoxide in massive copper becomes appreciable only above 0°, the temperatures selected for the supported copper

were 0 and 100°. Those for the two platinum sorbents were −78.5 and 0°, for von Hemptinne[7] found that a marked increase in the sorption of carbon monoxide on platinum takes place around −40°.

Experimental

The apparatus[8] and general method of making the runs[9] and the purification of carbon monoxide[1] have been described. The supported copper sample was the same as in a previous study.[2] The platinum samples also had been used before and their preparation reported.[10] Since it is not possible completely to remove adsorbed carbon monoxide from platinum surfaces by simple evacuation, its removal was accomplished by burning off with oxygen at 250° between runs. The oxygen was then washed off with hydrogen and the latter removed by pumping off at 250°. As usual, helium was employed as a reference gas.

Results

On each of the three sorbents a run was first made to measure the sorption at the lower temperature (0° for copper; −78.5° for platinum) at several pressures up to one atmosphere. Then a run was made at the higher temperature (100° for copper; 0° for platinum). After this three runs were made on each sorbent with temperature variation, using progressively greater volumes of carbon monoxide. The results are summarized in the tables and figures. Table I lists the data obtained with supported copper, and Tables II and III give the results for the platinum sorbents. The values in Row (2) of the tables represent the adsorption at the higher temperature for a given experiment (plus solution, if any, at the lower temperature). The differences given in Row (4) are the volumes of carbon monoxide dissolved at the higher temperature and at pressures of Row (2), while the differences given in Row (8) are the volumes dissolved at the higher temperature at pressures of Row (5). The sums of adsorption and solution are found in Rows (3) and (5).[9]

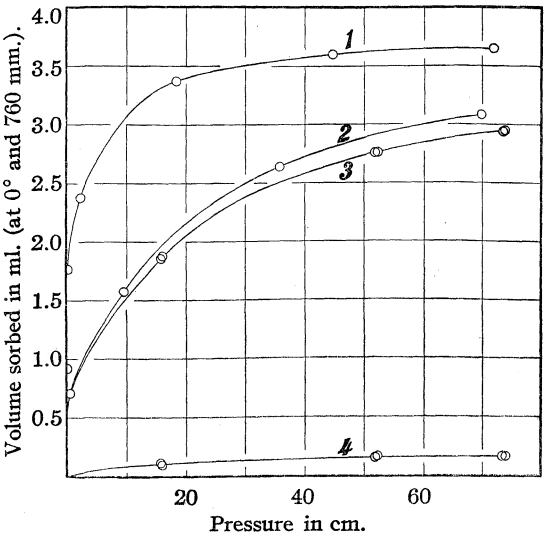

Fig. 1.—Sorption of carbon monoxide on supported copper, four moles of copper per 1000 g. of brick: curve 1, total sorption at 0°; 2, total sorption at 100°; 3, adsorption at 100°; 4, solution at 100°.

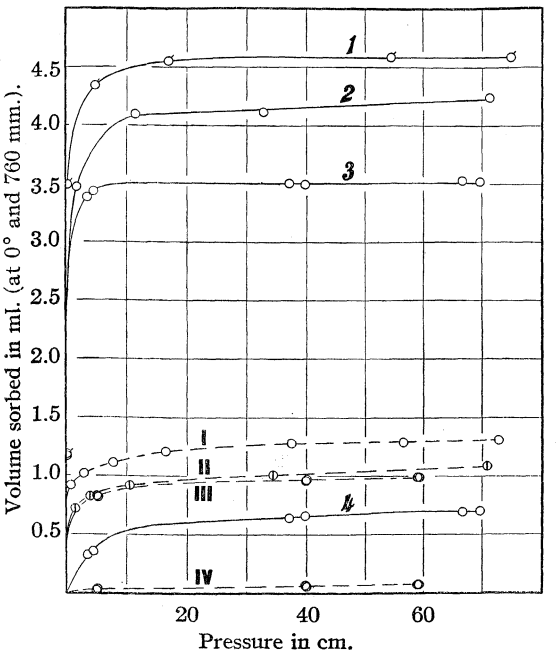

Fig. 2.—Sorption of carbon monoxide on platinum. Solid curves indicate massive platinum; broken curves indicate supported platinum, two moles of platinum per 1000 g. of brick: curves 1 and I, total sorption at −78.5°; 2 and II, total sorption at 0°; 3 and III, adsorption at 0°; 4 and IV, solution at 0°.

distinctly less than in massive metals. Thus, for carbon monoxide in platinum at 500 mm. pressure, the solution process accounts for 17% of the total 0° sorption for the massive form, and for only 5% for the supported form. For supported copper at 100° the figure is 5% both at 500 mm. and at 300 mm. pressure, whereas Benton and White found that for massive copper at 300 mm. pressure over 50% of the 100° sorption is due to solution.[11] The 17% solution for massive platinum is the smallest percentage yet found for a massive metal as may be seen from Table V of an earlier study.[10] Nevertheless, the present evidence substantiates the conclusion that when the sorbent is spread largely as surface the solution factor is much reduced.

The rate of sorption was rapid at low pressures for all three sorbents and somewhat slower at atmospheric pressure. The rate was about the same for massive as for supported platinum; this, as well as the rather unexpectedly low 17% solution for massive platinum, is believed due to the probability that there was a much greater amount of surface metal in this sorbent than is found in massive metals reduced from oxides in wire form. At atmospheric pressure two hours sufficed for equilibrium. This differs from the case of massive copper at 110° or higher under which conditions several days may not bring about equilibrium.

The rate of desorption of carbon monoxide on the two platinum sorbents when the temperature is elevated from −78.5 to 0° was slower than for hydrogen on platinum. As a result, the "initial sorption after warming to 0°," which is computed from the maximum pressure shown when the temperature is increased to 0°, (and which for hydrogen on platinum is almost immediate) was effected in about three or four minutes. Had the total desorption been immediate it follows that the "Initial values after warming to 0°" as shown in Row (2) of these tables would have been slightly higher for the observed pressures and thus somewhat lower for the calculated volumes. In turn this would mean that the values of Row (4), representing solution, would be rather greater. Because of these considerations the values in Row (8) for a given series of experiments should be more trustworthy than those of Row (4), and the fact that good checks have been obtained in Rows (4) and (8) (note that the pressures corresponding to the volumes for the two rows differ somewhat) indicates that in these particular experiments the maximum pressures of Row (2) did not materially differ from the actual values, had the latter been obtainable, which prevailed before the solution process had attained a finite value.

(11) Benton and White, THIS JOURNAL, 54, 1373 (1932), see Fig. 7.

Summary

Measurements with temperature variation have been made for the sorption of carbon monoxide on supported copper and on massive and supported platinum. The results are qualitatively similar to like measurements of hydrogen on massive and supported metals and show that the presence of a secondary sorptive force is probably a general characteristic of metallic sorbents. This factor, apparently solution, manifests itself only to a small extent with supported sorbents where the metal is largely exposed as surface. With massive metals and carbon monoxide the secondary action is over three times as great in the case of platinum, and about ten times as great in the case of copper, when compared with their respective supported forms.

Chemical Separation of the Isotopes of Hydrogen by the Addition of Metals and Compounds of Metals to Water, Acids and Bases. I. Relative Efficiencies of Specific Reactions. The Effects of Certain Factors other than Temperature[1]

BY HERRICK L. JOHNSTON AND CLYDE O. DAVIS

The possibility of obtaining separation of isotopes of hydrogen by displacement reactions of metals with acids was suggested by Washburn and Urey.[2] The first experimental results on displacement reactions were reported independently by L. and A. Farkas[3] and by ourselves.[4] Horiuti and Szabo[5] confirmed our own value of 2.5 for the separation coefficient in the Na–H_2O reaction, in experiments in which they introduced water vapor onto metallic sodium. More extensive observations at 90° have been reported by Hughes, Ingold and Wilson,[6] whose data differ somewhat from our own. Recently, Reyerson, Johnson and Bemmels[7] have reported qualitative data on the isotope separation which results when calcium carbide is treated with water.

The present paper describes quantitative investigations of the reactions of lithium, sodium, potassium, calcium, calcium carbide and aluminum carbide with water; magnesium, granulated and mossy zinc, C. P. and commercial iron, manganese, aluminum and ferrous sulfide with sulfuric acid; and aluminum with sodium hydroxide. In a following paper[8] the results of an investigation of temperature coefficients of the separation factors in several of the reactions are presented.

In both this and the following paper the specific gravity of pure D_2O at 27° is taken to be $d^{27}_{27} = 1.10768$[9] and that of pure protium water with the normal oxygen isotope ratio $d^{27}_{27} = 0.999982$.[10] Account is also taken of the slight non-additivity of H_2O and D_2O volumes reported by Luten.[11] This makes the equation for the specific gravity of a D_2O–H_2O mixture, in terms of the absolute mole fraction of D

$$S_{27^\circ} = 0.999982 + 0.10770\ N_D - 0.0012\ N_H N_D \quad (1)$$

While equation (1) is set up for 27°, it is applicable with high accuracy for moderate concentrations of D for the whole temperature range between 25 and 30°.

Experimental Description

(a) **The Reaction System.**—A diagram of an improved form[12] of the reaction system is shown in Fig. 1.

At the beginning of each run a weighed quantity (400–800 g.) of water, acid or base, with an enriched D content, was placed in the reaction vessel A, and a weighed quantity of the solid reagent (in small pieces) was placed in C.

(1) Except for slight modification for newer values of oxygen isotope abnormality in the electrolyte and in air and for the densities of pure D_2O and pure protium oxide, the values in this paper were presented before the Division of Physical and Inorganic Chemistry at the Cleveland Meeting of the American Chemical Society (September, 1934) and the Symposium on Deuterium, held with the Pittsburgh Meeting of the American Association for the Advancement of Science (December, 1934). Original manuscript received September 19, 1941.

(12) This is actually a diagram of the reaction system used by Johnston and Hall.[8] In the original design the reaction flask was not thermostatted but was either exposed to air, or sprayed with a continuous stream of tap water (*cf. seq.*). The semi-automatic levelling bulbs (H, H) and calibrated flowmeters (J, J) were not included in the original design.

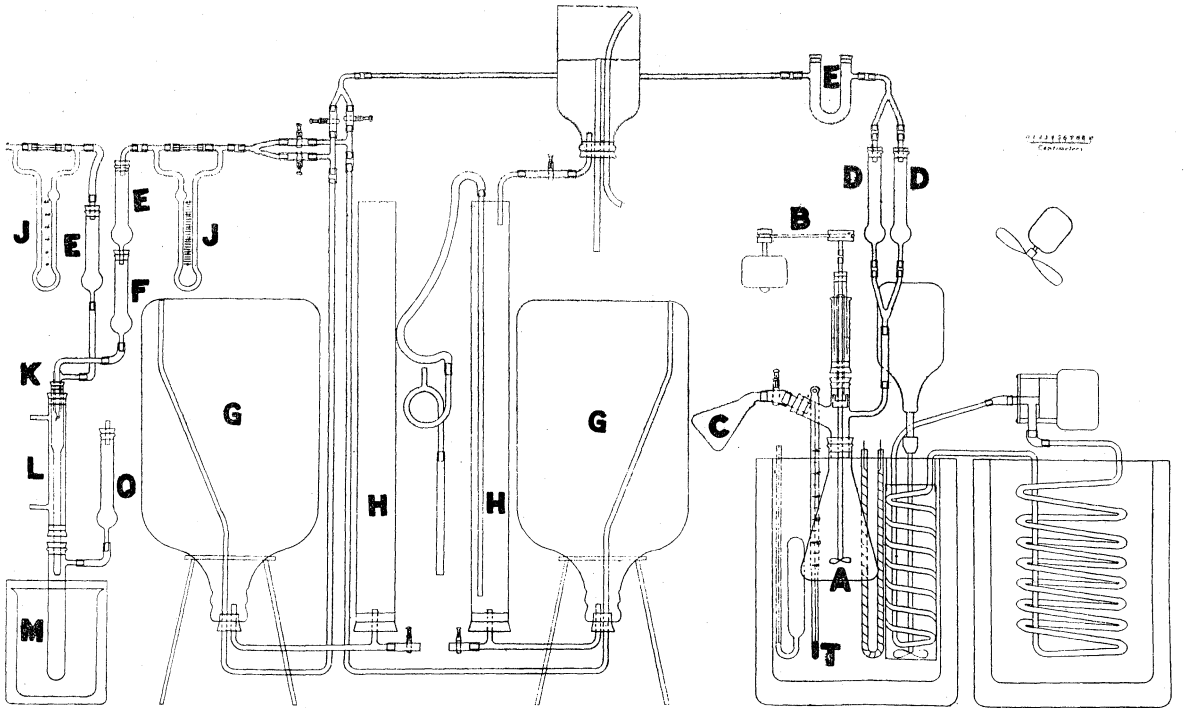

Fig. 1.—Reaction system: A, reaction vessel; B, stirrer; C, reagent flask; D,D,O, weighed $CaCl_2$ drying tubes; E,E,E, unweighed $CaCl_2$ drying tubes; F, sand trap; G, gas storage carboys; H,H, water levelling tubes to control pressure heads in the carboys; J,J, calibrated flowmeters; K, Pyrex oxyhydrogen torch; L, Pyrex condenser; M, ice-jacketed receiver; T, thermostat.

During the run the solid reagent was added slowly to the rapidly stirred liquid in the reaction vessel, and the evolved gas was: (1) dried, (2) collected over water (hydrogen sulfide and acetylene were collected over mercury), (3) redried and (4) burned in an excess of dry, tank oxygen.

Runs were permitted to go to completion (*i. e.*, until all of the weighed solid reagent had reacted). Twenty-four to sixty grams of combustion water was formed in each run and, since the reagents were added slowly for the faster reactions, the duration of each run was from twelve to forty-eight hours.

Full gravimetric data were taken (*cf.* Table III) and isotopic analyses were carried out for: (1) the initial water, acid or base and (2) the water formed by combustion. In a few instances densities were taken on water from the residual solution but these were not essential since the change in the deuterium concentration in the reaction flask can be determined more accurately from the mass and the D concentration of the water produced by combustion of the evolved gas than by a direct measurement. Correction was applied for the gas that remained in the reaction vessel or other portions of the reaction system.

(b) **Densimetric Analyses with the Buoyancy Balance.**—Analyses were based on the specific gravities of purified water samples and were made by the "free submerged float" method,[13] in which the temperature of the water sample is varied until the density matches that of a calibrated glass float. This is a method which we have used extensively in this Laboratory with excellent results.[4,8,10,14]

The 1.5-cc. Pyrex float was calibrated at frequent intervals against purified samples of Columbus tap water, and the calibration points were graphed against time. When first made the float came to equilibrium in pure normal water at 26.773° but the calibration temperature rose steadily over a period of several months. We attribute this to gradual solution of the outer surface of the float.[15]

Flotation temperatures of samples analyzed, relative to normal water, are considered reliable to within ±0.001 to 0.002° (2 to 5 γ in density). The densities of normal water between 25 and 30° were taken from the "International Critical Tables."[16] In computing the density differences correction was applied for the thermal expansion of the Pyrex float.[17]

It has been our experience that the limiting factor in the accuracy attainable with the buoyancy balance is ordinarily the purification of water samples for analysis. In this work we repeated the purification of samples until constant density (to within 1 p. p. m.) was obtained.

(13) T. W. Richards and G. W. Harris, THIS JOURNAL, **38**, 1000 (1916); G. N. Lewis and R. T. Macdonald, *J. Chem. Phys.*, **1**, 341 (1933).

(14) (a) R. D. Snow and H. L. Johnston, *Science*, **80**, 210 (1934); (b) W. H. Hall and H. L. Johnston, THIS JOURNAL, **57**, 1515 (1935); (c) *ibid.*, **58**, 1920 (1936). A more detailed description of our procedures in densimetric analyses will be published in the *Journal of the Ohio Academy of Science*.

(15) There appears to be some relation between this behavior and the dimensions of the float. Earlier calibrations of an 8-cc. Pyrex float showed little change in a period of several weeks.

Table I is an illustration for a particularly troublesome sample, for which the density changed by about 8 p. p. m. in the second and third processings.

TABLE I

PURIFICATION RECORD OF A TROUBLESOME SAMPLE

Processings	1	2	3	4	5
Flotation temp. (Beckmann), °C.	3.695	3.675	3.664	3.663	3.664

(c) **Reagents.**—**The deuterium-rich water** used in this investigation was prepared by ourselves out of old electrolyte from electrolytic hydrogen cells of the Capital City Products Co. of Columbus. Water distilled from this electrolyte was further electrolyzed between nickel or iron electrodes in potassium hydroxide solution to a volume fraction of approximately $1/16$, which resulted in water whose hydrogen content was approximately 0.5% in D. The alkaline solution was neutralized with excess carbon dioxide and the water distilled away from the sodium bicarbonate in a copper still and redistilled in Pyrex. While the O^{18} abnormality must have amounted to about 9 p. p. m. on the density of the water at the end of the electrolyses,[10] the carbon dioxide treatment must have nearly or completely removed this abnormality.[14c] We have therefore taken the initial water in the several runs as normal in its oxygen isotope ratio.

The acid solution was prepared by adding Baker and Adamson C. P. fuming sulfuric acid to a weighed amount of deuterium-rich water. A sufficient amount was prepared at one time to serve for all of the runs with metals. Its concentration was found, by titration with standard base, to be 6.983 equivalents per 1000 g. of acid. Its deuterium content was 0.400 atomic % of hydrogen. The latter was determined: (1) by a direct density measurement on a middle fraction of water distilled from the sulfuric acid solution and (2) by deuterium analysis on the original water and computation of the amount of dilution by normal hydrogen from the fuming sulfuric acid. The two analyses agreed to within 1 p. p. m. on the measured and computed densities.

A second quantity of acid was prepared in a similar manner for the ferrous sulfide run.

The **basic solution** was prepared with C. P. sodium hydroxide, in a similar manner. The strength of the solution was 3.340 equivalents per 1000 g. of base.

The oxygen used in the combustions was from a commercial cylinder and had been prepared from air by the Linde process. Its oxygen isotope composition, relative to air, was determined by comparison of densities of two water samples—one prepared by combustion of tank hydrogen in an excess of the tank oxygen, the other by combustion of the same tank hydrogen in air. The combustions were brought about in the burner K. This manner of combustion will, in itself, have produced no change in the isotopic composition of either the hydrogen or the oxygen.[14c] The two water samples agreed in density to within 0.5 p. p. m. Our combustion samples must, therefore, have possessed the same oxygen abnormality as oxygen in air. We have accordingly applied a correction of −6.5 p. p. m.[14c,18] to densities of *combustion waters only.*

(18) M. Dole, *J. Chem. Phys.*, **4**, 268 (1936). See also Table VI of the recent paper by Swartout and Dole, THIS JOURNAL, **61**, 2025 (1939).

Coleman and Bell standard laboratory quality sodium and potassium were employed. Thick slices of the outer surface were cut away, in an atmosphere of nitrogen, and the metals cut into small pellets. The lithium was a reputedly pure metal supplied by A. D. Mackay of New York. The calcium metal was in the form of thick, silvery chips and was packaged, without analysis, for a local supply house.

Two C. P. samples of zinc were employed. The granular zinc was a J. T. Baker product and bore an analysis on the label which showed only 0.024% of total impurity, of which 0.02% was Pb. The mossy sample was Baker and Adamson's C. P. mossy zinc with an analysis on the label which showed 0.05% Pb and 0.002% of other impurities.

Also two samples of iron were employed. One was a 99.8% pure sample, from J. T. Baker, while the other was from a stock supply of "commercial iron filings" and contained 10 to 15% of impurities, principally carbon.

The aluminum was a granular C. P. product of Coleman and Bell and the magnesium was purchased from a local supply house as "A1 turnings for Grignard reagent." Manganese, calcium carbide, aluminum carbide and ferrous sulfide were stock chemicals of unknown origin and purity. The three last, in particular, may have contained considerable impurity.

(d) **Temperatures.**—No effort was made to thermostat the reactions. However, most of the runs were carried out at room temperature, which usually varied between 25 and 30° during the period of the experiments, and can be directly compared. The other reactions were carried out by spraying hot water from the laboratory pipes (55–60°) onto the wall of the reaction flask in order to accelerate otherwise sluggish rates. This was done in both of the runs with aluminum in acid; in the second lithium run, in which lithium was added to an already strong solution of lithium sulfate; in both runs with granular zinc and in both runs with C. P. iron. Cold tap water was sprayed onto the reaction vessel during the runs with sodium and with potassium in order to maintain the reaction mixtures close to room temperature.

Because the reactions were run relatively slowly, the temperatures of the reaction mixtures can seldom have differed by as much as 5° from the wall of the flask.

Because of the extreme slowness with which aluminum reacted with the acid a small quantity of mercury was added to promote the reaction. For the same reason copper strips were added to the reaction vessel in Run 11, with granular zinc.

Experimental Data

(a) **Sample Data and Calculations for a Typical Run.**—Table II contains the data obtained in a typical run (magnesium with sulfuric acid).

The separation coefficient, α, is defined by the equation

$$d \ln H = \alpha d \ln D \qquad (2)$$

with the symbols H and D used to represent the H_2O and D_2O equivalents of the quantities of

TABLE II

SAMPLE DATA AND CALCULATIONS

Run 18, 42.50 g. of Mg added to an excess of 6.983 *N* H_2SO_4.

	Initial acid	Combustion H_2O	Residue in reaction flask
Weight, g.	958.27	31.35 (obs.)[19]	995.57[25]

Quantity of D (as D_2O)	3.06987	.08635	2.98352[24]
Quantity of H (as H_2O)	687.41013[21]	31.40365[20]	656.00648[24]

$$\alpha = \frac{\log (656.00648/687.41013)}{\log (2.98352/3.06987)} = 1.640$$

H and D, respectively, in the acid solution. The equation is integrated between initial and final amounts.

The good agreement between the observed[19] and calculated[20] weights of combustion water, and likewise the check on the gravimetric data through the observed and calculated weights of residue,[25] are good evidence against any significant amount of reduction by the reaction[26]

$$Mg + 2H_2SO_4 = Mg^{++} + SO_4^{=} + 2H_2O + SO_2 \quad (3)$$

Failure to observe an odor of sulfur dioxide in the slow streams of excess oxygen from the burner is further confirmation of this.

(b) Complete Tabulation for All Fifteen Reactions in Water of Approximate 0.5% D Content.—Complete tabulations of the essential experimental data for all runs in the fifteen reactions investigated, together with the values of α, are given in Table III. Except as noted, calculations were carried out in the same manner as illustrated by the run recorded in Table II. Temperatures were approximately 30°, with the exception of certain runs in which the reaction flask was heated to about 55°. These runs were referred to previously.

Run 1 is the preliminary run with sodium, previously reported.[4] Its value of α has been recomputed with corrections made for oxygen isotope abnormality in both the combustion water and the initial water and for the improved H/D ratio in ordinary water.

Comparisons[25] of the weight of residue found in the reaction vessel with that calculated from the initial weighings and the quantity of hydrogen (or hydrogen bearing gas) evolved are not included in the table. With few exceptions[27] calculated and observed weighings of residue agreed to within a few tenths of a gram. This can be considered to be within experimental limits of error. However, the observed amount of *combustion water* was usually *less* than the calculated weight. In some instances this was due to known accidental losses of hydrogen while the apparatus was allowed to run overnight, or to impurities in certain of the reagents (commercial iron, aluminum carbide and possibly calcium carbide, calcium and ferrous sulfide as examples). However, it can easily be shown that even relatively large errors in the *amounts* of combustion water, should they exist, do not affect the values of α significantly.

The precision with which α may be determined depends primarily on the precision with which compositions of Initial Water and of Combustion Water are determined. It can be shown, simply, that any percentage error in either of these compositions will influence α in the same proportion.

(19) The sum of: 29.55 g. collected in M (Fig. 1); 1.25 g. collected in O (no ice was on hand when this run was made); and 0.55 g. computed as the H_2O equivalent of an approximate 800 cc. of unburned H_2 left in the apparatus at the end of the run.

(20) Calculated from the weight of metal reacted.

(21) Corrected by 0.65 g. for loss of 1.31 g. of vapor to drying tube D.

(22) Corrected by 0.023° for the O^{18} abnormality of the tank oxygen.

(23) Wt. fractions were computed with the molecular weight values: H_2O = 18.0156, D_2O = 20.0283.

(24) Computed by difference between entries in the "Initial Acid" and "Combustion H_2O" columns.

(25) This weighing was taken as a check on the gravimetric data. It compares with the calculated value 996.06. The latter makes allowance for the 1.31-g. vapor loss to the drying tube D (ref. 21) and for the 3.60 g. of H_2 (0.25% in D) represented by the 31.35 g. of H_2O collected.

(26) The good gravimetric check on the weight of residue is significant in ruling out this reaction since SO_2 is 32 times as heavy as the equivalent amount of hydrogen. For example, in the run recorded in Table II, 100% reaction by (3) rather than by displacement would have liberated 32 × 3.60 = 115.2 g. of SO_2, a weight difference of 112.6 g., and 1% reaction by (3) would have therefore, introduced an error of +1.13 g. in the computed weight of residue. The observed discrepancy is only 0.5 g. and is within limits of error.

(27) Among the reactions that evolve H_2 (Runs 1 to 26 inclusive) only Runs 9, 10 and 13 showed disagreements in the gravimetric data amounting to more than 1 g. The average disagreement in this group (Runs 9, 10 and 13 not included) was ±0.4 g. In Run 13 the disagreement was 2.9 g. and for the combined K runs it was 11 g. The 11-g. disagreement in the gravimetric data for the K runs may be due in part to the presence of K_2O, which would not have been distinguished from 2K in the titrations of residue. We also encountered experimental difficulties resulting from explosions of small pieces of potassium in the reaction vessel, that caused some losses of material and weakened the validity of any gravimetric comparison. It can easily be shown, however, that the experimental values of α cannot have been influenced by these difficulties by more than a few hundredths of a unit.

The gravimetric check was less accurate with the residues from runs 27–32 inclusive. With CaC_2 the average disagreement was 3 g.; with Al_4C_3, 1 g.; and with FeS, 10 g. With CaC_2 and Al_4C_3 the disagreements may be accounted for by not unreasonable losses of hydrocarbon gases from the stirrer or gas train. It is possible that soluble impurities in the FeS may have been responsible, in whole or in part, for the relatively large discrepancy in the observed and calculated weight of residue in that reaction.

TABLE III

GRAVIMETRIC AND DENSITY DATA, AND VALUES OF THE ISOTOPIC SEPARATION FACTOR, FOR ALL RUNS WITH APPROXIMATE 0.5% D CONTENT IN THE INITIAL WATER[28]

Run	Reaction	Amounts, grams: Metal[29] (or compound)	Amounts, grams: Initial liquid	Relative flotation temps., °C.: Combustion water[30]	Relative flotation temps., °C.: Initial water	Relative flotation temps., °C.: Combustion water[22]	α

If we take the ΔT's of flotation to be reliable to within about 0.004° (equivalent to 1 p. p. m. in density) in the present group of runs, this would amount to about ±2% in the precision of the values for α, for the majority of runs. This corresponds pretty closely to the reproducibilities observed in the experimental α's. Other factors, including inaccuracies in temperatures for certain of the runs, may increase the limits of error to ± about 5% for purposes of comparison with other work.

(28) Acid and basic concentrations of solutions used were as follows: Runs 11–24, 3.492 moles of H_2SO_4 per 1000 g. of acid; Runs 25–26, 3.340 moles of NaOH per 100 g. of base; Runs 31–32, 3.487 moles of H_2SO_4 per 1000 g. of acid.

(29) The amounts of Na, Li and K used in runs with the alkali metals were determined by titrations of the alkaline solutions left in the reaction vessel. Except for K, which may have been contaminated with K_2O, these calculations agree well with those based on the amounts of combustion water collected as well as with those based on the weights of residues in the reaction flask.

(30) The values recorded in this column for runs with the alkali metals, *commercial* iron, and the compounds CaC_2, Al_4C_3 and FeS are the observed weights of combustion water (with corrections applied for water collected in the drying tube O and for the water equivalent of unburned gas in the apparatus). Values for all other runs were computed from the weights of reacted metal.

(31) Runs 2, 3 and 4 with Na form a single series which were carried out by adding successive portions of metal to an original 849.7 g. of water, and collecting three successive fractions of combustion water. The residue was weighed and titrated only after all 367.9 g. of Na had been added. In computing α's we have calculated the amounts of H and of D present in the reaction vessel after removal of each of the three fractions of combustion water, by subtracting from the original amounts the quantities of H and D collected in the receiver (corrected for losses to the $CaCl_2$ tubes and for H_2 in the apparatus). Each α is therefore an individual value at the mean alkalinity of each of the three successive runs—not a cumulative value. Runs 5 and 6, with Li, and 9 and 10, with K, were carried out in a similar manner except for the fact that only two fractions of combustion water were taken.

Hughes, Ingold and Wilson[6] criticized the accuracy of our preliminary determination[4] of α for the Na–H_2O reaction (Run 1 of Table III) on the grounds that it was somewhat sensitive to the choice of the H/D ratio in ordinary water. Due to improvements in the determination of the latter ratio, which is now known to within relatively close limits,[10,32] and to three-fold increase in the deuterium concentration of the starting water, the inaccuracy from this source cannot exceed 1 or 2% in the least favorable runs reported in the present paper (Run 1 not included).

(c) **Reaction at High Concentration of Deuterium.**—A. and L. Farkas[3] have published results for displacement reactions with water and acid 25 mole % in deuterium. For calcium they obtained a value for α (1.5) close to our own with 0.5% D. But with sodium, zinc and aluminum, respectively, their values of α were only about one-half of ours.

To check whether or not these results were due to a real dependence on the deuterium composition we carried out a single careful run with sodium in water of approximately 30 mole % deuterium. The reaction was carried out in the same manner as for the 0.5% D runs except that a smaller reaction vessel was employed and that no cooling water was used. Although special care was taken to add the sodium slowly the (undetermined) temperature of the reaction mixture must have been somewhat above that of the previous, water-cooled sodium runs. Specific gravities of the initial water and of the combustion water were made by pycnometer, in an approximate 11-cc. pycnometer of special design. The significant data of this run are entered in Table IV, together with the value of α.

TABLE IV

DATA ON REACTION OF Na WITH WATER 31.083 MOLE % IN D (56.12 G. OF Na ADDED TO 116.21 G. OF INITIAL WATER)

	Amounts, grams	Sp. gravity, d^{26}_{26}	Composition, wt. per cent. of D
Initial water	115.70[33]	1.03372	33.396
Combustion water	20.64 (obs.)[34]	1.01780	17.893
Final residue water	95.06[35]		36.761[35]

α = 2.473.

Aside from the possible influence of a small temperature coefficient in the separation efficiency the value of α obtained from this run should be reliable to the four figures recorded. It is seen that the results do not agree with those of A. and L. Farkas with 25% heavy water (α = 1.2, which corresponds to only 13% of the separation efficiency observed by ourselves) but agree well with our own results in water of 0.5% D.

We made no check of the Farkas values for zinc and aluminum in acid of high D content.

Discussion of Results

It is apparent that the displacement reactions, and the reactions with the carbides and with ferrous sulfide, bring about isotopic separations that are properly characterized by definite coefficients (α's) that are relatively insensitive to experimental conditions other than temperature[8] and the purity of reagents. The values of these coefficients lie on both sides of the equilibrium α for the exchange equilibrium between gaseous and liquid phases, which is close to 3.0 at 30°.[36] From this it is apparent that differences in reaction *rates* contribute to the separation.

There appear to be definite, though small, increases in α with increase in alkalinity of the reaction mixture for the alkali metal–water reactions. This conclusion is based on trends observed in series of runs with sodium (Runs 2–4), lithium (Runs 5–6) and potassium (Runs 9–10). The trends are within error limits but seem too often repeated to be fortuitous. There is nothing to distinguish between *p*H and ionic strength as cause for the trends, but the point of greatest significance appears to be that neither of these factors has more than a barely significant influence on α. For example, in the series of runs with sodium the sodium hydroxide concentration varied from 0 at the initiation of the runs to 28.3 *M* at their conclusion. Average sodium hydroxide molalities for the three successive runs were 3.07, 11.1 and 22.2, respectively. Yet α changed by only 0.1 unit.

We confirm the observations of Ingold and coworkers regarding the relatively large influence of impurities in the reacting metals. The α's

Japan*, **11**, 403 (1936); *ibid.*, **13**, 419 (1938); Hall and Jones, THIS JOURNAL, **58**, 1915 (1936); Gabbard and Dole, *ibid.*, **59**, 181 (1937); Swartout and Dole, *ibid.*, **61**, 2025 (1939).

(33) This includes a correction of 0.51 g. for 1.02 g. of water vaporized during the run.

(34) This compares with a calculated value of 22.4 on the basis of 56.1 g. of Na, assumed pure.

(35) Computed from the data for initial and combustion waters. The computed and observed values of total residue in the reaction flask agree well for this run. Thus, the computed value of the residue is 169.01 g. while the observed value was 168.90 g.

(36) L. and A. Farkas, *Trans. Faraday Soc.*, **30**, 1071 (1934).

in Runs 21 and 22, with impure iron, are almost a full unit below those in Runs 19 and 20, with pure iron. The α's in our Runs 23 and 24, with impure manganese, are lower than the value obtained by the extrapolation of Johnston and Hall's data,[8] who used pure manganese, by about the same amount. Accidental entrance of mercury into the reaction vessel during Runs 14 (Zn, H_2SO_4) and 26 (Al, NaOH) do not appear to have influenced the α's beyond the limits of experimental accuracy, but the mercury may not have become intimately mixed with the metals.

The order of the α's, among the displacement reactions, at 30° is: Ca, K, Mg, Li, Na, Al, Mn (pure[8]), Zn, Fe. This follows the order found by Hughes, Ingold and Wilson, at 90°: Li, Ca, K, Mg, Na, Al, Fe, Mn, Zn, except for the positions of Li and of Fe. Extrapolation of the curves of Johnston and Hall[8] to higher temperatures would give the order Zn, Mn, Fe at 90°, which is the reverse of the order reported by Hughes, Ingold and Wilson.

It is interesting to observe that the α's for the three metathetic reactions (CaC_2, H_2O; Al_4C_3, H_2O; FeS, H_2SO_4) are nearly identical.

There have been direct comparisons of heterogeneous reaction velocities with H_2O and D_2O, respectively, for the Al_4C_3–H_2O reaction. Urey and Price[37] reported the very high value of 23 for the ratio of reaction rates at 80°. This is ten times higher than our measured α at 30°. However, Barrer,[38] who used a more careful procedure obtained a reaction velocity ratio of 3.9 at 0°.

One of us has taken some preliminary data on reaction rates of aluminum with 4.5 *N* sulfuric acid, at 50°, as a function of the H/D ratio in the aqueous acid.

The results of these experiments are shown in graphical form in Fig. 2, where the rates are shown relative to the rate with ordinary 4.5 *N* sulfuric acid taken as unity. Each point on this graph is the average of two independent rate determinations with the same lot of acid. It is apparent that the reaction rate is linear with the D concentration, to within the limits of error, and that extrapolation to 100% D gives a reaction rate of about half that with acid 100% in H. This does not compare very accurately with the α of 4.5 found by us in the Al–H_2SO_4 reaction. However, the conditions of reaction may not have been comparable, due to the presence of mercury in runs (15–16). Probably, both in this comparison and in that with aluminum carbide, the agreements obtained are as close as could be expected under the conditions of experiment. Investigations on reactions more suitably chosen for this comparison are in progress in this Laboratory.

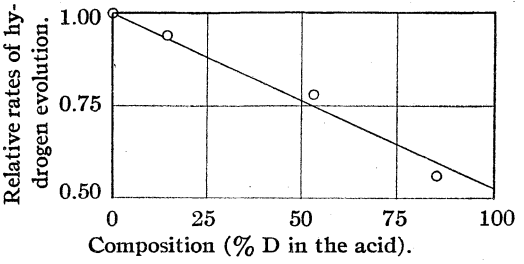

Fig. 2.—Relative velocities of the dissolution of aluminum in 4.5 *N* sulfuric acid, at 50°, as a function of the H/D ratio in the acid.

We accept the suggestion of Horiuti and Szabo[5] that the α's of displacement reactions are not necessarily the ratios of reaction velocities in pure H and pure D media, respectively, since the character of the reaction mechanism may lead to rates that are not strictly proportional to the relative numbers of H and D atoms. However, we fail to perceive the validity of their argument that the α for sodium cannot be the ratio of reaction rates since they obtained the same degree of isotopic separation in the reaction of water vapor with *excess* sodium as we had obtained in the reaction with excess liquid water. In view of our observation that α remains constant, within error limits, between 0.5 and 30% heavy water, it appears that the relative reactivities of OH and OD linkages remain the same when OH and OD are in the same molecule (*i. e.*, HDO) as when they exist in different molecules (*i. e.*, H_2O and D_2O).

To us, it seems of greater significance to stress the observation that Horiuti and Szabo obtained nearly the same α's[39] with *water vapor* as we obtained with *liquid water*, since the reaction with water vapor is clearly a molecular, as distinct from an ionic, mechanism. This implies that the reaction of the alkali metals with *liquid water* occurs by a molecular mechanism—a conclusion reached by Hughes, Ingold and Wilson by other reasoning, and previously suggested by Polanyi, who pic-

(38) R. M. Barrer, *Trans. Faraday Soc.*, **32**, 486 (1936).

(39) Horiuti and Szabo did not compute α's for their four runs (two with sodium in excess and two with water vapor in excess) but tabulate data which we have used to compute their α's. The four runs yield an average α of about 2.2, with extremes of about 2.0 and 2.4, respectively.

tures[6] "the attachment of water molecules through their oxygen atoms to the metallic surface, and the subsequent elimination of hydrogen from two bound molecules in accordance with the (bond activation) mechanism of Horiuti and Szabo."

A fuller discussion of mechanisms will be left to the following paper.[8]

Summary

Quantitative data were secured on the extent of isotopic separation which occurs in the following respective reactions which liberate hydrogen or gaseous hydrides: Li, Na, K, Ca, CaC_2 and Al_4C with water; Mg, Zn, Fe, Mn, Al and FeS with aqueous sulfuric acid; and aluminum with aqueous sodium hydroxide. With a few exceptions the runs were made at or near room temperature. The hydrogen and hydrides were burned in a flame, with a slight excess of tank oxygen, and the water of combustion carefully purified and analyzed for its hydrogen isotope proportions by the free submerged float method. Correction was applied for the O^{18} abnormality of the tank oxygen, which was separately determined.

The data were quite reproducible, for a given set of reagents, and confirm the applicability of the quantitative relationship $d \ln [H] = \alpha d \ln [D]$, in which [H] and [D] are instantaneous values of the amounts of protium and deuterium, respectively, in the liquid phase, and α is the "isotopic separation factor," different for each reaction. The form of this relationship is identical with that which pertains to the isotopic separations by electrolysis.

A discussion of regularities observed in the results, and their bearing on some phases of the reaction mechanism is included.

Iodine Monochloride. IV. The System Potassium Chloride–Iodine Monochloride[1]

BY JACOB CORNOG AND ELDON E. BAUER[2]

This paper describes a series of studies in which existing vapor pressure data of iodine monochloride have been extended, the system potassium chloride–iodine monochloride has been formulated, and earlier work with the polyhalides potassium dichloroiodide, KCl·ICl or $KICl_2$, and potassium dibromoiodide, KBr·IBr or $KIBr_2$, has been reviewed.

1. The Vapor Pressure of Iodine Monochloride.—The vapor pressure of iodine monochloride was measured by Cornog and Karges,[3] who used the static method of Smith and Menzies[4] for measurements within the temperature range 35 to 70°. A modified form of the dynamic method of Pearce and Snow[5] was used to measure all of the vapor pressure data included in this paper. The vapor pressure of iodine monochloride was measured between the temperatures −15 and 50°. This served both to validate the method and to extend existing data. The iodine monochloride used in these measurements froze at 27.3°. Measurements were made in a thermostat in which temperatures were constant within ±0.02°. Vapor pressure measurements were reproducible within ±0.1 mm. at low pressures and ±0.3 mm. at higher pressures. The vapor pressure data for iodine monochloride are shown in Table I and are graphically represented in Fig. 1.

fort was expended in attempts to measure the vapor pressures of the labile beta form of iodine monochloride. While the labile form was readily obtained, transformation to the stable form was too rapid to permit vapor pressure measurements by this method.

The data in Table I may be used to calculate the heats of vaporization, sublimation and fusion of iodine monochloride by use of the Clausius–Clapeyron equation. By this means the heat of vaporization of iodine monochloride was found to be 9950 cal./mole, the heat of sublimation was 11,800 cal./mole. By difference the heat of fusion was found to be 1850 cal./mole.

2. Potassium Dichloroiodide, KCl·ICl or $KICl_2$.—Some earlier workers[6,7,8] have applied this name and formula to a compound, perhaps the hydrate, having a much lower melting point than the product obtained in this Laboratory. The hydrate is discussed in Part 7. Anhydrous potassium dichloroiodide is formed when equal molecular quantities of potassium chloride and iodine monochloride are joined in a glass-stoppered bottle and maintained at or somewhat above room temperature for several weeks. The initial mixture, nearly black in color, slowly changes to the bright orange-yellow characteristic of this compound. This compound melts sharply at 195° in a closed glass tube, and is so stable that a specimen was kept in a glass-stoppered bottle for more than one year with less than 1% loss in weight. The dissociation pressure of potassium dichloroiodide was measured by use of the method mentioned in Section 1 (see Table II).

TABLE II

THE DISSOCIATION PRESSURE OF POTASSIUM DICHLOROIODIDE

1 Temperature, °C.	2 Dissociation pressure, mm.
25	0.20

40	.55
45	.70
50	1.00
55	1.35
60	1.80

The probable limit of accuracy of the figures in column 2 is 0.05 mm.

3. Potassium Trichlorodiiodide, KCl·2ICl or KI_2Cl_3.—This compound has not been reported previously. It is the stable solid phase formed when solutions of potassium chloride in iodine monochloride are brought to crystallization at temperatures below 45°. The needle-like crystals are nearly black when viewed in masses but are ruby-red in thin sections. In a closed tube these crystals melt at 45° but when exposed to the air at room temperature they decompose rapidly into potassium dichloroiodide crystals and iodine monochloride vapor. The composition of these crystals was determined by (a) determining the loss of weight on heating and (b) determining the iodine monochloride content. The latter was accomplished by converting the iodine monochloride in the crystals to free iodine by means of potassium iodide and titrating the free iodine with sodium thiosulfate solution. These data are shown in Table III.

(7) Ephraim, *Ber.*, **50**, 1069 (1917).
(8) Cremer and Duncan, *J. Chem. Soc.*, 1857 (1931).

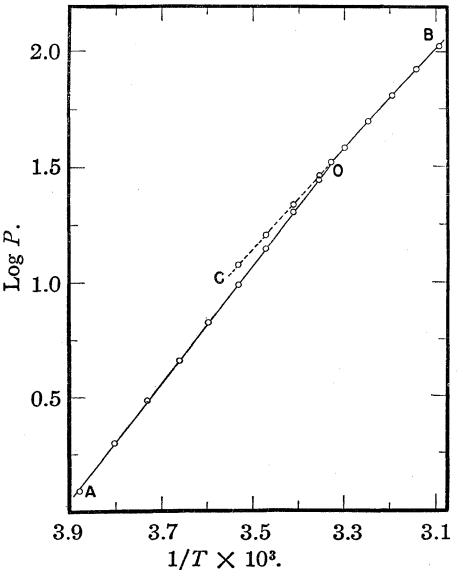

Fig. 1.—Vapor pressure of iodine monochloride: Point O is 27.3° the m. p. of ICl, AO vapor pressure solid ICl, OB is the vapor pressure of liquid ICl above the m. p., OC is the vapor pressure of undercooled ICl.

TABLE III

(a) Loss of weight on heating	Run 1	Run 2
Sample taken, g.	0.954	0.351
Wt. KCl obtained, g.	.1726	.064
Calcd. wt. KCl·2ICl	.924	.343
(b) By $Na_2S_2O_3$ titration		
Wt. of sample, g.	0.200	
Vol. 0.0966 N $Na_2S_2O_3$, ml.	21.67	
Equiv. of oxidizing halogen	0.00209	
Calcd. equiv. of oxidizing halogen	.00200	

Inspection of Table III part (a) shows that the "Sample taken" is greater than the "Calculated weight of KCl·2ICl" by 3% in Run 1 and by 2% in Run 2. This discrepancy is probably caused by the fact that the potassium dichloroiodide crystals are very fine needles and were crystallized from iodine monochloride solution, some of which adhered to the crystals and was lost when the crystals were heated.

The method mentioned in Section 1 was used to get the dissociation pressure data shown in Table IV, which are represented graphically in Fig. 2.

In Fig. 2 the line OB represents the vapor pressure of the univariant system potassium trichlorodiiodide–potassium dichloroiodide–vapor. The line OA represents the univariant system potassium trichlorodiiodide–solution–vapor. The point O (45°) represents the invariant system potassium trichlorodiiodide–potassium dichloroiodide–solution–vapor. Below 45° potassium trichlorodiiodide is the stable phase in equilibrium, while above 45° potassium dichloroiodide (*cf.* Section 4) is the stable phase in equilibrium with saturated solutions. The apparent melting that occurs when potassium trichlorodiiodide is heated to 45° in a closed tube is, in reality, the decomposition of

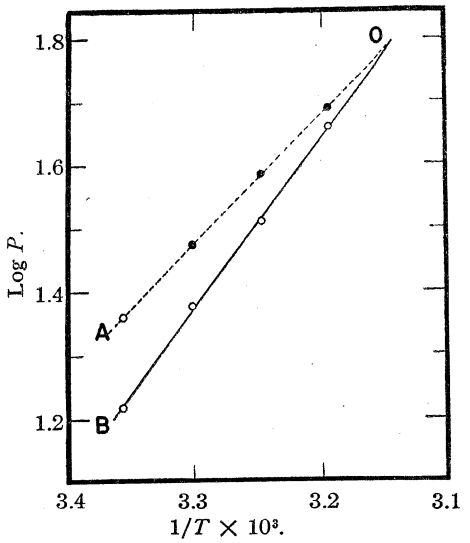

Fig. 2.—The line OB, dissociation pressure of KI_2Cl_3, intersects the dotted line, vapor pressure of saturated KI_2Cl_3 solution, at 45° the melting point of KI_2Cl_3.

solid potassium trichlorodiiodide into solid potassium dichloriodide and saturated solution of potassium dichloroiodide in iodine monochloride. Cremer and Duncan[9] have suggested similar ideas regarding the melting points of polyhalide compounds.

TABLE IV

DISSOCIATION PRESSURE OF POTASSIUM TRICHLORODIIODIDE

1	2	3
Temp., °C.	Dissociation pressure KI_2Cl_3, mm.	V. p. satd. soln. KI_2Cl_3 in ICl, mm.
15	8.3	...
25	16.5	23.05
30	23.8	29.8[a]
35	32.5	38.5[a]
40	45.6	48.5[a]

[a] Calculated by assuming that vapor pressure lowering is proportional both to the quantity of dissolved potassium chloride and to the vapor pressure lowering at 25° and by applying this assumption to the experimental data in Tables I, V and VI.

4. The Potassium Trichlorodiiodide–Potassium Dichloroiodide Transition Temperature.—The location of this transition temperature was learned by getting the solubility curves of the tri and pentahalide compounds and observing where the two curves intersected (see Table V and Fig. 3). Each solubility datum in Table V was obtained by saturating iodine monochloride, contained in a flask, with potassium chloride at a temperature well above that at which solubility was later measured. The flask containing the saturated solution was plugged with glass wool and placed in a thermostat in which the temperature variation did not exceed ±0.02°. Equilibrium between the solid and the solution was assumed to exist when the potassium chloride content of successive portions of saturated solution removed at twenty-four to forty-eight hour intervals were in agreement. The glass wool plugs served as filters in removing such portions. The potassium chloride content of portions thus removed was determined by weighing the portion, removing iodine chloride by heating and weighing the potassium chloride residue. Separate experiments were performed to establish the identity of the solid phases by methods previously described by Cornog and Olson[10] (see Table V and Fig. 3).

5. The Vapor Pressure of Solutions of Potassium Chloride in Iodine Monochloride.—The general procedure described in Part 1 was used to obtain the vapor pressure of solutions of potassium chloride in iodine monochloride as recorded in Table VI and graphically represented in Fig. 4.

The calculations used in getting the figures in column 5 Table VI and the dotted line in Fig. 4 are based on the assumption that the dissolved potassium chloride, or the derived solute, is dissociated into two ions, each of which

(10) Cornog and Olson, THIS JOURNAL, **62**, 3328 (1940).

TABLE VI

THE VAPOR PRESSURE OF SOLUTIONS OF POTASSIUM CHLORIDE IN IODINE MONOCHLORIDE AT 25°

1 Mole fraction KCl	2 P, mm.	3 [a] $P_0 - P$, mm.	4 $(P_0 - P)/P_0$	5 $(P_0 - P)/P_0$ calcd.
0.005	29.00	0.30	0.010	0.0099
.02	28.30	1.00	.034	.0392
.04	27.25	2.05	.070	.0769
.05	26.45	2.85	.097	.0952
.06	25.85	3.45	.118	.1131
.0875	24.05	5.25	.197	.1608
.1015[b]	23.05	6.25	.213	.1843

[a] $P_0 = 29.3$ (Table I). [b] Saturated.

acts as a perfect solute. At the lower concentrations, the observed vapor pressure lowering is less than, and at higher concentrations, greater than the calculated values.

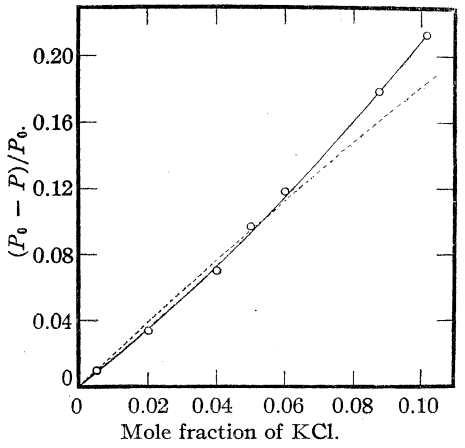

Fig. 4.—The vapor pressure of KCl–ICl solutions. The solid line represents experimentally determined values of vapor pressure lowerings. The dotted line represents calculated vapor pressure lowerings assuming dissociation of the solute into two different ions.

Although these data are probably insufficient in quantity and precision to warrant calculations of activities, they serve as the basis of the tentative conclusion that potassium chloride, or its derivative, is ionized in iodine monochloride. Further, since the crystalline material separating from the solution at 25° is represented by the formula KI_2Cl_3, the tentative inference is drawn that the ions in solution are probably represented by the formula K^+ and $I_2Cl_3^-$. The data in Table VI are also used in plotting curve AB Fig. 5, Section 6.

6. The System Potassium Chloride–Iodine Monochloride.—The vapor pressure data in the preceding sections have been used to construct the vapor pressure–composition diagram of the system potassium chloride–iodine monochloride at 25° as shown in Fig. 5.

The similarity in general outline between Fig. 5 and corresponding diagrams for hydrate systems is obvious.

7. Potassium Dichloroiodide Monohydrate, $KCl{\cdot}ICl{\cdot}H_2O$.—This compound is obtained when the product mentioned in Section 2 is recrystallized from water solution. The hydrated crystals thus obtained are much like potassium dichromate in general appearance and melt at 43°

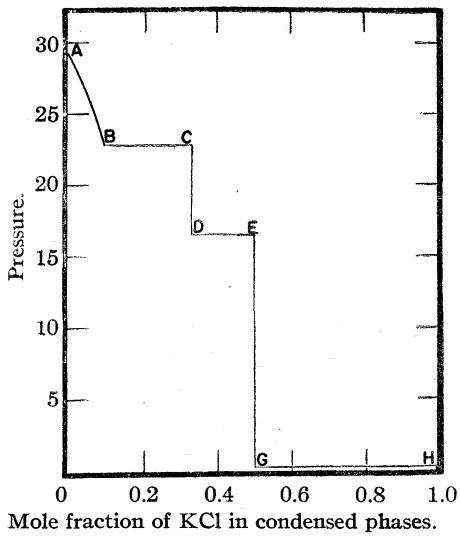

Fig. 5.—Vapor pressure–composition diagram of the system KCl–ICl at 25°: AB represents the vapor pressure of unsaturated solutions of KCl in ICl. At B solid KI_2Cl_3 begins to form and continues to C where the liquid phase disappears. DE represents the KI_2Cl_3–$KICl_2$ equilibrium at constant pressure. At E only $KICl_2$ is present. GH represents the $KICl_2$–KCl equilibrium at constant pressure. At H only KCl is present.

in a closed tube. The composition of the hydrated crystals was estimated by heating weighed portions in an oven at 110° to constant weight. These data follow.

	1	2
Weight of sample taken, g.	3.572	2.342
Weight of KCl residue, g.	1.045	0.686
Calcd. corresponding wt. $KICl_2$	3.321	2.180
Calcd. corresponding wt. $KICl_2{\cdot}H_2O$	3.573	2.346

An indication of the water content of the hydrated crystals was given by the weight of the residue obtained when crystals were dried in a desiccator over phosphorus pentoxide.

Weight of sample, g.	1.570
Weight of residue from drying with P_2O_5	1.452
Weight of sample calcd. from wt. residue	1.562

The melting point of the material changed from 43° before drying to approximately 195° after drying. A small quantity of iodine monochloride was doubtless lost in drying.

The dissociation pressure of the monohydrate, Table VII, was measured in such a way as to distinguish between the partial pressures of water and of iodine monochloride.

The segregation and estimation of the partial pressures of water vapor and iodine monochloride vapor which together made up the dissociation pressure of the monohydrate, was accomplished by passing the vapor from dissociation through two absorbers arranged in series. The first absorber, containing phosphoric anhydride, retained water vapor but passed iodine monochloride vapor, while the second absorber contained soda lime and retained iodine monochloride vapor.

TABLE VII

THE DISSOCIATION PRESSURE OF $KCl \cdot ICl \cdot H_2O$

1	2	3	4	5
Temp., °C.	P_{ICl}, mm.	P_{H_2O}, mm.	$P = P_{ICl} + P_{H_2O}$, mm.	Interpolated Cremer and Duncan dissociation pressure, mm.
25	0.1	9.9	10.0	9.2
30	.2	15.0	15.2	14.2
35	.4	20.6	21.0	20.6
40	.7	29.6	30.3	29.5

The data in column 2 show that the partial pressure of iodine monochloride in the hydrated compound is virtually the same as the dissociation pressure of anhydrous potassium dichloroiodide (see Part 2). Comparison of columns 2 and 3 indicates that the dissociation pressure of the hydrate is due almost entirely to the partial pressure of water vapor. Comparison of columns 4 and 5 indicates that the substance measured by Cremer and Duncan[11] was probably the hydrate.

The preparative methods described by Ephraim[7] were repeated in this Laboratory. The compound thus obtained was identical in properties with the monohydrate described above.

8. Potassium Dibromoiodide, KBr·IBr or $KIBr_2$, and Potassium Dibromoiodide Monohydrate, KBr·IBr·H_2O or $KIBr_2 \cdot H_2O$.—Potassium dibromoiodide was prepared by Cremer and Duncan[1] by exposing "dry" potassium iodide to bromine vapors in a desiccator for three days. The product thus obtained melted at 58–60° and was converted to potassium dichloroiodide by chlorination. When this work was repeated in this Laboratory, several weeks were required for potassium iodide to absorb the theoretically required quantity of bromine, the resulting potassium dibromoiodide melted in a closed tube at 180° and the rate of conversion to the dichloroiodide by chlorination was so slow as to render the method impractical. Upon recrystallizing the potassium dibromoiodide of melting point 180° from water solution, the resulting crystals melted at 58° in a closed tube. The composition of the material crystallized from water solution is indicated by the following data.

A. Loss of weight on heating crystals ($KIBr_2 \cdot H_2O$)	
Weight of sample taken, g.	0.961
Weight of KBr residue, g.	.332
Calculated weight assuming $KIBr_2$	.910
Calculated weight assuming $KIBr_2 \cdot H_2O$	.960
B. Loss of weight $KIBr_2 \cdot H_2O$ by drying over P_2O_5	
Weight of sample taken, g.	3.290
Weight of residue after drying with P_2O_5	3.104
Weight of sample computed from wt. of residue assuming $KIBr_2H_2O$	3.280

These data and the melting point data together indicate that the low melting substance is potassium dibromoiodide monohydrate while the high melting substance is potassium dibromoiodide.

Potassium dibromoiodide of melting point 180° is expeditiously prepared by joining equivalent quantities of potassium iodide and bromine in a glass-stoppered bottle, at room temperature. The initially nearly black mixture begins to assume the bright red color of potassium dibromoiodide in a day or two and the reaction goes to completion in about a week.

(11) Cremer and Duncan, *J. Chem. Soc.*, 2245 (1931).

Summary

1. A dynamic method has been used to measure the vapor pressure of iodine monochloride between −15 and 50°. These data have been used to compute the heats of fusion, vaporization and sublimation of iodine monochloride.

2. Potassium dichloroiodide has been prepared by the direct union of iodine monochloride and potassium chloride. The dissociation pressure of this compound has been measured.

3. A new compound, potassium trichlorodiiodide, has been prepared by direct union of iodine monochloride and potassium chloride at temperatures below 45°. The dissociation pressure of the compound has been measured.

4. Solubility curves for potassium dichloroiodide and potassium trichlorodiiodide in iodine monochloride have been plotted and the transition temperature between these compounds has been established at 45° from the intersection of these curves.

5. The vapor pressure–composition relations for the system potassium chloride–iodine monochloride have been formulated.

6. Methods for preparing both the anhydrous and hydrated forms of potassium dichloroiodide and potassium dibromoiodide have been described. The melting points of all four different compounds have been determined.

Compound Formation between the Isomeric Phenylphenols and Pyridine

BY STEWART E. HAZLET AND RAYMOND W. MORROW

In the course of some synthetic work which was reported earlier,[1] heat changes were noted when the phenylphenols were dissolved in pyridine, and the effects for the isomeric phenols were different: (a) with *o*-phenylphenol, there was evidence of a definitely exothermic reaction; (b) practically no temperature change was noted when the meta isomer was dissolved in the base; (c) the temperature was lowered slightly upon dissolving *p*-phenylphenol in pyridine.

In an attempt to gain some insight into the types of changes involved in these situations, especially to determine the character of compound formation if any, thermal analyses of the three binary systems were made—freezing point-concentration curves were obtained—in much the same manner as in Kendall's studies.[2]

Experimental Part[3]

A. Purification of Materials

Pyridine.—Pyridine was allowed to stand over sodium hydroxide pellets for from six to eight weeks and then distilled through a 30-cm. Vigreux column. The middle fraction with a boiling range of not over 0.5° was collected. Different lots had $n^{21}D$ varying between 1.5089 and 1.5087.[4] It was stored in a brown glass-stoppered bottle, and over a period of two months the change in $n^{21}D$ was never more than 0.0002. The freezing point (from cooling curve) was −41.7°.[5]

o-Phenylphenol.—Eastman Kodak Company best grade product was recrystallized from ligroin, which had been dried over sodium hydroxide pellets and distilled from 70 to 80°. After standing in a vacuum desiccator containing paraffin shavings, the product had a freezing point (from cooling curve) of 57.1°.[6]

m-Phenylphenol.[7]—The *m*-phenylphenol was recrystallized from carbon tetrachloride ("analytical reagent") and allowed to stand in a vacuum desiccator in the same manner as described for the ortho isomer. The freezing point (from cooling curve) of the product was 75.3°.[8]

p-Phenylphenol.—Eastman Kodak Co. *p*-phenylphenol was recrystallized from carefully dried and redistilled benzene and placed in a desiccator as indicated for the other phenols. The freezing point (from cooling curve) of this material was 165.1°.[9]

B. Apparatus

The apparatus used in this work was essentially the same as that conventionally employed in such experiments. It consisted of a 2 cm. × 15 cm. "Pyrex" test-tube fitted with a two-hole cork covered with tin foil. Through one hole there was the appropriate thermometer and through the other there was a short glass sleeve through which the stirrer passed. This inner vessel was surrounded by another test-tube with a diameter about 7 mm. greater than the smaller one; this provided an air jacket to smooth out and to retard the rate of cooling or heating. The whole apparatus was securely clamped in a larger beaker or unsilvered Dewar flask which served as a control bath. The materials in this bath were varied to suit the range of temperatures involved; in order of decreasing temperature they were: cottonseed oil, water, ice–water, ice–salt–water, and ethyl acetate–methanol–solid carbon dioxide. For temperatures above −10°, a set of 15-cm. Anschütz pre-

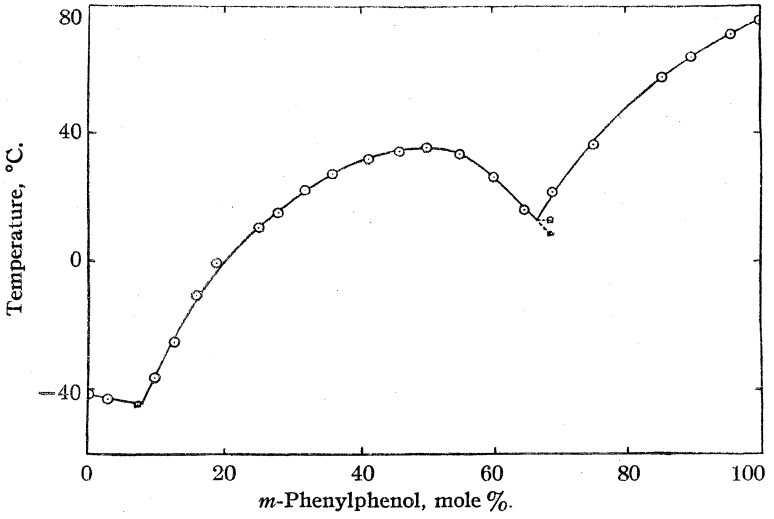

Fig. 2.—*m*-Phenylphenol + pyridine: ⊙, freezing point; ⊡, eutectic temperature; ◬, freezing point, metastable state.

cision thermometers graduated in one-fifth degrees was used for determining freezing points. These were calibrated against a thermometer certified by the United States Bureau of Standards. For temperatures below −10°, a −50 to 50° alcohol thermometer graduated in one-fifth degrees was used. This thermometer was calibrated against the freezing points of mercury and water. The temperature of the outer bath was determined by an ordinary laboratory thermometer when above 0° and by a copper–constantan thermocouple when below that temperature. As an aid in observing temperatures, which were read to the nearest 0.1° through a magnifying glass, and the condition of the material in the reaction tube, a source of light was placed in the rear of the apparatus. In the study of the *p*-phenylphenol–pyridine system where temperatures near or above the boiling point of pyridine were involved, the stirrer was dispensed with and only a thermometer in a tight-fitting cork was used; mixing was accomplished by shaking the melted material; no loss of pyridine was detected.

C. Procedure

The phenols were weighed by difference and placed in the freezing point apparatus. The approximate quantity of pyridine was delivered to the apparatus from a weight buret, and the exact weight of the sample was determined by difference. In general, the weight of each mixture was 6 to 8 g., but for those samples with compositions within 10 mole % on either side of eutectics the amount was doubled or trebled.

A mixture was warmed slightly if necessary to effect solution, thoroughly stirred, and, while stirring was continued, cooled slowly to obtain an approximate freezing point. From the information thus obtained, the bath was regulated to an appropriate temperature, and the freezing point of the mixture was determined from the cooling curve.

For compositions representing a nearly pure compound there was very little tendency to supercool, but for other compositions considerable supercooling was encountered. To induce crystallization, seeding with a crystal of the solid phase was done at approximately the expected freezing point.

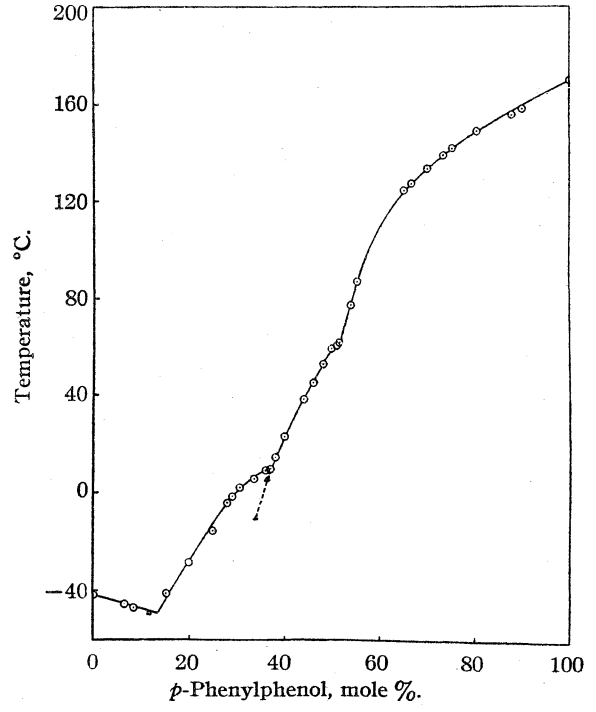

Fig. 3.—*p*-Phenylphenol + pyridine: ⊙, freezing point; ⊡, eutectic temperature; ◬, freezing point, metastable state.

D. Results

Below in tabular and graphical form the experimental data are shown. Compositions, as indicated, are shown in mole %.

Discussion

From the graphical representations of the three systems studied the following conclusions can be drawn.

A. Pyridine and *o*-phenylphenol form a compound, $C_5H_5N \cdot C_{12}H_{10}O$, f. p. 38.2°, which appears to be quite stable. The two eutectics are: (1) 7.5 mole % *o*-phenylphenol, f. p. −44.7°, and (2) 69.3 mole % *o*-phenylphenol, f. p. 14.3°. The determination of freezing points near the eutectic at 69.3 mole % was difficult; supercooling often caused the phenol to crystallize in the metastable state.

B. Pyridine and *m*-phenylphenol form one compound, $C_5H_5N \cdot C_{12}H_{10}O$, f. p. 35.5°, much the same as the ortho isomer. In this case the two

		100.00	75.3

[a] See note, Table I. [b] Obtained by seeding the mixture with compound $C_5H_5N \cdot C_{12}H_{10}O$.

eutectics are: (1) 8 mole % *m*-phenylphenol, f. p. −44.3° and (2) 66.5 mole % *m*-phenylphenol, f. p. 12.6°. Freezing points of mixtures with between 30 and 70 mole % *m*-phenylphenol were got only by seeding the liquid with a sample of material obtained by freezing a mixture of the latter composition in carbon dioxide–ethyl acetate.

C. Pyridine and *p*-phenylphenol appear, from the shape of the graph, to form two compounds. Both are unstable at their melting points and crystallize only from solutions containing an excess of pyridine. A sample (approximately 7 g.) of one of these, apparently $C_5H_5N \cdot C_{12}H_{10}O$, was cooled to −5° (uncor.); at this temperature it

[a] See note, Table I. [b] Uncorrected.

was in the form of a crumbly, snow-white solid. It was allowed to warm slowly. At 8–9° (uncor.) it showed signs of softening—the snow-white solid became rather glassy; this corresponds approximately to the incongruent melting point. As the temperature was increased, the material became soft and sticky at 15–17° (uncor.); this may be the approximate melting point of the compound. Between 55 and 60° (uncor.), which corresponds approximately to a composition of 50 mole % *p*-phenylphenol as read from the freezing point curve of the system, the last crystals disappeared. A small sample of the other material, apparently $C_5H_5N \cdot 2C_{12}H_{10}O$, was isolated, excess pyridine was absorbed on porous plate, and its melting range was determined in a capillary tube. It softened at 62–64° (uncor.) which corresponds to its incongruent melting point. On raising the temperature, the material showed signs of further change over the range of 85–90° (uncor.); possibly this corresponds to the approximate melting point of the material. Above 90° the system behaved as an equilibrium mixture and the last crystals disappeared at 125–128° (uncor.), which corresponds to the freezing point of the system containing approximately 67 mole % of the phenol. The only eutectic is 13.3 mole % *p*-phenylphenol, f. p. −49.3°.

Summary

The freezing point–composition diagrams have been determined for the two component systems of pyridine and of the three isomeric phenyl-

phenols. With (1) pyridine and *o*-phenylphenol: one compound, $C_5H_5N \cdot C_{12}H_{10}O$, is formed; (2) pyridine and *m*-phenylphenol: one compound, $C_5H_5N \cdot C_{12}H_{10}O$, is formed; (3) pyridine and *p*-phenylphenol: two compounds, (a) $C_5H_5N \cdot C_{12}H_{10}O$ and (b) $C_5H_5N \cdot 2C_{12}H_{10}O$, are formed; both are unstable at their melting points.

An Electrophoretic Study of the Proteins in Rubber Latex Serum

BY CHARLES P. ROE AND ROSWELL H. EWART

The proteins in rubber latex serum (*Hevea brasiliensis*) have been the subject of several researches during the past fifteen years. Some of this work has been concerned with the chemical properties of the proteins[1] and some with their electrophoretic properties.[2] Recently, the improvements introduced by Tiselius[3] in the electrophoretic technique have made it possible to increase the precision and significance of electrophoretic measurements very considerably. The work here reported is part of a program of electrophoretic research on latex proteins. This program was initiated in an attempt to obtain information which would be helpful in correlating protein behavior with the colloidal and other properties of latex.

Experimental

The Electrophoresis Apparatus.—The apparatus was supplied by the Klett Manufacturing Company of New York City and was built according to specifications furnished by Dr. L. G. Longsworth of the Rockefeller Institute in New York. Details may be found in Longsworth's publications.[4] A few modifications of the apparatus are described in the following paragraphs.

Illumination System.—Many latex serum samples used in this work did not transmit the visible lines of the mercury spectrum very well. In some cases this was on account of slight turbidity, in others, on account of color. The transmission coefficient of such solutions was found to be much greater in the red. Consequently, the mercury arc supplied with the apparatus was replaced by a 500-watt Tungsten filament projection lamp in conjunction with a Corning no. 246 lighthouse red filter. The object of this arrangement was to produce the most uniform possible exposure of photographic plate over the entire length of the cell image when the cell contained either a turbid or colored protein solution separated from a colorless buffer solution by a boundary in the exposed part of the cell. This expedient did not in all cases yield perfect results, but it was much more generally practicable than the use of the mercury arc, and well-defined Schlieren patterns were obtained.[5] Wratten and Wainwright Contrast Thin Coated Panchromatic plates were used. They are insensitive at wave lengths greater than 6800 Å. and the red filter cuts out all light of wave length less than 5600 Å. These figures are extreme values. The range of practical intensities lies between 5800 and 6600 Å.

In using the mercury arc in cases where this was feasible, it was found advantageous to introduce a Corning yellow–yellow filter in order to filter out the violet part of the mercury spectrum. This resulted in the production of straighter base lines in the schlieren diagrams through the elimination of a small dispersion effect due to some undetermined cause in the optical system.

The Electrodes and Source of Potential.—The silver–silver chloride electrodes were replaced by copper electrodes dipping into a concentrated copper sulfate solution. These electrodes are perfectly reversible and are easier to prepare than the silver–silver chloride system. In addition, they require no special care or attention after they are made. The authors used no. 14 copper wire wound into a compact flat coil and soldered to a small copper tube which was cemented to a piece of glass tubing just as in the case of the silver electrodes. When an alkaline buffer solution was used, a layer of saturated sodium sulfate solution was introduced between the buffer and copper sulfate solutions in order to prevent the formation of insoluble basic copper compounds at the liquid junction.

The potential difference applied to the electrophoresis cell and electrodes was furnished by a bank of 45-volt heavy duty B batteries. Conditions were always adjusted so as to make the power consumption less than three watts in the cell and electrode system.

The field strength within the electrophoresis cell was calculated from measured values of the current passing, the specific conductance of the solution and the cross section of the cell.

The Compensating Device for Shifting Boundaries.—The motor-driven compensating device was replaced by a gravity feed through a one-meter U-shaped length of capillary glass tubing of 1-mm. inside diameter which was connected at one end to the closed electrode vessel and at the other end to a separatory funnel which served as a reservoir.

(5) Verbal communication from Prof. J. W. Williams has informed the writers that a similar expedient has also been used successfully in his laboratory.

Ammonia Preserved Serum from Sumatra Normal Latex.—This was a one-gallon lot which was prepared on the plantations of the U. S. Rubber Company in Sumatra by freezing fresh unpreserved normal Hevea latex. Freezing caused complete coagulation of the rubber into a coherent clot. After thawing, the rubber-free serum was expressed, preserved with 2% ammonia and shipped to America in a stoppered glass container.

Serum from Unpreserved Sumatra Normal Latex.—Fresh unpreserved normal Hevea latex was frozen on the plantations in Sumatra and shipped in the frozen state to America. After this material had been thawed, the rubber-free serum was expressed and refrozen as quickly as possible to prevent deterioration. Serum thus prepared and containing no chemical preservative had a light straw color and a perfectly sweet odor. Its *p*H value was 6.4 at 25°. When kept stored in glass in the frozen state at −20° it retained these characteristics over a period of months with no signs of any deterioration.

Serum from Unpreserved Normal Florida Latex.—This latex (Hevea) was treated exactly like that prepared in Sumatra but it originated in the Plant Introduction Garden of the United States Department of Agriculture, Coconut Grove, Florida. The *p*H value of this serum was also 6.4 at 25°.

Direct Preparation of Latex Serum for Electrophoresis.—All electrophoresis determinations were made in solutions which were well buffered so as to secure adequate *p*H control. Each serum sample was, therefore, dialyzed exhaustively against the appropriate buffer solution at the temperature of the Tiselius thermostat. Conductance measurements were used to determine the extent of dialysis. Conductance and *p*H measurements (glass electrode) were made at the temperature of the cold thermostat which was held at +1°.

Concentration of Latex Serum Proteins.—It was necessary in several cases to have a more concentrated solution of the serum proteins than that in which they naturally occur in serum from frozen latex. For this purpose dry serum solids were prepared by the technique of vacuum sublimation of rubber-free frozen serum. This technique has been used extensively in the past by workers with animal sera.[6] The latex serum solids thus obtained contained some hygroscopic material which could be largely removed by dialysis with distilled water for twenty-four hours before starting the vacuum sublimation process. Dialysis could not be carried farther than this without causing partial flocculation and denaturation of the proteins. When properly prepared, the dried serum solids showed no outward signs of deterioration and could be completely redissolved in aqueous solutions at all *p*H values at which the original serum was stable. All concentrated latex protein solutions used in this work were prepared from completely vacuum dried samples. Dialysis against buffer solutions was carried out prior to electrophoresis in the case of these concentrated solutions just as in the case of the native serum samples.

Buffer Solutions.—All buffer solutions were made by use of uni-univalent electrolytes at an ionic strength equal to 0.1. In the following table the acid–base combinations used to cover the various segments of the *p*H interval between 2.0 and 10.5 are listed. *p*H values were measured

*p*H Interval	Acid	Base
2 – 4	HCl	Glycine
4 – 5.5	Acetic	NaOH
5.5– 7	Cacodylic	NaOH
7 – 8.5	HCl	Triethanolamine
9 –10.5	Glycine	NaOH

with the glass electrode at 1°. In order to calibrate the electrode, it was assumed, following Harned and Ehlers[7] that the ionization constant of acetic acid at 0° was $10^{-4.79}$ at an ionic strength of 0.1.

Results and Discussion

General Remarks on the Interpretation of Schlieren Diagrams.—The detailed theory of the schlieren scanning method of measuring refractive index gradients has been described elsewhere[4,8] It will be recalled that in electrophoretic schlieren diagrams the position and the time rate of displacement of a given peak along the axis of abscissas give, respectively, a direct index of the position and the rate of motion of the corresponding protein boundary within the cell. From this may be calculated the electrophoretic mobility by the introduction of the appropriate magnification and electric field factors. Each peak corresponds to a separate boundary. The ordinate of a schlieren diagram is proportional to the gradient of refractive index, and hence the area under the diagram included between two abscissas is proportional to the total refractive index change between the two abscissas. If the relationship between concentration and refractive index is known, then the area under a schlieren diagram, upon introduction of the proper optical factors, gives a measure of the concentration change of solute from one part of the cell to another.

Protein Components of Latex Serum.—Figure 1 shows electrophoretic schlieren diagrams (rising boundaries) at three *p*H levels for each of two samples of protein from Sumatra and Florida unpreserved whole latex serum. The presence of seven resolvable components is evidenced by inspection at the *p*H values of 6.85 and 8.43. Only six components are resolvable at *p*H 10.4, since I and V have the same mobility at this point.

Complete electrophoretic schlieren diagrams for the proteins in whole latex serum can be obtained only with concentrated serum, since two of the minor components (VI and VII) are present in such small quantities that they are not detect-

able at their natural concentrations in serum from frozen latex.

It is not known at present how to classify these electrophoretically resolvable components in terms of usual protein nomenclature. So far as the authors are aware, the only classification which has ever been made depends upon the separation of the whole protein into the so-called glutelin, globulin and albumin fractions.[1] Probably the protein components of unpreserved latex serum can be fitted into this classification, but it will require a combination of analytical results with those of electrophoresis experiments.

Comparison of Florida and Sumatra Latex Serum Proteins.—The schlieren diagrams of Fig. 1 show that the Florida and Sumatra protein samples are electrophoretically very similar in most respects. The number of resolvable components is the same, and the mobilities and relative abundance of the various components are nearly the same. The mobility figures are given in Table I and are represented graphically in Fig. 2.

Inspection of the diagrams in Fig. 1 shows that the relative abundance is about the same in the sera from the two sources and also that the total protein content is not much different in the two cases. A quantitative comparison of the areas under the schlieren diagrams is impossible since through an unfortunate oversight base line photographs were not recorded in all cases. No attempt has been made to fit the correct base lines in any case, since no use is made of them. The principal difference between the Florida and Sumatra diagrams lies in the sharpness of the peaks. The sharper peaks in the Florida sample indicate a greater degree of electrophoretic homogeneity of the several components in this than in the Sumatra sample. The cause is not definitely known, but the difference probably indicates more sanitary handling and less incipient deterioration before freezing on the Florida experimental plot than on the Sumatra plantation.

TABLE I

MOBILITY *versus* *p*H VALUES FOR TOTAL SERUM PROTEINS FROM SUMATRA AND FLORIDA LATEX

	Mobility in microns per second per volt per cm.					
	*p*H = 6.85		*p*H = 8.43		*p*H = 10.4[a]	
Component	Sumatra	Florida	Sumatra	Florida	Sumatra	Florida
I	−0.200	−0.210	−0.355	−0.335	−0.575	−0.580
II	− .590	− .615	− .690	− .680	− .880	− .980
III	+ .255	+ .240	+ .120	+ .110	− .230	− .165
IV	+ .090	+ .120	− .150	− .160	Not resolved	
V	− .335	− .360	Not resolved		− .575	− .580
VI	− .800	− .825	− .850	− .825	−1.18	−1.21
VII	− .955	− .915	− .985	− .915	−1.39	−1.53

[a] This *p*H value is actually an average figure. The Sumatra values were measured at *p*H 10.2 and the Florida values at 10.6.

The similarity of schlieren patterns obtained from latex sera with such widely different geographical origins is not surprising. Workers with human sera[9] have found that the schlieren pattern of normal human serum is nearly independent of the source of the serum and that only abnormal or pathological conditions cause large departures from the characteristic normal pattern. The results here reported on latex serum proteins are not sufficiently extensive to be accepted as proof that the geographical origin of latex from a healthy tree has no effect on the schlieren pattern of the serum proteins, but the close similarity of the patterns here presented, taken together with the findings of investigators in other related fields, makes such an assumption seem plausible. If this is true, it is a matter of some practical interest in latex technology. It would indicate that variations in normal latex from healthy trees cannot be ascribed to qualitative variations in the protein content of the serum prior to tapping. Variations traceable to the proteins must be due, then, to variations in handling conditions and preservation procedures.

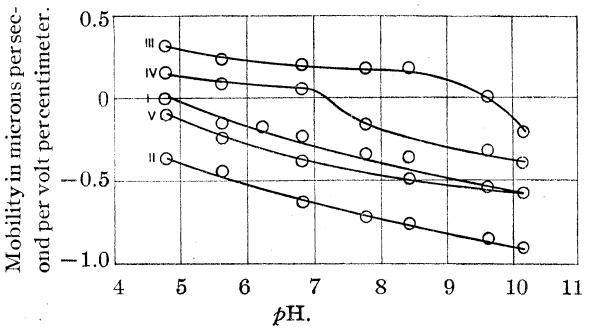

Fig. 2.—Mobility–*p*H curves for five protein components of latex serum.

Relationship between *p*H and Electrophoretic Mobility.—Figure 2 shows the mobility–*p*H curves for five of the seven protein components of whole unpreserved latex serum. These curves were plotted from data obtained from the electrophoresis of unconcentrated serum before the discovery of the minor components VI and VII, which were detectable only after concentration. It was found impossible to follow these curves below *p*H 4.79. Some insoluble material was precipitated below *p*H 5.7, but schlieren diagrams continued to exhibit peaks corresponding in an orderly way to five components down to *p*H 4.79. Below this level it is not possible on the basis of data in hand to correlate the diagrams obtained with the behavior of the proteins above *p*H 4.79.

TABLE II

MOBILITY *versus* *p*H DATA ON SUMATRA LATEX SERUM PROTEINS

*p*H	Component..I	II	III	IV	V
4.79	0	−0.360	+0.330	+0.160	−0.105
5.66	− .150	− .445	+ .245	+ .089	− .245
6.85	− .230	− .630	+ .200	+ .064	− .385
7.81	− .340	− .735	+ .170	− .170	.....
8.43	− .365	− .755	+ .177	.....	− .495
9.67	− .530	− .850		− .325	− .530
10.18	− .575	− .910	− .212	− .395	− .575

The wide distribution of isoelectric points on the *p*H scale is a matter of interest. Since two of these isoelectric points occur at *p*H 7.2 and *p*H 9.7, the persistence of positively charged protein components at high *p*H values is demonstrated. This may be accountable for the known stability of fresh unpreserved latex toward the addition of acid, whereas the negative components stabilize with respect to added alkali.

Effect of Ammonia Treatment of Latex Serum.—The progressive effects of free ammonia at high *p*H levels on the proteins from unpreserved latex serum are shown by a comparison of the schlieren diagrams (falling boundaries at *p*H 6.85) contained in Fig. 3. The final effect of am-

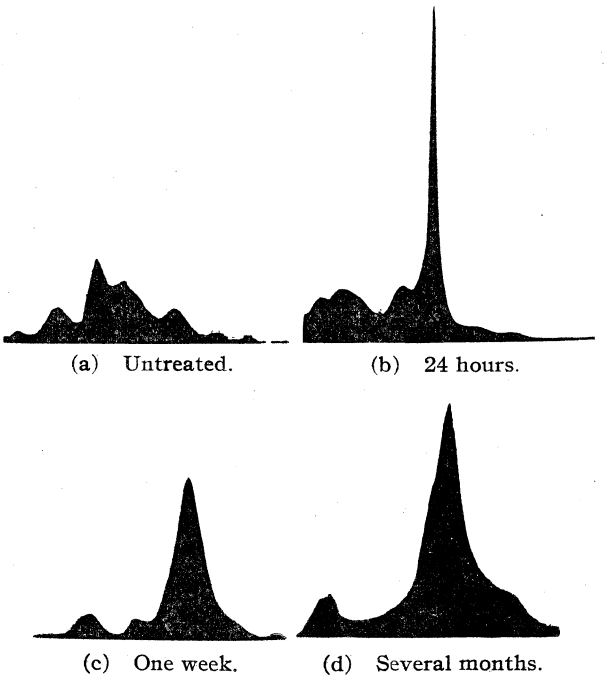

Fig. 3.—Schlieren diagrams showing effects of treatment of latex serum with 1% NH_3 for various lengths of time: (a), (b), (c) concentrated 3/1; (d) concentrated 5/1; *p*H = 6.85.

monia treatment is to reduce the number of resolvable components from seven to two.

Ammonia is of interest because of its commercial importance as a latex preservative. In its effect on latex proteins the presence of ammonia constitutes an abnormal condition in the serum and would be expected to produce departures from the characteristic normal pattern for untreated latex serum. It has been found that pathological conditions in human sera sometimes cause an abnormal change in the ratios of the various protein components of the sera. Although the detailed nature of the change in latex protein dissolved in ammonia solution is not known, one important observation may be made. The principal component of the exhaustively ammoniated protein solution has a higher numerical value of negative mobility than the principal component of unpreserved latex protein on the alkaline side of the isoelectric point. This is shown in Table III and probably accounts at least in part for the well-known rise in mechanical stability of latex within a short time after ammonia preservation is applied on the plantations.

TABLE III

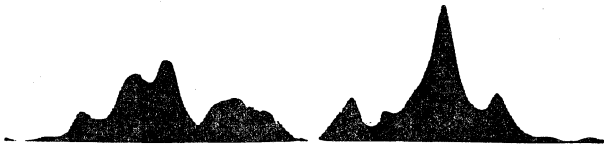
MOBILITY VALUES OF PRINCIPAL PROTEIN COMPONENT OF LATEX SERUM AFTER VARIOUS LENGTHS OF TIME IN 1% NH_3 SOLUTION *p*H 6.85

Time in 1% NH_3	Mobility in microns per sec. per volt per cm.
Untreated	−0.210
24 hours	− .332
7 days	− .565
Several months	− .465

It should be noted that soaps produced by the hydrolysis of resins may also be partially responsible for this increase in stability.

These experiments were all carried out on vacuum dried protein redissolved at a concentration three times that occurring in serum from frozen latex, except as indicated in Fig. 3.

Unconcentrated, *p*H = 6.85. Unconcentrated, *p*H = 10.18.



Concentrated, *p*H = 6.85. Concentrated, *p*H = 10.18.

Fig. 4.—Schlieren diagrams showing effects of vacuum sublimation on latex serum proteins.

Effects of Vacuum Sublimation.—Figure 4 shows a comparison of schlieren diagrams obtained with unconcentrated serum and diagrams obtained with concentrated solutions of vacuum dried serum solids.

The diagrams made in experiments with concentrated protein solutions show more detail than those made with dilute solutions, and tend to confirm the latter. The correspondence of the peaks representing the various components is taken to be an indication that no important change in the electrophoretic properties of the proteins was produced by the sublimation process.

Acknowledgment.—The writers wish to acknowledge their indebtedness to Mr. H. F. Loomis, of the United States Department of Agriculture, for his courtesy and coöperation in furnishing the fresh unpreserved latex from Florida. The writers are also indebted to Dr. L. G. Longsworth, Dr. Dan Moore and Dr. E. J. Cohn for helpful discussions of experimental methods.

Summary

1. The serum from unpreserved rubber latex (*Hevea brasiliensis*) contains seven electrophoretically distinct protein components. The proteins from whole serum originating in Sumatra and Florida give very similar results in electrophoresis experiments.

2. The relationship between electrophoretic mobility and *p*H has been determined for five of the seven protein components of unpreserved total latex serum. The results are considerably different from those reported by workers with ammonia preserved latex, and tend to clarify observed differences in the stability behavior of unpreserved and preserved latex.

3. Ammonia preservation treatment rapidly alters the electrophoretic behavior of the native protein components of latex serum and reduces the number of resolvable components from seven to two.

4. The preparation of dry latex protein from rubber free latex serum can be accomplished by the vacuum sublimation of frozen serum. This process does not appear to produce important changes in the electrophoretic properties of the total serum proteins.

5. Minor modifications of the electrodes and of the standard illumination system in the electrophoresis apparatus are described.

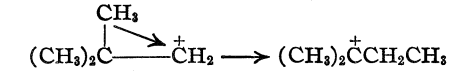
The Reactions of Certain Neopentyl Systems with Electrophilic Reagents[1]

BY PHILIP SKELL AND CHARLES R. HAUSER

Whitmore and co-workers have shown that neopentyl systems react with electrophilic reagents to yield largely rearranged products. Thus, neopentyl alcohol with hydrogen bromide gives mainly *t*-amyl bromide,[2] while neopentyl iodide with silver nitrate or mercuric chloride yields largely *t*-amyl alcohol.[3] These reactions have been considered to involve the removal of X (hydroxyl or halogen) with its complete octet of electrons, leaving a carbon atom with only a sextet of electrons.[4] This carbon atom is stabilized by acquiring an electron pair from the adjacent carbon atom, the shifting electron pair carrying with it the attached methyl group.



The tertiary carbonium ion thus formed acquires the bromide or hydroxyl ion from the medium, yielding the *t*-amyl bromide or alcohol.

A corollary to this theory (applied to various carbon skeletons) might be that the ease of rearrangement is dependent upon the relative electron-attraction of the α-carbon atom in the positive fragment and upon the ease of migration of the electron pair with its attached group. On this basis one might expect that the tendency to rearrangement in the neopentyl system would be decreased if the hydrogens on the α-carbon atom were substituted by electron donating groups, such as alkyl or phenyl groups.[5] That the substitution of two alkyl groups on the α-carbon atom may impede rearrangement in the neopentyl system is indicated by the fact that, in contrast to α-methylneopentyl alcohol which on dehydration gives mainly rearranged olefins,[6] α,α′-methylethylneopentyl and α,α′-dimethylneohexyl alcohols on dehydration yield mainly unrearranged olefins.[7] We have demonstrated that even one α-phenyl substituent stabilizes the neopentyl system.

In contrast to the reactions of unsubstituted neopentyl systems, α-phenylneopentyl alcohol reacts with hydrogen bromide to yield largely the corresponding bromide, and this bromide reacts with silver nitrate to regenerate mainly the original alcohol. Other workers have shown that α,α-diphenylneopentyl systems can similarly be made to undergo "metathetical" reactions with electrophilic reagents to yield largely unrearranged products,[8] although rearrangement products have also been obtained under certain conditions.[9] Thus, α,α-diphenylneopentyl alcohol with thionyl chloride gives the corresponding chloride which with silver acetate yields the corresponding acetate; the latter on hydrolysis regenerates an alcohol which may be converted to the original chloride.[8]

The first step in these reactions probably involves the formation of a coördination complex between the alcohol or halide and the electrophilic reagent (ROH_2^+ or $RBr \rightarrow Ag^+$). This facilitates the removal of X with its complete octet of electrons. With neopentyl systems having at least one phenyl or two alkyl groups (in which the unrearranged product is formed) the complex decomposes probably yielding the carbonium ion as intermediate[10] which then acquires an anion (halide or hydroxyl) from the medium. The reaction of α-phenylneopentyl bromide with silver ion, for example, may be represented as

$$(CH_3)_3CCH(C_6H_5)Br \longrightarrow Ag^+ \xrightarrow{-AgBr} [(CH_3)_3CCHC_6H_5]^+ \xrightarrow{+OH^-} (CH_3)_3CCH(C_6H_5)OH$$

With neopentyl alcohol or halide, however, the

(3) Whitmore, Wittle and Popkin, *ibid.*, **61**, 1586 (1939).

(4) Whitmore, *ibid.*, **54**, 3274 (1932).

(5) That alkyl and phenyl function as electron donating groups when present on the α-carbon atom of alkyl halides is demonstrated by the increased tendency to ionization of the halides; see, especially, Hughes, Ingold, Masterman and McNulty, *J. Chem. Soc.*, 899 (1940).

(6) Whitmore and Meunier, THIS JOURNAL, **55**, 3721 (1933).

(7) Whitmore and Laughlin, *ibid.*, **54**, 4011 (1932). While the rearrangements may be precluded to some extent because of the dehydration (possibly involving the simultaneous elimination of the elements of water from adjacent atoms) it would appear that the tendency to rearrangements is less with these alcohols, since the α-methylneopentyl alcohol which also has the required structure for dehydration without rearrangement, nevertheless mainly rearranges. Moreover, Bartlett and Knox (THIS JOURNAL, **61**, 3191 (1939)) have shown that, in contrast to the reaction of neopentyl alcohol with hydrogen bromide, α,α′-diethylneopentyl alcohol reacts with anhydrous hydrogen chloride apparently without rearrangement.

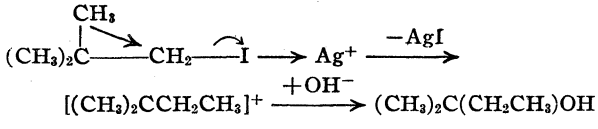
complex may never actually yield the neopentyl carbonium ion, but may produce directly the more stable tertiary amyl carbonium ion, the removal of X and the shift of the electron pair and its methyl group occurring simultaneously. This modification of the original hypothesis would account for the apparent absence of unrearranged products. The reaction of neopentyl iodide and silver ion, for example, may be illustrated as follows.



Since the phenyl group is known to migrate more easily than the methyl group, it might be expected that if the three methyl groups of the α-phenylneopentyl system were replaced by three phenyl groups, the resulting compound would exhibit a greater tendency to rearrangement. In agreement with this, it has been found that asymmetrical tetraphenylethyl alcohol on treatment with hydrogen bromide readily undergoes rearrangement, accompanied by elimination, yielding tetraphenylethylene. The alcohol is also dehydrated very readily by sulfuric acid, tetraphenylethylene being formed rapidly even at room temperature. Schmidlin[11] has reported that asymmetrical tetraphenylethyl bromide with aluminum chloride in benzene or even with boiling water undergoes rearrangement eliminating hydrogen bromide to yield tetraphenylethylene.

Experimental[12]

α-Phenylneopentyl Bromide.—α-Phenylneopentyl alcohol, contaminated with phenyl *t*-butyl ketone[13] (detected as its 2,4-dinitrophenylhydrazone), was prepared from *t*-butylmagnesium chloride and benzaldehyde, essentially as described by Conant and Blatt.[14] A solution of 36.0 g. of the slightly impure alcohol (b. p. 96–98° at 6 mm.) in 50 cc. of purified petroleum ether (b. p. 52–58°) was saturated with dry hydrogen bromide (the solution acquiring a yellow color immediately and a heavy yellow layer soon separating) at 0° for one hour and at room temperature for four hours. Anhydrous calcium bromide was added and the mixture filtered. After removing the solvent *in vacuo*, the residue on fractionation through a 6-inch Vigreux column yielded 37.5 g. (75%) of α-phenylneopentyl bromide, b. p. 103–104° at 7.5 mm. (reported, b. p. 106–112° at 9 mm.)[14]; d. 1.24.

(11) Schmidlin, "Das Triphenylmethyl," Verlag von Ferdinand Enke, Stuttgart, 1914, p. 146.

(12) Melting and boiling points are corrected.

(13) Reduction of the ketone with aluminum isopropoxide and isopropyl alcohol yielded the pure α-phenylneopentyl alcohol, boiling at 111.0–111.3° at 15 mm., and freezing sharply at 42°.

(14) Conant and Blatt, THIS JOURNAL, **50**, 551 (1928).

The bromide is hydrolyzed very slowly by water, is converted in high yield to the corresponding methyl ether (b. p. 94–95° at 20 mm.) by treatment with methanol in the presence of anhydrous potassium carbonate, and is converted to the corresponding acetate (b. p. 123–124° at 16 mm.) by refluxing with anhydrous potassium acetate in glacial acetic acid.

Reaction of α-Phenylneopentyl Bromide with Aqueous Silver Nitrate.—To a solution of 10 g. (0.059 mole) of silver nitrate in 50 cc. of distilled water was added 9.3 g. (0.41 mole) of α-phenylneopentyl bromide. Silver bromide separated immediately and the solution warmed perceptibly. After wrapping in paper (as a protection against light) the flask (with a ground glass stopper) was shaken mechanically overnight. The colorless organic layer was extracted with pure ether, and the ethereal solution was washed well with water and dried with anhydrous potassium carbonate. The solvent was removed through a 12-inch Vigreux column. The residue on fractionation *in vacuo* through a 6-inch Vigreux column yielded 6.2 g. (92%) of distillate (A), boiling at 96–101° (mainly at 99–100°) at 7.5 mm., leaving 0.5 cc. of yellow residue. The distillate (A) (which was solid at room temperature, the last crystal disappearing at 27°) was shown to consist mainly of α-phenylneopentyl alcohol. Pressing (A) between filter paper and washing it with a little petroleum ether yielded the alcohol melting at 38–41° (m. p. of the pure alcohol is 42°) which on oxidation with chromic anhydride in glacial acetic acid gave phenyl *t*-butyl ketone; the latter was identified as its oxime (m. p. 164–165°) and as its 2,4-dinitrophenylhydrazone (m. p. 190–191°). The freezing point constant of α-phenylneopentyl alcohol was determined by adding 0.264 g. of benzene to 4.152 g. of the pure alcohol (m. p. 42.0°), the last crystal disappearing at 37.4°; this indicated a depression of 5.6° for one mole of solute per 1000 g. of the alcohol. On this basis, the distillate (A) (m. p. 27°) contained 0.43 mole of "impurity" to 1.0 mole of α-phenylneopentyl alcohol. Assuming that all of the "impurity" was an isomeric alcohol, the maximum extent of rearranged product in (A) was only 30%.

Reaction of Asymmetrical Tetraphenylethyl Alcohol with Hydrogen Bromide.—Asymmetrical tetraphenylethyl alcohol (m. p. 151°) was prepared from sodium triphenylmethyl and benzaldehyde essentially as described by Schlenk and Ochs.[15]

A solution of 9.90 g. (0.0282 mole) of the alcohol in 100 cc. of pure anhydrous benzene (containing "Drierite" to absorb the water formed during the reaction) was saturated at 0° with dry hydrogen bromide (the solution acquiring immediately a deep yellow color which faded to a light yellow within one-half hour). No color change was observed on standing seven hours at room temperature. The solution was filtered in a dry-box and the solvent removed (at 40°) *in vacuo*. The residue after washing with purified petroleum ether yielded 8.0 g. (85%) of tetraphenylethylene (m. p. 225°), identified by its tetrabromide (m. p. 248°) and by ozonolysis to benzophenone (good yield) which was isolated as its 2,4-dinitrophenylhydrazone.

Asymmetrical tetraphenylethyl alcohol has also been dis-

(15) Schlenk and Ochs, *Ber.*, **49**, 611 (1916).

solved in concentrated sulfuric acid at room temperature. A momentary flash of bright yellow was produced and on pouring the solution into water a high yield of pure tetraphenylethylene was obtained.

Summary

1. In contrast to unsubstituted neopentyl systems, α-phenylneopentyl systems react with electrophilic reagents to yield largely unrearranged products. α-Phenylneopentyl alcohol with hydrogen bromide yields largely the corresponding bromide, and the latter with silver nitrate regenerates mainly the original alcohol.

2. Asymmetrical tetraphenylethyl alcohol with hydrogen bromide or concentrated sulfuric acid at room temperature yields tetraphenyl ethylene.

3. The effect of substituents on the tendency to rearrangement of neopentyl systems is discussed.

Acetylenic Ethers. III.[1] Halogen Derivatives of Phenoxyacetylene

BY THOMAS L. JACOBS AND WENDELL J. WHITCHER[2]

At the outset of our study of acetylenic ethers it seemed possible that these compounds would exhibit many of the peculiarities of halogenated acetylenes since in both classes the carbon–carbon triple bond is directly attached to an atom bearing unshared pairs of electrons. Actually very few close similarities have been observed. The only one worthy of mention is the great tendency toward polymerization exhibited in both series by those members which have an acetylenic hydrogen (HC≡COR and HC≡CX); compounds in which this hydrogen is replaced by an alkyl group are relatively stable. Dihalogenated acetylenes, XC≡CX, are likewise characterized by ready polymerization. The preparation of halogenated phenoxyacetylenes, $C_6H_5OC{\equiv}CX$, was therefore undertaken in order to compare these two series more closely and to examine further the reactions of acetylenic ethers. Since phenoxyacetylene was the most readily available of these ethers it was used throughout this investigation.

Three general methods have been used for the preparation of halogenated acetylenes: the action of halogens or certain halogenating agents on metallic derivatives of acetylenes, the reaction between hypohalite ion and acetylenes, and the treatment of dihaloethylenes with alkaline reagents.

Iodoacetylenes have been prepared in excellent yield by the action of iodine on acetylenic Grignard reagents; at 0° neither diacetylene formation nor iodine addition occurred.[3] Sodium, copper and silver acetylides have also been used and the iodination of the first of these in liquid ammonia is a good synthetic method.[4] Diiodoacetylene has been prepared in excellent yield by passing acetylene into potassium hydroxide solution while iodine in potassium iodide solution was being added.[5] This reaction has not been applied to the synthesis of substituted iodoacetylenes.

All of these methods were tried unsuccessfully in an attempt to prepare iodophenoxyacetylene. The reaction of phenoxyethynylmagnesium bromide with the theoretical amount of iodine at 0° failed to give this compound. Phenoxytriiodoethylene was obtained in fair yield and was the only product isolated. Sodium phenoxyacetylide was similarly treated with iodine and only a small amount of phenoxytriiodoethylene resulted. The main product polymerized when distillation was attempted at 4 mm. pressure, but at much lower pressures a clear distillate was obtained. This was a mixture containing phenoxyacetylene and unstable iodo compounds. Treatment with iodine gave only phenoxyacetylene diiodide and no phenoxytriiodoethylene. The distillate darkened rapidly and could not be purified successfully. An attempt to hydrate the undistilled product with mercuric acetate and hydrochloric acid was unsuccessful.

Phenoxyacetylene and iodine in potassium iodide solution were added simultaneously to cold potassium hydroxide solution. Phenoxytriiodoethylene was isolated from the reaction mixture by ether extraction and concentration. The residual liquid polymerized when distillation was attempted. The formation of the triiodo compound is accounted for readily only on the assumption that the iodoacetylenic ether is first produced and that iodine is then added.

The synthesis of bromophenoxyacetylene was attempted next in the hope that this compound could be isolated more readily. An early report of its preparation[6] by the action of alcoholic potassium hydroxide on dibromovinyl phenyl ether could not be confirmed by later workers[7,8] who obtained only phenol and ethyl bromoacetate (1).

$$\underset{\text{I}}{BrHC{=}CBrOC_6H_5} \xrightarrow[C_2H_5OH]{KOH} CH_2BrCO_2C_2H_5 + C_6H_5OH \quad (1)$$

$$\xrightarrow{H^+} CH_2BrCO_2H + C_6H_5OH \quad (2)$$

$$\xrightarrow{HNO_3} CHBr_2CO_2C_6H_3(NO_2)_2 \quad (3)$$

$$\underset{\text{II}}{Br_2C{=}CHOC_6H_5} \xrightarrow{H^+} (CHBr_2CHO) \xrightarrow[\text{phenylhydrazine}]{\text{2,4-Dinitro-}} \text{Glyoxal 2,4-dinitrophenylosazone} \quad (4)$$

$$\xrightarrow{KOH} C_6H_5OCH_2CO_2H + \text{polymer} \quad (5)$$

$$\xrightarrow{O_2} C_6H_5OCHBrCOBr \xrightarrow{C_6H_5OK} (C_6H_5O)_2CHCO_2C_6H_5 \quad (6)$$

Lawrie tried many alkaline reagents including powdered potassium hydroxide, but was unable to isolate any of the bromoacetylenic ether. All of these workers believed their starting material, prepared by the reaction of tribromoethylene and potassium phenolate, was 2,2-dibromovinyl phenyl ether, II, because it was converted by fuming nitric acid to dinitrophenyl dibromoacetate, (3). Biltz[9] pointed out that the compound was almost certainly 1,2-dibromovinyl phenyl ether, I, since on hydrolysis it yielded a derivative of (mono)bromoacetic acid, (2). He explained the formation during the nitric acid reaction of a compound with both bromines on one carbon as an oxidative rearrangement. It is interesting that Nef's acetylidene theory[8,10] was based largely on structural evidence invalidated by such rearrangements. Since phenoxyacetylene dibromide[11] is identical with the dibromovinyl phenyl ether described above, it would have been assigned an acetylidene structure, $C_6H_5OCH{=}C$, by Nef. These early workers explained the hydrolytic reactions on the basis of the 2,2-dibromovinyl phenyl ether structure by postulating the intermediate formation of bromophenoxyacetylene and assuming that it added water rapidly

$$Br_2C{=}CHOC_6H_5 \longrightarrow BrC{\equiv}COC_6H_5 \xrightarrow{H_2O} CH_2BrCO_2H + C_6H_5OH$$

The removal of hydrogen bromide in acid solution to produce a triple bond is of course very unlikely.

Slimmer[7] synthesized a second dibromovinyl phenyl ether by the reactions

$$C_6H_5OCH{=}CHBr + Br_2 \longrightarrow C_6H_5OCHBrCHBr_2 \xrightarrow{KOH} C_6H_5OCH{=}CBr_2$$

Since the 2,2-dibromo- structure had already been assigned to the compound prepared earlier, he assumed this second one had the 1,2-dibromo- structure. We repeated his synthesis and proved that the compound was 2,2-dibromovinyl phenyl ether, II, by hydrolysis to derivatives of glyoxal, (4).

An attempt to prepare bromophenoxyacetylene from this second dibromo ether by distillation from potassium hydroxide under reduced pressure was not successful. The products were tar and a little phenol and phenoxyacetic acid. The acid was probably formed by hydrolysis of the vinyl ether, but it might also have been produced by hydration of bromophenoxyacetylene, since bromoacetylenes are known to give acids by refluxing with alcoholic potassium hydroxide.[12]

The action of fuming nitric acid at $-10°$ on 2,2-dibromovinyl phenyl ether was very vigorous and the only products isolated were 2,4-dinitrophenol and picric acid. We had no difficulty in confirming the report[8] that under the same conditions 1,2-dibromovinyl phenyl ether underwent a smooth oxidative rearrangement to a dinitrophenyl ester of dibromoacetic acid. It was observed that the 2,2-dibromo compound autoxidized rapidly in the air. It was, therefore, shaken with dry oxygen and the oxidation product treated with potassium phenolate yielding phenyl diphenoxyacetate by an oxidative rearrangement, (6). Foster[13] obtained ethyl diethoxyacetate in a

similar manner from 2,2-dichlorovinyl ethyl ether which was prepared by a method that left no question regarding its structure.

Since 1,2-dibromovinyl phenyl ether, m. p. 38–39°, should exist in *cis*- and *trans*-forms, an attempt was made to isomerize it by irradiation with ultraviolet light.[14] The product was a liquid from which only a third of the starting material could be recovered. A similar liquid mixture with the composition of dibromovinyl phenyl ether was obtained by adding bromine to phenoxyacetylene.[11] Irradiation of 2,2-dibromovinyl phenyl ether produced no change.

The preparation of bromo- and chloro-acetylenes by the reaction of halogens and acetylenic Grignard reagents is complicated by the ease of addition of the halogen to the triple bond. In view of the isolation of phenoxytriiodoethylene during the addition of iodine to metallic derivatives of phenoxyacetylene, no attempt was made to prepare bromophenoxyacetylene by this method. Since phenoxyacetylene is stable to cold potassium hydroxide its reaction with hypobromite ion in alkaline solution[15] was investigated. Some polymerization of the phenoxyacetylene occurred during the reaction, but the darkening was hardly more than observed with phenoxyacetylene alone. Distillation of the product even at 0° with a mercury vapor pump usually resulted in polymerization to a black, solid mass with evolution of heat. On one occasion this polymerization occurred almost explosively while the distilling flask was standing at 0° at atmospheric pressure. One successful distillation was carried out yielding a substance which darkened rapidly. Addition of bromine to this distillate gave phenoxytribromoethylene and a little phenoxyacetylene dibromide. Undistilled bromophenoxyacetylene gave phenoxytribromoethylene on addition of bromine, and phenyl bromoacetate on hydration.

These experiments show that bromophenoxyacetylene can be prepared, but that purification is very difficult due to polymerization.

Experimental Part

Phenoxytriiodoethylene.—Phenoxyethynylmagnesium bromide[11] from 8.0 g. (0.068 mole) of phenoxyacetylene was cooled to 0° under nitrogen and treated with stirring with 17.2 g. (0.068 mole) of iodine in 150 cc. of ether during two and one-half hours. Stirring was continued for twenty minutes and the solution was hydrolyzed with cold 5% ammonium chloride solution, washed with water and dried over sodium sulfate. On concentration under reduced pressure a total of 10.3 g. (60% yield) of phenoxytriiodoethylene was deposited in several fractions, m. p. 120–122.5° and 124–126°. These were recrystallized several times from ether and petroleum ether, m. p. 129–129.5°.

Anal. Calcd. for $C_8H_5OI_3$: C, 19.30; H, 1.01; I, 76.48. Found: C, 19.63; H, 1.04; I, 76.66.

Similar addition of iodine to sodium phenoxyacetylide[11] gave phenoxytriiodoethylene in only 1% yield; the main product was an unstable liquid which was distilled using a mercury vapor pump. The distillate was crystalline at −80°, but melted to a colorless liquid at room temperature and rapidly turned green. Analysis showed only 34.28% iodine as compared with 52.00% calculated for iodophenoxyacetylene. The addition of iodine to an ether solution of this liquid gave a little impure phenoxyacetylene diiodide; there was no evidence for phenoxytriodoethylene which is less soluble than the diiodide and readily separated from it.

The yield of phenoxytriiodoethylene obtained by the simultaneous addition of phenoxyacetylene and iodine in potassium iodide solution to cold potassium hydroxide solution was 28.5%.

2,2-Dibromovinyl phenyl ether was prepared according to Slimmer's direction[7] except that a nitrogen atmosphere was maintained throughout. The product was an oil which was carefully fractionated through a small Podbielniak column packed with a spiral of platinum wire; b. p. 117–118° (6 mm.), $n^{20}D$ 1.6046; yield 48%. This material solidified on standing in the cold; m. p. 29–29.5°. A mixed m. p. with 1,2-dibromovinyl phenyl ether, m. p. 38–39°, showed a depression.

Anal. Calcd. for $C_8H_6Br_2$: Br, 57.50. Found: Br, 56.89.

Hydrolysis.—Only partial hydrolysis resulted when 1.7 g. (0.006 mole) of 2,2-dibromovinyl phenyl ether was refluxed for four hours with 2.4 g. (0.012 mole) of 2,4-dinitrophenylhydrazine and 20 cc. of concd. hydrochloric acid in 50 cc. of alcohol. A yellow precipitate formed rapidly but even at the end of the reaction the solid present was a mixture with a broad melting point. The odor of unchanged dibromoether was apparent. The reaction mixture was filtered and soluble impurities partly removed from the precipitate by refluxing in ethyl acetate and filtering. The insoluble portion was recrystallized from nitrobenzene giving reddish-orange needles, m. p. 311–312°; Strain[16] reported m. p. 326–328°.

Anal. Calcd. for $C_{14}H_{10}N_8O_8$: C, 40.20; H, 2.41. Found: C, 40.29; H, 2.66.

Autoxidation.—Dry oxygen was passed slowly through 10 g. of 2,2-dibromovinyl phenyl ether with shaking during three days. The product was taken up in 75 cc. of dry benzene and added dropwise to a suspension of 10.5 g. of potassium phenolate in 50 cc. of benzene with cooling. The reaction mixture was stirred and allowed to come to room temperature during two hours and finally refluxed for twenty-five minutes. The benzene solution was washed with water, dried and concentrated. Addition of

(14) These experiments were carried out by Mr. Eugene V. Kleber.

(15) Straus, Kollek and Heyn, *Ber.*, **63**, 1868 (1930).

(16) Strain, THIS JOURNAL, **57**, 758 (1935).

ligroin gave 2.9 g. of phenyl diphenoxyacetate (25% yield). It was recrystallized from benzene and ligroin, m. p. 94.5–95° in good agreement with recorded values.[17]

Anal. Calcd. for $C_{20}H_{16}O_4$: C, 74.99; H, 5.04. Found: C, 74.81; H, 4.92.

Bromophenoxyacetylene.—A mixture of 0.112 mole of phenoxyacetylene and 200 cc. of 0.56 *M* potassium hypobromite solution containing potassium hydroxide (2.2 *M*)[15] was stirred under nitrogen at −5 to −8° for three hours. The product was taken up in ether and the ether solution washed with cold 5% potassium hydroxide and water. After drying over sodium sulfate the ether was partly removed and the solution was transferred to a 25-cc. Claisen flask which had a side arm 2 cm. in diameter bent into a U-shape to serve as a receiver. The flask was partly filled with glass wool to prevent bumping and the remaining ether and unchanged phenoxyacetylene were removed with an oil pump and collected in a trap cooled with acetone and dry-ice. Readmission of air to the flask at this point resulted in polymerization, sometimes almost explosively. Polymerization usually resulted even when distillation was continued without interruption simply by cooling the U-tube side arm in dry-ice and starting the mercury vapor pump. One successful distillation was accomplished yielding 8 g. of a lachrymatory almost colorless substance which was a liquid even at −80°. Small samples rapidly turned green and then black when allowed to warm up to room temperature. Purified carbon tetrachloride was, therefore, added to the remaining material and this solution in an ice-bath was treated dropwise with 3.4 cc. of bromine in carbon tetrachloride. At first, each drop of bromine solution reacted vigorously producing white fumes. The dark solution was washed with water and cold 5% potassium hydroxide. After drying over calcium chloride the carbon tetrachloride was removed under reduced pressure and the product distilled at 2 mm. The first fraction was phenoxyacetylene dibromide (3.65 g.) and the second tribromophenoxyethylene (3.85 g.), m. p. 92–93.5° as shown by a mixed m. p. Polymer accounted for the rest of the starting material.

Bromine in carbon tetrachloride was added similarly to the crude undistilled bromophenoxyacetylene from 14 g. of phenoxyacetylene, yielding 18.5 g. (43%) of phenoxytribromoethylene. There was no evidence of phenoxyacetylene dibromide in this experiment.

A concentrated ether solution of undistilled bromophenoxyacetylene from 7.6 g. of phenoxyacetylene was shaken with a solution of 65 g. of mercuric acetate and 3 cc. of concd. hydrochloric acid in 140 cc. of water at 10°. A greenish, flocculent solid separated, but this redissolved with continued shaking for twenty minutes and intermittent addition of concd. hydrochloric acid (total of 50 cc.). The ether solution was washed with water, dried and the ether removed under reduced pressure. Two distillations of the residue gave 4.2 g. (30% yield) of phenyl bromoacetate, b. p. 140–142° (25 mm.), m. p. 28–28.5°.

(17) Scheibler and Depner, *Ber.*, **68**, 2139 (1935).

Summary

1. Iodophenoxyacetylene could not be obtained by the action of iodine on phenylethynylmagnesium bromide or sodium phenoxyacetylide; triiodophenoxyethylene was the main product in the first case. Phenoxyacetylene and iodine reacted in alkaline solution yielding triiodophenoxyethylene. Liquids which polymerized rapidly were obtained in each instance.

2. The dibromovinyl phenyl ether prepared by Slimmer was shown to be 2,2-dibromo-1-phenoxyethylene. It yielded no bromophenoxyacetylene when distilled from potassium hydroxide.

3. Bromophenoxyacetylene was obtained by the action of potassium hypobromite in alkaline solution on phenoxyacetylene. It polymerized very readily, was successfully distilled only at very low pressures and could not be purified. It was hydrated yielding phenyl bromoacetate; the addition of bromine gave tribromophenoxyethylene.

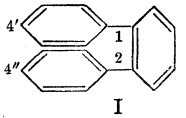
[COMMUNICATION NO. 872 FROM THE EASTMAN KODAK RESEARCH LABORATORIES]

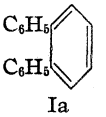
The Chemistry of *o*-Terphenyl. II. Derivatives Prepared from the Hydrocarbon

BY C. F. H. ALLEN AND F. P. PINGERT

The chemical behavior of *o*-terphenyl has not hitherto been determined, mainly on account of its inaccessibility.[1] All derivatives reported in the literature have contained the substituent groups in the central ring. They have resulted from degradation of more complex molecules or from diene syntheses.[2] Indeed, this last reaction furnishes the most suitable procedure for synthesizing such derivatives. Having accumulated a supply of the hydrocarbon,[3] its reactions were investigated, using standard procedures. Predictions as to the position to be taken by entering groups would vary according to which mode of representation was used. Thus, formula Ia would lead one to expect substitution on the central ring, while I would suggest the more likely possibilities of groups entering the side rings. The system of numbering adopted regards the side rings as substituents, and the numbers are, therefore, primed.[3]



I



Ia

The Friedel–Crafts reaction was of particular interest because the first simple degradation product previously secured had been a benzoyl-*o*-terphenyl[2a]; this was not identical with the ketone found by the action of benzoyl chloride upon *o*-terphenyl in the presence of anhydrous aluminum chloride. Since the latter reagent, by itself or in a melt with sodium chloride gives rise to side reactions,[3] a mixture of products usually results.

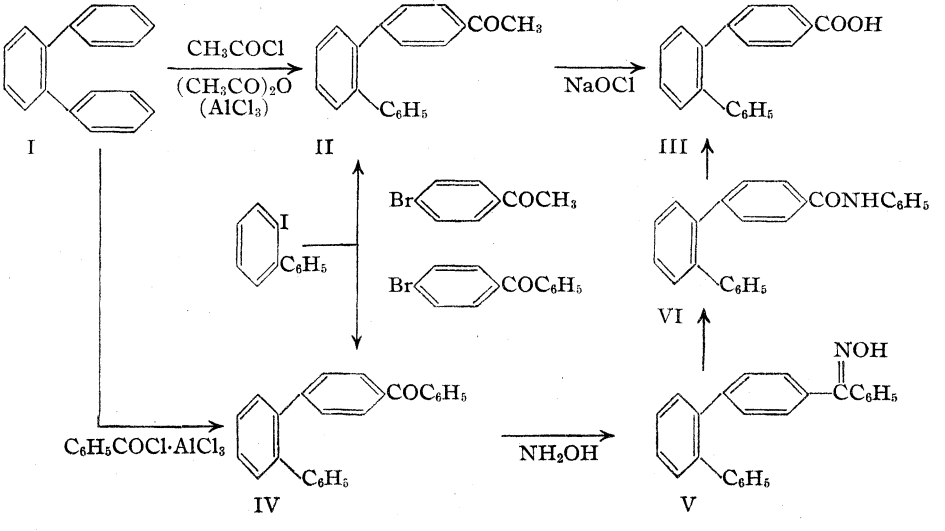
4'-Acetyl-*o*-terphenyl II is secured by the action of acetyl chloride or acetic anhydride upon the hydrocarbon in the presence of anhydrous aluminum chloride. It was also synthesized by a Wurtz reaction from *o*-iodobiphenyl and *p*-bromoacetophenone, to confirm its structure. By means of sodium hypochlorite, it was converted to the 4'-carboxylic acid III.

When benzoyl chloride was employed, a difficultly separable mixture resulted, but by using the Perrier double compound, $C_6H_5COCl \cdot AlCl_3$, a phenyl ketone IV was obtained in high yield and purity. The same ketone was also secured by a Wurtz synthesis. This ketone gave an oxime V, which formed an anilide VI by the Beckmann rearrangement; hydrolysis of the anilide furnished 4'-carboxy-*o*-terphenyl III and aniline. These reactions are summarized in Chart I.

Bromination, as would be anticipated, gave a mixture, but by variations in technique it was possible to isolate several homogeneous substitution products. The first homogeneous product is 4',4''-dibromo-*o*-terphenyl, VII. The structure was determined by oxidation, when *p*-bromobenzoic acid was secured; therefore, in the dibromo derivative the bromine atoms are in the para position.

The further action of bromine gave first a tribromo and then a tetrabromo substitution prod-

CHART I

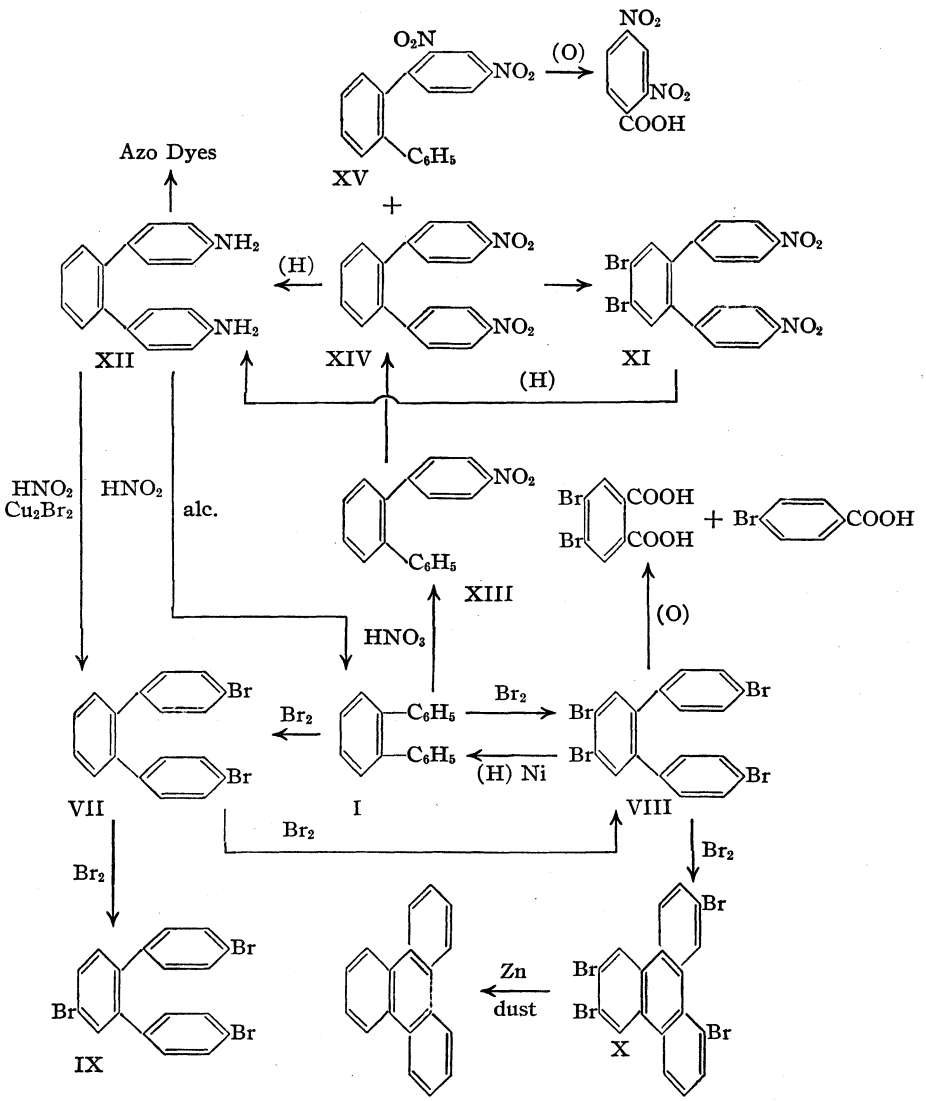


(1) It has recently been called to our attention by Dr. R. L. Jenkins, of the Monsanto Chemical Company that their product, "Santowax O," is about 85% *o*-terphenyl.

(2) (a) Allen and Spanagel, THIS JOURNAL, **55**, 3773 (1933); (b) Allen, Bell, Bell and VanAllan, *ibid.*, **62**, 656 (1940); (c) Allen and VanAllan, *ibid.*, **64**, 1260 (1942).

(3) Allen and Pingert, *ibid.*, **64**, 1365 (1942).

CHART II



uct. Upon oxidation of the latter a large amount of *p*-bromobenzoic acid and a small quantity of 4,5-dibromophthalic acid were produced; the substance is, therefore, 4,4′,4″,5-tetrabromo-*o*-terphenyl, VIII. The tribromo derivative, IX, has the bromine atoms in the 4,4′,4″-positions, for (a) further bromination gives the tetrabromo-*o*-terphenyl, and (b) oxidation gives a high yield of *p*-bromobenzoic acid. The end-product of the action of bromine is 3,5,10,11-tetrabromotriphenylene, X, the halogen acting as a dehydrogenating agent, upon the tetrabromo-*o*-terphenyl. That the four-ring system is present is shown by the formation of triphenylene on zinc dust distillation.

4′,4″-Dinitro-*o*-terphenyl gives a dibromo derivative, XI, upon bromination, which presumably has the bromine atoms in the same positions as the tetrabromo compound, for it has the same general appearance and physical properties. The melting points are identical and there is no depression on admixture—one of the uncommon instances in which two different substances have no effect on their respective melting points. On reduction by hydrogen in the presence of Raney nickel, the bromine is removed and the corresponding amine, XII, is found—thus triphenylene ring closure has not occurred. Attempts to synthesize 4′,4″-dicyano-*o*-terphenyl by the Rosenmund method were unsuccessful. The reactions are shown in Chart II.

Nitration gives first the 4′-nitro derivative, XIII, and then a mixture of two isomeric dinitro-*o*-terphenyls; the nature of the product is largely controllable according to the experimental conditions. One of the dinitro derivatives is the 4′,4″-isomer, XIV, and the other is the 2′,4′-isomer, XV, since upon oxidation the former gives only *p*-nitrobenzoic acid, and the latter, 2,4-dinitrobenzoic acid. Mixed acid gave a mixture of products that appeared to contain some of a trinitro derivative.

Reduction of the nitro compounds yields the corresponding amines; the 4′,4″-diamine, XII, was converted by means of the diazo reaction into (a) *o*-terphenyl, showing the ring system was still intact, and (b) 4′,4″-dibromo-*o*-terphenyl, VII, thus affording additional proof of structure in

both series. The diamine was also diazotized and coupled with some of the common naphthalene dye intermediates to give azo dyes.

Experimental

The behavior of *o*-terphenyl in chemical reactions is very subject to slight changes in technique, and an understanding of certain of its peculiarities is essential for successful repetition of the procedures. Under comparable conditions, it is less active than the meta- and para-isomers, so that some degree of forcing may be necessary to initiate a reaction. However, complications due to isomerization and ring closure[3] render it important not to drive the reactions to completion in most instances. Mixtures are thus produced, the separation of which is not always readily accomplished; if the conditions are such as to favor the formation of products in molecular proportions, the mixed crystals may defy as many as twenty fractional crystallizations from several solvents.

One of the obscure factors that may influence the experimental results is the solvent from which the hydrocarbon was crystallized. This effect is not understood. As an example, traces of moisture or alcohol favor polybromination; this is in line with the view that aromatic halogenation proceeds through an ionic mechanism.[4] *o*-Terphenyl and some of its derivatives retain traces of solvent very tenaciously; one-quarter to one-half per cent. of ethanol is not removed over a long period of time *in vacuo;* this affects analytical results only slightly, but may determine the course of substitution to a large degree. Small amounts of acetic acid have a strong inhibiting effect upon bromination and nitration; it is also possible to boil glacial acetic acid solutions of the hydrocarbon with bromine or fuming nitric acid without appreciable substitution.

A. The Ketones, I; 4′-Benzoyl-*o*-terphenyl; 4-*o*-Xenylbenzophenone, II. (a). Friedel–Crafts Synthesis.—To the Perrier double compound from 1.4 g. each of benzoyl chloride and aluminum chloride in 8 cc. of carbon disulfide was added 2.3 g. of *o*-terphenyl, and the mixture was refluxed for a half hour, left at room temperature for several hours and again refluxed a half hour. It was then decomposed in the usual manner, extracting with ether; on evaporation, the residue, 3.3 g., was steam-distilled from a solution made alkaline by 1 g. of potassium carbonate—only a trace of unchanged hydrocarbon was removed. The ketone was taken up in ether, treated with decolorizing carbon, and the solvent removed. After recrystallization from absolute ethanol, the ketone formed compact prisms, m. p. 111°. It crystallizes readily from dry methanol and benzene.

Anal. Calcd. for $C_{25}H_{18}O$: C, 89.8; H, 5.4. Found: C, 89.3; H, 5.3.

(b) Ullmann Synthesis.—An intimate mixture of 5 g. each of *p*-bromobenzophenone and *o*-iodobiphenyl, and 10 g. of copper bronze[5] was heated in a sealed tube at 240° for four hours. The contents were then extracted with benzene in a Soxhlet apparatus, and the extract distilled *in vacuo*, collecting the portion boiling above 190° at 3 mm. After a redistillation, the substance was fractionally crystallized from absolute ethanol, when 0.35 g. of *o*-xenylbenzophenone was secured. There was no depression of melting point when mixed with the ketone described in (a).

(c) The Oxime, V.—This was obtained in two modifications, the lower-melting form first obtained changing into the higher-melting on standing, or inoculating, or in the presence of hydrochloric acid. Once the higher-melting point had been obtained, it was thereafter impossible to isolate the low-melting form again.

A solution of 200 mg. of the purest ketone in 7 cc. of ethanol was mixed with an equal weight of hydroxylamine hydrochloride, and 15 drops of 35% sodium hydroxide was added. After gently refluxing for four hours, it was diluted with 28 cc. of water and acidified to litmus with *sulfuric* acid (*hydrochloric* acid gave the higher-melting form at once). After a thorough washing it was recrystallized from absolute ethanol, and then from petroleum ether at −60°. The oxime (210 mg.) then had a melting point of 68°. As described above, it changed to another form, which melted at 138°, showing a barely perceptible shrinking at about 68°. Both oximes gave the same anilide.

Anal. Calcd. for $C_{25}H_{19}ON$: N, 4.0. Found: N, 4.2, 4.0.

(d) Hydrolysis of the Anilide to 4′-Carboxy-*o*-terphenyl, III.—The anilide was not easily hydrolyzed without resinification. The best procedure was to reflux a mixture of 0.15 g. of anilide, 50 cc. of ethanol, and 15 cc. of 40% sodium hydroxide for seventy-two hours. After acidification and three recrystallizations, the acid (yield, 0.1 g.) was pure; m. p. 203°.

II. 4′-Acetyl-*o*-terphenyl, II.—(a) Direct acetylation of the hydrocarbon in solution invariably leads to mixtures, the aluminum chloride causing rearrangements.[3] Until a pure specimen is available for inoculation, it is almost a hopeless task to try to separate the mixtures. When acetic anhydride in nitrobenzene was used, the decomposed reaction product was extracted with ether, and this extract shaken two hours with Norite (without this treatment crystallization did not take place). The yield of ketone was 2.1 g., m. p. 94°; from 9.2 g. of *o*-terphenyl. After two months, 2.6 g. more of the less pure ketone, m. p. 93°, had separated, making the total yield 43%. Acetyl chloride, or carbon disulfide as a solvent, resulted in low-melting ketone.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.2; H, 5.9. Found: C, 88.0; H, 5.8.

(b) Ullmann Synthesis.—A mixture of 22 g. of *o*-iodobiphenyl and 19.4 g. of *p*-iodoacetophenone was heated

TABLE I

PROPERTIES OF BROMINATED HYDROCARBONS

No.	Substituents	M. p., °C.	Crystal form	Empirical formula	Analyses, % Calcd.	Found
VII	4′,4″-Dibromo-	170[a]	Rods or leaflets	$C_{18}H_{12}Br_2$	41.2	41.1
IX	4,4′,4″-Tribromo-	170[a,e]	Rods	$C_{18}H_{11}Br_3$	51.4	52.2
VIII	4,4′,4″,5-Tetrabromo-	228[b,d]	Prisms	$C_{18}H_{10}Br_4$	58.3	58.2
X	3,5,10,11-Tetrabromotriphenylene	+450[c]	Microcrystalline powder	$C_{18}H_8Br_4$	58.8	58.7

[a] Mixed melting point, about 155°. [b] In one instance, an isomer, m. p. 120°, with previous sintering, was isolated—it contained 58.4% bromine. [c] On a copper block; a specimen, synthesized from triphenylene, melted at the same point under the same conditions. [d] A 1:1 mixture of tri- and tetrabromo compounds, m. p. 212–214°, often crystallized—it could not be separated by crystallization. [e] Mol. wt. calcd., 467; found (in benzene) 469, 479.

with stirring in an oil-bath until the temperature had reached 220°. Then 40 g. of activated[5] copper bronze was added over a period of one hour. After cooling, the acetone extract was distilled in a Hickman vacuum (at about 3 micra). The fraction that passed over at 200–205° was fractionally crystallized from absolute ethanol; the yield was 6.7 g.

(c) **Oxidation with sodium hypochlorite** in aqueous methanol gave 4′-carboxy-*o*-terphenyl, m. p. 203°, identical with the product from the phenyl ketone, described above.

B. Bromination.—The three isomeric terphenyls in the crystalline state in aqueous suspension react readily with bromine; *o*-terphenyl exhibits this behavior more strongly than the isomers. Furthermore, it is practically impossible to brominate *o*-terphenyl dissolved in an organic solvent, though there is no difficulty with the isomers. The products of the bromination are mixtures, whatever the technique, but certain individuals predominate in each variation. In some instances, elution by a solvent removes a considerable quantity of undesirable by-products. In practically every case it is essential to submit the mixture of products to systematic fractional crystallization.[6] Glacial acetic acid seems to be the most generally useful solvent. In some instances, polybrominated products are very soluble and are largely removable in the first wash, along with unreacted hydrocarbon. Since space requirements prohibit the complete detailed procedures, only a brief description of the more essential features of each bromination will be given.

i.—Solid *o*-terphenyl and dry bromine vapor in a closed vessel at room temperature gave mainly di-, tri-, and tetrabromo-*o*-terphenyls. The hydrocarbon slowly liquefies and resolidifies; at this point the yield of 4′,4″-dibromo-*o*-terphenyl is at the maximum. The time (two to twenty hours) depends upon variable factors, such as size of the run.

ii.—Similar conditions but in the presence of water vapor; here the tribromo compound predominates. The same result is attained if the hydrocarbon is ground in a mortar with water, and triturated with bromine for short periods of time. A curious but unexplained observation is that in the presence of water the tribromo compound is the end-product.

iii.—Longer exposure (one to thirty days) to bromine by either of the foregoing procedures; in this case the tetrabromo-*o*-terphenyl predominates. If this is desired as a principal product, it can be obtained very quickly by adding solid hydrocarbon to excess liquid bromine, evaporating to dryness, and separating the polybromotriphenylenes.

iv.—Further exposure of the lower bromo compounds to bromine either as vapor or liquid first gives the tetrabromotriphenylene, X, *quantitatively* which is further very slowly polybrominated, but no other pure individual substance was isolated. The triphenylene derivatives have high melting points (450–600°) and are easily removed because of their relative insolubility.

The properties of the various brominated products are collected in Table I.

Ring closure of the tetrabromo-*o*-terphenyl to the tetrabromotriphenylene was brought about by heating with nitrating acid, and separating the resinous mixture by suitable manipulations. This reaction thus affords confirmatory proof that the tetrabromo-*o*-terphenyl is still open-chained; *i. e.*, the ring has not been closed in the brominations.

V. Proofs of Structure.—(a) **4′,4″-Dibromo-*o*-terphenyl** was oxidized in the usual manner, using chromium trioxide in acetic acid for forty-eight hours. The yield of *p*-bromobenzoic acid was 58%; it was identified by comparison with an available specimen.

(b) **4,4′,4″,5-Tetrabromo-*o*-terphenyl** was synthesized by further bromination of 4′,4″-dibromo-*o*-terphenyl, thus locating two of the bromine atoms. Upon oxidation with chromium trioxide in acetic acid for four days and appropriate manipulation, a 60% yield of *p*-bromobenzoic acid was isolated, showing that none of the additional bromine had entered the end rings already containing bromine. There was also isolated a small amount of 4,5-dibromophthalic acid, identified by conversion to the anhydride, m. p. 215°, and identical with a sample at hand.[7]

(c) **3,5,10,11-Tetrabromotriphenylene** was reduced by heating micro samples with zinc dust in a 10-in. capillary tube; the triphenylene sublimed into the upper end of the tube. This was cut off and the hydrocarbon identified as such by comparison with an authentic sample. The ordinary macro zinc dust distillation takes place too slowly and yields mixtures.

VI. 3,6-Dimethyl-4,4′,4″,5-tetrabromo-*o*-terphenyl, m. p. 205°, was prepared by a similar procedure from some available 3,6-dimethyl-*o*-terphenyl.[2c]

Anal. Calcd. for $C_{20}H_{14}Br_4$: Br, 55.8. Found: Br, 55.8.

Upon oxidation only *p*-bromobenzoic acid was isolated. In this substance, the bromine atoms can only be in the

(6) The material losses are prohibitive unless the purification is carried out in accordance with some such procedure, recombining all mother liquors and recovering all residues.

(7) We are indebted to Dr. C. V. Wilson for this authentic specimen.

4,5-positions of the central ring, the 3 and 6 positions being occupied by methyl groups.

C. Nitration. I. 4′-Nitro-*o*-terphenyl, XIII, and Related Products.—(a) To a solution of 23 g. of *o*-terphenyl in 150 cc. of 99–100% acetic anhydride below 0° was added, dropwise, and with stirring, 8.5 cc. of nitric acid (sp. gr. 1.44). The temperature was kept below 5° for two hours, then allowed to rise to room temperature and stirred overnight. It was then poured upon ice and sodium carbonate, and, when all the acid had been neutralized, extracted with ether. The dried ether extract was concentrated and 2–3 g. of dinitro derivatives filtered; a small further amount was filtered on further concentration, rinsing the solid with dry ether. The combined filtrate and rinse was redried over anhydrous magnesium sulfate and the residual oil after removal of the solvent distilled *in vacuo*. After recovering about 1 g. of hydrocarbon, the fraction, b. p. 180–200° (3 mm.), was collected and redistilled (b. p. 191–193° (3 mm.)); the yield was 21.6 g. (78%) of a thick oil which solidified to a honey-colored glass. After one year, during which it was remelted and resolidified several times, it crystallized. It separates in flakes from acetic acid, m. p. 105–106°.

Anal. Calcd. for $C_{14}H_{13}O_2N$: N, 5.1. Found: N, 5.3.

(b) **4′-Amino-*o*-terphenyl.**—Reduction was carried out in alcoholic solution in the presence of a Raney nickel catalyst. It crystallizes in rosets of fine needles; the melting point, at first 108°, drops, on standing, to 103–104° and the amine becomes slightly pasty.

Anal. Calcd. for $C_{18}H_{15}N$: N, 5.8. Found: N, 6.1.

The benzoyl derivative, obtained through a Schotten–Baumann reaction, formed needles when crystallized from absolute ethanol; m. p. 175°.

Anal. Calcd. for $C_{25}H_{19}ON$: N, 4.0. Found: N, 3.9.

II. 4′,4″-Dinitro-*o*-terphenyl, XIV; (a) **From *o*-Terphenyl.**—A solution of 6.9 g. of the hydrocarbon in 50 cc. of 99–100% acetic anhydride was treated, dropwise, with 5 cc. of fuming nitric acid (sp. gr. 1.52) at 10°; after two hours, cooling was discontinued—a solid slowly separated. The mixture was decomposed as usual by iced sodium carbonate, ether extracted, and the solid filtered; the ether contains most of the mononitro compound and any unreacted hydrocarbon. The solid (6.4 g.) was fractionally crystallized from acetic acid, giving about equal amounts of the 4′,4″-dinitro-*o*-terphenyl, m. p. 218°, and its 2′,4′-isomer, m. p. 169°—this is more soluble.

Anal. Calcd. for $C_{18}H_{12}O_4N_2$: N, 8.8. Found: (4′,4″-) N, 8.7; (2′, 4′-) N, 8.7.

(b) **From Mononitro Derivative in Ia.**—A solution of 5 g. of XIII in 120 cc. of acetic anhydride was cooled to 10°, and five 2-cc. portions of fuming nitric acid were added. After allowing to stand overnight and working up in the usual way, 6 g. of material was obtained, from which 3.1 g. of 4′,4″-dinitro-*o*-terphenyl was isolated after several recrystallizations.

(c) **Oxidation.**—This was carried out by the customary procedure using chromium trioxide in acetic acid overnight. The yield of *p*-nitrobenzoic acid from the 4′,4″-dinitro-*o*-terphenyl was 56%; a mixed melting point was not depressed. The 2′,4′-isomer gave 2,4-dinitrobenzoic acid, m. p. 181°.[8]

(d) **4′,4″-Diamino-*o*-terphenyl, XII,** was secured by reduction of the corresponding nitro compound essentially as described under the monoamine. It crystallizes in hard, waxy rosets from absolute ethanol, m. p. 149°.

Anal. Calcd. for $C_{28}H_{20}O_2N_2$: N, 6.7. Found: N, 6.6.

It is stable in an inert atmosphere, but in the laboratory air soon turns waxy and the melting point falls.

The diamine was tetrazotized in the usual way, except for the replacement by hydrogen reaction, which will be described below. It is essential to work in dilute solutions (1.5 g. per liter) to avoid resin formation. For the Sandmyer reaction, the tetrazotized solution was run into a 48% hydrobromic acid solution containing freshly prepared cuprous bromide. The 4′,4″-dibromo-*o*-terphenyl was filtered and recrystallized from acetic acid. It was identical with the product of dibromination.

For the reduction reaction, 0.64 g. of diamine in 50 cc. of cold, absolute ethanol, containing 10 cc. of concentrated sulfuric acid, was tetrazotized at 0°. It was then warmed gently in warm tap water, and finally heated on the steam-bath. After dilution with water, the doughy precipitate was manipulated, and 0.14 g. (22%) of *o*-terphenyl isolated and identified. The remainder had a phenolic odor and failed to crystallize.

A separately prepared tetrazo solution was coupled with alkaline β-naphthol; an immediate scarlet precipitate was formed; it melted, with decomposition, at 209°. Analysis indicated that but one end had coupled, the other, apparently, having been hydrolyzed to a phenolic group.

Anal. Calcd. for $C_{28}H_{20}O_2N_2$: N, 6.7. Found: N, 6.6.

Other, water-soluble dyes will be described in a later paper.

(e) **4′,4″-Dinitro-4,5-dibromo-*o*-terphenyl, XI,** was prepared by exposing the dinitro-*o*-terphenyl to bromine vapor for twenty-four hours, as described under bromination. Purification was accomplished through the judicious use of alcohol and acetic acid; there is some insoluble material, presumably the corresponding triphenylene derivative. The dibromodinitro derivative crystallizes in fine rods, m. p. 228°.

Anal. Calcd. for $C_{18}H_{10}O_4N_2Br_2$: N, 5.9. Found: N, 6.2.

Summary

The chemical behavior of *o*-terphenyl has been determined in the Friedel–Crafts reaction, and with the reagents bromine and nitric acid. The structures of the resulting substances have been determined; their reactions and those of related products are described.

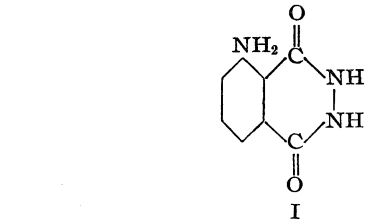
The Synthesis of Aminobenzoyleneureas and of Dihydroxyquinoxalines Isomeric with "Luminol"

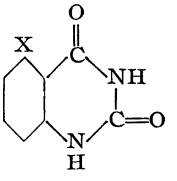
BY ERNEST H. HUNTRESS AND JEANNE V. K. GLADDING[1,2]

The brilliant chemiluminescence produced during alkaline oxidation of 3-aminophthalhydrazide ("Luminol"[3]) has long been the subject of investigation by many workers. Some of these workers have been concerned with the influence of structural changes upon the chemiluminescent properties. With such progress as has been made in this direction this paper cannot in general be concerned in detail. However, Drew[4] has pointed out that since hydrazides in five-membered rings do not show chemiluminescence, a six-membered hetero ring may be essential. It has also been established[4c] that in 3-aminophthalhydrazide both imino hydrogens of the cyclohydrazide ring must be free to enolize. It does not appear, however, that any attempt has been recorded to show that in the heterocyclic portion of 3-aminophthalhydrazide the two imino groups must be adjacent to each other, *i. e.*, that a hydrazine derivative is imperative for the possession of chemiluminescent properties on oxidation.

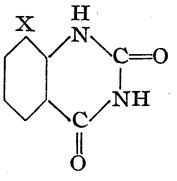
The work reported in this paper is primarily concerned with the preparation of certain hitherto unreported compounds isomeric with 3-aminophthalhydrazide and whose carbocyclic nucleus is precisely the same as in "Luminol," but in which although the heterocyclic ring is varied it still retains the characteristic of being a six-membered ring with two potentially enolizable hydrogen atoms. The particular individual compounds thus constituting the primary interest of this work are the two aminobenzoyleneureas II and IV (X = NH_2) together with the aminodihydroxyquinoxaline VI (X = NH_2). Syntheses of the two other possible aminobenzoyleneureas III and V and the one other possible aminodihydroxyquinoxaline VII (X = NH_2) have been included, although admittedly in them the amino group of the carbocyclic ring is not in the same relationship to the heterocyclic nucleus as in 3-aminophthalhydrazide.



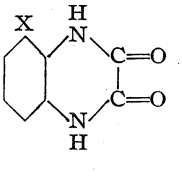
I



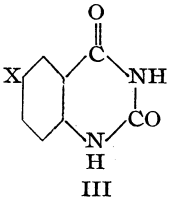
II



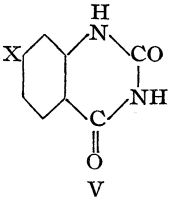
IV



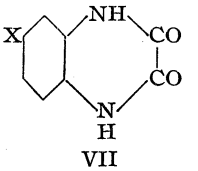
VI



III



V



VII

All six of these new compounds have been prepared and characterized. Each amino compound has been obtained by reduction of the corresponding nitro relative. The three nitro compounds corresponding to structure II, IV and V (X = NO_2) were obtained from the correspondingly substituted nitroanthranilic acids. The first (II, X = NO_2) was prepared by condensation of 6-nitroanthranilic acid with potassium cyanate in acetic acid, the second (IV, X = NO_2) and third (V, X = NO_2) by fusion of 3-nitro- and of 4-nitroanthranilic acids, respectively, with urea. 6-Nitrobenzoyleneurea (III, X = NO_2) was prepared by nitration of benzoyleneurea according to Bogert and Scatchard.[5]

The position of the nitro group in 6-nitrobenzoyleneurea had already been established[5] by its preparation from methyl 2-(ω-nitrocarbamido)-5-nitrobenzoate. The position of the nitro group in the other three isomers is here estab-

(1) This paper is constructed from part of a dissertation submitted in June, 1941, by Miss Jeanne V. Kitenplon (Mrs. E. K. Gladding) to the Faculty of the Massachusetts Institute of Technology in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(5) Bogert and Scatchard, THIS JOURNAL, **41**, 2058–2059 (1919).

lished by their mode of preparation from the corresponding anthranilic acids. In the case of 8-nitrobenzoyleneurea (IV, X = NO_2) this evidence is also supported by its further nitration to the same 6,8-dinitrobenzoyleneurea previously obtained by nitration of 6-nitrobenzoyleneurea.

All four mononitrobenzoyleneureas are pale yellow crystalline solids with high melting or decomposition points. They are all phenolic in character and are therefore soluble in dilute aqueous alkalies forming deeply colored solutions from which the parent compounds are reprecipitated by carbon dioxide. They are but sparingly soluble in organic solvents.

The four aminobenzoyleneureas (II, III, IV, V, X = NH_2) have been obtained by stannous chloride reduction of the corresponding nitro compounds. Their hydrochlorides separated from the hot reduction solution in high purity and no complexes with the reagent have been observed. From the salts the amines were released by dilute ammonia. The free amines are white crystalline solids, some melting at high temperatures, others decomposing before true fusion. The free bases are amphoteric and readily dissolved in dilute aqueous alkalies or carbonates. The presence of the amino group was evidenced by the formation of colored coupling products when the diazotized amines were treated with alkaline β-naphthol.

The results of tests for possible chemiluminescence on oxidation, however, were uniformly negative. No significant light evolution occurred. Formation of highly colored red to brown solutions occurred in all cases and suggested that oxidation was taking place. Since no light was observed, however, and since such colored solutions would be poorly adapted for study if there had been, the nature of the reaction products was not further examined.

Experimental Work

All melting points were taken in a Berl and Kullmann copper block on a 360° rod form melting point thermometer set in the block up to its zero point.

The Nitrobenzoyleneureas

5-Nitrobenzoyleneurea (II, X = NO_2).—Potassium cyanate (5.25 g., 0.065 mole) dissolved in water (25 ml.) was added dropwise to a stirred suspension of 6-nitro-2-aminobenzoic acid (9.1 g., 0.05 mole) in water (300 ml.) and glacial acetic acid (4.5 ml., 0.08 mole). After the orange colored solution had been stirred for half an hour, it was treated with flaked sodium hydroxide (80 g., 2 moles) in small portions the temperature being kept below 40° and the alkaline solution allowed to stand overnight in a refrigerator. After removal of any precipitate by filtration the product was precipitated by acidification with sulfuric acid. It separated from these solutions in fine, light yellow crystals or from boiling water in pale tan, thin, regular hexagons. After treatment with decolorizing carbon it was thrice recrystallized from boiling 50% acetic acid; weight, 7.0 g., representing 67% of theoretical; m. p. 339–340° dec. uncor. in sealed tube, 357–358° cor.

Anal. Calcd. for $C_8H_5O_4N_3$: N, 20.3. Found: N, 21.0, 21.1.

5-Nitrobenzoyleneurea is insoluble in ether, benzene, carbon tetrachloride, ligroin, carbon disulfide or toluene; slightly soluble in cold water, ethyl acetate, chloroform or 95% ethanol; moderately soluble in boiling water, boiling 50% acetic acid, methanol, acetone, or pyridine. Its solutions in aqueous sodium hydroxide, sodium carbonate or concentrated ammonium hydroxide are bright yellow, but the compound is precipitated on saturation with carbon dioxide.

5-Nitrobenzoyleneurea N,N'-Dimethyl Ether.—Treatment of 5-nitrobenzoyleneurea (1.03 g., 0.005 mole) dissolved in 5% potassium hydroxide (15 ml.) by shaking with dimethyl sulfate (1.5 g. = 0.010 mole) for half an hour caused evolution of heat and separation of a pale yellow precipitate of the N,N'-dimethyl ether; weight 0.905 g., representing 77% of the theoretical. From boiling 50% ethanol this material separated in fine white needles.

This material was refluxed for twenty minutes with concentrated hydrochloric acid (to hydrolyze any O-ethers) washed with 5% potassium hydroxide, filtered and recrystallized from boiling methanol. Its melting point was 263–265° uncor. (275–277° cor.).

Anal. Calcd. for $C_{10}H_9O_4N_3$: N, 17.9; for $C_{10}H_9O_4N_3 \cdot H_2O$: N, 16.6. Found: N, 16.5, 16.8.

6-Nitrobenzoyleneurea (III, X = NO_2).—This was prepared from benzoyleneurea by nitration with a mixture of concentrated sulfuric acid and fuming nitric acid according to the directions of Bogert and Scatchard.[5] The yield was 86% of theoretical and the product showed a melting point of 315–316° dec. uncor., 331–332° dec. cor. (recorded 330–331° cor.).

6-Nitrobenzoyleneurea-N,N'-dimethyl Ether.—By treatment with dimethyl sulfate exactly as for the 5-nitro isomer, the dimethyl ether was obtained in 85% yield. Although from boiling 50% ethanol this separated in fine white crystals, yet after boiling with concentrated hydrochloric acid (to split any O-ethers) and treatment with potassium hydroxide, recrystallization of the alkali insoluble product from boiling methanol yielded bright yellow needles, melting at 204–205° uncor. (213–214° cor.).

Anal. Calcd. for $C_{10}H_9O_4N_3$: N, 17.9. Found: N, 18.3, 18.5.

7-Nitrobenzoyleneurea (V, X = NO_2).—A mixture of 4-nitro-2-aminobenzoic acid (3.0 g., 0.0165 mole) and urea (3.0 g., 0.05 mole) was heated from room temperature to 200° during thirty minutes and then fused at 200° for one hour. The material was contained in a large Pyrex test-tube suspended within an air-bath, the temperature of the melt being measured by a thermometer inserted directly into the fused material.

During fusion ammonia was evolved and a feathery yellow sublimate formed at the top of the test-tube. After cooling the porous yellow-brown mass was washed with water (50 ml.) to remove ammonium salts. The residual solid was then extracted with warm 5% aqueous sodium bicarbonate (50 ml.) followed by warm 10% aqueous sodium carbonate (50 ml.). This treatment converted the 7-nitrobenzoyleneurea into the sparingly soluble sodium salt and removed unchanged 4-nitro-2-aminobenzoic acid or other acidic material. The solid residue was then treated with dilute sulfuric acid (50 ml.) and small amounts of by-product 4-nitro-2-aminobenzamide extracted with boiling methanol (50 ml.) from the free 7-nitrobenzoyleneurea. Crystallization from boiling 50% acetic acid gave fine cream-colored needles; weight 2.6 g. (76% theoretical); m. p. 323° uncor. or 337° cor. dec. in a sealed capillary tube. Further crystallizations from 50% acetic acid accompanied by the use of decolorizing carbon gave lustrous white plates.

For analyses the potassium salt was recrystallized from very dilute potassium hydroxide solution, followed by acidification with 10% acetic acid and final recrystallization from boiling 50% acetic acid.

Anal. Calcd. for $C_8H_5O_4N_3$: N, 20.3. Found: N, 20.4, 20.5.

7-Nitrobenzoyleneurea is slightly soluble in boiling water, cold 95% ethanol, ether or ethyl acetate. It is moderately soluble in boiling methanol, 95% ethanol or pyridine. Its solutions in aqueous alkali are deep yellow and from them 7-nitrobenzoyleneurea is precipitated by carbon dioxide.

A long series of experiments on the influence of time and temperature on this fusion showed clearly that below 170° both 7-nitrobenzoyleneurea and 4-nitro-2-aminobenzamide were formed as a result of which the yields of former were low. At 170° or above, however, no amide was detectable and the yield of 7-nitrobenzoyleneurea was very satisfactory. The best conditions are given above, but a similar fusion at 170° for seven hours gave 67% yield, showing that the temperature rather than prolonged time is the critical governing factor. This was confirmed by the observation that 4-nitro-2-aminobenzamide (1.0 g., 0.006 mole) fused with urea (1.0 g., 0.017 mole) for two hours at 180–200°, gave 35% yield of purified 7-nitrobenzoyleneurea, m. p. 337° dec. cor.

7-Nitrobenzoyleneurea-N,N'-dimethyl Ether.—This was obtained (85% yield) from its parent with dimethyl sulfate and alkali essentially as for the preceding isomers; from boiling methanol it separates in pale yellow needles, m. p. 229–230° uncor.

8-Nitrobenzoyleneurea (IV, X = NO_2).—The preparation of this compound was effected by fusion of 3-nitro-2-aminobenzoic acid with urea according to the general procedure used for the 7-nitro isomer. Both the desired 8-nitrobenzoyleneurea and the by-product 3-nitro-2-aminobenzamide were always formed, their yields varying considerably with fusion temperature, time and proportion of reactants. Conditions were finally established for obtaining satisfactory yields of the 8-nitrobenzoyleneurea, but (unlike the corresponding 7-nitro isomer) it was always accompanied by at least a small amount of the amide from which it had to be separated.

A mixture of 3-nitro-2-aminobenzoic acid (5.0 g., 0.0274 mole) and urea (10.0 g., 0.167 mole) was heated at 180–190° (thermometer in melt) for five hours. Ammonia was evolved and a yellow sublimate formed at the mouth of the tube. After cooling the yellow-brown solid was extracted with warm 5% aqueous potassium hydroxide and the filtered solution treated with carbon dioxide until precipitation was completed. The resultant small brown crystals were recrystallized from boiling 50% acetic acid; weight 3.9 g. (68% theoretical); m. p. 263–264° uncor. (272–273° cor.) in a sealed capillary tube.

Anal. Calcd. for $C_8H_5O_4N_3$: N, 20.3. Found: N, 20.0, 20.2.

8-Nitrobenzoyleneurea after three crystallizations from boiling 50% acetic acid using decolorizing carbon was obtained in hard yellow-green prisms. It is moderately soluble in methanol, 95% ethanol, acetone, or pyridine; insoluble in ether, benzene, toluene, carbon tetrachloride or carbon disulfide. Its solutions in cold aqueous sodium hydroxide, sodium carbonate or ammonium hydroxide are yellow but from these the original compound is precipitated by carbon dioxide.

6,8-Dinitrobenzoyleneurea.—8-Nitrobenzoyleneurea (0.90 g. = 0.0043 mole) dissolved in concentrated sulfuric acid (10 ml.) was slowly treated with concentrated nitric acid (6 ml., d. 1.42). After heating the solution at 100° for one hour, cooling, and pouring onto ice, the pale yellow solid was filtered, washed with water and dried at 110°. From boiling 50% acetic acid it separated as light yellow prisms; weight 1.10 g. (100% theoretical); m. p. 263–265° uncor.; recorded,[6] 274–275° cor. dec.

Anal. Calcd. for $C_8H_4O_6N_4$: N, 22.2. Found: N, 22.1, 22.3.

The melting point of a 50–50 mixture of this product and authentic 6,8-dinitrobenzoyleneurea was not depressed. The melting point of a 50–50 mixture of 8-nitrobenzoyleneurea and either this product or the authentic sample of 6,8-dinitrobenzoyleneurea was depressed to 219–227° uncor.

8-Nitrobenzoyleneurea-N,N'-dimethyl Ether.—8-Nitrobenzoyleneurea (1.03 g., 0.005 mole) dissolved in 5% aqueous potassium hydroxide (15 ml.) first gave a clear deep red solution which soon solidified to an orange paste. After dilution with water this was shaken for half an hour with dimethyl sulfate (1.5 g., 0.01 mole) at room temperature, then heated at 100° for an hour, cooled and filtered. After washing with water and drying at 100° the crude product weighed 1.035 g. Recrystallization from boiling 50% ethanol gave light tan needles which were refluxed fifteen minutes with concentrated hydrochloric acid (15 ml.), treated with 5% aqueous potassium hydroxide (25 ml.), and finally recrystallized again from boiling methanol; yield, 0.54 g. (45% theoretical); m. p. 217–218° uncor.

Anal. Calcd. for $C_{10}H_9O_4N_3$ (dimethyl ether): N, 17.9. Found: N, 17.8. Calcd. for $C_9H_7O_4N_3$ (monomethyl ether): N, 19.0.

3-Nitro-2-aminobenzamide.—This compound constituted the residue from alkali extraction of the fusion of 3-nitro-2-aminobenzoic acid with urea. From boiling methanol, 95% ethanol or acetone it crystallized in long

(6) Bogert and Scatchard, THIS JOURNAL, **38**, 1612 (1916).

lustrous orange needles, m. p. 226–227°, uncor. (234–235° cor.).

Anal. Calcd. for $C_7H_7O_3N_3$: C, 46.4; H, 3.87. Found: C, 46.3, 46.6; H, 3.70.

Its identity was further supported by hydrolysis on long boiling with either dilute sodium hydroxide or 6 *N* hydrochloric acid which gave 3-nitro-2-aminobenzoic acid and ammonia. Furthermore, on refluxing with acetic anhydride followed by warming of the intermediate 3-nitro-2-acetylaminobenzoic acid with 5% aqueous potassium hydroxide, treatment with carbon dioxide precipitated 8-nitro-2-methyl-4-ketodihydroquinazoline in 36% yield. After recrystallization from boiling 50% acetic acid this separated as hard brown-red crystals; m. p. 260–261° dec. uncor. (267–268° dec. cor.); recorded,[7] m. p. 264° dec. Finally it was observed that 3-nitro-2-aminobenzamide (4.0 g., 0.022 mole) fused with urea (8.0 g., 0.134 mole) for five hours at 200° gave 8-nitrobenzoyleneurea (4.0 g. or 87.0% theoretical), m. p. 262–263° uncor. (271–272° cor.).

3-Nitro-2-aminobenzoic Acid.—This compound was prepared in two ways, *viz.*, by oxidation of 3-nitro-2-aminotoluene and by Hofmann degradation of 3-nitrophthalamic-2-acid-1.

The first sequence started with **3-nitro-*o*-toluidine**, converted[8] it to 3-nitro-2-acetylaminotoluene (91% yield), m. p. 156° uncor. (recorded[8] 156°), oxidized[8] with *neutral* potassium permanganate to 3-nitro-2-acetylaminobenzoic acid (74% yield), and finally by hydrolysis with boiling 50% sulfuric acid gave 3-nitro-2-aminobenzoic acid (87% yield), m. p. 202–203° uncor. (recorded, 205°,[8] 208–9°).[9] The over-all yield by this method was therefore 58.6%.

The alternative procedure started from 3-nitrophthalic acid, converted[10] it to the anhydride (78% yield), ammonolyzed in warm concentrated ammonium hydroxide to 3-nitrophthalamic-2-acid-1 (70% yield), followed by Hofmann degradation[9] to 3-nitro-2-aminobenzoic acid (90% yield), m. p. 201–203° uncor. By this sequence the over-all conversion of 3-nitrophthalic acid to the 3-nitroanthranilic acid was 48%.

6-Nitro-2-aminobenzoic Acid.—This was prepared by starting with 3-nitrophthalic acid, converting it to the acid ammonium salt in 100% yield, fusing this at 235–250°[11] to obtain 94% yield of 3-nitrophthalimide, converting this imide to 6-nitrophthalamic-2-acid-1 by solution in 2 equivalents of 0.5 *N* sodium hydroxide and precipitation at 0° with excess concentrated hydrochloric acid (yield 76%), and finally degrading the amide group to amino (90% yield) via the Hofmann method as employed by Kahn.[12] The over-all yield of this preparation thus represented 64.3% of the theoretical and gave a product melting at 181° dec. uncor.

The Aminobenzoyleneureas

All four isomeric nitrobenzoyleneureas on reduction with stannous chloride in boiling concentrated hydrochloric acid gave the corresponding aminobenzoyleneureas in the form of their hydrochlorides. These were all sparingly soluble in the excess acid and separated during the reduction. No tin double salts were observed. The general method was based upon the procedure reported[13] for the reduction of 6,8-dinitrobenzoyleneurea. It was worked out specifically for the reduction of 6-nitrobenzoyleneurea (see below) and applied without change to the other isomers.

5-Aminobenzoyleneurea (II, X = NH_2).—The hydrochloride separated in very fine white needles from the hot concentrated hydrochloric acid solution. It was also sparingly soluble in cold water. When dissolved in boiling water and treated with ammonium hydroxide, the free base separated in pale green needles which after four recrystallizations from hot water (using decolorizing carbon) became lustrous white needles, m. p. 284° dec. uncor. (295° dec. cor.), in sealed capillary tubes. The yield of amine hydrochloride was 71% theoretical.

Anal. Calcd. for $C_8H_7O_2N_3$: N, 23.7. Found: N, 24.4, 24.6.

The free base was somewhat soluble in hot water, methanol, ethanol or ethyl acetate, the solutions possessing a purple fluorescence. The base is also soluble in dilute sodium hydroxide, dilute sodium carbonate, or concentrated ammonium hydroxide and these solutions were pale yellow. Diazotization of the amine and coupling with alkaline β-naphthol gave a deep brown-red solution.

6-Aminobenzoyleneurea (III, X = NH_2).—6-Nitrobenzoyleneurea (10.5 g., 0.05 mole) was added gradually to a boiling solution of stannous chloride dihydrate (50 g., 0.22 mole) in concentrated hydrochloric acid (160 ml.). After refluxing for four hours the mixture was cooled, the insoluble amine hydrochloride filtered, washed with water, and dried at 110°. To remove any occluded tin salts this material was refluxed with concentrated hydrochloric acid (40 ml.) for fifteen minutes, water (40 ml.) was added, and the mixture boiled five minutes more. The amine hydrochloride separated in fine light tan needles, weight 9.8 g. (91% theoretical).

This salt is only sparingly soluble in cold water, cold dilute acids or hot concentrated hydrochloric acid. When dissolved in a large volume of freshly boiled water (to avoid oxidation) and ammonium hydroxide added to the boiling solution, the free base separated in pinkish-tan needles, which after three recrystallizations from boiling water (using decolorizing carbon) separated as fine lustrous white needles. This base does not show a melting point, but becomes black above 330°.

Anal. Calcd. for $C_8H_7O_2N_3$: N, 23.7. Found: N, 24.0, 24.2.

The free base was only slightly soluble in cold water, but moderately soluble in hot water, in methanol or 95% ethanol. Its alcoholic solutions showed a green fluorescence. Solutions of the amine in dilute aqueous sodium hydroxide, 10% sodium carbonate or in concentrated ammonium hydroxide were light yellow. Diazotization of the amine and coupling with alkaline β-naphthol gave deep red solutions.

7-Aminobenzoyleneurea (V, X = NH_2).—The hydrochloride separated in fine light tan needles from boiling

(13) Ref. 5, p. 2060.

concentrated hydrochloric acid. This salt was also sparingly soluble in either cold or hot water. The yield of hydrochloride was 90% theoretical.

The free base was obtained from boiling water as a white flocculent precipitate from hot water. Above 200° it colored yellow, but did not melt up to 350°.

Anal. Calcd. for $C_8H_7O_2N_3$: N, 23.7. Found: N, 24.0, 24.1.

The amine is almost insoluble in cold water, slightly soluble in boiling water, or in methanol, 95% ethanol, acetone or pyridine. Solutions in concentrated sulfuric acid had a purple fluorescence. Diazotization and coupling with alkaline β-naphthol gave a deep red solution.

8-Aminobenzoyleneurea (IV, X = NH_2).—By the stannous chloride method the base hydrochloride separated from the boiling solution in light tan needles (55% yield). This hydrochloride was sparingly soluble in cold water or in either hot or cold concentrated hydrochloric acid; it was moderately soluble in hot water.

When its solution was treated with dilute ammonium hydroxide and saturated with carbon dioxide, the free base was precipitated in light tan needles, purified by recrystallization from boiling water, m. p. 270–272° dec. uncor. (279–281° cor.).

The free base was also obtained by reduction of a glacial acetic acid solution of 8-nitrobenzoyleneurea in the presence of Adams catalyst with hydrogen at atmospheric pressure, yield 40% of the theoretical.

Diazotization of this amine yielded a clear yellow solution which with aqueous alkali turned a yellow-brown and with alkaline β-naphthol gave a heavy yellow-green precipitate.

The Nitro- and Amino-2,3-dihydroxyquinoxalines

5-Nitro-2,3-dihydroxyquinoxaline (VI, X = NO_2).—3-Nitro-*o*-phenylenediamine (2.03 g., 0.0132 mole) was treated with diethyl oxalate (25 ml.). The solid diamine slowly became red-orange and heat was evolved but solution did not occur. The mixture was therefore refluxed until (after about two hours) its color had faded. After heating about five minutes a heavy precipitate of lustrous tan plates separated. After cooling the solid was filtered, washed with alcohol and dried at 100°. After three recrystallizations from boiling 50% acetic acid (using decolorizing carbon) the product was obtained in fine bright yellow plates, m. p. 284° dec. uncor. (295° dec. cor.) in sealed capillary tubes, weight 1.60 g. (60% theoretical).

Anal. Calcd. for $C_8H_5O_4N_3$: N, 20.3. Found: N, 19.8, 19.6.

The compound was only slightly soluble in benzene, toluene, ether, chloroform, carbon tetrachloride or carbon disulfide; was moderately soluble in methanol, 95% ethanol, acetone, ethyl acetate or pyridine. From its deep red solutions in dilute sodium hydroxide, potassium carbonate or concentrated ammonium hydroxide, carbon dioxide precipitated the free base.

6-Nitro-2,3-dihydroxyquinoxaline (VII, X = NO_2).—4-Nitro-*o*-phenylenediamine (7.15 g., 0.0465 mole) mixed with anhydrous oxalic acid (10.7 g., 0.12 mole) was finely powdered, placed in a Pyrex test-tube, the latter arranged for heating in an air-bath. After slowly raising the temperature of the melt to 150°, it was maintained for one hour, then raised to 180–200° for another hour. After cooling the light brown to black product was extracted with warm 5% aqueous sodium hydroxide from which red solution carbon dioxide precipitated small brown crystals. After four recrystallizations from boiling 50% acetic acid (using decolorizing carbon) the product separated in clusters of white needles, m. p. 329–330° dec. uncor. (343–344° dec. cor.) both in sealed capillary tubes. The yield was 7.1 g. (73% theoretical).

Anal. Calcd. for $C_8H_5O_4N_3$: N, 20.3. Found: N, 19.6.

This compound was moderately soluble in methanol, 95% ethanol, ethyl acetate, acetone or pyridine; it was almost insoluble in ether, benzene, toluene, chloroform, carbon tetrachloride or petroleum ether. Its solutions in dilute aqueous sodium hydroxide, potassium carbonate or concentrated ammonium hydroxide were deep orange-red and from these carbonation precipitated the parent compound.

The Amino-2,3-dihydroxyquinoxalines

5-Amino-2,3-dihydroxyquinoxaline (VI, X = NH_2).—5-Nitro-2,3-dihydroxyquinoxaline (1.6 g., 0.008 mole) suspended in a solution of sodium sulfide (nonahydrate) (5 g. = 0.021 mole) in water (25 ml.) was refluxed for one and one half hours. The deep orange suspension gradually dissolved, yielding a clear brown solution. After cooling the solution was strongly acidified, boiled and filtered (to remove free sulfur). Upon neutralization with sodium bicarbonate the flocculent orange precipitate was filtered. After two recrystallizations from boiling water the amine separated in fine light-yellow crystals, blackening at 336° uncor. with decomposition about 344° uncor. in sealed m. p. tubes. The yield was 0.6 g. (44% theoretical). This compound was also prepared by stannous chloride reduction.

Anal. Calcd. for $C_8H_7O_2N_3$: N, 23.7. Found: N, 23.1, 22.9.

Diazotization in hydrochloric acid yielded a clear yellow solution which with alkali turned clear brown and with alkaline β-naphthol gave a yellow-green precipitate.

6-Amino-2,3-dihydroxyquinoxaline (VII, X = NH_2).—6-Nitro-2,3-dihydroxyquinoxaline (5.0 g., 0.024 mole) suspended in a solution of sodium sulfide crystals (20 g., 0.083 mole) in water (100 ml.) was refluxed for two hours, yielding a deep red solution which gradually turned brown. After cooling and diluting with 100 ml. of water, and strongly acidifying with hydrochloric acid, the solution was boiled and filtered from sulfur. Addition of sodium bicarbonate precipitated the free amine as flocks of pale yellow microscopic needles. On heating the compound becomes black at about 330°, but does not melt up to 350°. The yield was 3.22 g. (75% theoretical).

Because the amine is insoluble in almost all ordinary solvents, it cannot be satisfactorily crystallized and analyses are low.

Anal. Calcd. for $C_8H_7O_2N_3$: N, 23.7. Found: N, 23.3, 23.1.

The amine hydrochloride is moderately soluble in either cold or hot water, but the sulfate is sparingly soluble in cold though moderately soluble in hot water. The amine dissolves in aqueous sodium or potassium hydroxides,

sodium carbonate or concentrated ammonium hydroxide to give clear yellow-brown solutions from which the base is reprecipitated by carbon dioxide.

Aqueous solutions of the salts give with ferric chloride a clear blue color. Diazotization and treatment with alkaline β-naphthol gives a deep red solution.

Test for Chemiluminescence.—The four aminobenzoyleneureas and the two amino-2,3-dihydroxyquinoxalines were tested at 28° for possible chemiluminescence on oxidation by visual observation in a dark room. A 10-ml. sample of a 0.04 molar solution of each compound in 0.5 *N* sodium hydroxide was successively treated with 1 ml. of 3% hydrogen peroxide, 1 ml. of 3% potassium ferricyanide. In a second series of tests each 10-ml. sample was treated first with a trace of the catalytic salicylaldehyde ethylenediimine ferric chloride complex,[14] followed by 1 ml. of 3% hydrogen peroxide. In a third series of tests each 10-ml. sample was treated with 10 ml. of 8% sodium hypochlorite solution.

(14) Thielert and Pfeiffer, *Ber.*, **71**, 1401 (1938).

Summary

1. All four isomeric aminobenzoyleneureas and both possible amino-2,3-dihydroxyquinoxalines have been prepared by reduction of the corresponding nitro compounds.

2. None of them shows significant chemiluminescence under conditions which with the isomeric 3-aminophthalhydrazide give intense effects.

3. Previous assumption regarding the indispensability of the hydrazine residue for chemiluminescent power has thus been demonstrated.

CAMBRIDGE, MASS. RECEIVED MAY 14, 1942

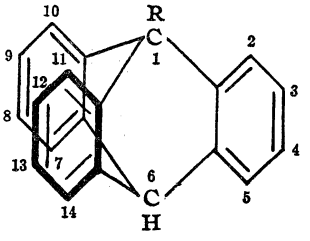
Triptycene[1] (9,10-*o*-Benzenoanthracene)

BY PAUL D. BARTLETT, M. JOSEPHINE RYAN AND SAUL G. COHEN

Previous publications from this Laboratory have brought out the special properties of substituents located on the bridgehead of a bicyclic ring system.[2] These findings would lead us to

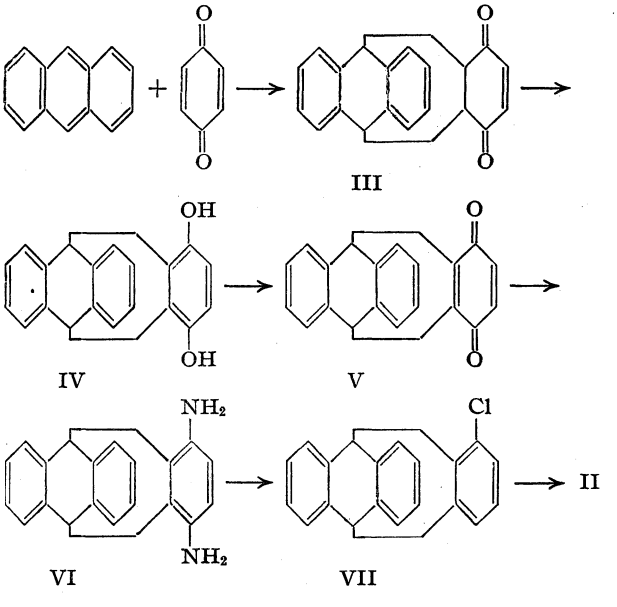


I, R absent

II, R = H

predict that the analog (I) of the triphenylmethyl radical in which the ortho positions of the three phenyl groups are united to a common CH should have much less tendency to exist as a free radical than triphenylmethyl itself, as a result of its inability to assume the coplanar form demanded by the usual resonance structures.[3] With the eventual purpose of testing this prediction we have prepared the parent hydrocarbon II (9,10-*o*-benzenoanthracene, or tribenzobicyclo(2,2,2)octatriene) and studied some of its chemical properties. For convenience, the name "triptycene" is suggested for this symmetrical hydrocarbon.[1]

The steps in the synthesis of triptycene are as follows



The removal of the functional groups was achieved only after very many unsuccessful attempts. We tried to dehydroxylate the hydroquinone IV with zinc dust, to convert it into a dibromide or diiodide with phosphorus halides, to reduce the quinone by hydrogenation, by the

(1) This name is proposed because the shape of this ring system suggests the triptych of antiquity, which was a book with three leaves hinged on a common axis. We are indebted to Professor Mason Hammond of the Harvard Department of Classics for this suggestion.

(2) Bartlett and Knox, THIS JOURNAL, **61**, 3184 (1939); Bartlett and Cohen, *ibid.*, **62**, 1183 (1940); Bartlett and Woods, *ibid.*, **62**, 2933 (1940).

Clemmensen and Wolff–Kishner procedures, to gain a start in the reduction by replacing benzoquinone with Δ^2-cyclohexenone in the initial step, as well as several less rational procedures. The hydroxylated ring was successfully reduced, but the hydrogenation product could not be converted to triptycene. Finally, numerous ways were tried for the deamination of the diamine VI, by tetrazotization in dilute and concentrated hydrochloric acid, sirupy phosphoric and concentrated sulfuric acid and mixtures, with nitrous acid and nitrous fumes, followed by attempted reduction with stannous chloride, alkaline formaldehyde, alcohol, and also attempted Sandmeyer reactions. The difficulties appeared to result from the combined facts of the ready nuclear substitution in a diamine and the great tendency of this ring system to yield anthracene under even relatively mild conditions, and especially when the treatment of the substituted ring enabled this to occur irreversibly. Successful deamination of the diamine was accomplished only by tetrazotizing at 10° in a mixture of sulfuric acid, acetic acid and water, destroying the excess nitrous acid, and reducing with hypophosphorous acid.[4] Control of the temperature proved to be of great importance.

The product of the hypophosphorous acid reduction was not triptycene, but monochlorotriptycene accompanied by a little dichlorination product. Apparently the *p*-diazonium substituent, like the *p*-nitro-, activates the N_2-group toward replacement, at the same time deactivating it toward reductive elimination. The replacement of the first N_2-group by chlorine allows the remaining N_2-group to be eliminated, yielding 2-chlorotriptycene as the principal product. The same treatment using the hydrobromide instead of the hydrochloride of the diamine yielded a small amount of dibromotriptycene. Each of these halogenated products was smoothly reduced to triptycene by the method of Busch.[5] In each case the deamination was the weak step in the synthesis giving poor yields.

Triptycene crystallizes in fine white rhomboids melting at 254.8–255.2°, and is advantageously crystallized from methanol–water. It is very soluble in benzene, soluble in ethyl alcohol, ether, acetone, chloroform and slightly soluble in methanol.

To the extent to which the central hydrogen atom of triphenylmethane is activated by the possibility of resonance in the triphenylmethide ion, such activity should be diminished or absent in triptycene. Triptycene in fact yields no exchange with phenylisopropylpotassium under conditions which lead to immediate reaction in the case of triphenylmethane; it is not chlorinated by sulfuryl chloride in the presence of benzoyl peroxide whereas toluene, under identical conditions, gives a high yield of benzyl chloride; and chromic anhydride, under conditions which lead to the formation of triphenylcarbinol from triphenylmethane, gives only anthraquinone and carbon dioxide from triptycene. Moderation of the conditions permitted recovery of only a mixture of unchanged starting material and anthraquinone, showing that if 1-hydroxytriptycene is produced at all under these conditions it is immediately decomposed.

In view of the complete failure of the hydrogen in the 1-position of triptycene to show the reactivity characteristic of the central hydrogen of triphenylmethane, it seems rather likely that the oxidative decomposition of triptycene to anthraquinone is initiated not by attack at the 1-position but by attack upon one of the benzene rings. In seeking a possible reason why these rings should be more susceptible to oxidative attack than normal benzene rings, we observe that the internal bond angles of the bicyclo(2,2,2)octane ring system must always be close to the normal value of 109°28′. This would lead us to expect a Mills–Nixon effect[6] tending to damp the resonance in each benzene ring by giving preference to the bond structures represented in the formula II. Any such effect would render the oxidative disruption of one of the benzene rings more likely, but would disappear upon opening of the bicyclic ring, system and formation of the dihydroanthracene type. In a quantitative oxidation by chromic anhydride in acetic acid slightly more than enough carbon dioxide was produced to account for the missing benzene ring. The Mills–Nixon effect, if present, is not sufficiently extreme to permit reaction of triptycene with maleic anhydride or with triphenylmethyl, since negative results were obtained with both these compounds.

Experimental

Formation of the Adduct III from Anthracene and Quinone.—The route of Clar[7] to the quinone IV was

(4) Adams and Kornblum, THIS JOURNAL, **63**, 188 (1941).

(5) Busch and Stöve, *Ber.*, **49**, 1063 (1916).

(7) Clar, *Ber.*, **64**, 1676 (1931).

modified, yielding, under our conditions, an improved product. Anthracene (108 g.) twice recrystallized from xylene, and 73 g. of reagent grade quinone were heated under reflux in 650 cc. of xylene for two hours.[7] The solid was collected on a filter and thoroughly washed with hot water to remove quinone and quinhydrone. It was recrystallized from xylene giving 143 g. (83%) of pale yellow rhomboids. This compound has the characteristic melting behavior observed by Clar, which depends on the rate of heating; it is yellow at 207°, red at 210°, and at higher temperatures it carbonizes.

Rearrangement of the Adduct III to the Hydroquinone IV.—To a solution of 11.5 g. of the adduct III in 150 cc. of glacial acetic acid at the boiling point, four drops of 40% hydrobromic acid were added. A vigorous evolution of heat followed and the solution took on an orange color which gradually faded as a fine white solid precipitated out. After another half hour at the boiling point, the reaction mixture was cooled and filtered; yield 10.3 g. (90%); m. p. 338–340° dec.

Hydrogenation of 2,5-Triptycenediol (IV) with Raney Nickel.—A solution of 2 g. of the hydroquinone IV in 38 cc. of warm dioxane was treated with hydrogen at 1140 lb. pressure in the presence of 1 g. of Raney nickel, and the temperature was gradually raised. At 200° hydrogen absorption took place and had ceased after seventeen hours. The mixture was filtered into water, the resulting solid was washed with petroleum ether and recrystallized from benzene. The product, 0.68 g. of white plates, melted at 220–224°. Its solution in alcoholic alkali turned red on shaking in air and the color was discharged by sodium hydrosulfite. Evidently the triptycenehydroquinone had become hydrogenated in the two unhydroxylated benzene rings.

Anal. Calcd. for $C_{20}H_{26}O_2$: C, 80.50; H, 8.78. Found: C, 80.20; H, 8.61.

Hydrogenation of the Adduct III with Copper Chromite.—To a solution of 2 g. of the direct addition product III of quinone to anthracene in 35 cc. of dioxane, 0.25 g. of copper chromite was added. The hydrogenation was conducted at 160° under 2200 lb. pressure for ten hours; the solution was filtered in an atmosphere of carbon dioxide and concentrated in a stream of nitrogen. This precaution was found useful in minimizing the dark coloration which always appeared when the hydrogenated solution was exposed to the air. Precipitation with petroleum ether, followed by crystallization from alcohol, yielded 67% of almost colorless crystals melting at 226–228°.

Anal. Calcd. for $C_{20}H_{20}O_2$: C, 82.15; H, 6.90. Found: C, 82.06; H, 7.10.

This pure product was not oxidized in air in the presence of alkali. It yielded a diacetate, m. p. 177–178°. Apparently the action of copper chromite on the non-aromatic ring of the adduct was to hydrogenate this ring preferentially, whereas the nickel catalyst selected from three aromatic rings the two carrying no oxygenated substituents.

Attempts to Dehydrate the Saturated Diol.—Heating of 0.1 g. of the diol under nitrogen at 300° for thirty minutes, followed by vacuum sublimation, led to the isolation of 0.05 g. of anthracene (mixed melting point).

A mixture of 0.1 g. of the diol and 0.5 g. of anhydrous oxalic acid was heated in an atmosphere of nitrogen. The temperature was slowly raised from 110 to 135° in twenty-five minutes and then to 190° in ten minutes. Anthracene sublimed to the top of the tube.

In the same experiment, but with phosphoric acid instead of oxalic, anthracene appeared somewhat above 100°. The use of *p*-toluenesulfonic acid led to no solid products.

Oxidation of the Hydroquinone IV to the Quinone V.—Nineteeen grams of the hydroquinone IV was dissolved in a minimum amount of hot glacial acetic acid (app. 1100 cc.) and then a solution of 4 g. of potassium bromate in 300 cc. of hot water was added. A deep orange color developed immediately. The solution was boiled for a minute or two and then 200 cc. more of hot water was added and the boiling continued for a few minutes. The solution was cooled and the orange solid collected. The quinone was washed with acetic acid and then with water; yield 17.5 g. (93%); m. p. 292–296°.

The dioxime was prepared by two hours of boiling of a solution of 0.25 g. of V and 1 g. of hydroxylamine hydrochloride in 25 cc. of ethanol. The dioxime was isolated by pouring into water and was crystallized (78% yield of five yellow rosets) from acetic acid. Drying *in vacuo* at 100° for twenty-four hours was necessary to remove acetic acid from the product; m. p. 246° dec.

Anal. Calcd. for $C_{20}H_{14}N_2O_2$: C, 76.42; H, 4.49. Found: C, 76.16; H, 4.67.

Reduction of the Dioxime to the Diamine VI.—Twenty grams of the dioxime was dissolved in 750 cc. of alcohol on the steam-bath. When the alcoholic solution was at about 60°, a solution of 88 g. of stannous chloride in 200 cc. of concentrated hydrochloric acid was added to it with stirring. The mixture was heated for a few minutes more and then cooled and filtered. The solid was washed with alcoholic hydrochloric acid and then with ether. Further purification was effected by dissolving in hot water and precipitating again by the addition of concentrated hydrochloric acid. Each successive reprecipitation makes the salt grayer, probably because of oxidation. The yield was 19.8 g. (86%). The hydrochloride gradually decomposed above 210°.

The free base was prepared by dissolving the diamine hydrochloride in hot water and gradually adding 10% sodium hydroxide. This product turns a grayish-purple in air; m. p. 307° dec. The best analysis obtained was still not good but the compound is extremely difficult to burn.

Anal. Calcd. for $C_{20}H_{16}N_2$: C, 84.50; H, 5.64; N, 9.85. Found: C, 83.06; H, 5.99; N, 9.65.

The diacetyl derivative is obtained as small white crystals from acetic acid, dec. 370°.

Anal. Cacld. for $C_{24}H_{20}N_2O_2$: C, 78.23; H, 5.47. Found: C, 78.05; H, 5.62.

Deamination of the Diamine VI.—A suspension of 5 g. of the amine hydrochloride in 150 cc. of glacial acetic acid was cooled to 10° and to it was added a similarly cooled mixture of 100 cc. of concentrated sulfuric acid, 100 cc. of acetic acid, and 60 cc. of water. The temperature was carefully controlled during the reaction because sulfonation takes place above 15°. Five grams of sodium nitrite was dusted in gradually, turning the solution blood red.

After all the nitrite was added the mixture was stirred in the cold for at least an hour and then urea was added until the solution no longer turned starch–iodide paper blue. The thick solution was added to a filtered solution of 12 g. of sodium hypophosphite in 300 cc. of concentrated hydrochloric acid and allowed to stand overnight. The addition of a quantity of water precipitated 3.8 g. of a flaky tan solid melting at 175° with decomposition. All this material was then subjected to sublimation by heating at 195° at a pressure of 2 mm. The best yield obtained was 1.8 g. of shiny white crystals, m. p. 219–221°. After three recrystallizations from methanol the melting point was 222–223°. A quantitative analysis for chlorine indicated that the product was monochlorotriptycene with a small amount of dichlorotriptycene.

Anal. Calcd. for $C_{20}H_{13}Cl$: C, 83.18; H, 5.17; Cl, 12.30. Found: C, 82.16; H, 4.95; Cl, 13.67.

2,5-Dibromotriptycene.—Reduction of the diazonium compound was attempted in the absence of halogen acid and no reaction whatever took place even over a long period of time. Hydrobromic acid had the same effect as hydrochloric and gave dibromotriptycene, m. p. 227–228°, in very poor yield. Debromination of this compound gave the same product as the dechlorination of chlorotriptycene.

Anal. Calcd. for $C_{20}H_{12}Br_2$: C, 58.43; H, 2.95. Found: C, 58.79; H, 2.73.

Triptycene (II).—This reaction was run by the method of Busch and Stöve;[5] 0.2 g. of the chloro compound was dissolved in 40 cc. of alcohol and 10 cc. of 10% alcoholic potassium hydroxide was added. Four grams of the catalyst, palladium on calcium carbonate, and 12 drops of hydrazine hydrate were added. After refluxing on the steam-bath for one-half hour the mixture was cooled slightly, filtered free of catalyst, and poured into water. There was obtained 0.18 g. of fine white crystals which could be crystallized from methanol–water; m. p. 254.8–255.2°. Like the rest of these compounds the hydrocarbon was hard to burn in a carbon–hydrogen analysis.

Anal. Calcd. for $C_{20}H_{14}$: C, 94.50; H, 5.51. Found: C, 94.13, 93.25, 93.87, 94.01; H, 5.40, 5.62, 5.32, 5.27.

Triptycene and Phenylisopropylpotassium.—Triptycene (0.1 g.) was placed in a round-bottom, long-necked flask with two side arms. The flask was swept out with nitrogen for a short time and then sealed tightly. Ten cc. of 0.055 *N* phenylisopropylpotassium in dry ether, prepared by Dr. J. E. Jones, was added slowly through one of the side arms. After the solution had stood for twenty-one hours with occasional shaking, no color change could be detected. Dry carbon dioxide was bubbled into the solution and the material removed from the flask. After evaporation of the ether and extraction with alkali, 0.08 g. of triptycene was recovered, m. p. 252–253°, mixed m. p. with known sample 253–254°.

Triptycene and Chlorine.—Triptycene (0.2 g.) was dissolved in 50 cc. of purified carbon tetrachloride. The flask was partially evacuated, and then 25 cc. of the chlorine gas was added from a gas buret. The contents of the flask were thoroughly shaken and left in the sunlight for several days. When the carbon tetrachloride was evaporated, there remained a dirty white solid, m. p. 224°. After sublimation the melting point was 246–248° and a mixed melting point with triptycene was 244–246°. A carbon–hydrogen analysis indicated that a very small amount of chlorine had been taken up.

Anal. Calcd. for $C_{20}H_{14}$: C, 94.50; H, 5.51. Found: C, 91.48; H, 5.10.

In proportions which led to bromination of toluene in good yield[8] without solvent, sulfuryl chloride and benzoyl peroxide had no action on triptycene in carbon tetrachloride, 85% of the hydrocarbon being recovered unchanged.

Oxidation of Triptycene.—Triptycene was oxidized under conditions which oxidize triphenylmethane to triphenylcarbinol. Triptycene (0.2 g.) was dissolved in 50 cc. of purified glacial acetic acid and 0.5 g. of chromic anhydride was added slowly. The flask was heated very gently on the steam-bath overnight. The green solution was poured into water and a yellow solid precipitated which could be crystallized from benzene; m. p. 283–285°; mixed melting point of the sample with anthraquinone 284–285°.

To determine what became of the rest of the molecule during the oxidation, triptycene was oxidized in a stream of dry air. The air was then passed through an absorption tube containing dehydrite and one containing ascarite. A sample of 0.70 g. of triptycene was heated at 55° with 3.5 g. of chromic anhydride, and 0.782 g. of carbon dioxide was absorbed in the ascarite tube. Since the calculated amount would be 0.726 g. if the third benzene ring were completely oxidized, some other formation of carbon dioxide such as further oxidation of anthraquinone or oxidation of acetic acid must be occurring. Anthraquinone was recovered from the reaction flask in 76% yield.

In an attempt to isolate an intermediate in this oxidation 0.2-g. samples of triptycene were put away for a week at room temperature with 0.05 g. of chromic anhydride and 0.12 g. of potassium permanganate, respectively, in acetic acid solution. From the chromic anhydride only triptycene was recovered, but from the reaction with permanganate both anthraquinone and triptycene were recovered, showing that the intermediate products formed are more susceptible to oxidation than triptycene.

Triptycene and Maleic Anhydride.—Triptycene (0.2 g.) and maleic anhydride (1 g.) in 50 cc. of nitrobenzene were refluxed on a hot-plate for four hours. The nitrobenzene was removed *in vacuo* and the black residue was extracted with alcohol. The alcoholic solution was decolorized with charcoal and poured into water. A white solid weighing 0.13 g. was obtained and recrystallized from methanol. It melted at 253–254° alone and at 254° when mixed with triptycene.

Acknowledgment.—We are indebted to the Associates of Physical Sciences of Harvard University for grants in support of this and related work to be published later.

Summary

The symmetrical hydrocarbon, 9,10-*o*-benzenoanthracene or tribenzobicyclo(2,2,2)octatriene (II)

(8) Kharasch and Brown, THIS JOURNAL, **61**, 2142 (1939); Kharasch and Read, *ibid.*, **61**, 3089 (1939).

has been prepared and its properties studied. The name "triptycene" is proposed for this hydrocarbon. Being an analog of triphenylmethane whose symmetrical anion cannot assume the coplanar form demanded by the usual resonance structures, triptycene is entirely lacking in the activity of its aliphatic hydrogen toward potassium exchange, chlorination, and oxidation which characterizes triphenylmethane.

Tetrahydrocannabinol Analogs with Marihuana Activity. XV[1]

BY ROGER ADAMS, S. LOEWE, C. W. THEOBALD AND C. M. SMITH

The study of analogs of synthetic tetrahydrocannabinol (I) wherein the left-hand ring was modified has comprised those molecules in which the methyl group was eliminated and those in which the methyl group was shifted to the 8- and 10-positions.[2] This investigation has now been extended, and a variety of products have been synthesized as shown in formulas II–VI.

molecules. Compound V, which has a potency not much below that of tetrahydrocannabinol (I), is the only exception; but the normal ataxia action is here accompanied by a convulsant action similar to that observed with tetrahydrocannabidiol.

Experimental

3-Ethylcyclohexanol.—Five hundred grams of *m*-ethylphenol (Eastman Kodak) was reduced with Raney nickel at 136 atm. and 200°. The product was rinsed from the bomb with ethanol, the catalyst removed by filtration, the ethanol removed on the steam-cone, and the residue distilled under reduced pressure. There was obtained 488 g. (89%) of a water-white liquid boiling at 96° (20 mm.) and 192.5–193° (748 mm.); $n^{20}D$ 1.4619; d^{20} 0.9164.

Anal. Calcd. for $C_8H_{16}O$: C, 74.94; H, 12.58. Found: C, 75.07; H, 12.67.

The 3,5-dinitrobenzoate of 3-ethylcyclohexanol after crystallization from aqueous ethanol melts at 133–134° (cor.).

Anal. Calcd. for $C_{15}H_{18}O_6N_2$: C, 55.89; H, 5.63; N, 8.69. Found: C, 56.26; H, 5.54; N, 8.67.

The 3,4-dimethylcyclohexanol[3] and the 3,5-dimethylcyclohexanol[4] were prepared in a similar manner. The constants were in agreement with those previously described.

3-Ethylcyclohexanone.—This was prepared by oxidation of 3-ethylcyclohexanol with sodium dichromate and sulfuric acid according to the "Organic Syntheses" procedure for the oxidation of menthol to menthone.[5] A yield of 72% of a liquid boiling at 81° (12 mm.) and at 99–100° (39 mm.) was obtained; $n^{20}D$ 1.4499; d^{20}_4 0.9145.

Anal. Calcd. for $C_8H_{14}O$: C, 76.21; H, 11.19. Found: C, 76.02; H, 11.27.

The semicarbazone of 3-ethylcyclohexanone melted at 166–167° after recrystallization from aqueous ethanol.

Anal. Calcd. for $C_9H_{17}ON_3$: C, 58.99; H, 9.36; N, 22.93. Found: C, 59.23; H, 9.57; N, 23.07.

The *p*-nitrophenylhydrazone of 3-ethylcyclohexanone after recrystallization from petroleum ether (b. p. 60–110°) melted at 128–129° (cor.).

These data are not completely in accord with those given by Braun, Mannes and Reuter.[6] They obtained this ketone by dry distillation of the calcium salt of β-ethylpimelic acid and report b. p. 192–194°, $n^{20}D$ 1.4543; semicarbazone, m. p. 184°, *p*-nitrophenylhydrazone, m. p. 130°.

3,4-Dimethylcyclohexanone[7] and 3,5-dimethylcyclohexanone[4] were prepared in 70 and 73% yields, respectively, in the same manner as 3-ethylcyclohexanone.

3,3-Dimethylcyclohexanone was synthesized by the method of Crossley and Renouf[8] and cycloheptanone by ring expansion of cyclohexanone.[9]

All the ketones were readily converted to the keto esters by addition of a mixture of one mole of ketone and one mole of ethyl oxalate to one mole of sodium ethoxide in ethanol to form the glyoxylic esters. These were pyrolyzed, without purification, over powdered soft glass and a trace of iron powder.[1,10] These keto esters, with the exception of ethyl cycloheptanone-2-carboxylate, are new compounds and are listed in Table II.

Ethyl Cycloheptanone-2-carboxylate.—This ester was obtained by the above-mentioned procedure in 14% yield, b. p. 77–79° (0.04 mm.); $n^{20}D$ 1.4700; copper salt, m. p. 193–194° (cor.); the 1-phenyl-3,4-pentamethylene-5-pyrazolone obtained by treatment of the ester with phenylhydrazine melted at 207–210° (cor.) with decomposition. Dieckmann[11] prepared this ester by the cyclization of diethylsuberate and reported b. p. 110–115° (12 mm.); copper salt, m. p. 195°; phenylpyrazolone, m. p. 210°.

1-Hydroxy-3-*n*-amyl-*x*-alkyl-7,8,9,10-tetrahydro-6-dibenzopyrones.—These were prepared from the keto esters

by the general procedure previously described.[12] The constants of these molecules are given in Table III.

1-Hydroxy-3-*n*-amyl-?-6,6-dimethyl-7,8,9,10-tetrahydro-6-dibenzopyrans.—The pyrans were formed in the usual way[12]; constants are given in Table IV.

Summary

1. The following pyrans: (1) 1-hydroxy-3-*n*-amyl-6,6-dimethyl-9-ethyl-7,8,9,10-tetrahydro-6-dibenzopyran, (2) 1-hydroxy-3-*n*-amyl-6,6,9,9-tetramethyl-7,8,9,10-tetrahydro-6-dibenzopyran, (3) 1-hydroxy-3-*n*-amyl-6,6,8,9-tetramethyl-7,8,9,10-tetrahydro-6-dibenzopyran, (4) 1-hydroxy-3-*n*-amyl-6,6,7,9-tetramethyl-7,8,9,10-tetrahydro-6-dibenzopyran, and (5) 2,2-dimethyl-3,4-pentamethylene-5-hydroxy-7-*n*-amyl-1,2-benzopyran have been synthesized.

2. The pharmacological potencies of (1), (2), (3), and (5) are only about 10 to 20% that of the synthetic tetrahydrocannabinol standard; the potency of (4) is only slightly less than that of the standard, but the activity of this compound is accompanied by a convulsant action.

The Condensation of Methyl Dipropyl Carbinols with Phenol in the Presence of Aluminum Chloride

BY RALPH C. HUSTON AND CARL R. MELOY[1]

Previous papers from this Laboratory[2,3] have described the condensations of *t*-butyl, *t*-amyl the *t*-hexyl and the *t*-heptyl alcohols with phenol in the presence of aluminum chloride. In a similar manner the dimethylamyl,[4] methylethylbutyl,[5] and diethylpropyl[6] carbinols have been condensed with phenol. In continuation of this investigation the methyldipropyl carbinols have now been prepared.

The 4-methylheptanol-4[7] was prepared by treating two moles of *n*-propylmagnesium bromide with one mole of ethyl acetate, while the 2,3-dimethylhexanol-3[8] resulted from the treatment of one mole of the above Grignard reagent with one mole of 2-methylbutanone-3. Methyl Grignard was used with 2,4-dimethylpentanone-3 in preparing 2,3,4-trimethylpentanol-3.[9]

The alcohols were condensed with phenol in the presence of the anhydrous aluminum salt. Yields of from 47 to 65% of the *p*-*t*-alkylphenols were obtained with no isolation of other isomers or disubstituted products. The α-naphthylurethans and 3,5-dinitrobenzoyl esters of the three *p*-*t*-alkylphenols were prepared.

Huston and Cline[10] isolated and identified from condensations between benzene and methyldipropyl carbinols, 4-methyl-4-phenylheptane, 2,3-dimethyl-3-phenylhexane, and 2,3,4-trimethyl-3-phenylpentane. These alkylbenzenes were nitrated, reduced, diazotized and hydrolyzed to the phenols.[2,3,4] The melting points and mixed melt-

ing point determinations of the α-naphthylurethans of the phenols thus prepared indicated that they were the same as those prepared in the condensations. The position of the entering group was established through oxidation[11] of the *p*-nitro-*t*-alkylbenzene by heating a portion with 6 *N* nitric acid in a sealed Carius tube at 130°. In each case the product obtained was *p*-nitrobenzoic acid, which was identified by melting point and mixed melting point.

In answer to the suggestion that the alkyl groups might rearrange during condensation and to eliminate any doubt as to the correctness of the formulas assigned the tertiary-octylphenols, attention is called to the following:

(a) The alcohols were prepared by standard methods and checked as to properties with the literature.

(b) In the rearrangement of alkyl groups during processes of condensation, primary groups may change to secondary or tertiary, and secondary groups may change to tertiary.[12]

We were unable to find instances of the reverse processes in which appreciable yields of primary or secondary groups were formed from groups of higher branching. These generalizations have been recently confirmd by a study of the condensation of secondary alcohols with benzene[13] and with phenol.[14]

(c) Two other possibilities of formation of tertiary octylphenols from 2,3,4-trimethylpentanol-2 might be proposed.

1. One of the tertiary hydrogens might shift to the number three carbon by the intermediate formation of 2,3,4-pentene-2 and the addition of hydrochloric acid. The product of condensation would then be 2,3,4-trimethyl-2-*p*-hydroxyphenylpentane[4] which melts at 74° and gives an α-naphthylurethan which melts at 115°.

2. The formation of the cation  might cause the migration of the methyl group on number three carbon to number two carbon which change might be followed by a migration of the tertiary hydrogen as outlined under (1). Condensation would then give 2,4,4-trimethyl-2-*p*-hydroxyphenylpentane.[4] This phenol melts at 83° and its α-naphthylurethan melts at 102°.

(d) There appears to be only one possibility of rearrangement in the case of 2,3-dimethylhexanol-3. Migration of the tertiary hydrogen would give 2,3-dimethyl-2-*p*-hydroxyphenylhexane[4] as the product of condensation. This compound is a liquid (b. p. 293°) which gives an α-naphthylurethan melting at 105°.

(e) Since 4-methylheptanol-4 contains no tertiary hydrogen, rearrangement without fragmentation does not appear to be possible.

(f) The *seventeen* possible tertiary octyl alcohols have been condensed with phenol yielding *seventeen* different *p*-*t*-octylphenols.[4,5,6]

Experimental

Condensations.—Since all of the condensations were carried out in a similar manner, a typical run is described. Thirty-five grams of phenol was dissolved in 32.5 g. of the octyl alcohol in a 500-ml., three-necked, round-bottomed flask equipped with a short reflux condenser, a

thermometer and a glycerol-sealed stirrer. Seventeen grams of anhydrous aluminum chloride was added in small portions by shaking from a small Erlenmeyer flask equipped with a long neck made of glass tubing. The reaction was carried out at 25–30° and the temperature kept constant by use of a water-bath, when necessary. After standing overnight the mixture was decomposed by pouring on ice and hydrochloric acid. The condensate was extracted from the water solution with ether and the phenols isolated from this ether extract by fractionation.

The 3,5-dinitrobenzoyl esters were prepared by the method of Shriner and Fuson.[15]

The use of pyridine as a catalyst resulted in high yields of the esters which were recrystallized from 60% alcohol.

The method of French and Wirtel[16] was employed in the preparation of α-naphthylurethans. Addition of a few drops of a solution of trimethylamine in ether caused an immediate reaction. Recrystallization was accomplished from warm petroleum ether.

Summary

1. The methyldipropyl carbinols have been condensed with phenol in the presence of aluminum chloride to give good yields of the corresponding *p-t*-octylphenols.

2. The 3,5-dinitrobenzoyl esters and the α-naphthylurethans of these *p-t*-octylphenols have been prepared.

3. The structures have been established by synthesis.

Water-soluble Compounds with Antihemorrhagic Activity

BY B. R. BAKER AND G. H. CARLSON

In a search for water-soluble compounds with antihemorrhagic activity, a number of derivatives of 2-methyl-1,4-naphthohydroquinone and of the quinone have been prepared and, to minimize duplication of efforts, the experience of this Laboratory is reported at this time.

The highly active sodium salts of 1-acetoxy-2-methyl-4-naphthyl hydrogen succinate[1] (a summary of bioassays is given in Table III) and of the corresponding hydrogen glutarate were sufficiently soluble for parenteral use but were rapidly decomposed in solution even at ordinary temperature.[2] Both the mono- and the disodium salts of the hydroquinone *bis*-hydrogen glutarate were readily hydrolyzed. Likewise the salt of the hydrogen succinate of 3-methyl-1-naphthol,[3] though somewhat more stable than that of 2-methyl-1,4-naphthohydroquinone, gradually decomposed in aqueous solution and further work with partially esterified polycarboxylic acids was discontinued.

Chloroacetyl chloride readily converted 1-acetoxy-2-methyl-4-naphthol to the acetoxy-monochloroacetoxy derivative and the latter, with trimethylamine, yielded the readily soluble quaternary ammonium salt which, like the corresponding diammonium salt prepared from the 1,4-*bis*-chloroacetoxy-2-methylnaphthalene as well as the hydrochloride of 1-acetoxy-4-(β-aminopropionoxy)-2-methylnaphthalene, hydrolyzed in warm, aqueous solution. Accordingly, the purely organic esters proved impractical whether employed in alkaline or acidic media and were not further considered.

Partial esterification of phosphoric, thiophosphoric and sulfuric acids with 1-acetoxy-2-methyl-4-naphthol gave compounds which, as sodium salts, were stable in aqueous solution and could be sterilized by autoclaving. Whereas the phosphate and the sulfate showed antihemorrhagic activity equal to 50 and 35%, respectively, of that of an equimolecular amount of 2-methyl-1,4-naphthoquinone, the thiophosphate was less than

(1) Orientation of the substituents is established by the following reactions. Partial deacetylation of 1,4-diacetoxy-2-methylnaphthalene, prepared by reductive acetylation of 2-methyl-1,4-naphthoquinone [for the method see THIS JOURNAL, **64**, 1096 (1942)], gave an acetoxy-2-methylnaphthol, and its methyl ether, after deacetylation and treatment with ammonium sulfite at 180°, yielded an amine which, as the acetate, was identical with that prepared by reducing the coupling product of 3-methyl-1-naphthol and diazotized sulfanilic acid, acetylating the resulting 2-methyl-aminonaphthol (the hydrochloride of which was readily oxidized to 2-methyl-1,4-naphthoquinone) and converting the acetaminonaphthol to the corresponding methyl ether. By this series of reactions the methoxyl in the acetamino derivative and the acetoxyl group in the acetoxy-2-methylnaphthol are fixed in the 4- and 1-positions, respectively.

(2) The instability of apparently this same hydrogen succinate has been reported also by Buck and Ardis, THIS JOURNAL, **64**, 725 (1942).

(3) The naphthol and 3-methyl-1-tetralone [(a) Bachmann and Struve, THIS JOURNAL, **62**, 1618 (1940); (b) Tishler, Fieser and Wendler, *ibid.*, **62**, 2879 (1940)] were prepared by the improved methods given in the experimental section.

20% as active and was required in too large dosage to be generally applicable in practice. The response with both the phosphate and the sulfate, however, was rapid and these essentially neutral solutions are especially advantageous since administration may be either intravenous or intramuscular.

Whereas the diglucoside of 2-methyl-1,4-naphthohydroquinone is too insoluble for practical use of the aqueous solution,[4] about 3 mg. of the monoglucoside dissolves per milliliter and the solution, like that of the more soluble monomaltoside, showed approximately two-thirds the antihemorrhagic activity of an equimolecular amount of the parent quinone. Aqueous solutions of the glycosides are slowly oxidized by air but are stable in the absence of oxygen and under such conditions, or in the presence of reducing agents such as bisulfite, may be sterilized by autoclaving.

In contrast to the glycosides described above, those of 3-methyl-1-naphthol were less active and showed complete response at a minimum of 10 and 20 micrograms, respectively. Glycoside formation, apparently, had decreased the activity of the naphthol somewhat more than that of 2-methyl-1,4-naphthohydroquinone, but, whereas the naphthol has been reported as active at concentrations of 0.6 microgram,[5] complete response was obtained with no less than 5 micrograms and the relative decrease in the activities appears to be very nearly the same. Comparatively large doses of the naphthol derivatives are required for therapeutic uses, but these compounds have the advantage of being stable in aqueous solution without addition of stabilizers.

Complete response was obtained with 50 and 3 micrograms of the mono- and the dihydrochlorides, respectively, of 1-amino- and 1,4-diamino-2-methylnaphthalene,[6] but, on conversion to the monoacetates, these compounds were inactive at the high concentration. The N-(2-methyl-1-naphthyl)-gluconamide and the N-(1-amino-2-methyl-4-naphthyl)-succinamic acid[7] showed corresponding low activities and were inapplicable. Furthermore, because aqueous solutions of the hydrochlorides of these amines were photosensitive and oxidized very easily, commercial application, even of stabilized solutions, seemed inadvisable.

The decreased activity of 2-methyl-1,4-naphthoquinone-ω-potassium sulfonate,[8] of 2-piperidino-1-naphthol[9] and of 1-amino-2-naphthylacetic acid as compared with the parent compounds substantiates the now widely held opinion that, for high antihemorrhagic activity, the methyl group must remain intact in the 2-methylnaphthalene derivatives and the inactivity of 3-methyl-1,4-dihydroxyisoquinoline[10] indicates that alteration in the nuclear structure similarly results in inactivation.[11]

Experimental

1-Acetamino-2-methyl-4-methoxynaphthalene. (A) From 1,4-Diacetoxy-2-methylnaphthalene.—A mixture of 20 g. of 1-acetoxy-2-methyl-4-naphthol,[1] 20 cc. of dimethyl sulfate, 40 g. of anhydrous potassium carbonate and 200 cc. of acetone was boiled for fourteen hours, the filtered solution, diluted with benzene, was washed with water, cold 2% alkali containing a little sodium dithionite, again with water and solvent was distilled from the benzene solution *in vacuo*. The residue, crystallized from petroleum ether, gave 19 g. of the methyl ether, melting at 67–68° after crystallization from ethanol. *Anal.* Calcd. for $C_{14}H_{14}O_3$: C, 73.0; H, 6.1. Found: C, 72.7; H, 6.5.

Deacetylation of the methyl ether (15 g.) with sodium methylate gave 4-methoxy-2-methyl-1-naphthol (5.5 g.; m. p. 101–103° after crystallization from carbon tetrachloride. *Anal.* Calcd. for $C_{12}H_{12}O_2$: C, 76.7; H, 6.4. Found: C, 76.9; H, 6.6), but a better yield was obtained by adding, during ten minutes, 80 cc. of 10% sodium hydroxide containing 0.5 g. of sodium dithionite to a boiling solution of 19 g. of 1-acetoxy-2-methyl-4-methoxynaphthalene in 80 cc. of methanol and, after forty-five minutes, diluting the cooled solution with water. Extraction of the benzene solution of the product with 5% alkali and acidification of the alkaline extract yielded 13 g. of the methoxynaphthol, m. p. 101–103°.

In the conversion to the 1-amino- derivative, an agitated mixture of 2-methyl-4-methoxy-1-naphthol (15 g.), 25 g. of ammonium sulfite and 75 cc. of 9% ammonia water was heated at 175–180° for thirty hours, the oily product was dissolved in benzene, unchanged naphthol was removed by 10% alkali containing a little sodium dithionite, solvent was evaporated from the washed benzene solution and the residue was distilled at 1 mm. A solution of the crude 1-amino-2-methyl-4-methoxynaphthalene in 10 cc. of benzene was treated with 1 cc. of acetic anhydride and,

(5) Fieser, Tishler and Sampson, *J. Biol. Chem.*, **137**, 685 (1941).

(6) In contrast, 1-amino-3-methylnaphthalene was inactive in concentrations of 25 micrograms.

(7) Identity of the acetate of the succinamic acid prepared from 1,4-diamino-2-methylnaphthalene with that obtained by converting 1-acetamino-2-methyl-4-aminonaphthalene to the succinamic acid established the structure.

(8) Attempts to prepare the ω-sulfonic acid by oxidation of bis-ω-(2-methyl-1,4-dimethoxynaphthalene)-disulfide led to the formation of 2-methyl-3-hydroxy-1,4-naphthoquinone-ω-sulfonic acid. See the experimental section for details.

(9) Prepared according to the method of Auwers, *Ann.*, **344**, 289 (1906).

(10) Prepared according to the method of Gabriel and Colman, *Ber.*, **33**, 989 (1900).

(11) Christiansen and Dolliver [THIS JOURNAL, **63**, 1470 (1941)], report that 6-methyl-5,8-quinolinequinone is inactive.

TABLE I

Expt.	Substance	G.	Anhydride, g.	Pyridine, cc.	Time, hr.	Yield, g.	M. p., °C.	Analyses: Calcd. for	C	H	Found C	Found H
I	1-Acetoxy-2-methyl-4-naphthol	4.3	8	30	24	2.2	136–138	$C_{17}H_{16}O_4$	64.6	5.1	65.4	5.5
											65.3	5.3
II	1-Acetoxy-2-methyl-4-naphthol	2.5	5	10	43	2.4	109–110	$C_{18}H_{18}O_6$	65.4	5.5	65.7	5.6
III	3-Methyl-1-naphthol	1	2.5	10	50	0.85	109–111	$C_{15}H_{14}O_4$	69.7	5.5	69.4	5.3
IV	2-Methyl-1,4-naphthohydroquinone	1.5	4.0		16	3.0	156–158	$C_{21}H_{22}O_8$	62.7	5.5	62.6	5.1

after two hours at room temperature, the amide (0.5 g.; m. p. 197–199° after crystallization from ethanol) was filtered off. *Anal.* Calcd. for $C_{14}H_{15}O_2N$: C, 73.3; H, 6.6; N, 6.1. Found: C, 73.5; H, 7.0; N, 6.3.

(B) From 3-Methyl-1-naphthol.—The naphthol (4 g.; preparation described below) was treated with a solution prepared by diazotizing 5.3 g. of sulfanilic acid, the azo-derivative was reduced with 16 g. of sodium dithionite and the precipitated aminonaphthol, purified by recrystallization from hydrochloric acid containing stannous chloride, yielded 3.4 g. of pure 1-amino-2-methyl-4-naphthol hydrochloride (charred at 270°). *Anal.* Calcd. for $C_{11}H_{12}NOCl$: C, 63.1; H, 5.8; N, 6.7. Found: C, 63.2; H, 5.7; N, 6.9.

Oxidation of 1 g. of the aminonaphthol with acidified potassium dichromate gave 0.75 g. of 2-methyl-1,4-naphthoquinone (m. p. 103–105°) which did not depress the melting point of an authentic sample.

A solution of 1 g. of the aminonaphthol hydrochloride in 25 cc. of water at 75°, treated with 0.6 cc. of acetic anhydride and 0.5 g. of sodium acetate in 3 cc. of water, gave 0.98 g. of 1-acetamino-2-methyl-4-naphthol, m. p. 206–208° after crystallization from diluted ethanol. *Anal.* Calcd. for $C_{13}H_{13}O_2N$: C, 72.6; H, 6.1; N, 6.5. Found: C, 72.9; H, 6.5; N, 6.5.

The acetaminonaphthol (0.67 g.), methylated in the usual way with dimethyl sulfate and anhydrous potassium carbonate in acetone solution, gave 0.53 g. of the ether which, crystallized from diluted ethanol, melted at 198–200° and did not depress the melting point of the 1-acetamino-2-methyl-4-methoxynaphthalene prepared as previously described. *Anal.* Calcd. for $C_{14}H_{15}O_2N$: C, 73.3; H, 6.6; N, 6.1. Found: C, 73.0; H, 6.9; N, 6.1.

Preparation of the Esters of the Polycarboxylic Acids.—The naphthols were treated at room temperature with succinic anhydride (glutaric anhydride, expt. II) in pyridine solution, ether was added, and the solution was extracted successively with dilute hydrochloric acid and sodium bicarbonate (expt. I); or the reaction product was added to cold hydrochloric acid, the mixture was extracted with ether, and the acidic product, isolated by extraction with sodium bicarbonate, was crystallized from a carbon tetrachloride–chloroform (expts. I and II), or benzene–heptane solution (expt. III). The ether solution of the original reaction mixture (expt. II), after extraction with sodium bicarbonate and concentration, was diluted with carbon tetrachloride and yielded 0.8 g. of *bis*-(1-acetoxy-2-methyl-4-naphthyl) glutarate, m. p. 164–166° after crystallization from an alcohol–benzene solution. *Anal.* Calcd. for $C_{31}H_{28}O_8$: C, 70.3; H, 5.3. Found: C, 70.4; H, 5.4.

In experiment IV the hydroquinone was boiled with glutaric anhydride and 5 cc. of dimethylaniline in 25 cc. of chloroform, the solution was washed successively with dilute hydrochloric acid and sodium bicarbonate, the alkaline extract was acidified and the precipitated product crystallized from ethanol. The results are summarized in Table I.

Preparation of the Esters of the Amino Acids. (A) 1-Acetoxy-2-methyl-4-naphthyl N-Trimethylglycinate Chloride.—The acetoxynaphthol (5 g.) was treated with 4 cc. of chloroacetyl chloride and 10 cc. of dimethylaniline in 50 cc. of chloroform and, after one hour at 25°, the mixture was boiled thirty minutes. After extraction with dilute hydrochloric acid and sodium bicarbonate solution, solvent was distilled *in vacuo* and the residue, crystallized from ethanol, gave 6 g. of the chloroacetate; m. p. 103.5–104° after recrystallization from a chloroform–heptane solution. *Anal.* Calcd. for $C_{15}H_{13}O_4Cl$: C, 61.5; H, 4.5. Found: C, 61.6; H, 4.9.

A solution of 3 g. of the chloroacetate in 30 cc. of acetone containing 1.2 g. of trimethylamine gave, after twenty-four hours at room temperature, 3.3 g. of the glycinate chloride, m. p. 217° after crystallization from an alcohol–acetone solution. *Anal.* Calcd. for $C_{18}H_{22}O_4NCl$: C, 61.4; H, 6.3; N, 4.0. Found: C, 61.2; H, 6.9; N, 3.9.

(B) 2-Methyl-1,4-naphthohydroquinone *bis*-N-Trimethylglycinate Chloride.—The hydroquinone (5 g.), acylated as previously described with 7.5 cc. of chloroacetyl chloride and 13 cc. of dimethylaniline in 50 cc. of chloroform, gave 7 g. of the *bis*-chloroacetate (m. p. 109–110° after recrystallization from heptane. *Anal.* Calcd. for $C_{15}H_{12}O_4Cl_2$: C, 55.1; H, 3.7. Found: C, 54.7; H, 3.9) a portion (3.3 g.) of which, dissolved in 20 cc. of dioxane, was treated with a solution of 1.5 g. of trimethylamine in 15 cc. of acetone and, after twenty-four hours at room temperature, the deposited gummy product, triturated with acetone and crystallized from a methanol–acetone solution, yielded 1.3 g. of the *bis*-glycinate chloride, m. p. 204° after recrystallization. *Anal.* Calcd. for $C_{21}H_{30}O_4N_2Cl\cdot 2H_2O$: C, 52.4; H, 7.1; N, 5.8; Cl, 14.8. Found: C, (1) 52.4, (2) 52.6; H, (1) 6.9, (2) 7.3; N, 6.0; Cl, 14.9.

(C) 1-Acetoxy-2-methyl-4-naphthyl β-Alanate Hydrochloride.—A mixture of carbobenzoxy-β-alanyl chloride (prepared from 10 g. of carbobenzoxy-β-alanine), 7 g. of the acetoxynaphthol and 10 cc. of dimethylaniline in 50 cc. of chloroform was boiled for thirty minutes, the product, purified as previously described, gave 5.5 g. of the carbobenzoxy-β-alanate (m. p. 106.5–108°. *Anal.* calcd. for $C_{24}H_{23}O_6N$: C, 68.5; H, 5.5; N, 3.3. Found: C, 68.2; H, 5.6; N, 3.5), a portion (2 g.) of which, hydrogenated in the usual manner in glacial acetic acid, yielded, after treatment with hydrogen chloride, removal of the

solvent *in vacuo*, trituration with chloroform and crystallization from a methanol–ether solution, 0.65 g. of the β-alanate hydrochloride, m. p. 164–167° after crystallization from a chloroform–acetone solution. *Anal.* Calcd. for $C_{16}H_{18}O_4NCl \cdot H_2O$: C, 56.2; H, 5.9; N, 4.1. Found: C, 55.8; H, 6.1; N, 4.1.

Preparation of the Sodium Salts of the Inorganic Esters of 1-Acetoxy-2-methyl-4-naphthol.—Pyridine solutions of the acid halide and the naphthol (except that the naphthol was boiled ten minutes with a carbon tetrachloride solution of pyridine and chlorosulfonic acid in the preparation of the sulfate) were mixed (at 15–20° and 40°, respectively, in the preparation of the sodium phosphate and the thiophosphate), the product was poured onto ice (except that in the preparation of the sulfate, solvent was decanted and the residue dissolved in 30 cc. of water), the mixture was neutralized with sodium carbonate and the pure sodium salt was isolated as described below.

(A) 1-Acetoxy-2-methyl-4-naphthyl Sodium Sulfate.—The sodium carbonate solution of the product obtained from 3 g. of the naphthol and 1.5 cc. of chlorosulfonic acid was extracted with chloroform and added to an equal volume of saturated sodium chloride solution. The precipitated sulfate (3.6 g.) was recrystallized twice from water. *Anal.* Calcd. for $C_{13}H_{11}SO_6Na$: C, 49.1; H, 3.5; Na, 7.2. Found: C, 48.5; H, 3.6; Na, 7.3.

(B) 1-Acetoxy-2-methyl-4-naphthyl Sodium Phosphate.—The sodium carbonate solution of the phosphate prepared from 20 g. of the naphthol and 13 cc. of phosphoryl chloride was evaporated to dryness *in vacuo*, the residue was extracted with hot butanol, the extract was concentrated to a sirup *in vacuo*, hot isopropyl alcohol was added and the deposited salt (31.5 g.) recrystallized from a butanol–isopropyl alcohol solution, gave 20 g. of the pure phosphate. *Anal.* Calcd. for $C_{13}H_{11}O_6PNa_2 \cdot H_2O$: C, 43.6; H, 3.1. Found: C, 43.1; H, 3.5.

(C) 1-Acetoxy-2-methyl-4-naphthyl Sodium Thiophosphate.—The thiophosphate, prepared from 5 g. of the naphthol and 3.5 g. of thiophosphoryl chloride, was purified as the corresponding phosphate and gave 3 g. of pure compound. *Anal.* Calcd. for $C_{13}H_{11}SPO_3Na_2 \cdot H_2O$: C, 43.3; H, 4.1; S, 8.9. Found: C, 44.2; H, 4.8; S, 8.3.

Preparation of the Glycosides. (A) Glucosides.—Solutions of α-glucose pentaacetate in acetic acid (60 cc. and 15 cc., respectively, in expts. I and III) were saturated with hydrogen bromide. After fifteen hours at room temperature in experiment I, but after two hours in experiment II, chloroform (200 cc. and 50 cc. in the respective experiments) was added, the solutions were washed with ice-water, dried with calcium chloride and stirred twenty-four hours and seventeen hours, respectively, with the naphthol, anhydrous potassium carbonate and reagent acetone. Solvent was distilled *in vacuo* from the filtered solutions, the residue was crystallized from methanol and was recrystallized from an acetone–methanol solution in experiment I.[12] In experiment III the filtered solution of the acetylated glycoside was washed successively with 1% sodium chloride solution, 10% alkali containing a little sodium dithionite and with dilute acetic acid. Solvent was distilled *in vacuo* and the residual acetate was crystallized from ethanol.

(B) Maltosides.—In experiment II the solution of the maltose octaacetate in 260 cc. of acetic acid was added to a solution of 40 g. of hydrogen bromide in 120 cc. of acetic acid at 0° and, after thirty minutes, 200 cc. of chloroform was added, the mixture was extracted twice with ice-water and the dried solution was stirred for twenty-four hours with the naphthol, reagent acetone and anhydrous potassium carbonate. The filtered solution was washed successively with water, 2% alkali, acetic acid and solvent was evaporated *in vacuo*. The residue (m. p. 175–177° with sintering at 140° after crystallization from methanol) was purified by crystallization from a benzene–heptane solution. The acetylated bromomaltose used in experiment IV was prepared as described above from a solution of maltose octaacetate in 60 cc. of acetic acid and 26 cc. of acetic acid saturated with hydrogen bromide at 0° and the acetylated maltoside was purified by crystallization from ethanol.

(C) Deacetylations.—The acetylated glycosides were treated with hot sodium methylate solutions, the solutions were acidified with acetic acid, solvent was distilled *in vacuo* and the residual glycosides were purified in (Ia) by trituration with ethyl acetate followed by crystallization from 75 cc. of water and separation from a methanol solution by dilution with ethyl acetate; (IIa) by trituration with ethyl acetate and crystallization from water; (IIIa) by trituration with chloroform (the insoluble product, 0.63 g., melted at 223–225°) and crystallization from 50% acetic acid; and (IVa) by crystallization from a butanol–ethyl acetate solution. The results are summarized in Table II.

3-Methyl-1-tetralone.—A mixture of diethyl α-phenyl-β-methylglutarate[13] (70 g.), 400 cc. of concentrated sulfuric acid and 80 cc. of water was heated on the steam-bath for three hours, poured into 500 cc. of ice-water, the solidified precipitate was crystallized from a benzene–petroleum ether solution and gave 37.5 g. of 2-methyl-4-keto-1,2,3,4-tetrahydro-1-naphthoic acid, m. p. 107–110° after recrystallization from benzene. *Anal.* Calcd. for $C_{12}H_{12}O_3$: C, 70.7; H, 5.9. Found: C, 70.8; H, 6.1.

A mixture of 46.5 g. of the naphthoic acid, 0.5 g. of cupric oxide and 47 g. of quinoline was heated seventy minutes at 200–215°, the cooled mixture was added to cold, dilute hydrochloric acid, extracted with petroleum ether, the extract was washed successively with dilute hydrochloric acid, alkali, acetic acid and, after removal of solvent, distilled to give 28.5 g. of 3-methyl-1-tetralone, b. p. 142–143° at 16 mm.; oxime, m. p. 121–122.5°.[3]

3-Methyl-1-naphthol. (a) From 2-Methyl-4-keto-1,2,3,4-tetrahydro-1-naphthoic Acid.—The acid (3 g.) and 0.5 g. of sulfur were heated to 255–265° for thirty minutes and, after addition of a small amount of copper oxide, the product was distilled at 1 mm. A benzene solution of the distillate was washed successively with sodium bicarbonate and alkali containing sodium dithionite. Upon acidification, the alkaline extract gave the naphthol which, after two crystallizations from a heptane–petroleum ether solution, melted at 88–90°, resolidified and

(12) The method of preparation of glycosides developed by Montgomery, Richtmyer and Hudson [THIS JOURNAL, 64, 690 (1942)] also gave the acetate.

(13) Connor and McClellan, *J. Org. Chem.*, 3, 573 (1939).

In experiment IIa the maltoside at first appeared to be hydrated with no definite melting point and even after twenty-four hours *in vacuo* over potassium hydroxide the compound melted over a range of 5°. Deacetylation of 60.5 g. of 1-acetoxy-2-methyl-4-naphthyl-β-maltoside heptaacetate in an atmosphere of nitrogen, using 600 cc. of methanol and 0.5 g. of sodium, gave 35 g. of crude maltoside, a portion (31.5 g.) of which was recrystallized from water and yielded 29 g. of pure product.

melted at 92.5–93°.[3] *Anal.* Calcd. for $C_{11}H_{10}O$: C, 83.5; H, 6.4. Found: C, 83.2; H, 6.6.

(b) **From 3-Methyl-1-tetralone.**—The tetralone (15 g.) was brominated in the usual manner, boiled with dimethylaniline and gave 10.2 g. of the naphthol, m. p. 87–89°.

2-Methyl-1-naphthylamine.—A suspension of 40 g. of 1-nitro-2-methylnaphthalene[14] in 160 cc. of methanol was reduced with Raney nickel at 1–3 atmospheres pressure, the filtered solutions of three similar preparations were combined, treated with 70 cc. of concentrated hydrochloric acid and yielded, after filtration and concentration, 122 g. of the hydrochloride, m. p. 228–231° with decomposition after crystallization from methanol.[15] *Anal.* Calcd. for $C_{11}H_{12}NCl$: C, 68.2; H, 6.3; N, 7.2; Cl, 18.3. Found: C, (1) 68.0, (2) 67.7; H, (1) 6.6, (2) 6.4; N, (1) 7.7, (2) 8.1; Cl, (1) 20.0, (2) 19.7.

The amine hydrochloride (5 g.), treated with 7 cc. of acetic anhydride and 25 cc. of pyridine gave 3.8 g. of the acetamino derivative (m. p. 191–192° after crystallization from benzene.[15] *Anal.* Calcd. for $C_{13}H_{13}ON$: C, 78.3; H, 6.6; N, 7.0. Found: C, (1) 78.1, (2) 78.2; H, (1) 6.6, (2) 6.1; N, (1) 7.2, (2) 7.2) and the same product was obtained by acetylating the free amine in chloroform solution.

N-(2-Methyl-1-naphthyl)-gluconamide.—A mixture of 3 g. of 1-amino-2-methylnaphthalene, 3.5 g. of δ-gluconolactone, 2 cc. of water and 4 cc. of acetic acid was heated at 100° in an atmosphere of nitrogen for eighteen hours. After dilution with chloroform and water, the precipitated product (3.4 g.) was filtered off and crystallized from 50% acetic acid, m. p. 212–214°. *Anal.* Calcd. for $C_{17}H_{21}O_6N$: C, 60.8; H, 6.3. Found: C, 60.3; H, 6.6.

1-Amino-2-naphthylacetic Acid.—A mixture of 5.5 g. of 1-nitro-2-naphthylacetic acid,[16] 75 cc. of methanol and 10 cc. of 10% sodium hydroxide was hydrogenated in the usual manner with Raney nickel at room temperature. The filtered solution, diluted with 100 cc. of water and acidified with acetic acid, yielded 3.8 g. of the amine, m. p. 238–240° (with decomposition) after crystallization from methanol. *Anal.* Calcd. for $C_{12}H_{11}O_2N$: C, 71.7; H, 5.6; N, 7.0. Found: C, (1) 71.8, (2) 72.0; H, (1) 5.7, (2) 5.6; N, (1) 6.9, (2) 7.0.

3-Methyl-1-naphthylamine Hydrochloride.—An agitated mixture of 5 g. of 3-methyl-1-naphthol, 7.5 g. of ammonium sulfite, 7.5 cc. of 28% ammonia water and 15 cc. of water was heated at 165° for sixteen hours. A benzene solution of the oily product was washed with 10% alkali and water, treated with 50 cc. of 5% hydrochloric acid and yielded 4.7 g. of the amine hydrochloride, m. p. 265–267° after crystallization from 60% hot ethanol by addition of concentrated hydrochloric acid. *Anal.* Calcd. for $C_{11}H_{12}NCl$: C, 68.2; H, 6.3; N, 7.2. Found: C, 68.3; H, 6.7; N, 8.0.

1,4-Diamino-2-methylnaphthalene. (a) **From 2-Methyl-1,4-naphthohydroquinone.**—The hydroquinone (7.8 g.), heated as above with 20 g. of ammonium sulfite, 20 cc. of 28% ammonia water and 40 cc. of water, gave an oily product which, treated as described above, yielded 5.5 g. of the diamine dihydrochloride (m. p. 287–290°; 299–301° after recrystallization from hot water by addition of concentrated hydrochloric acid. *Anal.* Calcd. for $C_{11}H_{14}N_2Cl_2$: C, 54.3; H, 5.8; N, 11.5. Found: C, 54.8; H, 6.3; N, 11.2).

The diacetamino compound (0.8 g., prepared by heating a solution of 1 g. of the dihydrochloride in 10 cc. of water and 25 cc. of acetic acid with 3 cc. of acetic anhydride and 1 g. of sodium acetate) melted at 306–308° and was identical with that prepared from the diamine obtained on reduction of the coupling product of diazotized sulfanilic acid and 1-amino-2-methylnaphthalene as described below.

(b) **From 4-(*p*-Sulfo-phenylazo)-1-amino-2-methylnaphthalene.**—A solution of 2.5 g. of the azo-derivative[15] in 40 cc. of 2.5% sodium hydroxide was reduced at 70° with 3.5 g. of sodium dithionite, 25 cc. of ethylene dichloride was added and concentration of the extract, followed by dilution with petroleum ether, yielded 0.7 g. of the diamine, m. p. 113–114° after crystallization from a benzene–petroleum ether solution.[17] The dihydrochloride was obtained in a similar reduction by treating the ethylene dichloride extract with 5 cc. of concentrated hydrochloric acid, evaporating to dryness and crystallizing the residue from hot water by addition of concentrated hydrochloric

(14) Prepared by the method of Fierz-David and Mannhardt, *Helv. chim. acta*, **20**, 1027 (1937).

(15) Lesser [*Ann.*, **402**, 1 (1913)] gives a value of about 230°, with decomposition, for the hydrochloride and 188° for the acetylated amine.

(16) Mayer and Oppenheimer, *Ber.*, **49**, 2110 (1916).

(17) Vesely and Kapp [*Rec. trav. chim.*, **44**, 360 (1925)] prepared this compound by reduction of 1-amino-2-methyl-4-nitronaphthalene and gave the m. p. as 111–113°.

acid, m. p. 300–301°. *Anal.* Calcd. for $C_{11}H_{14}N_2Cl_2$: C, 54.3; H, 5.8; N, 11.5; Cl, 28.4. Found: C, (1) 54.4, (2) 54.7; H, (1) 5.9, (2) 6.1; N, (1) 11.1, (2) 11.2; Cl, (1) 28.7, (2) 28.9. Similarly, a suspension of the azo-compound (3.5 g.) in 35 cc. of water was reduced with 5 g. of stannous chloride in 15 cc. of hot concentrated hydrochloric acid and gave 1.5 g. of the dihydrochloride, m. p. 297–300° after crystallization from dilute hydrochloric acid.

The diamine (5 g.), treated with 15 cc. of acetic anhydride in 35 cc. of dioxane, deposited 7.2 g. of pure 1,4-diacetamino-2-methylnaphthalene (m. p. 308–309° after crystallization from an acetic acid–benzene solution. *Anal.* Calcd. for $C_{15}H_{16}N_2O_2$: C, 70.2; H, 6.3; N, 11.0. Found: C, (1) 70.2, (2) 70.0; H, (1) 6.4, (2) 6.4; N, (1) 11.0, (2) 10.8).

(c) From 4-(*p*-Carboxyphenylazo)-1-amino-2-methylnaphthalene.—A solution of diazotized *p*-aminobenzoic acid (prepared from 1.4 g. of the acid) was added at 2° to a solution of 1.6 g. of 1-amino-2-methylnaphthalene in 120 cc. of water and 1.5 cc. of concentrated sulfuric acid, the precipitated azo-compound was reduced in the usual manner with palladinized carbon and the filtered solution, after appropriate manipulations, deposited 0.8 g. of the diamine (m. p. 109–111°: 0.3 g. of impure material separated from the filtrate).

1-Acetamino-2-methyl-4-aminonaphthalene.—A mixture of 14.5 g. of 1,4-diacetamino-2-methylnaphthalene, 70 cc. of ethanol and 70 cc. of concentrated hydrochloric acid was boiled for three hours and, after several hours at 5°, the deposited hydrochloride (12.9 g.) was filtered off. A solution of 14.1 g. of the crude product in 350 cc. of hot water, basified with ammonium hydroxide, deposited the free amine which, crystallized from ethylene dichloride, gave 8 g. of 1-acetamino-2-methyl-4-aminonaphthalene (m. p. 190–191°. *Anal.* Calcd. for $C_{13}H_{14}N_2O_4$: C, 72.8; H, 6.6; N, 13.1. Found: C, 73.1; H, 6.7; N, 13.1), identical with the product (0.99 g. *Anal.* Found: C, 72.9; H, 6.8; N, 13.3) obtained by reduction of 1.25 g. of 1-acetamino-2-methyl-4-nitronaphthalene[17] in 25 cc. of ethanol with Raney nickel at room temperature.

N-(1-Acetamino-2-methyl-4-naphthyl)-succinamic Acid. (A) From N-(1-Amino-2-methyl-4-naphthyl)-succinamic Acid.—A hot chloroform solution of 1 g. of 2-methyl-1,4-diaminonaphthalene was treated with 0.7 g. of succinic anhydride, the crude product (1.57 g.) was crystallized from ethanol and gave 1 g. of the pure succinamic acid, m. p. 192° with decomposition. *Anal.* Calcd. for $C_{15}H_{16}O_3N_2$: C, 66.2; H, 5.9; N, 10.3. Found: C, 66.4; H, 6.8; N, 10.6. The acetyl derivative, prepared from 20 mg. of the acid, 1 cc. of acetic acid and 0.1 cc. of acetic anhydride, melted at 250° (with decomposition when fused in a block preheated to 240°), resolidified and then melted at 268–270°. *Anal.* Calcd. for $C_{17}H_{18}O_4N_2 \cdot HOAc$: C, 60.9; H, 5.9; N, 7.5. Found: C, 60.8; H, 5.6; N, 7.8.

(b) From 1-Acetamino-2-methyl-4-naphthylamine.—A hot dioxane solution of 3 g. of the amine and 1.6 g. of succinic anhydride gave 2.7 g. of the succinamic acid, m. p. 245°. After recrystallization from acetic acid the compound melted at 250°, resolidified and melted at 269–271° (the melting point was not depressed by addition of the acetate prepared as above described). *Anal.* Calcd. for $C_{17}H_{18}O_4N_2 \cdot HOAc$: C, 60.9; H, 5.9; N, 7.5. Found: C, 61.2; H, 5.8; N, (1) 7.8, (2) 7.8. When dried at 100° and 1 mm. over potassium hydroxide, the compound lost the acetic acid of crystallization. *Anal.* Calcd. for $C_{17}H_{18}O_4N_2$: C, 65.0; H, 5.8; N, 8.9. Found: C, 64.8; H, 6.2; N, 8.9.

2-Chloromethyl-1,4-dimethoxynaphthalene.—Dimethoxynaphthalene[18] (73 g.) was dissolved in a warm solution of 80 cc. of monochloromethyl ether in 200 cc. of acetic acid and, after fifteen hours at 25°, water was added and the mixture extracted with benzene. The extract was washed with sodium bicarbonate, solvent was distilled from the dried, filtered solution, the residue was extracted with petroleum ether, the solution was treated with active carbon, filtered and solvent was distilled *in vacuo*. The residue was distilled (1 mm.; bath temperature 180–190°) and the crystalline distillate (56.5 g.), crystallized from petroleum ether, gave 50.5 g. of the pure product, m. p. 62–63°. The product from a similar preparation was analyzed. *Anal.* Calcd. for $C_{13}H_{13}O_2Cl$: C, 65.9; H, 5.4. Found: C, 66.2; H, 5.8.

2-Methyl-1,4-naphthoquinone-ω-potassium Sulfonate.—An agitated mixture of 5 g. of 2-chloromethyl-1,4-dimethoxynaphthalene, 15 cc. of methanol and a solution of 3.8 g. of sulfur dioxide in 7 cc. of 28% ammonia water and 15 cc. of water was heated at 135° for sixteen hours. After extraction with chloroform, the aqueous solution was diluted with 10 g. of potassium chloride in 30 cc. of water and the deposited salt, reprecipitated from 20 cc. of warm water by addition of 5 g. of potassium chloride in 15 cc. of water, yielded 1.1 g. of impure potassium sulfonate. *Anal.* Calcd. for $C_{13}H_{13}SO_5K$: K, 12.2. Found: K, 15.4.

A solution of 1 g. of the impure potassium salt in 5 cc. of water, treated with a solution of 2.4 g. of potassium dichromate and 2.4 cc. of concentrated sulfuric acid in 15 cc. of water, gave, after fifteen minutes at 90–100°, a solution which, diluted with 4 g. of potassium chloride in 15 cc. of water and cooled to 5° for four hours, yielded 0.46 g. of the quinone sulfonate. The salt was further purified by recrystallization from acidulated water. *Anal.* Calcd. for $C_{11}H_7SO_5K$: K, 13.5. Found: K, 13.0.

The S-benzylthiuronium salt, crystallized from 50% ethanol, melted at 182–183° with decomposition. *Anal.* Calcd. for $C_{19}H_{18}N_2S_2O_5$: C, 54.5; H, 4.3; N, 6.7. Found: C, 54.4; H, 4.2; N, 7.1.

***ω-bis*-(1,4-Dimethoxy-2-methylnaphthalene)-disulfide.**—A solution of 10 g. of potassium hydroxide in 150 cc. of absolute ethanol was saturated with hydrogen sulfide and boiled for ninety minutes with a suspension of 18.8 g. of 1,4-dimethoxy-2-chloromethylnaphthalene in 100 cc. of absolute ethanol, the diluted mixture was acidified, the separated oil dissolved in ether and the solution was extracted with 10% alkali. The diluted, cold extract was shaken with chloroform containing 25 g.

(18) Prepared in 91% yield by adding (in a nitrogen atmosphere) 40 cc. of dimethyl sulfate to the mixture formed by hydrogenating 16 g. of 1,4-naphthoquinone in 50 cc. of methanol, then adding a solution of 48 g. of potassium hydroxide in 100 cc. of water during thirty minutes and, after forty-five minutes at the temperature of the steam-bath, precipitating the product by addition of water. After recrystallization from ethanol, the ether (17.3 g.) melted at 86–87.5°. Sah [*Rec. trav. chim.*, **59**, 1029 (1941)] reported a yield of 58% and a m. p. of 85°.

of iodine, the chloroform solution was then washed with sodium bisulfite, evaporated to dryness *in vacuo* and the residue, crystallized from heptane–ether solution, yielded 11.2 g. of pure disulfide, m. p. 116–117°. *Anal.* Calcd. for $C_{26}H_{26}O_4S_2$: C, 66.9; H, 5.6. Found: C, 66.5; H, 5.8.

Concentration of the filtrate yielded 0.5 g. more of the disulfide and 0.4 g. was obtained from the original ether solution of the sulfhydryl compound.

In another preparation, a mixture of 48 g. of 2-chloromethyl-1,4-dimethoxynaphthalene, 15.5 g. of thiourea and 150 cc. of ethanol was boiled for two hours, a solution of 12 g. of sodium hydroxide in 120 cc. of water was added and the mixture boiled two hours longer. On acidification, the diluted product yielded the oily sulfhydryl derivative which, dissolved in chloroform, was treated with 20 g. of sodium hydroxide in 200 cc. of water, ice and 40 g. of iodine, unchanged iodine was removed with sodium bisulfite, the chloroform solution was evaporated *in vacuo* and the residue, crystallized from a heptane–ether solution, yielded 35.5 g. of the disulfide, m. p. 115–116°.

TABLE III

Expt.	Compound	Active at micrograms
1	2-Methyl-1,4-naphthoquinone	1
2	2-Methyl-1,4-naphthoquinone-ω-potassium sulfonate	>50
3	2-Methyl-3-hydroxy-1,4-naphthoquinone-ω-potassium sulfonate	>50
4	2-Methyl-1,4-naphthohydroquinone	1
5	2-Methyl-1,4-naphthohydroquinone-*bis*-hydrogen glutarate	10
6	2-Methyl-1,4-naphthohydroquinone-N-trimethylglycinate chloride	12
7	1-Hydroxy-2-methyl-4-naphthyl-β-glucoside	3
8	1-Hydroxy-2-methyl-4-naphthyl-β-maltoside	5
9	1-Acetoxy-2-methyl-4-naphthol	2
10	1-Acetoxy-2-methyl-4-naphthyl-hydrogen succinate	3
11	1-Acetoxy-2-methyl-4-naphthyl-hydrogen glutarate	4
12	1-Acetoxy-2-methyl-4-naphthyl-N-trimethylglycinate chloride	4
13	1-Acetoxy-2-methyl-4-naphthyl-β-alanate hydrochloride	4
14	1-Acetoxy-2-methyl-4-naphthyl-sodium sulfonate	6
15	1-Acetoxy-2-methyl-4-naphthyl-sodium phosphate	4
16	1-Acetoxy-2-methyl-4-naphthyl-sodium thiophosphate	10
17	2-Methyl-1-naphthol	5
18	2-Piperidinomethyl-1-naphthol	>50
19	3-Methyl-1-naphthol	5
20	3-Methyl-1-naphthyl-β-glucoside	10
21	3-Methyl-1-naphthyl-β-maltoside	20
22	3-Methyl-1-naphthyl hydrogensuccinate	10
23	2-Methyl-1-naphthylamine hydrochloride	50
24	1-Acetamino-2-methylnaphthalene	>50
25	N-(2-Methyl-1-naphthyl)-gluconamide	>50
26	1-Amino-2-naphthylacetic acid	>200
27	1-Amino-3-methylnaphthalene hydrochloride	>25
28	2-Methyl-1,4-diaminonaphthalene dihydrochloride	3
29	1-Acetamino-4-aminonaphthalene	>50
30	N-(1-Amino-2-methyl-4-naphthyl)-succinamic acid	>50

2-Methyl-3-hydroxy-1,4-naphthoquinone-ω-potassium Sulfonate.—A suspension of 5 g. of *bis*-ω-(1,4-dimethoxy-2-methylnaphthalene)-disulfide in 25 cc. of 30% hydrogen peroxide and 125 cc. of acetic acid was stirred ten hours at room temperature, the resulting solution was evaporated to dryness *in vacuo*, the residue dissolved in water, the solution washed with chloroform and the product crystallized by adding a solution of 10 g. of potassium chloride in 25 cc. of water. After two similar recrystallizations from acidulated potassium chloride solution, the crude product (2.05 g.) gave the pure salt. *Anal.* Calcd. for $C_{11}H_9SO_6K$: K, 12.8. Found: K, 12.5.

Titration[19] of the potassium salt showed the presence of an acidic group with a pK of 4.65; phthiocol, the corresponding 3-hydroxyquinone, has a value of 4.5.

A solution of 0.48 g. of the potassium salt in 15 cc. of cold water containing a drop of concentrated hydrochloric acid was treated with 0.4 g. of S-benzylthiuronium chloride in 5 cc. of water and the precipitated product, recrystallized from ethanol, gave the pure S-benzylthiuronium salt, m. p. 200–201° with decomposition. *Anal.* Calcd. for $C_{19}H_{18}O_6N_2S_2$: C, 52.5; H, 4.2; N, 6.5. Found: C, 52.4; H, 4.4; N, 6.7.

Bioassays.—Day-old chicks were used for these tests made by Drs. L. W. McElroy and J. J. Oleson as described previously.[1] In experiments 5, 6, 16 and 22 only 30, 36, 73 and 69%, respectively, of the chicks showed a clotting time of less than fifteen minutes. The results are summarized in Table III.

Summary

1. The compounds prepared by partial esterification of polycarboxylic acids with 2-methyl-1,4-naphthohydroquinone and its derivatives, esters of 1-acetoxy-2-methyl-4-naphthol formed with succinic and glutaric acids, the *bis*-hydrogen glutarate of 2-methyl-1,4-naphthohydroquinone, the hydrogen succinate of 3-methyl-1-naphthol, 1-acetoxy-2-methyl-4-naphthyl-β-alanate hydrochloride, the N-trimethylglycinate chloride and the corresponding diammonium salt were all hydrolyzed in warm aqueous solution.

2. Esters of 1-acetoxy-2-methyl-4-naphthol formed with sulfuric, phosphoric and thiophosphoric acids (showing activities of 35, 50 and 20%, respectively, of that of 2-methyl-1,4-naphthoquinone) were stable in hot solution as were the monoglucoside and the maltoside of 2-methyl-1,4-naph-

(19) The determination was made by Dr. T. H. Davies of this Laboratory.

thohydroquinone (activities about 66% of that of 2-methyl-1,4-naphthoquinone) in the absence of oxygen. The corresponding glycosides of 3-methyl-1-naphthol gave complete response in minimum concentrations of 10 and 20 micrograms. The active 1-amino- and 1,4-diamino-derivatives of 2-methylnaphthalene were almost inactivated by conversion to the monoacetyl derivatives and these compounds as well as N-(2-methyl-1-naphthyl)-gluconamide and N-(1-amino-2-methyl-4-naphthyl)-succinamic acid were inapplicable.

3. An improved method for the preparation of 3-methyl-1-naphthol and 3-methyl-1-tetralone is described.

4. The structures of the esters of acetoxy-2-methylnaphthol and of the succinamic acid of 1,4-diamino-2-methylnaphthalene were established. From these orientation determinations structures of the new compounds examined for antihemorrhagic activity were ascertained. Substituents in the methyl of 2-methylnaphthalene lower the activity of the derivatives as compared with the parent quinone; 3-methyl-1,4-dihydroxyisoquinoline was inactive.

Heats of Organic Reactions. XIV. The Digestion of β-Lactoglobulin by Pepsin

BY GOTFRED HAUGAARD AND RICHARD M. ROBERTS

It is the aim of the experiments described here to apply calorimetry to the study of proteolytic processes. During the hydrolysis of a protein peptide bonds adjacent to many different types of side-chains are broken, and the peptides and amino acids formed have widely different ionization properties. The thermochemistry of the process is thus of such complexity that it is scarcely to be hoped that measurement of the net heat evolution would yield results of thermodynamic significance. We proposed, therefore, to use the calorimeter as an indicator, and to supplement the thermal measurements by simultaneous chemical determinations.

Acid or alkali have two drawbacks as hydrolytic catalysts for our purposes. The high temperature required for a reasonable rate of reaction is impractical for calorimetric work. Furthermore, acid and alkali are relatively unspecific in their attack of peptide bonds. Enzymatic catalysis eliminates both of these difficulties. The reaction can be carried out near room temperature. Proteolytic enzymes are specific in their action; each enzyme attacks only a few types of peptide bonds, so that a smaller number of processes is involved in the reaction.

Crystalline β-lactoglobulin was chosen as the substrate for the present work. This protein is easily prepared in a salt-free condition, contains no lipid or carbohydrate, and is homogeneous in the ultracentrifuge and electrophoresis cell.

Experimental Procedure

The enzyme selected was crystalline pepsin, which has a *p*H optimum around 1.5. In this case the buffering power of hydrochloric acid is sufficient to maintain constant *p*H. Complication of the heat evolution in an unknown manner by ionization effects, as would be the case for other enzymes requiring solutions buffered near neutrality, is thus avoided.

Enzyme and substrate solutions were made up in sufficient quantity for two simultaneous digestions to be made, one in the calorimeter, to measure heat evolution, and the other separately in a thermostat at the same temperature, using the same proportions of enzyme and substrate solutions in both digestions. Samples of the latter digest were removed at frequent intervals for determination of the following quantities: amino nitrogen, nitrogen not precipitable by trichloroacetic acid, and nitrogen dialyzable through cellophane.

Lactoglobulin.—Crystalline β-lactoglobulin was prepared from raw, skim milk by a modification of the original procedure suggested to one of the authors by Dr. A. H. Palmer.[1] After removal of the casein by coagulation at *p*H 4.5, the *p*H of the whey was readjusted to 6.0–7.0. The less soluble whey proteins are first precipitated by addition of solid ammonia sulfate to half saturation.[2] Solid ammonium sulfate was added to the filtrate from this first precipitate to 80–85% saturation. This second precipitate was redissolved in a minimum amount of water, adjusted to *p*H 6.0–6.5, and the subsequent dialysis and crystallization were carried out in the manner described in Palmer's article cited above.

The crystalline β-lactoglobulin so obtained was recrystallized as follows. The crystals were suspended in water and dissolved by addition of the minimum amount

(1) Palmer, *J. Biol. Chem.*, **104**, 351 (1934).

(2) See, in this connection, M. and S. P. L. Sörensen, *Compt. rend. trav. lab. Carlsberg. Sér. chim.*, **23**, 61 (1939).

of 0.1 *N* alkali, filtered and readjusted to *p*H 5.2 with 0.1 *N* hydrochloric acid. After seeding, the solution was allowed to stand at room temperature for three to four hours, and then left in the refrigerator for one to two days. The crystals were filtered on a Büchner filter, dried over calcium chloride, and then ground to a powder in a mortar. The powder was dried over phosphorus pentoxide, and was stored in a tightly stoppered bottle in the refrigerator. It is our experience that β-lactoglobulin, treated in this way, can be kept for years without losing its ability to crystallize, and upon dissolving in salt solution leaves behind only a trace of insoluble material.

To make solutions of β-lactoglobulin, the dry powder was dissolved in weak potassium chloride solution. The faintly cloudy solution was clarified by filtration. The filtrate was diluted so as to contain about 3 mg. N/cc. and be 0.15 *N* in electrolyte. Lactoglobulin solutions appear to keep well in the cold for at least two weeks, but in the present work the solutions were always used one to two days after preparation.

Preliminary work showed that β-lactoglobulin is made very much more digestible by pepsin at *p*H 1.5 by previous exposure to *p*H 11. It was found that denaturation of β-lactoglobulin occurs slowly at *p*H 9.5, and that the rate increases with the *p*H. The protein is completely insoluble at *p*H 5.2 after exposure to *p*H 11 for a few minutes. On the other hand, β-lactoglobulin appeared to be stable at fairly low acid *p*H. After exposure to *p*H 1.5 for four hours no precipitate formed upon titration to *p*H 5.2. We therefore assumed that the protein was unaltered by *p*H 1.5. Subsequent work proved that this assumption was false. Samples of the digest of native protein were adjusted to *p*H 6–7 and dialyzed as described below. After the prolonged dialysis the contents of the bags were brought to *p*H 5.2 and seeded with a few crystals of β-lactoglobulin. Some amorphous precipitate settled out on standing, but no sample showed any evidence of formation of new crystals. In order to decide whether the pepsin or the acid was responsible for destroying the ability of the protein to crystallize, a control experiment without the pepsin was carried out. A solution of native protein at *p*H 5.2 was brought to *p*H 1.5 with 0.27 *N* hydrochloric acid. Samples were removed at frequent intervals, starting at five minutes, were adjusted to *p*H 6–7 with 0.28 *N* potassium hydroxide, and dialyzed as before. A sample of the native protein solution at *p*H 5.2 was dialyzed under the same conditions. After dialyzing with frequent changes of water for ten days, all samples were brought to *p*H 5.2 and seeded. Only amorphous material was found in the samples which had been exposed to *p*H 1.5. The sample of native protein solution untreated with acid contained only β-lactoglobulin crystals. That the denaturation was not caused by the alkali during back titration of the acid-treated protein to *p*H 6–7 is proved by the fact that native β-lactoglobulin at *p*H 5.2 can be recrystallized without loss after titration with 0.28 *N* potassium hydroxide to *p*H 9.5.

Exposure to *p*H 1.5 for only five minutes, therefore, destroys the ability of lactoglobulin to crystallize. When the protein has been thus treated with acid, it must be regarded as a different substance, although its complete solubility at *p*H 5.2 makes it appear likely that less alteration of the molecule has occurred than in the case of the protein treated with alkali at *p*H 11.

In order to avoid circumlocution in what follows, "denatured protein" and "native protein" will refer to the previous history of the protein *before* adjusting it to *p*H 1.5 for peptic digestion.

Pepsin.—Crystalline pepsin was prepared from Cudahy Spongy Pepsin 1:10,000 and recrystallized once by the method outlined by Northrop.[3] The pepsin crystals were stored in the cold under saturated magnesium sulfate solution. About one-third of the weight of the crystalline paste was protein.

Pepsin solutions to be used in the digestions were made in the following way. The crystalline paste was suspended in water and dialyzed for two days against water acidified to *p*H 4.5 until most of the sulfate was removed. A measured quantity of potassium chloride solution was then added to the suspension, which was kept at 30–35° for an hour or two to hasten solution. The solution was filtered and diluted so as to be 0.15 *N* in potassium chloride and contain about 0.7 mg. N/cc. Pepsin solutions were stored in the cold under toluene and were always used within one day after preparation.

Determination of Amino Nitrogen.—The increase in amino nitrogen during the digestions was measured by the manometric method of Van Slyke.[4] The saturated solution of sodium nitrite used contained 10 g. of potassium iodide per liter.

Deamination of β-lactoglobulin for five minutes in the Van Slyke apparatus yields 25.5 equivalents of amino nitrogen per mole; in ninety minutes, 36.1 equivalents per mole are produced,[5] part of which is accounted for by the 29 lysine residues found by analysis. This large evolution of non-α-amino nitrogen in the time interval (three to four minutes) required for complete deamination of the α-amino groups leads to a high initial point for the digestion. Thus in order to obtain reproducible and comparable results the time of reaction in the Van Slyke apparatus must always be strictly the same at a given temperature. At the time these experiments were performed the authors were not fully aware of the fact that the lysine content of β-lactoglobulin is so large. It is possible that somewhat greater precision could have been obtained if longer reaction periods had been used, so that slight variations in time interval would give a less variable evolution of non-α-amino nitrogen.

Trichloroacetic Acid.—Of the many reagents used to precipitate proteins, trichloroacetic acid has the reputation of precipitating the least amount of polypeptide from a mixture of protein and its degradation products. We have tried several of the current recipes for using this reagent and found them unsatisfactory. The procedure we have used was finally standardized as follows. A given volume of a protein solution containing enough protein nitrogen to enable one to make a precise Kjeldahl analysis was mixed with an equal volume of a solution containing 20% by weight of trichloroacetic acid, both solutions being at room temperature. The mixture was allowed to stand at

room temperature for twelve to fifteen hours with frequent shaking. The shaking reduces the amount of non-protein nitrogen carried down by the precipitate. At the end of this period, the mixture is filtered and washed three times on the filter with small portions of 10% trichloroacetic acid. After filtration the filter paper containing the precipitate is placed in a Kjeldahl flask for determination of nitrogen. The success of this procedure is to be judged by the fact that both native and alkali-denatured β-lactoglobulin can be precipitated from solutions containing 0–80% of the total nitrogen in the form of peptic digestion products, without carrying down considerable amount of non-protein nitrogen, as shown in the case of denatured β-lactoglobulin in Table I.

TABLE I

DENATURED β-LACTOGLOBULIN

% of digestion products	Protein N per cc. found, mg.	Protein N per cc. calcd., mg.
0	2.46	2.46
18	1.98	1.97
36	1.49	1.48
56	1.03	0.99
77	0.54	.49

Further confirmation of the exactness of the trichloroacetic acid procedure is found in the excellent agreement between the trichloroacetic acid results and those from the dialysis experiments described below.

Dialysis Experiments.—The dialysis experiments made on samples of the digests in Runs A and B were performed in slightly different ways. In the case of Run B we wished to attempt to crystallize the unattacked protein, and for this reason could not use heat-treated protein for the dialysis.

Run A.—Twenty cc. of the heat-treated digest samples was dialyzed in Visking cellophane bags against 200 cc. of distilled water for ten days in the refrigerator. A little toluene was added to the dialyzate.

Run B.—Twenty-five cc. of the digest was brought to *p*H 6–7 with about 15 cc. of potassium hydroxide solution and dialyzed against 200 cc. of water for ten days as above.

At the end of ten days the dialyzates were removed and concentrated to about 50 cc. by vacuum distillation at 40°. Determinations of amino and total nitrogen were made on the concentrated solutions.

In order to measure the extent to which dialyzable nitrogen had been removed from the bags during the ten-day dialysis, and compare the undialyzable nitrogen with that precipitable by trichloroacetic acid, the dialysis was continued in the case of A for thirteen days and in the case of B for seven days longer, this time against frequently changed water. The dialyzates obtained during this period were evaporated on the steam-bath, and the total nitrogen was determined in each.

The Digestions.—A series of digestion experiments with both native and denatured lactoglobulin were carried out, using the same procedure in each case for heat evolution, trichloroacetic acid, and amino nitrogen determinations. The results of these experiments were consistent. All the digestions were carried out at 30 ± 0.1°. For the sake of brevity data from only the last pair, in which dialysis experiments were also performed, will be presented here.

Run A: Denatured Protein.—To 750 g. of β-lactoglobulin solution (*p*H 5.15, approx. 2.9 mg. N/cc.) was added 0.28 *N* potassium hydroxide with stirring until *p*H 11.10 was reached. As judged by completeness of precipitation at *p*H 5.2 upon back titration, denaturation is complete after standing a few minutes at *p*H 11. The solution was allowed to stand for one hour at room temperature. At the end of this time the *p*H was 10.85. 0.27 *N* hydrochloric acid and water were added until the final weight of the solution was 1390 g. and the *p*H was 1.52; 840 g. was placed in the larger compartment of the calorimeter; 500 g. was used for the simultaneous digestion and 50 g. for initial point determinations. This solution was 0.15 *N* in electrolyte.

To 35.0 cc. of pepsin stock solution (0.67 mg. N/cc.) was added 0.27 *N* hydrochloric acid, water, and 2 *N* potassium chloride solution to make a final weight of 134 g., with a *p*H 1.50, 0.15 *N* in electrolyte; 62 g. was placed in the smaller compartment of the calorimeter, 37 g. was used for the simultaneous digestion and 35 g. for initial point determinations.

Run B: Native Lactoglobulin.—To 749 g. of native β-lactoglobulin solution (*p*H 5.13, approx. 3.1 mg. N/cc.) 0.27 *N* hydrochloric acid, water, and 2 *N* potassium chloride solution were added in such quantity that the final weight was 1390 g., electrolyte normality 0.15, and *p*H 1.50. The same quantities as before were used for the calorimeter, concurrent digestion, and initial point.

To 95 g. of pepsin solution (0.784 mg. N/cc.) water and 0.27 *N* hydrochloric acid were added in such quantity that the final weight was 134 g., electrolyte normality 0.15, *p*H 1.48. The enzyme solution was divided into 62-g., 37-g., and 35-g. portions as in A.

Before making the concurrent digestion outside the calorimeter the enzyme and substrate solutions were allowed to come to the proper temperature in a thermostat, and were quickly mixed by pouring back and forth from one vessel to the other, then replaced in the thermostat. Sampling of the digest was done as follows. About 25 cc. was quickly removed, placed in an Erlenmeyer flask, stoppered tightly with a rubber stopper, and swirled in a water-bath at 80° for five minutes. Only a slight cloudiness resulted from this treatment. The sample was stored under toluene in the cold, and the several determinations were made as soon as possible. This method of killing the enzyme appears to cause no further hydrolysis of protein. We found no increase in amino nitrogen when lactoglobulin and pepsin were separately treated in this way.[6]

The Calorimeter.—The calorimeter and its operation have been described previously.[7] The calorimeter is divided into two compartments holding the liquids to be mixed; into one was placed 62 cc. of pepsin solution, and into the other 840 cc. of lactoglobulin solution. The calorimeter was brought to a low thermal head by electrical heating, and after waiting for thermal equilibrium to be reached, the enzyme and substrate were mixed and readings on the main thermel were made at frequent inter-

(6) L. Miller, *J. Biol. Chem.*, **109**, lxvi (1935), has found no further hydrolysis when peptic digests of lactalbumin were inactivated by heating five minutes at 80–85°.

(7) Conn, Kistiakowsky and Roberts, THIS JOURNAL, **62**, 1895 (1940); Conn, Gregg, Kistiakowsky and Roberts, *ibid.*, **63**, 2080 (1941).

vals over a period of three hours. Several non-stirring periods were interspersed through the run to determine the heat of stirring, which we found did not change appreciably during the calorimetric runs.

Blank runs were made in the calorimeter to determine whether native or denatured lactoglobulin or pepsin evolved heat when exposed to *p*H 1.5.

1. **Native Lactoglobulin.**—Native lactoglobulin was brought to *p*H 1.5, and 900 cc. was placed in the calorimeter; 0.75 mg. N/cc.

2. **Denatured Lactoglobulin.**—Native lactoglobulin was exposed to *p*H 11.1 for one hour, then brought to *p*H 1.5; 900 cc. was placed in the calorimeter; 0.76 mg. N/cc.

3. **Pepsin.**—900 cc. of pepsin solution at *p*H 1.5, 0.15 *N* in potassium chloride, was placed in the calorimeter; 0.024 mg. N/cc.

No heat evolution could be detected in any case. There was no increase in amino nitrogen in 1 or 2 after standing for two hours at *p*H 1.5, showing that no hydrolysis by acid occurred.

Heats of dilution of pepsin and lactoglobulin solutions used in the digestions were negligible.

Experimental Results

The experimental results of Runs A and B are compiled in Tables II and III. In Fig. 1 the experimental values for the increase in α-amino nitrogen are plotted against the increase in nitrogen not precipitable by trichloroacetic acid. The points lie on straight lines of different slopes. Thus as the digestion proceeds the increase in amino nitrogen is proportional to the increase in nitrogen not precipitable by trichloroacetic acid. The data of Tables II and III (except the dialysis results) are plotted in Figs. 2 and 3. The curves for amino nitrogen have been smoothed by taking values from the straight lines of Fig. 1.

			Average	.214	.0418	

The total non-dialyzable nitrogen and the nitrogen precipitated by trichloroacetic acid were found to be identical in amount, as seen from Tables II and III. Further tests showed that the concentrated dialyzates gave no precipitate with trichloroacetic acid, and the amino nitrogen content of the solutions in the dialysis bags after exhaustive dialysis was the same as that of undigested protein.

Referring to Tables II and III one can see that the ratio of amino to total nitrogen in the dialyzates is unchanged as the digestion proceeds. The amino nitrogen content of the dialyzates is easily seen to be in agreement with the slopes of the lines in Fig. 1. Native and denatured lactoglobulin both yield 4.3% of the total nitrogen as amino nitrogen in the standard reaction time for α-amino determination. The amino nitrogen found in the dialyzates will therefore be the sum of the amino nitrogen originally available and the α-amino nitrogen formed by hydrolysis. On the other hand the slopes of the lines of Fig. 1 take into account only the increase in α-amino nitrogen due to hydrolysis. Hence

$$\text{Slope of line} = (\text{amino N/total N})_{\text{dial.}} - 0.04$$

Substituting the experimental values

A. slope = 0.11, (amino N/total N) dial. = 0.15
B. slope = 0.17, (amino N/total N) dial. = 0.21

one finds that this relation is satisfied for both runs.

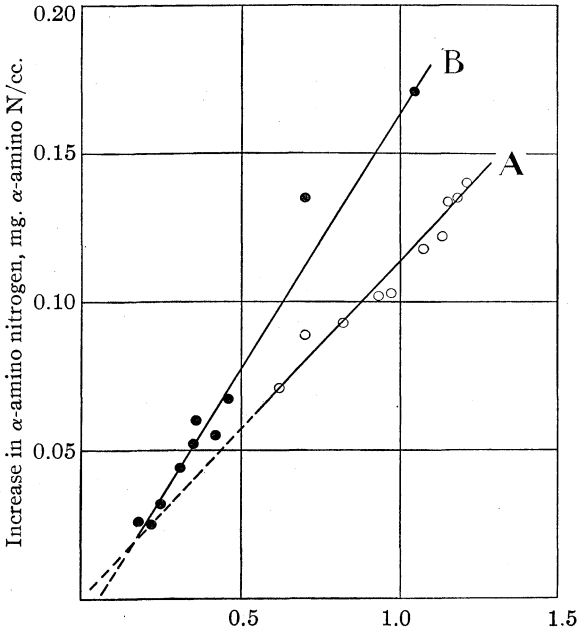

Fig. 1.—Increase in nitrogen not precipitable by trichloroacetic acid, mg. N/cc.

By applying the technique of solubility determinations it will probably be possible to improve the determinations of nitrogen precipitable by trichloroacetic acid, and the amino nitrogen determinations can, as previously mentioned, also be improved by using a longer reaction time. In this case the determinations in question may give figures of constitutional significance, especially when the specificity of the pepsin action is better known.

The amino nitrogen content of the dialyzates and of the inner solutions can be used to analyze the trichloroacetic acid and amino nitrogen data and confirm in a convincing way the existence of two fractions in the digests, whose amino nitrogen contents are independent of time. The trichloroacetic acid and amino nitrogen values in columns A and C of Table IV are taken from the curves of Fig. 1. The values in columns A and B are obtained by multiplying the precipitable nitrogen and the non-precipitable nitrogen present at a given time by the factors 0.04 and 0.153 given above for the amino nitrogen content of the inner solution and that of the dialyzate. The sums of

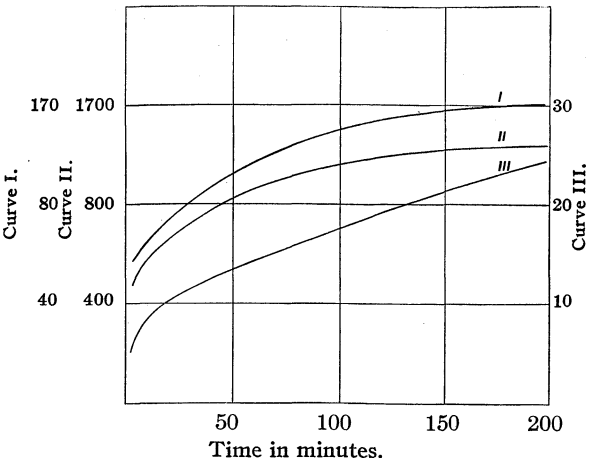

Fig. 2.—Curve I, total increase in α-amino nitrogen; II, total increase in nitrogen not precipitable by trichloroacetic acid; III, heat evolution in calories.

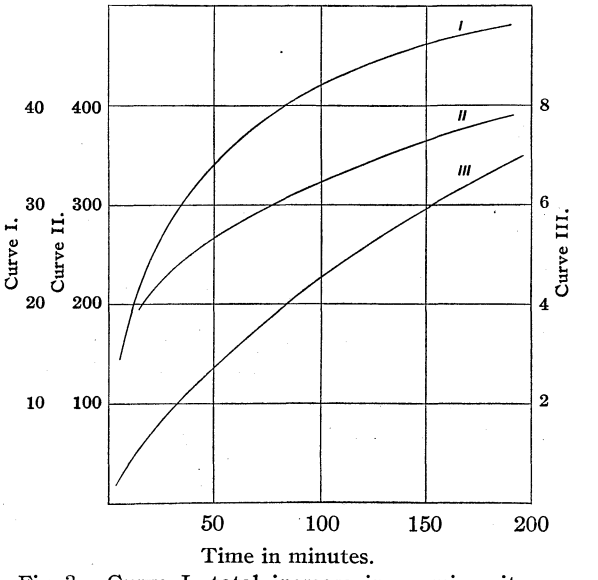

Fig. 3.—Curve I, total increase in α-amino nitrogen; II, total increase in nitrogen not precipitable by trichloroacetic acid; III, heat evolution in calories.

A and B in the next to the last column are to be compared with the experimental values for amino nitrogen in the last column. The excellent agreement is proof of the existence of two fractions in the digest: protein or protein-like material which is non-dialyzable and is precipitated by trichloroacetic acid, and a fraction consisting of much smaller particles which are completely dialyzable and are not precipitated by trichloroacetic acid. A similar analysis for Run B gave equally good results.

The ratio of amino to total nitrogen in the dialyzates is independent of time of digestion; and

TABLE IV

increase in amino nitrogen is proportional to increase in non-precipitable nitrogen (or to increase in dialyzable nitrogen). These facts suggest very strongly that when pepsin attacks the lactoglobulin molecule a definite number of fragments is produced at once, and these fragments are not further attacked by the enzyme. A similar conclusion was reached by Tiselius and Eriksson-Quensel after an electrophoretic study of peptic digests of egg albumin at the *p*H optimum.[8]

They found particles of unchanged size in the digest, but there was no evidence of particles intermediate in size between a molecular weight of 1000 and the original protein. That the nature of the digestion products is strongly influenced by the *p*H of digestion is shown by Petermann's ultracentrifugal analysis of the non-dialyzable fractions of peptic digests of beef serum pseudoglobulin between *p*H 2.7 and 4.5.[9] Besides particles unchanged in size, Petermann found particles which sedimented homogeneously which could be interpreted as halves and quarters of the original molecules; the distribution of nitrogen among the various fractions was a function of the *p*H. At *p*H 2.7 most of the nitrogen was in the unchanged and the dialyzable fractions; it thus appears likely that at the optimum *p*H there would be no evidence of products of intermediate size.

If our data are accepted as evidence of "explosion" of the lactoglobulin molecule, the number of bonds per molecule which can be hydrolyzed by pepsin can be determined from the slopes of the lines in Fig. 1. Taking the molecular weight of β-lactoglobulin as 39,000, and the value 0.11 for the slope of A, one finds that 46 peptide bonds per molecule have been broken in the case of denatured lactoglobulin, or 13.5% of the 341 peptide bonds in the molecule.[10] In the case of native lactoglobulin one finds that 71 peptide bonds per molecule, or 20.8% of the peptide bonds were split. It should be pointed out that although the native protein is attacked much more slowly, it is broken into smaller fragments. The average molecular weights of the split products are 870 for the denatured and 560 for the native protein. Particles deviating widely in molecular weight from the average may be present in the degradation products. We attempted to follow the evolution of free amino acids during the digestion by the ninhydrin–carbon dioxide method.[11] We found free amino acids to an extent of 1–2% of the total nitrogen in various digestions. Our results were not sufficiently accurate to detect an increase in the small amount of free amino acid with time of digestion. Blank runs showed that this hydrolytic product did not arise from exposure of pepsin or lactoglobulin to *p*H 1.5.

The calorimetric measurements were more accurate in the digestion of denatured protein. The heat evolution during the period of measurement was more than three times as large as in the digestion of native protein. The heat of stirring of the digests was about 0.04–0.05 cal./min. and could be measured during the reaction with a precision of only about ±5%. In Run A the error of measurement of the total heat evolution was ±2%, but in the digestion of native protein, where the rate of heating due to reaction was of the same order of magnitude as the heat of stirring, the measurement of the total heat evolution due to reaction was subject to very large error, estimated to be about ±13%.

In Fig. 4 the heat evolution is plotted against the increase in amino nitrogen after the same time of digestion. In both Runs A and B the heat evolved per peptide bond split increases markedly with time of digestion. From the slopes of the curves of Fig. 4 at various points one finds the following values:

Denatured protein	Native protein
2000 cal./mole peptide split at start	1300 cal./mole, at 15 min.
4000 cal./mole, at 90 min.	6000 cal./mole, at 190 min.
7000 cal./mole, at 150 min.

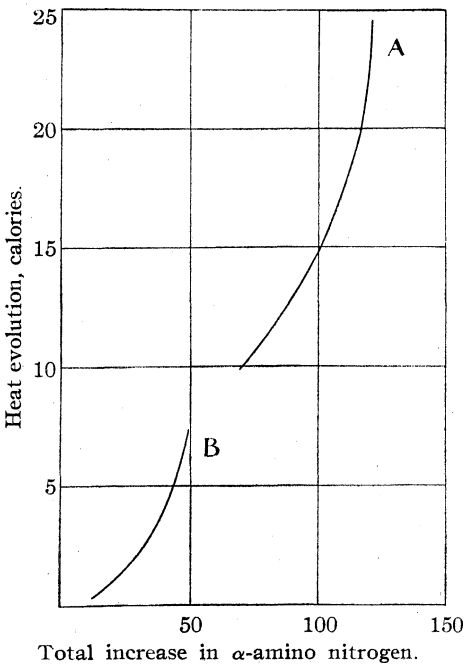

Fig. 4.

In case the degradation products were further hydrolyzed during the treatment with pepsin it could be expected that the heat per peptide linkage split would change as the process proceeded. The change would probably be small and the heat values consequently of the same order of magnitude. This is certainly not the case, and the most probable conclusion, therefore, is that not all the heat is due to the hydrolysis, but to processes we have not followed chemically. As we have shown that the degradation of β-lactoglobulin by pepsin is finished by the first attack, this secondary reaction—of unknown character—must be related to the breakdown products. Logically, of course, pepsin may attack other linkages of the degradation products than peptide bonds, but this is very unlikely. A rearrangement or an oxidation (or both) of some of the degradation products seems more probable.

Assuming that the heat value at the beginning of the experiment, where none or only a very small amount of the degradation products have reacted represents the true value of the heat of hydrolysis, we can use this value combined with the α-amino determinations to construct a heat–time curve which is related only to the degradation by pepsin of the lactoglobulin molecule. The difference between this curve and the actually found heat–time curve will thus represent the heat of the secondary reaction.

We have done this in the case of the run with denatured β-lactoglobulin using the value 2000 calories as representing the heat of hydrolysis. The set of curves are shown on Fig. 5, 1 is the actual heat curve, 2 the calculated heat curve, and 3 represents the heat evolution due to the secondary reaction.

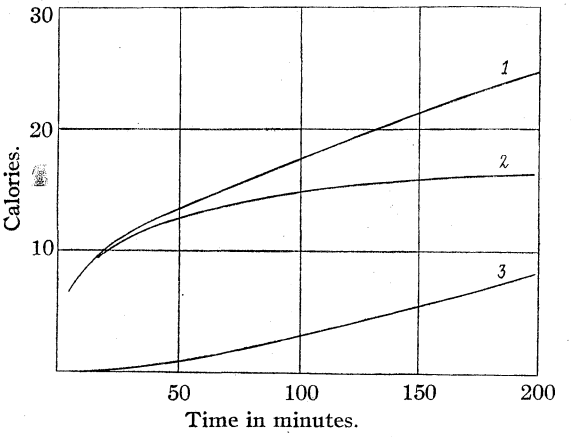

Fig. 5.

After an induction period at the beginning this third curve shows an increasing evolution of heat. The secondary reaction should thus be exothermic.

The lack of proportionality between heat evolution and extent of hydrolysis found in our experiments is reminiscent of dilatometric experiments of Linderström-Lang and Jacobsen on the digestion of native and denatured lactoglobulin and clupein by trypsin and chymotrypsin.[12]

The contraction per mole of peptide bond split was in the case of clupein, a protein considered of simple polypeptide chain structure and of low molecular weight, close to the normal value for peptides and was independent of time of digestion. In the digestion of native β-lactoglobulin, however, the contraction was initially about twice the normal value, and fell off slowly during the digestion. The contraction of heat denatured β-lactoglobulin was initially nearly normal, then rose to maximum almost twice the normal value, and thereafter decreased slowly. Linderström-Lang and Jacobsen believe that the abnormally large contraction may be due to the collapse of a "superstructure" originally present in the protein molecule.

In view of the experiments presented in this paper we should expect that the decreasing volume per peptide bond broken would be independent of

(12) Linderström-Lang and Jacobsen, *Compt. rend. trav. lab. Carlsberg, Sér. chim.*, **24**, 1 (1941).

the time as the degradation products are not further degradated. To prove this we have carried out a few dilatometric measurements using the technique described in detail elsewhere.[13,14]

The dilatometer used had two bulbs, the one (volume 45 cc.) containing at the beginning of the experiment the substrate, the other bulb (volume 8 cc.) containing the enzyme solution. Kerosene was filled in and the capillary tube inserted. The dilatometer was then immersed in water at 27 ± 0.005°. The concentrations of the enzyme and substrate were the same as in the digestion experiments presented on the foregoing pages. The β-lactoglobulin was alkali denatured. After the temperature equilibrium was reached the two solutions were mixed. The reading of the meniscus was continued for two hours. The results are tabulated in Table V.

TABLE V

Time, min.	Number of peptide bonds broken	Change in volume, cc.	Change in volume per peptide bond broken, cc.
5	0.000183	−0.00427	−23.4
10	215	528	24.6
15	241	586	24.4
20	260	630	24.2
30	286	698	24.4
40	305	748	24.6
50	318	783	24.6
75	344	841	24.5
100	360	867	24.1
125	373	877	23.5
		Average	−24.2

The contraction per peptide bond broken was found constant during the time of the experiment, which strongly confirms the results obtained by the trichloroacetic acid precipitations and α-amino nitrogen determinations (Fig. 1).

(14) Linderström-Lang in Myrbäck and Baman, "Die Methoden der Fermentforschung," Leipzig, 1940.

In conclusion it may be said that it is difficult to suggest a plausible mechanism for the "explosive" degradation of lactoglobulin and other substrates by pepsin. As Tiselius and Eriksson-Quensel have pointed out, anything less than a simultaneous rupture of a great many peptide bonds would result in an almost continuous spectrum of products, and in our case the linear relationship of Fig. 1 would not hold. However, the notion that the enzyme molecule is able to attack many bonds in the substrate at once is difficult to believe. One is tempted to suggest the following hypothetical process: The splitting of a single peptide bond by the pepsin makes the "superstructure" or the "protein pattern" unstable, whereupon it decomposes.

It is a great pleasure for the authors to thank Professor G. B. Kistiakowsky for his continuous interest and much profitable advice. The work was supported by a grant from the Rockefeller Foundation.

Summary

Native β-lactoglobulin and β-lactoglobulin denatured by alkali were digested by pepsin at *p*H 1.5. Heat evolution, nitrogen precipitable by trichloroacetic acid, increase in amino nitrogen, and dialyzable nitrogen were measured in the same digest as a function of time of digestion.

Precipitation with the trichloroacetic acid and dialysis through cellophane were found to be equivalent methods of fractionation of the total nitrogen in the digest.

Evidence for an "all-or-none" attack of lactoglobulin by pepsin is brought forward.

The heat evolution was not proportional to the extent of hydrolysis. It is suggested that digestion of lactoglobulin by pepsin is accompanied by an exothermic non-hydrolytic process.

The Spectrophotometric Determination of the Dissociation Constants of Diphenylselenium Dibromide and Diphenylselenium Diiodide

BY JAMES D. McCULLOUGH

Several properties of the diphenylselenium dihalides indicate a rather loose bonding of the halogen atoms to selenium. Krafft and Lyons[1] found that when heated just above its melting point in a sealed tube, diphenylselenium dibromide undergoes a self bromination in the ring, yielding *p,p'*-dibromodiphenylselenium, diphenylselenium and hydrogen bromide. The analogous reaction with the dichloride was also found to occur. Leicester[2] found that upon dissolving diphenylselenium dibromide in acetone, the solvent was brominated with formation of diphenylselenium. The dichloride did not undergo a similar reaction. X-Ray investigations of the crystal structure of diphenylselenium dibromide[3] and of diphenylselenium dichloride[4] show selenium–halogen bond distances which are somewhat large; the observed distances being 2.52 Å. for Se–Br and 2.30 Å. for Se–Cl. The distances calculated using covalent radii are 2.31 and 2.16 Å., respectively. The melting points,[5] 148° for the dibromide and 183° for the dichloride are somewhat out of line in view of the similarity in molecular and crystal structures for the two dihalides, indicating possible dissociation, at least in the case of the dibromide.

The object of the present work has been to establish the fact that diphenylselenium dibromide does dissociate into diphenylselenium and bromine, to show that diphenylselenium and iodine combine to a limited extent, even though the solid diiodide does not separate at room temperature, and to determine the dissociation constants for the dibromide and the diiodide.

Experimental

Preparation of Materials.—Diphenylselenium dibromide was prepared by adding pure bromine to Eastman Kodak Company diphenylselenium in carbon tetrachloride solution. The resulting solid was recrystallized from carbon tetrachloride three times. The purity of the material was checked by the analysis described later. A solution of pure diphenylselenium in carbon tetrachloride was prepared by adding excess powdered C. P. zinc and a weighed sample of pure diphenylselenium dibromide to the solvent. The mixture was shaken until all of the dibromide was dissolved and the solution became colorless. The solution was then filtered, the solid was washed several times with carbon tetrachloride and the washings were added to the filtrate. The filtrate was then made up to the desired volume. The concentration of diphenylselenium in the solution was based on the weight of the dibromide taken and the final volume of the solution. Bromine, iodine and carbon tetrachloride were purified by the usual methods.

Apparatus and Procedure.—All spectrophotometric measurements were made by means of a Beckman Quartz Photoelectric Spectrophotometer. Carbon tetrachloride was used as the solvent in all cases, and loss of volatile materials from the absorption cells was reduced so as to be inappreciable by capping the cells with cover glass slips held down firmly with cellulose tape. No provision was made for maintenance of constant temperature but in all cases a thermometer was kept near the absorption cells and read from time to time. At the end of each series of measurements, the temperature of the solutions was checked. All temperatures were within one degree of 26°. The transmission of light by a given solution is measured relative to the transmission of the pure solvent which is arbitrarily set at 1.000. The cells used had a depth of 1.30 cm. Corrections were applied for the slight differences in depth from cell to cell, the maximum correction being well under 1%.

Extinction coefficients for diphenylselenium, bromine and iodine were each determined at three different concentrations, and Beer's law was found to hold over the range of concentrations used in the equilibrium measurements. These extinction coefficients, as well as those of the dibromide and diiodide are shown in Table I and in Fig. 1.

TABLE I

MOLAR EXTINCTION COEFFICIENTS OF DIPHENYLSELENIUM DIBROMIDE, DIPHENYLSELENIUM DIIODIDE AND THEIR DISSOCIATION PRODUCTS

urements were made on solutions in which the dissociation was suppressed by the presence of a large excess of diphenylselenium. The values so obtained were verified over a part of the wave length range by a series of measurements in which the dissociation was suppressed by the presence of a large excess of bromine. The contribution of the excess reagent to the absorption of light was in each case determined by making measurements on solutions containing the excess reagent at the same concentration in the absence of diphenylselenium dibromide. Transmission data and the resulting extinction coefficients are shown in Tables II and III. In making these calculations, allowance was made for the fact that the dissociation was not completely suppressed, the degree of dissociation being calculated by use of the dissociation constant given later.

EXTINCTION COEFFICIENTS FOR DIPHENYLSELENIUM DIBROMIDE (BROMINE IN EXCESS)

Solution 1, 1.12×10^{-2} M in bromine; Solution 2, 1.12×10^{-2} M in bromine and 5.1×10^{-5} M in diphenylselenium dibromide.

λ, mμ	Transmission (1)	Transmission (2)	ε
320	0.887	0.232	8850
330	.895	.268	7900
340	.834	.292	6900
350	.667	.281	5650
360	.413	.201	4720

The dissociation constant for diphenylselenium dibromide is given by the expression

$$K_1 = \frac{[(C_6H_5)_2Se][Br_2]}{[(C_6H_5)_2SeBr_2]} = \frac{\alpha^2}{1-\alpha} M \qquad (1)$$

where α is the degree of dissociation and M the molarity. If we represent the extinction coefficients of diphenylselenium dibromide; diphenylselenium and bromine by ϵ_1, ϵ_2 and ϵ_3, respectively, then the optical density, d, of a solution of diphenylselenium dibromide is given by the equation

$$d = lM[\epsilon_1(1-\alpha) + \alpha(\epsilon_2 + \epsilon_3)] = \log_{10}(I_0/I) \qquad (2)$$

where l is the distance the light travels through the solution, I_0 the intensity of the incident light and I the intensity of the emergent light. From the measured values of the transmission, I/I_0, and the extinction coefficients, we may calculate α and hence K_1. Absorption data on solutions of diphenylselenium dibromide of various concentrations and values of K_1 derived therefrom are shown in Table IV.

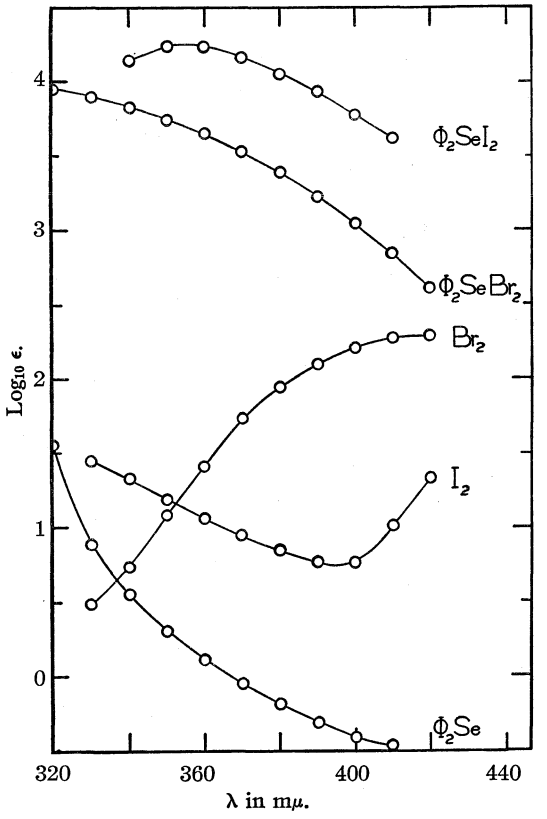

Fig. 1.—Molar extinction coefficients for several substances in carbon tetrachloride solution.

Because of the much larger dissociation constant of diphenylselenium diiodide, it is not practical to attempt complete suppression of the dissociation. The extinction coefficients and dissociation constant for the diiodide are accordingly simultaneously determined by a method different from that just employed for the dibromide.

When using light of such wave length that the undissociated molecule is the only important absorber, the measured optical densities, d_1 and d_2 at the molarities M_1 and M_2 are directly proportional to the concentrations of the undissociated compound. Using C_1 and C_2 to represent the concentrations of diphenylselenium (or of iodine) in the two solutions, we have

$$K_2 = C_1^2/(M_1 - C_1) = C_2^2/(M_2 - C_2) \qquad (3)$$

and

$$d_2/d_1 = (M_2 - C_2)/(M_1 - C_1) \qquad (4)$$

TABLE IV

THE TRANSMISSION, T, AND THE DISSOCIATION CONSTANT, K_1, FOR DIPHENYLSELENIUM DIBROMIDE AT SEVERAL CONCENTRATIONS

The upper figures are the transmissions and the lower figures (in parentheses) are the calculated values of $K_1 \times 10^4$.

		(5.1)	(5.3)	(4.9)

Av. K_1 5.02 $\times 10^{-4}$

For a given pair of solutions, the ratio d_2/d_1, should be constant with varying wave length. After correction is made for absorption due to diphenylselenium and iodine based on the assumption of complete dissociation, this ratio is actually fairly constant as shown in Table V.

TABLE V

TRANSMISSIONS AND OPTICAL DENSITIES OF SOLUTIONS OF DIPHENYLSELENIUM DIIODIDE

Solution 1, 6.0 $\times 10^{-4}$ M in iodine and 6.0 $\times 10^{-4}$ M in diphenylselenium; Solution 2, 12.0 $\times 10^{-4}$ M in iodine and 12.0 $\times 10^{-4}$ M in diphenylselenium.

	Solution 1		Solution 2		Ratio
λ	T	$d_{cor.}$	T	d_{cor}	d_2/d_1
340	0.698	0.139	0.260	0.544	3.91
350	.667	.162	.217	.635	3.92
360	.670	.165	.222	.632	3.83
370	.706	.142	.271	.550	3.87
				Av.	3.88

The average value of this ratio, 3.88, when used in equations 3 and 4 leads to a value 0.035 for K_2. Extinction coefficients for diphenylselenium diiodide are now readily calculated from the absorption data in Table V and are given in Table I. In the wave length range λ 380 to λ 410, the extinction coefficients are based on the 0.00120 M solution since the more dilute solution absorbs too little in this region for accurate measurements.

In order to check the value of K_2 obtained by the above method, measurements were made on several solutions containing diphenylselenium in excess of iodine. The concentrations of the various species present at equilibrium were calculated from the transmissions and extinction coefficients by means of the equation

$$d = l[\epsilon_1 C_1 + \epsilon_2(C_2 - C_1) + \epsilon_3(C_3 - C_1)] \qquad (5)$$

where the subscripts 1, 2 and 3 refer to diphenylselenium diiodide, diphenylselenium and iodine, respectively. The concentrations of diphenylselenium and iodine, as represented by C_2 and C_3 are those that would be present if no combination took place. The transmission data and values of K_2 calculated in this way are shown in Table VI. The agreement is excellent considering that the concentration ratio of diphenylselenium to iodine was over 300 in some runs while the data in Table V were obtained from solutions in which the two reactants were present in equimolar quantities.

				Av.	0.0360

Direct measurement of the dissociation constant for diphenylselenium dichloride was found to be impractical because of the low degree of dissociation even at low concentrations. An attempt was made to determine the value of this

constant by observing the extent of the reaction

$$(C_6H_5)_2SeCl_2 + Br_2 = (C_6H_5)_2SeBr_2 + Cl_2 \quad (6)$$

On adding bromine to diphenylselenium dichloride solution, the transmission is reduced much more than would be expected if no reaction took place, but the problem is complicated by two additional equilibria

$$Br_2 + Cl_2 = 2BrCl \quad (7)$$

$$(C_6H_5)_2SeBr_2 + (C_6H_5)_2SeCl_2 = 2(C_6H_5)_2SeBrCl \quad (8)$$

Reaction (7) is well known and (8) was demonstrated to occur by making absorption measurements on the three solutions (1) 0.0027 *M* in diphenylselenium dichloride, (2) 0.00022 *M* in diphenylselenium dibromide, (3) 0.0027 *M* in diphenylselenium dichloride + 0.00022 *M* in diphenylselenium dibromide.

The transmission of the third solution should be equal to the product of the transmissions of the first two if no reaction takes place. The individual transmissions and the product of the transmissions of solutions 1 and 2 are compared in Table VII.

TABLE VII

The dissociation of the diarylselenium dihalides makes possible a rapid and accurate volumetric procedure for their determination. When the dibromides or dichlorides are shaken either in the solid state or the dissolved state with excess aqueous potassium iodide, an equivalent quantity of iodine is liberated. This iodine may then be titrated as usual with sodium thiosulfate solution. The solid material (0.1 to 0.5 g.) is weighed and added to a glass-stoppered flask containing about 25 ml. of approximately 0.3 *N* potassium iodide solution which has been acidified with 1–2 ml. of 6 *N* sulfuric acid. The addition of about 5 ml. of carbon bisulfide just before adding the dihalide speeds up the reaction by dissolving the solid. This mixture is shaken for a few seconds and then titrated at once with standard sodium thiosulfate. Starch solution is added near the end-point. The concentration of a solution of a diarylselenium dihalide may be determined in the same manner. Data in support of the quantitative nature of this procedure are shown in Table VIII.

TABLE VIII

VOLUMETRIC ANALYSIS OF DIARYLSELENIUM DIHALIDES

Compound	Sample, g.	Volume $Na_2S_2O_3$ (0.05132 *N*), ml.	Equiv. wt. Anal.	Equiv. wt. Calcd.
Diphenylselenium dibromide	0.2594	25.76	196.4	196.5
	.2444	24.24	196.8	
Diphenylselenium dichloride	.1545	19.84	151.9	152.1

	.3567	33.08	210.1	

The dissociation of the diphenylselenium dihalides is, from a structural standpoint, analogous to the dissociation of phosphorus pentachloride and related molecules into the trihalides and free halogen. The similarity of molecular structure between diphenylselenium dihalides and phosphorus pentachloride was predicted by Pauling[6] and verified by crystal structure determinations.[3,4] The molecular structure of phosphorus pentachloride is that of a trigonal bipyramid, the phosphorus atom being at the center of the common base, three chlorine atoms being in the equatorial positions at a distance[6] of 2.04 Å. from the phosphorus atom and the other two chlorine atoms at the apices of the bipyramid at a distance of 2.11 Å. from the phosphorus atom. The last two chlorine atoms are less firmly bonded than the other three as indicated by the dissociation $PCl_5(g) = PCl_3(g) + Cl_2(g)$ which takes place in phosphorus pentachloride vapor and by the lower bond energy[6] (39.4 kcal./mole) for an apical P–Cl bond, as compared to the value 62.8 kcal./mole for a normal P–Cl bond. In the diphenylselenium dihalides, the halogen atoms occupy the apical positions and it is not surprising that the selenium–halogen bond distances are longer than for normal bonds and that the molecules dissociate into diphenylselenium and free halogen.

In a structural investigation of the trimethylantimony dihalides, Wells[7] found similar structures with the halogen atoms in the apical positions at distances somewhat greater than for normal Sb–X bonds. Considering all these facts, one might expect that in molecules of the general types R_3

(6) Pauling, "The Nature of the Chemical Bond," second edition. Cornell University Press, Ithaca, N. Y., pp. 57, 109, 111.

(7) A. F. Wells, *Z. Krist.*, **99**, 367 (1938).

(P, As, Sb, Bi)X_2, R_2 (S, Se, Te)X_2, and RIX_2, the halogen atoms would occupy apical positions in a trigonal bipyramidal structure at distances from the central atom which are greater than for normal M–X bonds. It is also reasonable to expect that all of these molecules show more or less tendency to dissociate in solution, giving the free halogen, X_2, as one product. A number of these dissociation constants are now being determined in this Laboratory.

Summary

1. Spectrophotometric studies of diphenylselenium dibromide and diphenylselenium diiodide indicate that these substances dissociate in carbon tetrachloride solution into diphenylselenium and the free halogen.

2. Dissociation constants for both compounds have been determined at 26° ± 1° at which $K_1 = [(C_6H_5)_2Se][Br_2]/[(C_6H_5)_2SeBr_2] = 5.02 \times 10^{-4}$; and $K_2 = [(C_6H_5)_2Se][I_2]/[(C_6H_5)_2SeI_2] = 3.60 \times 10^{-2}$.

3. Molar extinction coefficients for diphenylselenium, diphenylselenium dibromide and diphenylselenium diiodide are shown in Table I and in Fig. 1.

4. An accurate volumetric procedure for the determination of diarylselenium dihalides is described.

Photochemical Studies. XXXV. The Photochemical Decomposition of *n*-Butyl Methyl Ketone

BY WALLACE DAVIS, JR.,[1] AND W. ALBERT NOYES, JR.

The photochemical decompositions of *n*-butyl methyl ketone and of other ketones containing multi-carbon alkyl groups attached to the carbonyl have been investigated by Norrish and his co-workers.[2] On the basis of their results these authors have suggested that such ketones undergo two types of decomposition, which they designate as I and II

Type I: $R_1CH_2CH_2CH_2COR_2 = CO + (R_1CH_2CH_2CH_2R_2 + R_2R_2 + (R_1CH_2CH_2CH_2)_2)$

Type II: $R_1CH_2CH_2CH_2COR_2 = R_1CH{=}CH_2 + CH_3COR_2$.

Thus for *n*-butyl methyl ketone the reactions would be

Type I: $CH_3CH_2CH_2CH_2COCH_3 = CO +$ hydrocarbons (ethane, pentane, and octane)

Type II: $CH_3CH_2CH_2CH_2COCH_3 = CH_3CH{=}CH_2 + CH_3COCH_3$.

The theoretical discussion of this photochemical reaction will be reserved for a later article in which further data will be presented. It may be pointed out in passing that Norrish and his coworkers have come to the conclusion that the Type I reaction probably proceeds by a free radical mechanism whereas Type II proceeds in a single step leading to the final products. Others have discussed methods by which such a one-step process could occur,[3] and still others are inclined to the belief that Type II can also be explained by a free radical mechanism.[4]

Since acetone, if formed, would decompose photochemically to give carbon monoxide, any photochemical experiment leading to a large percentage decomposition of *n*-butyl methyl ketone would yield carbon monoxide as a secondary product. Furthermore, Norrish found that the yield of carbon monoxide was low. Since the stability of RCO radicals may vary markedly with the temperature, the quantum yields of all the products should be determined over a wide range of conditions.

The objects of the present investigation were as follows: (1) to apply and if necessary devise methods for the micro-analysis of the products formed during the photochemical decomposition of *n*-butyl methyl ketone so that the initial stages of the reaction could be investigated; (2) to determine the quantum yields of the various prod-

ucts under diverse experimental conditions to aid in the elucidation of the mechanism. Much of (2) was not accomplished, and the discussion will be postponed until a later date.

Experimental

Eastman Kodak Company *n*-butyl methyl ketone (b. p. approx. 127°) was converted to the semicarbazone and precipitated from a mixture of distilled water and ethyl alcohol; 250 cc. of water was added to 30 cc. of ketone and ethyl alcohol added until solution was complete. Sodium acetate and semicarbazide hydrochloride were added in slight excess of equivalent amounts and the derivative precipitated, m. p. 123°. The derivative was recrystallized from water and ethyl alcohol, hydrolyzed by refluxing with 15% sulfuric acid, and then distilled. The resulting product was dried with anhydrous magnesium sulfate, $n^{25}D$ 1.4003. The ketone was stored in the dark, under vacuum (usually at −77°).

In the first series of runs unfiltered light from a high pressure mercury arc lamp was used. In the second series the following filter was used to isolate the 3130 Å. line: (1) 5-cm. quartz cell filled with a solution made by adding 14 g. of $CoSO_4 \cdot 7H_2O$, 46 g. of $NiSO_4 \cdot 6H_2O$ to 330 cc. of water; (2) a 0.5-cm. cell filled with solution containing 10 g. of potassium acid phthalate per liter; (3) blue glass to remove the visible mercury lines.

After exposure, the reaction mixture was condensed with liquid nitrogen and the residual gases (CO, H_2, CH_4, part of the C_2H_6) were removed by a Toepler pump. This part was further fractionated and analyzed. It was always small. Next the gases uncondensed by a *n*-pentane mush at temperatures from −130 to −145° were removed and analyzed. As shown in the table this fraction consisted mostly of a compound of empirical formula C_3H_6, presumably propylene. Finally, a fraction removed at −77° gave fair agreement for the empirical formula of acetone. This agreement was obtained by measuring both carbon dioxide produced, water formed, and oxygen consumed during the burning of this fraction. It should be emphasized that the presence of acetone in the quantities indicated has not been definitely established. Difficulty was experienced in removing all of the acetone. The first pump-fulls gave a good analysis, but small amounts of material kept coming over for long periods, and these gave spurious results. If Type II decomposition occurs and the amount of propylene is really equal to

the amount of acetone, only about 75% of the acetone is recovered from the reaction mixture.

Two attempts were made to estimate the quantum yields, using a galvanometer and photocell circuit calibrated for another research. The values $\Phi_{C_3H_6} = 0.6$ and $\Phi_{CO} = 0.15$ should be given little weight, and further data will be presented in a later article.

Conclusions

The photochemical decomposition of *n*-butyl methyl ketone at room temperature (23–28°) at pressures from 5 to 13 mm. yields mainly compounds having the empirical formula C_3H_6 and C_3H_6O. This is true for unfiltered radiation of the mercury arc and for approximately monochromatic 3130 Å. radiation.

Small amounts of carbon monoxide are produced, the relative amount being greater for the unfiltered radiation than at 3130 Å. However, the amount of decomposition was several fold larger for the unfiltered radiation. In no case was more than a few per cent. of the parent ketone decomposed, and for the unfiltered radiation the amount did not exceed a few tenths of a per cent.

Some doubt may be expressed as to whether any carbon monoxide is formed by the decomposition of *n*-butyl methyl ketone. Carbon monoxide might be formed entirely from the decomposition of acetone formed in the initial reaction.

The Density of Selenium

BY A. N. CAMPBELL AND S. EPSTEIN

The only figures in existence for the density of liquid selenium are those of Dobinski and Wesolowski,[1] who carried their measurements up to 350° and reported a straight-line relationship between density and temperature. They made their determinations by a plummet method and, in view of the high viscosity of liquid selenium, we thought it desirable to repeat their measurements by an independent, pycnometric method. We extended our measurements to certain of the solid forms also.

Experimental

The selenium was of two kinds: (a) pure, from British Drug Houses, (b) crude. The crude material was purified by the method of Hugot,[2] followed by sublimation of the red amorphous selenium under reduced pressure: vitreous selenium was thus obtained. The results obtained with both samples were practically identical.

The method was to melt the selenium under an inert liquid in a calibrated pycnometer which was constructed of combustion tubing, since it was found that anything frailer than this cracked under the expansion of the solidified selenium. The inert liquid was Russian mineral oil (Paraffinol). The density of this oil was determined between 20 and 300° and was found to be represented by the equation

$$D = 0.8823 - 0.000622(t - 20.5)$$

but, of course, the density will vary somewhat for different samples.

Enough selenium (about 80 g.) was introduced to fill about three quarters of the pycnometer, when the selenium was molten. The oil was then added and the pycnometer kept in a bath at 250° until the selenium had melted. While the selenium was liquid, air bubbles were expelled by tapping and suction.

Before using the Paraffinol, experiments were carried out to determine its suitability. Its boiling point was found to be in the neighborhood of 310°. The solubility of selenium in the boiling oil was found to be 0.0013 g. per cc. of oil. The selenium did not react chemically with the oil for, on cooling the hot saturated oil, red selenium precipitated.

Density determinations for liquid selenium were made at temperatures ranging from 227 to 277°. Determinations at higher temperature were unsatisfactory because bubbles of vapor were evolved after prolonged heating. In all determinations the selenium was kept at one temperature for two hours to ensure attainment of a possible internal equilibrium. All determinations were repeated, with very good agreement.

(1) Dobinski and Wesolowski, *Bull. intern. akad. polon. sci., Classe sci. math. nat.*, No. 8-9A, 446 (1936).

(2) *Cf.* Hittorf, *Pogg. Ann.*, **84**, 214 (1851).

The Paraffinol proved to be too viscous for determining the density of solid (metallic) selenium. Benzyl benzoate gave satisfactory results. The density of benzyl benzoate at various temperatures is given in Table I.

TABLE I

Temperature in °C.	d^{t}_{4}
21.8	1.12000
175.0	0.99359
193.0	0.97723
203.0	0.96834

These results can be expressed by the equation

$$D = 1.12001 - 0.000834(t - 22)$$

After the powdered selenium had been introduced into the pycnometer, weighed and covered with benzyl benzoate, it was heated for several hours at 150° to ensure conversion of all the selenium into the metallic state. The results for metallic and for liquid selenium are contained in Table II.

TABLE II

in °C.	d^{t}_{4} Exptl.	Calcd.	Δd	Dobinski and Wesolowski[1]
		Metallic Selenium

188.5	4.6954	4.6989	+ .0035	
197.5	4.6940	4.6937	− .0003	
205.5	4.6919	4.6891	− .0028	
		Liquid Selenium		
225	3.9705	3.9727	+ .0022	3.976
241	3.9540	3.9479	− .0061	3.955
244.5	3.9394	3.9424	+ .0030	3.947
257	3.9276	3.9236	− .0040	3.929
277	3.8904	3.8925	+ .0024	3.891

[a] The figures of Kruyt [*Z. anorg. Chem.*, **64**, 310 (1909)] for the density of metallic selenium cannot refer to stable states; he gives densities ranging from 4.49 to 4.63. These figures are interpreted along the lines of Smits' theory of pseudo-components. The most recent treatment along these lines is that of Briegleb [*Z. physik. Chem.*, **144**, 321 (1929)].

In Table II, "*t*" represents the temperature, "*d* Exptl." the values of density obtained experimentally, and "*d* Calcd." those obtained from the formulas

$$D = 4.8073 - 0.0005753t \text{ (for metallic selenium)}$$

and

$$D = 3.9851 - 0.001551(t - 217) \text{ (for liquid selenium)}$$

These formulas were computed from the experimental results by the method of least squares: Δd represents the difference between "*d* Calcd." and "*d* Exptl." The figures calculated from Dobinski and Wesolowski's equation are given in the fifth column.

The density of vitreous selenium was also determined. In order to ensure that the sample might consist, as far as possible, entirely of vitreous selenium, liquid selenium was quenched in a steel mold. It was found possible only to determine the density of this form at room temperature because at higher temperatures, *e. g.*, 90°, the velocity of conversion to the stable metallic form was appreciably great. The result obtained was: $d^{21.3}_4 = 4.2524$.

Discussion

The formula obtained by Dobinski and Wesolowski for the density of liquid selenium is

$$D = 3.987 - 0.0016(t - 220)$$

The close agreement of Dobinski and Wesolowski's results with ours shows the suitability of the methods employed by both. The conclusion is that the results of Dobinski and Wesolowski are equally reliable throughout their range of measurement, *i. e.*, up to 345°. The linear relationship between density and temperature indicates that as far as density is concerned the behavior of both solid and liquid selenium is quite regular, *i. e.*, unaccompanied by a shifting internal equilibrium.

From our results, the change in volume on melting results as +0.03737 cc. per gram. Taking the heat of fusion as 13.4 cal. per gram,[3] we obtain for the change in fusion temperature with pressure +0.033° per atmosphere. This seems abnormally large and might make selenium an interesting subject for pressure experiments.

Summary

The densities of selenium (metallic and liquid) have been measured over the range 20–277°. In agreement with the conclusion of Dobinski and Wesolowski[1] these measurements give no indication of a shifting internal equilibrium. The rise of the melting point with pressure has been calculated.

The Systems: $LiNO_3$–NH_4NO_3 and $LiNO_3$–NH_4NO_3–H_2O

BY A. N. CAMPBELL

The system $LiNO_3$–NH_4NO_3 is interesting as one of the series of binary systems consisting of NH_4NO_3 and the nitrates of the univalent metals, *viz.*, $TlNO_3$, $AgNO_3$, $LiNO_3$, $NaNO_3$, KNO_3, all which have been studied. In some of these systems, compound formation occurs, in others solid solution, and in others again, the equilibrium diagram is of the simple eutectic form, unaccompanied by solid solution. This appears to be the case with lithium nitrate, according to Perman and Harrison,[1] who investigated the system up to a content of 45% $LiNO_3$.

Certain of the observations of Perman and Harrison are important in the present work and I quote: "On increasing the proportion of lithium salt, the stability was reduced, so that the range of the experiments at higher temperatures was very limited." I have not found this to be the case; on the contrary, measurements were carried as high as 230° (in presence of $LiNO_3$) before decomposition invalidated the results.

"The curve shows the usual two branches, with a eutectic at 97° and 25% $LiNO_3$. There is, however, a marked break in the left branch at 122° indicating a change (on cooling) from the δ to the γ-form of NH_4NO_3.

"A cooling curve was obtained for $LiNO_3$ (in a separate experiment) between 265° (its melting point) and 80°. It showed no breaks, thus proving that this salt exists in but one crystalline form between these limits of temperature."

I have repeated the work of Perman and Harrison, using a refined technique, and have carried the measurements to a higher content of lithium nitrate. The technique used was that of metallurgical practice, and consisted essentially in the use of a neutral body and two thermocouples in opposition: very small thermal changes in the system are thus rendered evident by large displacements of a sensitive galvanometer: the method is due to Roberts-Austen.[2] In the course of this investigation I frequently detected a point of recalescence which led me to suspect either limited solid solubility or the existence of a compound with incongruent melting point. I there-

(1) Perman and Harrison, *J. Chem. Soc.*, **125**, 1709 (1924).

(2) Fifth Report, Alloys Research Committee, Proc. Inst. Mech. Engrs. (London), (1899).

fore investigated the ternary system $LiNO_3$–NH_4NO_3–H_2O at 90, 60, 31 and 25° and have thus shown that neither compound nor solid solutions exist.

Experimental

Two large hard glass test-tubes were placed symmetrically in an electric furnace. One tube contained the $LiNO_3$–NH_4NO_3 mixture, in weighed proportions (from 60 to 100 g.), and the other the neutral body of silica, of such a weight as to have nearly equal thermal capacity. Each test-tube carried an iron–constantan thermocouple, connected in opposition through a delicate reflecting galvanometer. Temperatures were read directly on mercurial thermometers inserted in the system and in the neutral body. The thermometers were calibrated in boiling benzene, water, toluene, *m*-xylene, aniline, nitrobenzene and naphthalene and in freezing lead; an exposed stem correction was also applied. Systems consisting of mixtures of salts are at a disadvantage in comparison with similar systems consisting of metals, because of the low thermal conductivity of the former. It is, therefore, important to make provision for adequate stirring and in the present case this was achieved by means of a fine stream of compressed air passing through a capillary immersed in the melt. Unfortunately, no system of stirring is of any value after solidification, or even partial solidification, has taken place, and the full effect of poor thermal conductivity then comes into play.

In conducting the thermal analysis, the Plato method of graduated cooling[3] was applied; *i. e.*, the temperature of the furnace was reduced by equal decrements per unit of time, by increasing the resistance in the circuit. The lithium nitrate and ammonium nitrate used were British Drug Houses A. R. chemicals. To ensure their dryness, the ammonium nitrate was kept over sulfuric acid, with frequent grinding, and the lithium nitrate was fused just before use; lithium nitrate must not be kept fused for any length of time, or the temperature raised much above the melting point, lest decomposition become appreciable.

To ensure homogeneity of the mixtures, the following procedure was adopted: The ammonium nitrate was first weighed out and brought to the temperature of incipient fusion; the powdered and weighed lithium nitrate was then added, little by little and with constant stirring, until a completely clear and homogeneous melt was obtained. This was then placed in the furnace, which had previously been raised to a temperature above the freezing point of the mixture.

The observation of Lowry[4] that melts rich in ammonium nitrate invariably cracked the test-tube on cooling was confirmed. He attributes this to the transformation NH_4NO_3 II → NH_4NO_3 III at 82°, which occurs with expansion on cooling: the transformation III → IV at 32° is accompanied by a contraction.

Results

The results of the thermal analysis are given in Table I (in duplicate runs, the results were reproducible to ±0.5°). These figures are expressed graphically in Fig. 1.

TABLE I

TEMPERATURE–COMPOSITION DATA FOR THE SYSTEM: $LiNO_3$–NH_4NO_3

5	153	128	93
0	169	126	

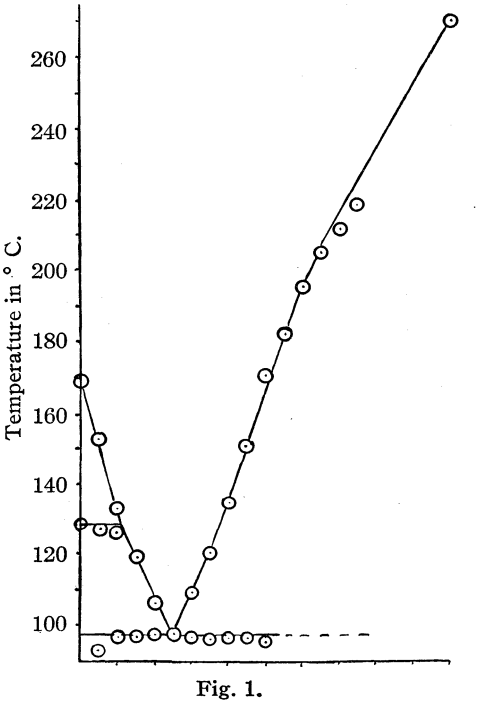

Fig. 1.

Discussion

The figures entirely confirm the results of Perman and Harrison. The only new observation is the so-called "peritectic point." A recalescence on the lithium nitrate curve, for mixtures between 60 and 40% $LiNO_3$, was frequently observed, at a temperature of about 110–120°. No explanation

has been found for this observation. It may be the result of some unknown experimental trouble; or it may indicate a polymorphic transition of lithium nitrate, although this could not be confirmed by the cooling curve of pure lithium nitrate. It does not seem to be the transition temperature of a compound of the two salts, since the ternary system revealed neither compound nor solid solution formation.

$LiNO_3$–NH_4NO_3–H_2O.—This system was investigated at 90, 60, 31 and 25°. Using a small thermostat, a low-lag electrical heating unit, and a sealed mercury arc relay, it was possible to maintain temperature constant to within 0.01° even at 90°. All solutions were stirred for twenty-four hours before analyzing them. In order to obtain a solid phase as free as possible from mother liquor, an all-glass apparatus was designed, incorporating a sintered glass filter and filtration by suction at the temperature of the thermostat. Ammonia was estimated by distillation and lithium by conversion to sulfate in a platinum dish. The accuracy of the ammonia estimation is high, certainly as high as 0.1%; that of the lithium determination not so high, 0.2% at best. The reproducibility was checked by taking solutions close together in composition: the analytical results lie on a smooth curve. Occasional discrepancies were due to insufficient time of stirring: these solutions attain equilibrium very slowly. The results are in Table II, and plotted in Figs. 2, 3, 4 and 5.

Since the hydrate, $LiNO_3 \cdot {}^1/_2H_2O$, described by Donnan and Burt,[5] nowhere occurs as solid phase in any of these systems, a dilatometric investigation of the transition points of hydrated lithium nitrate was carried out. The dilatometer contained anhydrous lithium nitrate to which water was added in amount more than sufficient to convert all the salt to hemihydrate but insufficient to convert it entirely to the trihydrate; the indicator fluid was *m*-xylene. The dilatometer was kept at room temperature overnight to ensure hydration and it was obvious to the eye that this had occurred. According to Donnan and Burt, the bulb should have contained a mixture of tri- and hemihydrates. A marked transition point was found at 28.8°. Donnan and Burt give 29.6° as the temperature of the transition

$$LiNO_3 \cdot 3H_2O \rightleftarrows LiNO_3 \cdot {}^1/_2H_2O + 2{}^1/_2H_2O$$

(5) Donnan and Burt, *J. Chem. Soc.*, **83**, 335 (1903).

These authors also give 61.1° as the temperature of the transition

$$LiNO_3 \cdot {}^1/_2H_2O \rightleftarrows LiNO_3 + {}^1/_2H_2O$$

I observed no second transition up to 78.8°.

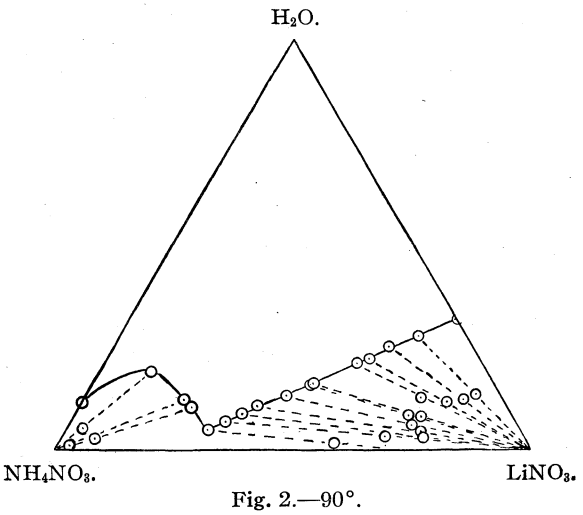

Fig. 2.—90°.

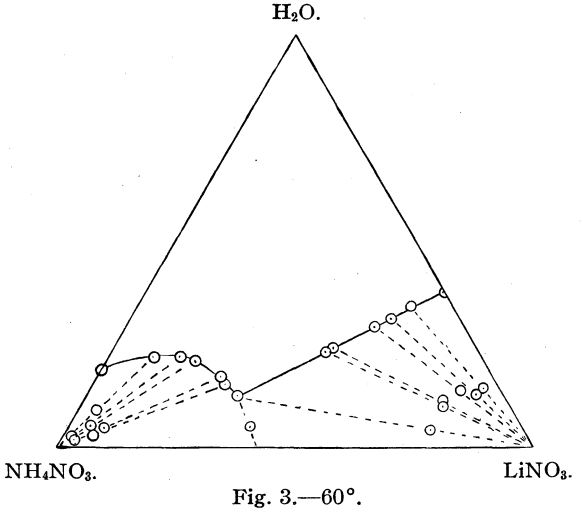

Fig. 3.—60°.

Discussion

It is apparent from the isotherms that no compound is formed between ammonium nitrate and lithium nitrate and that, in the solid state, ammonium nitrate is insoluble in lithium nitrate (up to 90°) and lithium nitrate insoluble in all four crystalline modifications of ammonium nitrate. It is well known that ammonium nitrate forms solid solutions with potassium and cesium nitrates, but not with sodium nitrate. It is pointed out by Tutton[6] that in some cases similarity in crystalline form alone, even when it is

(6) "Crystalline Structure and Chemical Constitution," Macmillan, London, 1910, p. 128.

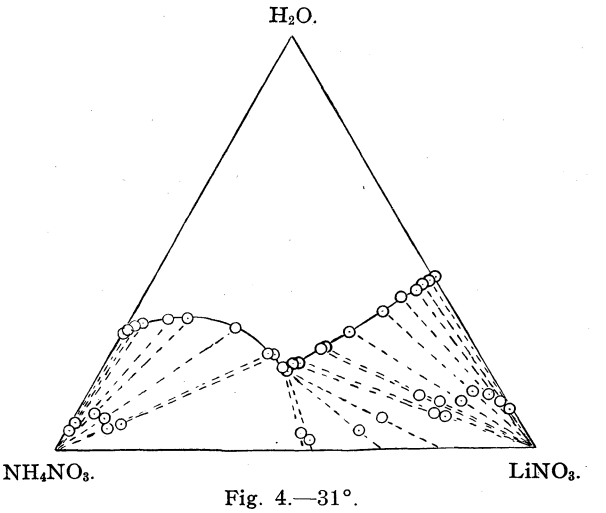

Fig. 4.—31°.

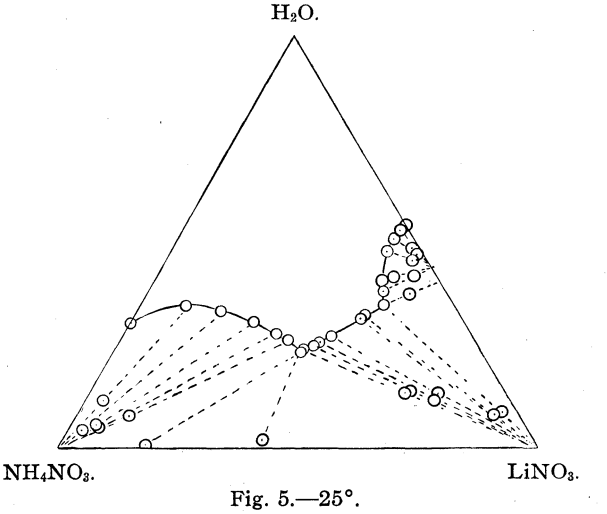

Fig. 5.—25°.

very marked, is not sufficient to cause miscibility in the solid state, but that the molecular volumes of the two substances must also be almost equal. The molecular volumes of the nitrates in cc. are

NH_4NO_3	KNO_3	$CsNO_3$	$LiNO_3$	$NaNO_3$
46.5	48.0	52.8	29.6	35.8

Another striking feature of the isotherms is that the hemihydrate, $LiNO_3 \cdot {}^1/_2H_2O$, nowhere occurs as stable solid phase. A similar observation was made by Massink,[7] working on a system comprising $LiNO_3$, who found that, with the exception of one experiment, anhydrous $LiNO_3$ always occurred as the solid phase, where the results of Donnan and Burt[5] would lead one to expect the hemihydrate. Donnan and Burt base their evidence for the existence of the hemihydrate on a direct determination of transition point in the dilatometer and on the occurrence of a break in

(7) Massink, *Z. physik. Chem.*, **92**, 356 (1916–1918).

their solubility curve for lithium nitrate in water. I have been unable to obtain the transition point dilatometrically and, if the solubility figures of Donnan and Burt are plotted, there seems no reason to give the curve the shape drawn by them; their figures are better represented by a smooth curve: in any case, their determinations are too far apart to settle the matter definitely. I conclude that the existence of the hydrate, $LiNO_3 \cdot {}^1/_2H_2O$, is doubtful.

Summary

1. The system $LiNO_3$–NH_4NO_3 has been investigated by thermal analysis. The results of Perman and Harrison are confirmed and extended.

2. The system $LiNO_3$–NH_4NO_3–H_2O has been investigated at 90, 60, 31 and 25° by the usual solubility technique.

3. No compound occurs, under any of the above conditions; neither is solid ammonium nitrate soluble in solid lithium nitrate (up to 90°), nor lithium nitrate in any of the four crystalline modifications of ammonium nitrate.

4. Lithium nitrate exists in but one crystalline form between room temperature and its melting point, in accordance with Perman and Harrison.

5. The hydrate, $LiNO_3 \cdot {}^1/_2H_2O$, described by Donnan and Burt, nowhere exists as stable solid phase. A direct investigation of transition point with the dilatometer failed to reveal the transition: $LiNO_3 \cdot {}^1/_2H_2O \rightleftarrows LiNO_3 + {}^1/_2H_2O$, which is said to occur at 61.1°. The existence of this hydrate is doubtful.

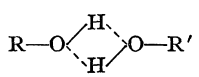
Spectroscopic Evidence of Intermolecular Transfer of Protons

BY DUDLEY WILLIAMS[1] AND W. DAVID STALLCUP[2]

The high degree of association exhibited by pure liquids and by liquid mixtures in which the molecules contain hydrogen atoms attached to atoms of the electronegative elements fluorine, oxygen or nitrogen has been explained, qualitatively at least, in terms of proton bonds or hydrogen bridges formed between neighboring molecules. According to the proton-bond theory, protons are "shared" between adjacent molecules in somewhat the following manner



In the case of water and other liquids having especially strong proton bonds, the proton can be transferred from one molecule to another when the molecules are separated. Whether actual intermolecular transfer of protons can occur in all liquid mixtures having association of the type indicated above is not entirely clear. The purpose of the present paper is to report a method for detecting intermolecular transfer and to give the results for a single binary mixture.

The method is rather simple: the hydrogen in one liquid is replaced by deuterium. Then the two liquids are mixed. After mixing, the liquids are separated by distillation and the liquid originally containing no deuterium is tested for the presence of deuterium. The changes in physical constants produced by the presence of deuterium are, in most cases, so slight that it was decided to use the infrared absorption of the liquids as a test for the presence of deuterium. The separation of OH and OD bands in alcohols is approximately 830 cm.$^{-1}$; the OH and OD absorption bands appear at 3.0 μ and 4.0 μ, respectively. The two liquids chosen for study were methanol and heavy butanol.

Experimental Results

Anhydrous methanol was prepared by treating a suspension of magnesium methylate in methanol with freshly distilled methanol and then separating the methanol from this mixture of magnesium oxide and magnesium methylate by distillation. The methanol thus prepared had the following physical constants: b. p. 64.5°, $n^{25}D$ 1.3268, and d^{25}_4 0.7896.

The deuterium butoxide was prepared by adding deuterium oxide to *n*-butyl borate. After standing a few hours, the precipitated boric acid was removed by filtration. The filtrate was then fractionated in order to separate the deuterium

(1) Present address: Radiation Laboratory, Massachusetts Institute of Technology, Cambridge, Mass.

(2) Present address: American Cyanamid Company, Stamford, Conn.

butoxide from unreacted butyl borate. The deuterium butoxide fraction was then refractionated through a thirty-plate column and the material distilling at 119.0–119.5° was collected. The physical constants of this material were: $n^{25}D$ 1.3974 and d^{25}_4 0.8131.

The transmission of samples of the methanol and the deuterium butoxide was then measured in the region between 2 and 5 μ. The absorption cells used were approximately 0.03 mm. in thickness. The spectrometer was a Littrow instrument equipped with a rock salt prism. The results obtained are shown in Fig. 1. Curve A is the transmission curve for methanol and exhibits only two absorption bands; the band at 3.0 μ arises from an OH vibration and the band at 3.4μ from a CH vibration. Curve B represents the transmission of the deuterium butoxide prepared in the manner described above. In this curve strong bands are found near 3.4 μ and 4.0 μ, arising from CH and OD vibrations, respectively; a rather weak band is also observed at 3.0 μ, indicating that some OH groups are also present in the heavy butanol.

After the spectra of the original liquids had been studied, equimolecular amounts of the liquids were mixed and heated for two hours. At the end of this time, the methanol and butanol were separated by fractionation through a forty-plate column. The first fraction was collected at the end of ninety minutes and, after discarding intermediate fractions, the final butanol fraction was collected three hours later. The recovered alcohols had the following physical constants

Methanol: b. p. 65.5° $n^{25}D$ 1.3270 d^{25}_4 0.7913
Butanol: b. p. 119° $n^{25}D$ 1.3970 d^{25}_4 0.8103

The spectra obtained for a sample of the recovered methanol is shown in Curve C of Fig. 1. Three absorption bands will be noted; these are produced by OH, CH, and OD vibrations. The OH band is weaker than in the spectrum of the original methanol and an OD band can now be observed near 4.0 μ. Curve D represents the transmission of a sample of the recovered butanol and also indicates absorption arising from OH, CH, and OD groups. The OH band is much stronger than in the original butanol, while the OD band is correspondingly weaker.

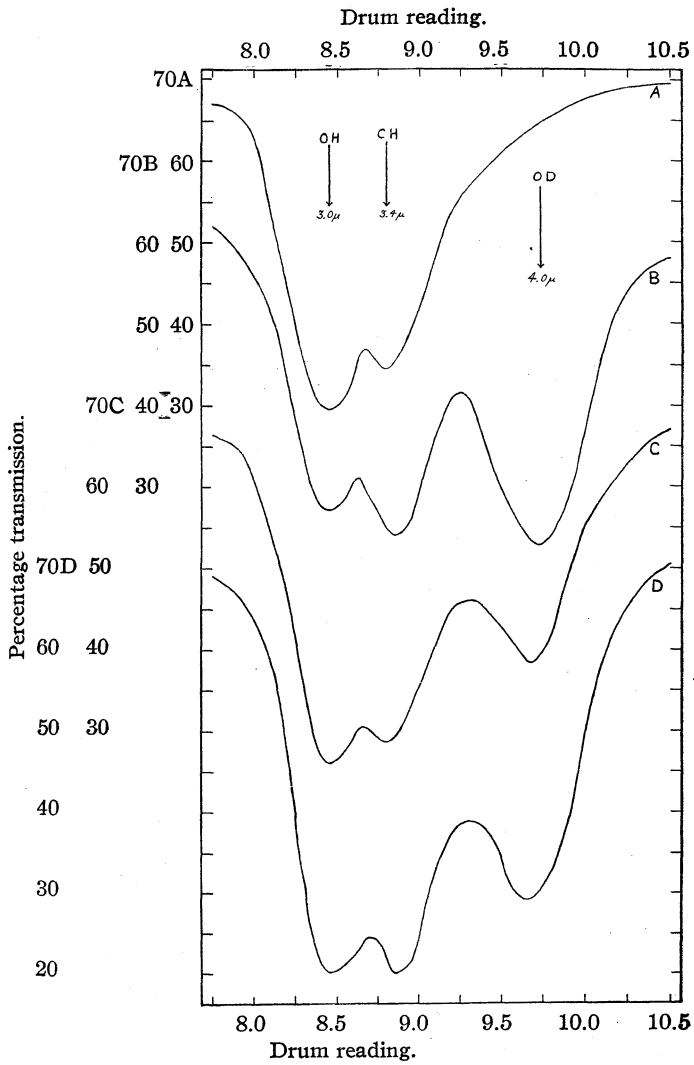


Fig. 1.—The infrared transmission of methanol and butanol: Curve A, original methanol; Curve B, original butanol (containing deuterium); Curve C, recovered methanol; Curve D, recovered butanol.

Discussion

The spectroscopic results indicated in Fig. 1 can be interpreted on the basis of the actual transfer of hydrogen atoms from methanol to butanol and the transfer of deuterium atoms from butanol to methanol. There are obvious extensions of the method developed in the present study to the study of other mixtures whose components can be separated by distillation. It was originally hoped to extend the present investigation to include the study of proton transfers between other alcohol molecules, between amine molecules, and be-

tween alcohols and amines. Numerous other applications of the method suggest themselves, but the pressure of other work will prevent pursuing the problem further at present.

Summary

When a mixture of MeOH and BuOD is fractionated, it is found that MeOH and MeOD are both present in the recovered methanol and that BuOH and BuOD are both present in the recovered butanol. It is concluded that the intermolecular hydrogen bonds involve the actual transfer of protons between molecules. Extension of the present study to include other compounds is suggested.

The Structures of Dimethyl Boron Fluoride and Methyl Boron Difluoride

BY S. H. BAUER AND J. M. HASTINGS

The structures of boron trifluoride and boron trimethyl as determined by Lévy and Brockway[1] were among the first items of information to suggest that rather artificial explanations may be necessary in some cases to make the observed interatomic distances harmonize with the Pauling and Huggins[2] table of covalent radii and with the postulate of the dependence of bond order on the distances between the atoms in a molecule.[3] The suggestion of Schomaker and Stevenson[4] that as a next best approximation the electronegativity difference between the atoms be considered in computing the separation for normal covalent bonding was a welcomed one since it permitted a reasonable interpretation of data otherwise not readily accounted for; it removed the necessity for the artificial postulates applied to various boron compounds.[5] The structures of the methyl boron fluorides discussed in this paper furnish critical tests for the applicability of the table of atomic radii as revised by them and of the use of their equation

$$r_{ab} = r_a + r_b - 0.09|x_a - x_b| \qquad (1)$$

Both the methyl boron difluoride and the dimethyl boron fluoride were furnished by Dr. Anton B. Burg.[6] We wish to acknowledge his coöperation and to thank him sincerely for this and other compounds he gave us.

The Apparatus and Photographs

The present electron diffraction apparatus resembles the latest model constructed by Brockway.[7] A simple but highly effective voltage regulator[8] and voltmeter have been set up so that the net voltage fluctuations have been reduced to a few hundredths of one per cent. The apparatus was designed to be flexible and special provision made for the incorporation of a rotating sector,[9] the assembly of which has now been completed. A more detailed description of this unit will be given in a future paper.

The photographs were taken with electrons having a wave length near 0.06 Å., and with the nozzle–plate distance equal to 13.69 cm. The visual appearance of the photographs is that indicated by curves V, Figs. 2 and 4; the $s_0 = \left[\frac{4\pi}{\lambda} \sin \Theta_0/2\right]$ values for the maxima and minima as determined by the usual visual technique, and their relative intensities above or below the estimated backgrounds (lines through curves V) are given in Tables II and III.

Analysis of the Data

Because of their relative simplicity, considerable information regarding the structures of these molecules can be obtained from their radial distribution curves. These were computed according to the method of Walter and Beach,[10] and are plotted in Fig. 1. The results are summarized in Table I. To facilitate the interpretation of these curves and to show the resolution which might be expected under ideal conditions, "synthetic" radial distribution curves for various

models are also included in Fig. 1. The approximate equations given by Debye[11] were used, as was also an average value for the temperature factor, a_{ij} (=0.042). The synthetic D(r)'s thus computed for planar models, boron valence angles equal to 120°, with B–C = 1.56 Å. and B–F = 1.30 Å., agree very well with the experimentally determined R. D. curves. It is clear that only slight distortions of these basic models (Table I) would be needed to obtain the best quantitative check between the calculated and observed patterns.

		∠CBF = 122° indicated

BCH_3F_2

Peaks at Å.	Interpreted as	Ratios
1.01	C–H	
1.31	B–F	B–F/F–C = 0.512
2.23	F–F	B–F/F–F = 0.586
2.55	C–F	F–F/F–C = 0.874
		∠CBF = 121½° indicated

To begin with, we considered models with 120° valence angles, varying the B–C/F–B ratio. The intensity curves, calculated in the usual manner, are shown in Figs. 2 and 4, with the description of the corresponding models given in the legends. In order to restrict the total number of computations for configurations with unequal boron valence angles, we made use of the following argument. If

$$I(s) = \sum_{ij}{}' Z_i Z_j \frac{\sin l_{ij}s}{l_{ij}s}$$

then

$$\frac{\partial I(s)}{\partial P_n} = \sum_{ij}{}' Z_i Z_j \frac{\partial}{\partial l_{ij}}\left[\frac{\sin l_{ij}s}{l_{ij}s}\right]\frac{\partial l_{ij}}{\partial P_n} \qquad (2)$$

where P_n is a given structure parameter. Furthermore

$$\frac{\partial l_{ij}}{\partial}\left[\frac{\sin l_{ij}s}{l_{ij}s}\right] = \frac{1}{2\epsilon}\left[\frac{\sin s(l_{ij}+\epsilon)}{s(l_{ij}+\epsilon)} - \frac{\sin s(l_{ij}-\epsilon)}{s(l_{ij}-\epsilon)}\right] - \frac{\epsilon^2 s^2}{2l_{ij}}\frac{\sin l_{ij}s}{l_{ij}s} \qquad (3)$$

to the approximation $\sin s\epsilon = s\epsilon$; $\cos \epsilon s = 1 - s^2\epsilon^2/2$; and $\epsilon^2 << l_{ij}^2$. Since with the available $\sin x/x$ strips, ϵ can be made as small as 0.01, equations 2 and 3 are quite accurate. Hence it is a simple matter to estimate the effect an increment in a particular structure parameter will have on the intensity pattern over any given interval of s. Knowing such trends is of considerable aid in deducing a configuration which is satisfactory. However, of greater value is the possibility thus presented of deducing the effects of increments

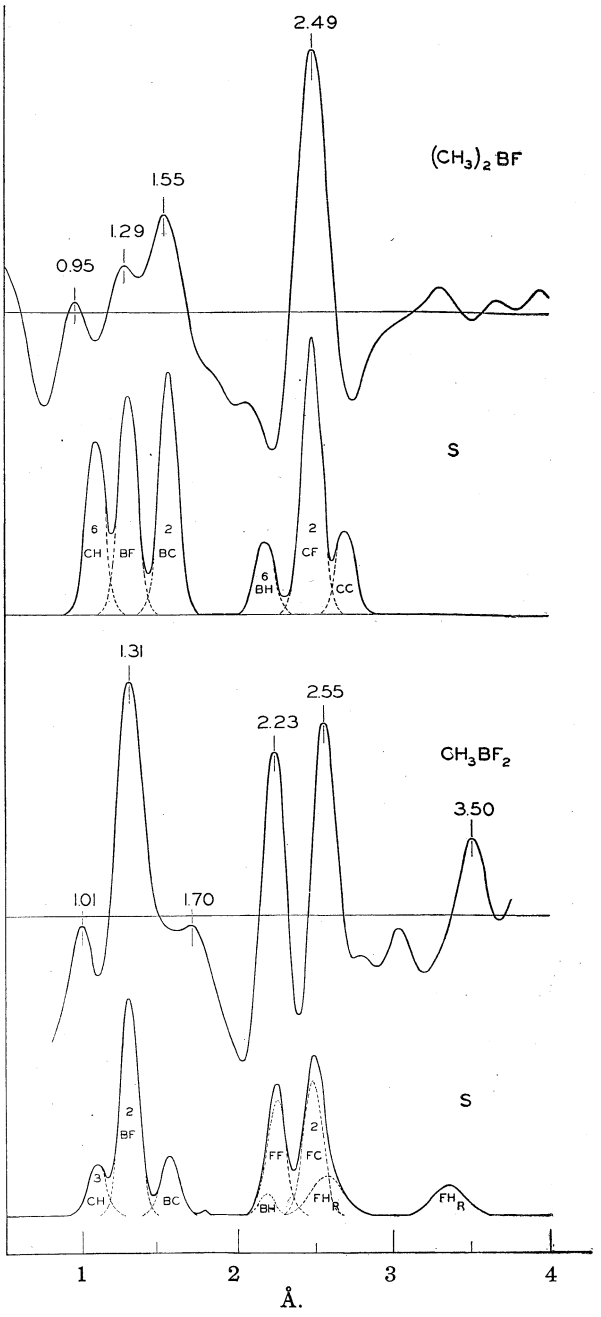

Fig. 1.—Radial distribution curves for methyl boron fluorides. Those marked "S" are synthetic curves for boron valence angles equal to 120°, B–C = 1.56 Å., B–F = 1.30 Å., C–H = 1.09 Å., a_{ij} = 0.042. The other curves were computed from the data quoted in Tables II and III, using the method of Walter and Beach.

(11) P. Debye, *J. Chem. Phys.*, **9**, 55 (1941).

in several parameters at once. Were one to start with a satisfactory model and values for $\partial I(s)/\partial P_n$ covering the critical regions, he can quickly estimate the effects of any combination of increments, if these are reasonably small, from

$$I(s)_{\text{new config.}} = I(s)_{\text{original}} + \sum_{P_n} \frac{\partial I(s)}{\partial P_n} \Delta P_n \qquad (4)$$

and thus conclude which combinations will still lead to satisfactory models. Limits on these increments are imposed by the radial distribution curve.

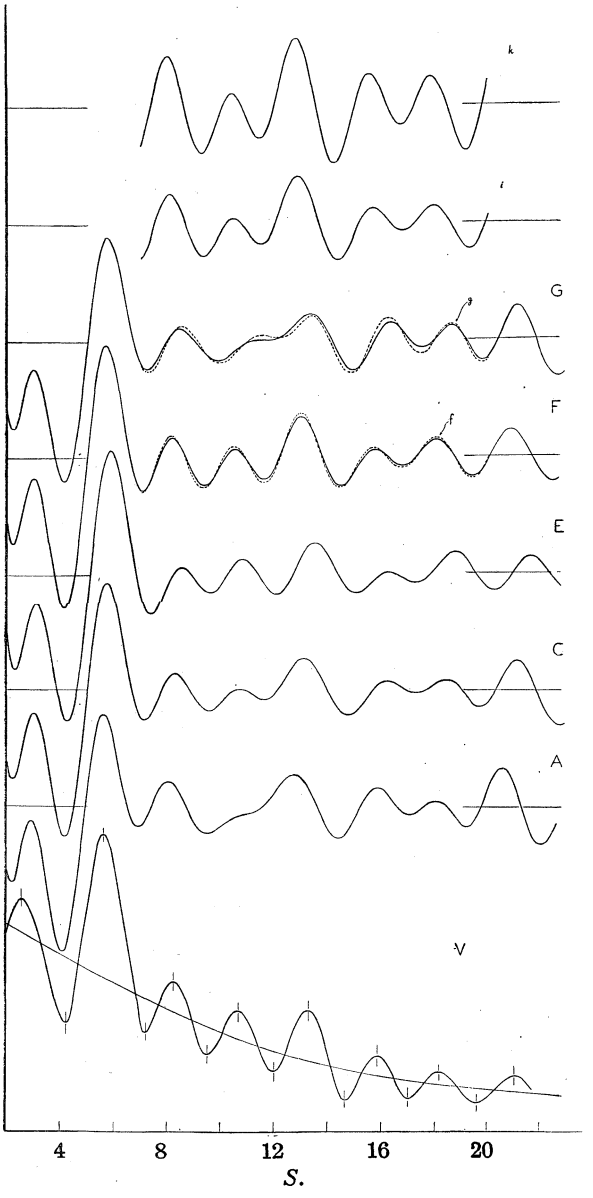

Fig. 2.—Intensity curves for dimethyl boron fluoride. Curve V is a sketch of the visual appearance of the pattern; the dashed curve is the supposed background above and below which our relative intensity estimates were made. For the computed curves, C–H = 1.09 Å., carbon valence angles tetrahedral (assumed); B–F = 1.29 Å., boron valences in a plane, and

B–C =	∠CBF =	Curve
1.61 Å.,	120°	A
1.55	120	C
1.49	120	E
1.55	122	F (usual method), f (eq. 4)
1.55	118	G (usual method), g (eq. 4)
1.58	122	i (eq. 4)
1.61	124	k (eq. 4)

Dimethyl boron Fluoride.—The critical points of comparison are the intensities of the fourth and seventh peaks relative to the maxima on either side of these. For configurations with 120° boron valence angles six curves were computed, with the B–C/B–F ratio varying from 1.61/1.29 to 1.49/1.29. Of these, curves A and E, Fig. 2, are the extremes. The curve marked C, for which B–C/B–F = 1.202, and B–C/C–F = 0.630, appears to be quite satisfactory, both qualitatively and quantitatively (Tables I and II). A change of 0.03 Å. in the B–C separation introduces features not experimentally observed in the photographs.

TABLE II

	∠CBF			120° 120°	122°	1.24°

The radial distribution curve suggests a small distortion in the boron valence angles. However, instead of calculating a whole series of curves covering a range in B–C/B–F ratio for various angles in the vicinity 120°, we computed $\partial I(s)/$

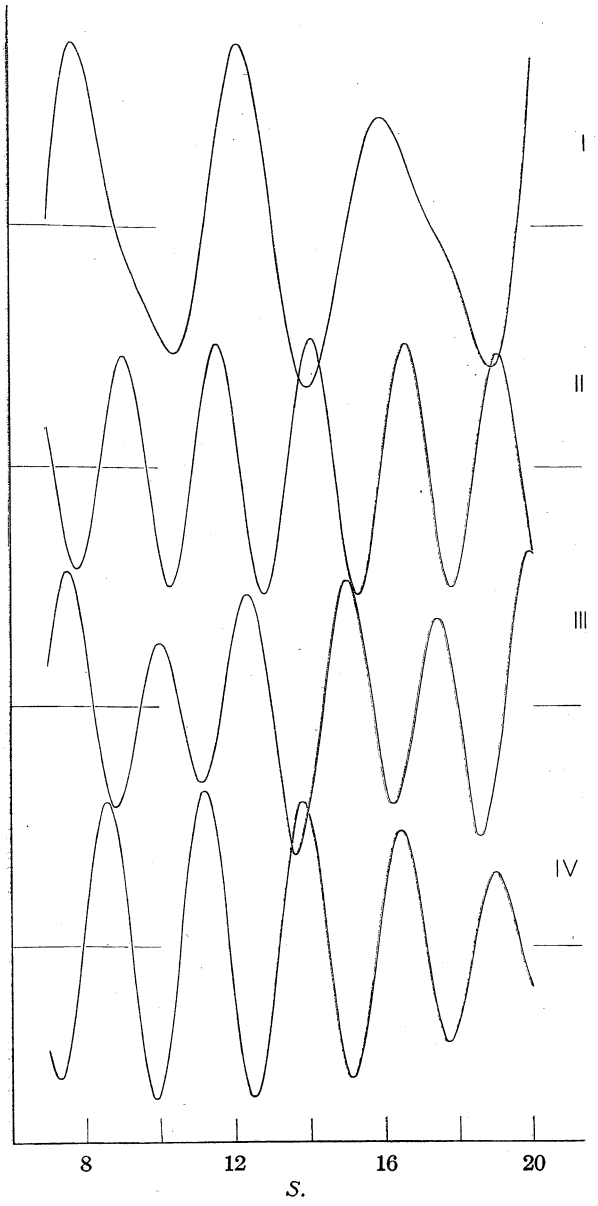

Fig. 3.—The variation of the intensity curves with distance and angle parameters, $(CH_3)_2BF$, curves I and II: $\partial I(s)/\partial$(B–C) and $\partial I(s)/\partial(\angle CBC/2)$, respectively. CH_3BF_2, curves III and IV: same distance parameter, while angle parameter is $\angle FBF/2$.

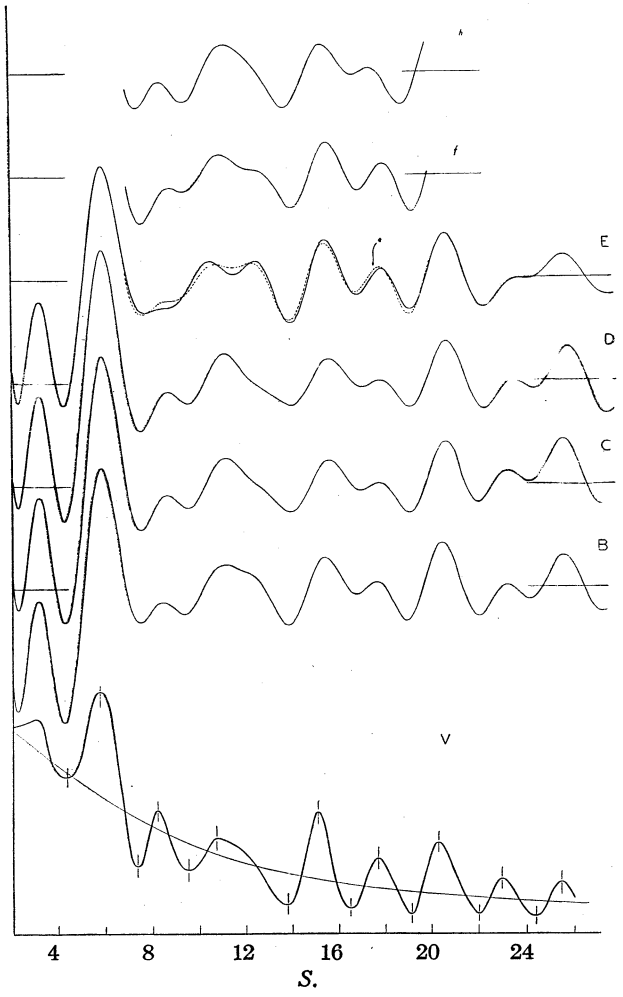

Fig. 4.—Intensity curves for methyl boron difluoride. Curve V is a sketch of the visual appearance of the pattern; the background curve is included. Once more, for the computed curves, C–H = 1.09 Å., carbon valence angles tetrahedral (assumed); B–F = 1.29 Å., boron valences in a plane, and

B–C = 1.61 Å.,	$\angle$CBF = 120°	Curve B
1.58	120	C
1.56	120	D
1.58	122	E (usual method), *e* (eq. 4)
1.55	122	*f* (eq. 4)
1.625	119	*h* (eq. 4)

∂(B–C) and $\partial I(a)/\partial\alpha$, where $\alpha = \angle$ CBC/2, using curve C as our basic model (Fig. 3, curves I and II, respectively). We then made use of equation 4 to obtain subsequent models, some of which are included in Fig. 2, f–k. The accuracy of the method can be judged from a comparison of curves F and G with *f* and *g*, the former two being computed in the usual manner, with B–C/B–F $\Delta\alpha$ = 1.202 and $\angle$ CBF = 122 and 118°, respectively, while the latter were obtained from eq. 4 (curve II, Fig. 3) with = −2 and +2°, respectively.

It soon became evident that in general increments in either parameter alone lead to unacceptable curves, the fit being least disturbed for $\Delta\alpha$ negative. However, the combination of positive increments in B–C and negative ones in α resulted in a series of curves having the proper form (typical ones are *i*, *k*, Fig. 2); however, due to the good resolution obtained in the R. D. curves,

	Average			1.007	1.012	1.017	1.027	1.006
	Mean deviation			0.011	0.013	0.012	0.010	0.013
Distances and angles deduced	B–F			1.299	1.305	1.312	1.325	1.298
	B–C			1.621	1.599	1.587	1.592	1.635
	C–F			2.538	2.520	2.512	2.557	2.535
	F–F			2.256	2.267	2.278	2.249	2.223
	∠CBF			120°	120°	120°	122°	119°

not all of these are acceptable. On weighing the various data, we concluded that dimethyl boron fluoride is a planar molecule, B–F = 1.29 ± 0.02 Å.; B–C = 1.55 ± 0.02 Å.; C–F = 2.48 ± 0.03 Å.; C–H = 1.09 Å. and tetrahedral carbon valence angles were assumed. The above combination of distances leads to ∠CBF = 121½°.

Methylboron Difluoride.—The critical region extends from $s = 7$ to 19. Due to the steeply decreasing background and the presence of a broad fourth maximum, the exact shape of the pattern in the interval $s = 8$ to 13 could not be clearly determined. Again, using 120° valence angles for boron, four curves were computed for the B–C/B–F ratio ranging from 1.66/1.29 to 1.56/1.29, with the best qualitative and quantitative fit being somewhere between curves B and C (Fig. 4 and Table III) B–C/B–F = 1.61/1.29 and 1.58/1.29, respectively.

With model B as a base, $\partial I(s)/\partial$(B–C) and $\partial I(s)/\partial\beta$ where β = ∠ FBF/2 (Fig. 3, III and IV, respectively) were obtained. It is clear that positive or negative increments in the two parameters would cancel each other except in the range $s = 8$ to 11. Thus, although the R. D. curve suggests that ∠ CBF is greater than 120°, a negative increment in β leads to unacceptable curves (E and e, Fig. 4), as do increments in either parameter alone. However, small positive increments both in B–C and in β lead to several acceptable curves (h, Fig. 4 is typical), as do small negative increments in both (f of Fig. 4). One may conclude that methyl boron difluoride is a planar molecule, B–F = 1.30 ± 0.02 Å.; B–C 1.60 ± 0.03 Å.; C–F = 2.53 ± 0.03 Å.; C–H = 1.09 Å. and tetrahedral carbon valence angles assumed. The above combination of distances leads to ∠ CBF = 121°.

Discussion

The electron diffraction results of Lévy and Brockway[1] coupled with the data obtained in this investigation show that the molecules comprising the series $B(CH_3)_3$, $B(CH_3)_2F$, BCH_3F_2, and BF_3 have the same configuration, and essentially the same interatomic distances. For quantitative comparison we have compiled Table IV. All but one of the reported B–C separations are equal to that expected for normal covalent bonding; at present writing we are unable to propose a theory which would account for the small increase in the B–C distance in BCH_3F_2 and which would not introduce difficulties for the remaining data. Empirically, the difference between the B–F separations observed in the methyl boron fluorides and those in $(CH_3)_2O:BF_3$, etc., may be

TABLE IV

Compound	B–C distance, Å.	B–F distance, Å.	Reference

Alkali fluoborates		1.43	15
Expected, for bonds of unit order: S and S	1.57	1.39	4, 5

ascribed to the transition in the coördination of boron from three to four, although reasoning on the basis of this postulate would lead one to expect a somewhat larger B–C distance in H_3BCO, wherein the boron atom is tetrahedrally bonded, than in the other compounds.

Introduction of the assumption of the dependence of bond distance on bond type always raises the question as to the interatomic distance one should select for a unit bond. Assuming that no distinction need be made between sp^2 and sp^3 type bonds (Table IV), it follows that the B–C linkages are all of unit order, whereas the B–F bonds in boron trifluoride are of an order higher than unity; *i. e.*, that the three excited structures $F_2B^-::F^+::$ contribute appreciably to the ground state. This is borne out by a rough comparison of the bond strengths in BF_3 and BF_4^- as deduced from their heats of formation,[16] and is further supported by the low parachor value which must be assigned to boron in BF_3 (8 as compared with about 15 in the other trihalides).[17]

If the postulate of sp^2 plus graphite type resonance presented above for boron trifluoride is extended to the methylboron fluorides, the fact that the B–F separation is the same for the three compounds appears to be fortuitous. Thus one has to assume that a bond order of about 1.2 may result either from the normal $(CH_3)_2B:F:::$ plus the single excited structure $(CH_3)_2B^-::F^+::$, or from the normal $F_2B:F:::$ plus the three excited structures $F_2B^-::F^+::$, in which each $B^-::F^+$ link is on the average only one-third double bond. Clearly, resonance among the latter three equivalent structures lowers some of the levels and raises others, so that the consequent resonance with the ground state is not strictly parallel to the case for dimethyl boron fluoride.

Finally one might point out the difference between the effects of successive substitutions of fluorine atoms on carbon and on boron. In CH_2F_2 the C–F separation is around 0.05 Å. less than in the monosubstituted methane,[18] whereas all the observed B–F distances are equal in the series BF_3, BF_2CH_3, $BF(CH_3)_2$.

Summary

An electron diffraction study of dimethyl boron fluoride and methyl boron difluoride leads to the following: the molecules are planar, $B(CH_3)_2F$: B–F = 1.29 ± 0.02 Å.; B–C = 1.55 ± 0.02 Å.; C–F = 2.48 ± 0.03 Å. BCH_3F_2: B–F = 1.30 ± 0.02 Å.; B–C = 1.60 ± 0.03 Å.; C–F = 2.53 ± 0.03 Å.

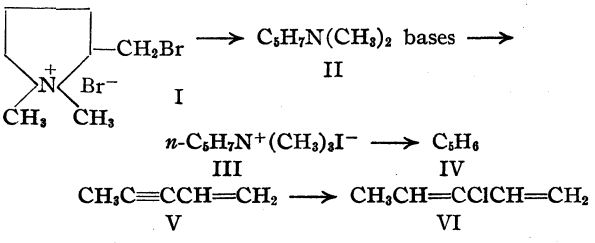
The Constitution of Pirylene: Chemical Evidence

BY HERBERT SARGENT, EDWIN R. BUCHMAN AND JOHN P. FARQUHAR

The C_5H_6 hydrocarbon pirylene (IV) was first prepared by Ladenburg[1] starting from piperidine and following essentially the path here indicated over the intermediates (I) to (III). The structure of these intermediates was but imperfectly known in Ladenburg's time,[2] so that a correct formulation of the pirylene molecule was out of the question. In 1928, von Braun and Teuffert[3] reinvesti-



gated the subject, and concluded that pirylene must possess a doubly unsaturated ring structure. A number of possibilities were cited; that of methylenecyclobutene[4] seemed most in accord with their observations. Because of our interest in cyclobutane derivatives the present study was undertaken.

It was found that degradation of (I) led to a mixture of bases (II), a fact which had been overlooked by previous investigators,[1,3,5] who had assumed the homogeneity of their $C_5H_7N(CH_3)_2$ base. From (II), a methiodide (III) was obtained which is without doubt the parent substance from which pirylene was formed. The straight-chain nature of the C_5H_7 radical in this quaternary salt was demonstrated by catalytic reduction of the corresponding chloride to *n*-amyltrimethylammonium chloride. From (III) pirylene (IV) was made in the usual way[1,3]; its properties, which agreed with the previous descriptions, were those of a pure substance.

A sample of this hydrocarbon has been submitted to Dr. V. Schomaker and Dr. R. Spurr of these Laboratories who have been able to work out its structure from the electron diffraction pattern.[6] Their investigation indicates that (IV) is not a ring compound, but possesses the structure (V) of 1-methyl-2-vinylacetylene, a known substance,[7] the physical properties of which agree well with those of pirylene.

The results of our chemical investigation are in full conformity with this conclusion. On catalytic reduction pirylene readily took up three moles of hydrogen; the reduced product was shown to be *n*-pentane. It also added one mole of hydrogen chloride, as has been demonstrated[8] for (V), giving 3-chloro-1,3-pentadiene (methylchloroprene) (VI).

Experimental

$C_5H_7N(CH_3)_2$ Bases (II).—The pyrrolidinium bromide (I)[5c] was degraded according to directions in the literature.[1b,3] From 136.5 g. (0.5 mole) of (I), 39 g. (70%) of mixed bases (II) was obtained, b. p. *ca.* 56–70° at 50 mm.; the exact composition of this mixture[9] was not determined due to its unstable nature. Fractionation through a precision column at 50 mm. gave 7.5 g. (13%) of material boiling constantly at 66.5°; examination of this fraction disclosed that it represented a substantially pure substance. It was used directly for conversion to the quaternary salt (III).

A portion of this base was further purified over the diliturate[10] which crystallized from alcohol in well-formed narrow rectangular crystals; m. p. 161–162°. The regenerated base, b. p. 65° at 49 mm., d^{25}_4 0.800, $n^{25}D$ 1.4430, entirely stable for months in an atmosphere free from carbon dioxide, was obtained by distilling the diliturate with excess aqueous alkali.

Anal. Calcd. for $C_7H_{13}N$: C, 75.60; H, 11.79. Found: C, 75.89; H, 12.10.

The picrate was prepared from the components in ether, cube-like crystals from ethanol–isopropyl ether, m. p. 100.5–101.0°.

Anal. Calcd. for $C_{13}H_{16}N_4O_7$: N, 16.47. Found: N, 16.25.

With methyl iodide the methiodide (III) described below was obtained.

***n*-$C_5H_7N(CH_3)_3I$ (III).**—To 54.3 g. of base (from fractionation of (II), b. p. *ca.* 66.5° at 50 mm.), in 250 cc. of ethanol, 76.4 g. of methyl iodide (10% excess) was added slowly, keeping the temperature at below 35° by cooling in an ice-bath. The crystalline product started to separate

almost immediately; after recrystallization from aqueous alcohol, the yield of (III) was 104 g. (84%), m. p. 259° d. (lit.[3] m. p. 257°), entirely stable when heated with water at 100° (compare ref. 3).

Anal. Calcd. for $C_8H_{16}IN$: C, 37.96; H, 6.36; N, 5.53. Found: C, 38.33; H, 6.60; N, 5.57.

The same methiodide (III) was obtained when the mixed bases (II) were methylated according to directions[1] in the literature. As a characteristic derivative, the picrate was prepared from concentrated aqueous solutions of (III) and of sodium picrate, needles from ethanol, m. p. 112.5–113.0°.

(III) was not amenable to catalytic reduction; it was converted to the corresponding chloride[3] which was hydrogenated in aqueous solution under two atmospheres pressure using a palladium–charcoal catalyst. Two moles of hydrogen was taken up; the product was characterized by conversion to the picrate, prisms, m. p. 93.2–94.0°, from ethanol–isopropyl ether, and to the bromide, needles, m. p. 181.0–181.5°,[11] from ethanol. These derivatives gave no depression when mixed with authentic samples of the corresponding *n*-amyltrimethylammonium salts made from *n*-amyl bromide and trimethylamine.

Pirylene (IV)[1].—Quaternary iodide (III) (57.5 g.) was introduced together with 27 g. of potassium hydroxide and 70 cc. of water into a flask, and the mixture distilled from an oil-bath into a receiver immersed in a bath at −15°. A smooth decomposition took place (bath temperature 120–135°); the distillate was acidified with 6 *N* hydrochloric acid, and the hydrocarbon separated and dried over potassium carbonate, and over sodium. After distillation through a precision column, 8.9 g. (59%) of (IV) was obtained which boiled constantly; in a second similar experiment the yield was 11.0 g. (73%) of material having a 0.3° range. The constants observed were: b. p. 59.4° at 744 mm., d^{25}_4 0.7339, $n^{25}D$ 1.4467 (lit. pirylene[3]: b. p. 60°, d^{19}_4 0.7443, $n^{19}D$ 1.4505; methylvinylacetylene (V)[7]: b. p. 59.2° at 760 mm., d^{20}_4 0.7401, $n^{20}D$ 1.4496); the material polymerized slowly (much less rapidly than (VI)) on standing (compare refs. 3, 7).

The hydrocarbon (IV) (2.140 g.) was hydrogenated in ethanol solution using a palladium–charcoal catalyst. The hydrogen adsorbed (2.415 l. at 23° and 745 mm.) corresponded to 3 double bonds. The reduced hydrocarbon was distilled from the reduction mixture, treated with concentrated sulfuric acid and redistilled through a precision column; the sole product detected was *n*-pentane, yield 1.0 g., b. p. 36.3–36.5° (lit.[12] 36.1°).

Methylchloroprene (VI) was prepared from 3.7 g. of (IV) according to directions in the literature.[8] Two and two-tenths grams of (VI) b. p. 98.5–101°, $n^{25}D$ 1.4745 (lit.[8] b. p. 99.5–101.5°, $n^{20}D$ 1.4785) was obtained, and 1.5 g. of hydrocarbon was recovered. (VI) was identified by condensing with α-naphthoquinone; the derivative[8] melted at 180.7–181.0° cor. (lit.[8] 181°). When excess of (IV) and α-naphthoquinone were heated for two hours in a sealed tube at 100° no reaction[13] was observed.

Summary

The conclusion, first arrived at as a result of the electron diffraction investigation,[6] that pirylene and 1-methyl-2-vinylacetylene are identical, is supported by the chemical evidence.

The Constitution of Pirylene: Electron Diffraction Investigation

BY ROBERT SPURR AND VERNER SCHOMAKER

In connection with the studies described in the foregoing article[1] we have carried out an electron diffraction investigation of the C_5H_6 hydrocarbon pirylene with the object of determining its structural formula. Our results show that pirylene does not contain a three or four-membered ring as suggested by von Braun and Teuffert[2] but that it is methylvinylacetylene, $CH_3—C{\equiv}C—CH{=}CH_2$. This identification is substantiated by the agreement[1] of the physical properties of pirylene with those reported for methylvinylacetylene and by chemical evidence.[1] We wish to express our thanks to Dr. E. R. Buchman for suggesting the problem and to him and his collaborators for providing the sample of pirylene used in the investigation.

Experimental

The preparation of the pirylene has been described.[1] The apparatus and technique used have been reviewed by Brockway.[3] Twenty photographs were taken of the scattering from the vapor. The camera distance was about eleven or about twenty centimeters, and the wave length of the electrons was about 0.06 Å. (based on a_0 = 4.070 Å. for Au). The diffraction pattern showed fine structure indicative of long inter-

(3) L. O. Brockway, *Rev. Modern Phys.*, **8**, 231 (1936).

atomic distances of the order of 5 Å. Thirty-one features were measured; the q values are represented by the arrows drawn through curves E′ and E $q = \frac{40}{\lambda} \sin \frac{\psi}{2} = \frac{10}{\pi} s$, where λ is the electron wave length and ψ is the scattering angle). The intensity pattern is well represented by curve E′ in the figure for $q < 40$ and by curve E for $q > 40$.

Discussion

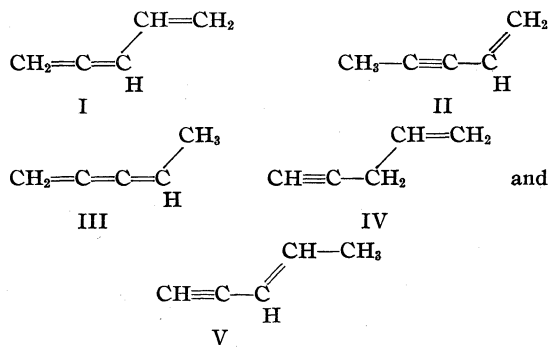
In most electron diffraction investigations the structural formula of the compound is known and the task is to find certain interatomic distances and bond angles. In the case of pirylene, however, only the molecular formula was known, and it was desired to find the correct structural formula (there are about 30 possibilities) even though a precise determination of the various important parameters seemed not to be feasible. To do this the expected molecular structures corresponding to the various structural formulas were compared with the information obtainable from the electron diffraction photographs with the aim of finding the satisfactory formula and eliminating all the others.[4] The procedure followed involved mainly the use of the radial distribution function[3] together with only a few theoretical intensity curves, as described below.

The radial distribution curve R is a plot of

$$rD(r) = \sum_{n=0}^{88} I_n e^{-an^2} \sin \frac{\pi}{10} rn \qquad (e^{-a(88)^2} = 0.1)$$

where the I_n are the ordinates at unit intervals of q of a curve drawn to represent the appearance of diffraction pattern, the measured positions of the rings, and the general characteristics of the simplified theoretical intensity function as defined below. With this interval of q, this radial distribution summation is still an entirely satisfactory approximation to the corresponding Fourier integral for $r = 5$ Å., and no false peaks of significant size are to be expected (except from possible errors in the I_n) for values of r less than about 10 Å. We have found that radial distribution summations of this kind are superior to the ordinary summations especially at large values of r, where the heights of the peaks of the ordinary summations are difficult to interpret and false peaks often appear. With these exceptions, the ordinary summations made for pirylene agreed well with R.

Since the radial distribution curve shows that there are important interatomic distances in the molecule up to about 5 Å., and none greater (the longest carbon–carbon distances expected for structures containing a ring or a branched chain is about 4.2 Å.), and since no branched chain or ring structures giving good general agreement with the radial distribution function could be found, an extended structure is indicated. Of the extended structures, only I and II will be



given detailed consideration here. It was found that the interatomic distances expected for structures III, IV, and V are in disagreement with the radial distribution curve, and that theoretical intensity curves (not shown here) drawn for models representing these structures bear little resemblance to the observed diffraction pattern; moreover, these structures are unlikely for chemical reasons.[5]

The intensity curves of Fig. 1 were drawn[6] for

(4) Since the present knowledge of the bond distances and bond angles in the lower hydrocarbons is very extensive (see L. Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca, New York, N. Y.; L. Pauling, H. Springall, and K. Palmer, THIS JOURNAL, **61**, 927 (1939)), the predictions made for pirylene are almost certainly sufficiently accurate for this choice of the structural formula, and the reliability of the choice will depend only on the accuracy and completeness of the electron diffraction data.

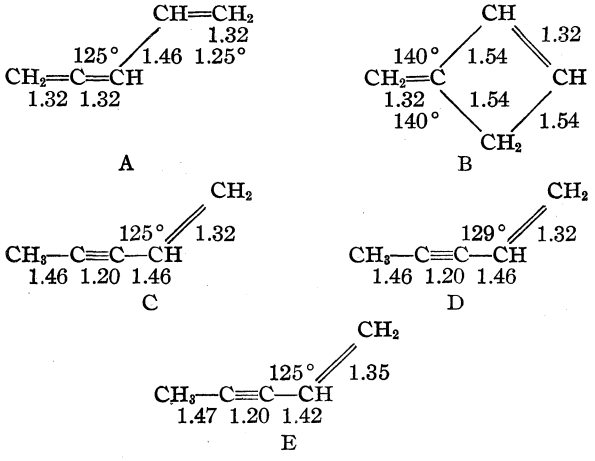
(5) Structures IV and V may be definitely excluded because pirylene does not undergo the typical reactions of substances which contain an acetylenic hydrogen atom. See Ladenburg, *Ber.*, **15**, 1024 (1882); *Ann.*, **247**, 56 (1888), and the procedure for the preparation of pirylene, ref. 1.

(6) The intensity functions were calculated according to the formula

$$I = \sum_{ij}{}' \frac{Z_i Z_j}{r_{ij}} e^{-a_{ij} q^2} \sin \frac{(\pi q r_{ij})}{10}$$

with the use of International Business Machines. In the temperature factor the coefficients a_{ij} were taken as zero for all except the C—H bonded interactions, for which the value 0.00022 was used. The non-bonded C...H terms, which require a more severe temperature factor, were omitted except for the best model, E. For it the intensity function E was calculated with the omission of these terms, and the function E′ with their inclusion with a_{ij} equal to zero. The probable effect of these terms was estimated for the other models by a comparison of E and E′. In the correlation of Model E with the measured q values a transition from curve E′ to curve E was made in the region where a_{ij} values of 0.00044 would reduce the non-bonded C...H terms to approximately one-half their initial amplitude. In the figure the arrows representing the measurements change from E′ to E at this point. The C—H distance was taken

the models shown below with the indicated distances and angles. All of the models are coplanar with respect to the carbon atoms; it is to be noted that A has the *trans* or extended configuration.



These models represent the remaining possible structures, I (model A) and II (C, D, and E; the parameters of C and D include small variations from the expected values used in E), and the ring structure most favored by von Braun and Teuffert.[2,7]

[a] Only the more easily measurable features are chosen for comparison with calculated q values.

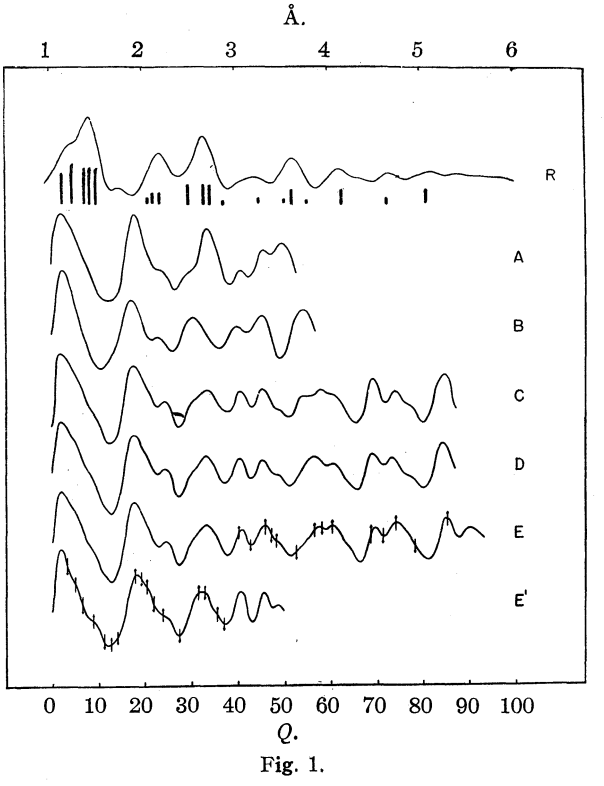

Fig. 1.

The appearance of the pictures is well represented only by curves E′ and E, although for $q < 50$ C and D are not significantly less satisfactory than E. The numerical comparison for E′-E,[6] given in the table, possesses satisfactory internal consistency and indicates that the over-all size of the model is essentially correct. The agreement between the radial distribution function and the interatomic distances of model E is

as 1.09 Å., the bond angles involving hydrogen were based on ethylene and methane, and for hydrogen Z was replaced by the value 1.25.

The use of the intensity function here described, which differs from the one usually used[3] by the factor q, will be discussed in detail at a later time; it offers advantages of convenience both in the construction of the radial distribution function and in the correlation procedure. Only at small values of q does the difference in behavior of the two functions become great. There, however, the measured ring diameters are not sufficiently reliable for use in the quantitative comparison anyway, and neither function faithfully represents the appearance of the photographs although either can be used to the extent that experience and comparison with molecules of known structure can be used as guides.

(7) The bond angles involving the side chain in this model were given a value (140°) larger than expected in an effort to obtain better agreement with the radial distribution function.

very satisfactory as shown by the vertical lines under the peaks in the figure.

The other intensity curves are quite unsatisfactory. Curve B is of some interest because it lacks the fine structure on the inside of the first minimum which appears on the other curves, apparently as a result of the terms above 4 Å. The possibility of obtaining a satisfactory curve with any reasonable variation of Model A seems remote. One cause of the disagreement with Curve A is revealed by the width and position (1.42 Å.) of the first peak of the radial distribution function. For Model A one would expect instead a rather sharp peak at about 1.34 Å. with weak shoulders or satellites at 1.46 Å. and 1.09 Å. Another factor is the absence of any distance which would correspond to the radial distribution peak at 4.12 Å.

Our electron diffraction investigation thus leads to the conclusion that pirylene is 1-methyl-2-vinylacetylene (Structure II) with the bond distances and bond angles which were assumed for Model E from the existing information regarding similar molecules. Because the agreement of the photographs and the radial distribution function with Model E is so detailed that it could hardly be fortuitous, we should have confidence in this conclusion even if no effort to eliminate other possible formulas had been made.

Summary

The electron diffraction investigation of pirylene shows it to be 1-methyl-2-vinylacetylene. The structural parameters found were those anticipated from a knowledge of the structures of similar molecules.

An approximation to the radial distribution integral which is more accurate than the usual summation is briefly described.

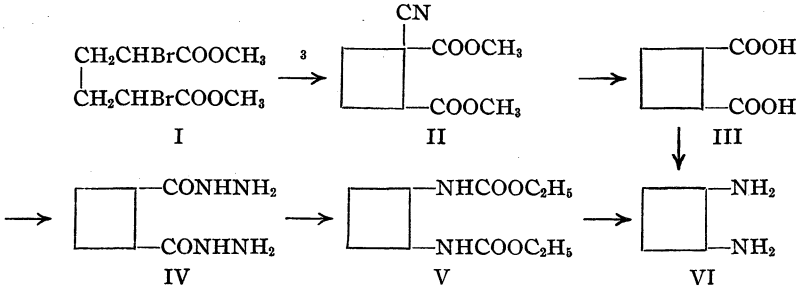
Cyclobutane Derivatives. I.[1] The Degradation of *cis*- and *trans*-1,2-Cyclobutanedicarboxylic Acids to the Corresponding Diamines

BY EDWIN R. BUCHMAN, ALF O. REIMS, THURSTON SKEI AND MAURICE J. SCHLATTER

According to scattered references in the literature,[2] the Curtius degradation of cyclic dicarboxylic acids proceeds in the normal fashion without change in configuration. In the present work it was found that the *cis*- and *trans*-isomers (III) could be converted, over the intermediates (IV) and (V), into the corresponding diaminocyclobutanes (VI). The diamine obtained from the *cis*-acid was shown to possess the *cis*-structure by the preparation from it of cyclic derivatives; under the same conditions cyclic products were not obtained from *trans*-(VI).

The K. F. Schmidt degradation[4] had not previously been applied to cyclic dicarboxylic acids. When *cis*- and *trans*-(III) were treated with hydrazoic acid according to this method they were transformed directly, with retention of configuration, to *cis*- and *trans*-(VI); thus the method affords an alternative preparative route to these substances.



(1) The results contained in this and the two following papers were presented before the Pacific Division of the American Association for the Advancement of Science at the Pasadena Meeting, June, 1941.

(2) (a) Curtius, *J. prakt. Chem.*, [2] **91**, 23 (1915); (b) Diels, Blom and Koll, *Ann.*, **443**, 242 (1925); (c) Alder and Stein, *ibid.*, **514**, 211 (1934). However, in the case of the 1,3-cyclohexanedicarboxylic acids, Skita and Rössler [*Ber.*, **72**, 461 (1939)] claim that the same diurethan results both from the *cis*- and from the *trans*-diazide.

(3) Fuson and Kao, THIS JOURNAL, **51**, 1536 (1929); Ellingboe and Fuson, *ibid.*, **56**, 1774 (1934).

(4) Hurd in Gilman's "Organic Chemistry," John Wiley and Sons, Inc., New York, N. Y., 1938, p. 698. From succinic acid a small yield of ethylenediamine has been obtained (Oesterlin, *Angew. Chem.*, **45**, 536 (1932)).

Experimental[5]

The cyclobutanedicarboxylic acids (III) were made by the method[3] of Fuson employing both the methyl and the ethyl esters of the intermediates. The use of the methyl esters is to be recommended as pure crystalline meso (I) can more conveniently be prepared than the corresponding diethyl ester. It is possible to utilize the crude liquid racemic dibromoadipic esters for ring closure or for conversion to the crystalline isomers but, since the crude esters contain[6] some α,α-dibromo isomer, additional purification steps are necessary.

α,α'-Dibromoadipic Dimethyl Ester (I).[7]—Adipic acid (1460 g. = 10 moles) was treated in all glass apparatus with thionyl chloride[7b,8] (2380 g. = 3% excess); the latter was added at two to three hour intervals in portions of about 750 g. while heating at 70–80°. When reaction was complete, 3520 g. of bromine (10% excess) was added dropwise (eighteen hours) with continued heating and the product finally heated for eight hours at 100°. The crude acid halide was added with stirring to 2000 cc. of methyl alcohol in a flask surrounded by an ice-bath; meso (I) crystallized on seeding and cooling. After filtering and washing with methanol the yield was about 50%. Crude (I) was recovered from the filtrate by distillation,[7b] b. p. *ca.* 163° at 3 mm., average[9] total yield 93%. Additional meso (I) was obtained from the distillate, needles, m. p. 73.5–74.0° from methanol, average total yield 2329 g. = 70% (corresponding yield in case of the diethyl ester, 46%).

The non-crystalline distillate consisted largely of the unstable racemic modification, which crystallized out slowly at about −10°. It was obtained pure by recrystallization from methanol at −78°, m. p. +11–12°.

Anal. Calcd. for $C_8H_{12}Br_2O_4$: C, 28.94; H, 3.64. Found: C, 29.07; H, 3.86.

1-Cyano-1,2-cyclobutanedicarboxylic Acid Dimethyl Ester (II).—Two moles[10] of meso[11] (I) (664 g.), 368 g. (5.5 moles) of potassium cyanide (Merck reagent[12]) and 360 cc. of methanol were refluxed for fifty-six hours from an oil-bath maintained at about 75°; occasional stirring was necessary to break up the solid cake which formed. The product was taken up in anhydrous ether and fractionated *in vacuo;* the average yield, b. p. *ca.* 128° at 3 mm. was 284 g. = 72% (82% in the ethyl ester series). The distillate crystallized in part; the resulting crystals (26% of the weight of the distillate) were recrystallized from methanol, colorless needles m. p. 89.5–90.0°. The non-crystalline part[13] was refractionated and the portion boiling at 119–120° at 2 mm. subjected to analysis; this material did not crystallize at 0°.

Anal. Calcd. for $C_9H_{11}NO_4$: C, 54.82; H, 5.62; N, 7.10. Found (solid): C, 55.15; H, 5.62; N, 7.15. Found (liquid): C, 54.49; H, 5.62; N, 6.85.

1,1,2-Cyclobutanetricarboxylic Acid.—This acid was prepared from crystalline (II) following essentially the procedure of Fuson.[3] The colorless barium salt was decomposed with the requisite amount of sulfuric acid and the filtrate evaporated *in vacuo.* The crystalline residue consisted of hydrated tricarboxylic acid, m. p. 135° dec. from dioxane on addition of benzene. The water of crystallization was not lost on drying *in vacuo* under the usual conditions; in one experiment which we have not since been able to reproduce, water was apparently removed during recrystallization. The anhydrous acid, colorless massive prisms from anhydrous ether in which it is soluble without difficulty at room temperature, melted at 91–92° and began to lose carbon dioxide at about 130°.

Anal. Calcd. for $C_7H_8O_6$: C, 44.69; H, 4.29. Found: C, 44.90; H, 5.12.

On treatment with water, the acid was reconverted to the stable hydrate.

***cis-* and *trans*-1,2-Cyclobutanedicarboxylic Acids (III).**—The crude liquid isomer (II) (789 g.) was refluxed with 2000 cc. of 6 *N* hydrochloric acid for twenty-four hours, the hydrolyzate evaporated on the steam-bath and the residue extracted with anhydrous ether (acetone may also be used). After removal of solvent, the crude acid was decarboxylated by heating at 170–180° at 20 mm. for three hours and the mixture refluxed[14] for an additional three hours with 2000 g. of acetyl chloride. Acetyl chloride and acetic acid were distilled off; the material remaining was heated from an oil-bath at 150–160° at 20 mm. for several hours and finally distilled at 2 mm. An 81% yield of *cis*-anhydride was obtained boiling at 127–130°; a portion was recrystallized from benzene, blades, m. p. 76.5–77.0°. Distillation residues from several runs were combined and subjected to a second treatment with acetyl chloride; a small additional amount of anhydride was recovered.

cis-Anhydride was heated to boiling with 0.8 its weight of water; *cis*-acid crystallized from the resulting solution on cooling. Saturation of the filtrate with dry hydrogen chloride yielded additional amounts of less pure material. The yield of *cis*-(III) was 85%; from benzene–dioxane it crystallized in rectangular prisms exhibiting extensive twinning, m. p. 139.5–140.0°. From the residual mother liquors, recovery was best effected via the anhydride.

trans-(III) has been prepared from the *cis*-isomer by treatment with hydrochloric acid[15]; in the present investi-

(5) All melting points are corrected. The authors are indebted to Dr. G. Oppenheimer and Mr. G. A. Swinehart for microanalyses reported in this and the two following papers.

(8) Fuson, Kreimeier and Nimmo, THIS JOURNAL, **52**, 4074 (1930).

(9) Average yields reported in this paper are based on the results of six or more identical experiments.

(10) A ten-mole batch gave only a 40% yield due to decomposition during distillation of the crude product.

(11) The racemic form of (I) behaved in the same way, giving a comparable yield of crystalline and liquid (II) with the latter predominating.

(12) A commercial grade of sodium cyanide proved satisfactory[3] for effecting ring closure of the meso diethyl ester in ethanol but its use in the present instance led to extensive tar formation.

(13) A portion which had stood in a loosely stoppered bottle for a year had deposited a small amount of crystals, colorless rectangular prisms from methanol, m. p. 172.5–173.5° dec., easily soluble in water and hot methanol, difficultly soluble in ether. Analyses point to the formula $C_{10}H_{12}N_2O_5$: Calcd.: C, 50.00; H, 5.04; N, 11.66. Found: (average) C, 50.23; H, 5.43; N, 11.36. The substance may be related to α,α'-dicyanoadipic ester.

(14) *trans*-(III) is converted by this treatment to a mixed anhydride with acetic acid which on stronger heating decomposes into *cis*-anhydride; compare however reference 15.

(15) Perkin, *J. Chem. Soc.*, **65**, 572 (1894).

gation two further methods for effecting the isomerization were found. *trans*-(III) may also conveniently be prepared, although the method is expensive, from the readily obtainable *trans*-dihydrazide (IV) by hydrolyzing with boiling 6 *N* hydrochloric acid and isolating by continuous extraction with ether.

cis-(III) (50 g.), heated[16] under reflux from a bath at 200° for five hours was partially isomerized. Recrystallization of the product from water yielded 25.5 g. of *trans*-(III), clusters of blades from benzene–dioxane, m. p. 130.5–131.0°.

Twenty grams of *cis*-(III) dimethyl ester was heated under reflux from a water-bath for two and one-half hours with 0.3 g. of sodium dissolved in 5 cc. of methyl alcohol.[17] The product was washed with water, dried and distilled, giving 16.3 g. of ester, b. p. 118–119° at 24 mm. A portion of this ester, hydrolyzed by heating with dilute hydrochloric acid, yielded 76% of *trans*-(III). From another portion the *trans*-dihydrazide (IV) was obtained in 86% yield; the amount of *cis*-ester present in the equilibrium mixture[18] must, therefore, be small.

***cis*- and *trans*-(III) Esters.**—Pure *cis*-(III) dimethyl ester was prepared in 94% yield from the acid with diazomethane, b. p. 85° at 3 mm. On a preparative scale the diethyl ester was made by heating under reflux 500 g. of *cis*-(III) (anhydride could be used directly) for four hours with 2000 cc. of absolute alcohol while passing in a slow stream of dry hydrogen chloride. The reaction mixture was then poured into water and worked up in the usual manner. The yield was 493 g. (71%), b. p. 99–100° at 2 mm., 123° at 24 mm.; this ester contained at most only small amounts of *trans*-isomer (best detected by the reaction with hydrazine hydrate). Incompletely esterified acid in the water and carbonate washings was recovered by evaporation and conversion to anhydride.

A suitable source material for the preparation of large amounts of *trans*-(IV) was made directly from crude (III), resulting from saponification of crude liquid (II) and subsequent decarboxylation. This was esterified by heating with alcohol, carbon tetrachloride[19] and aqueous hydrochloric acid; an average yield of 82% of a mixture consisting of about equal amounts of each isomer was obtained (in the case of the cyano diethyl ester intermediate, the average yield was 71% of a similar product).

***cis*- and *trans*-1,2-Cyclobutanedicarboxdihydrazides (IV).**—These compounds were prepared by adding *cis*- and *trans*-(III) esters dropwise to 10% excess of hydrazine hydrate (85%) which was heated under reflux from an oil-bath at 130° (lower temperatures gave incomplete reaction) and continuing the heating at this temperature for five hours. Under these conditions a practically quantitative yield of crude (IV) resulted. No changes in configuration took place; *cis*- and *trans*-(IV) on acid hydrolysis gave, respectively, *cis*- and *trans*-(III).

From *cis*-(III) dimethyl ester an 80% yield of *cis*-(IV) was obtained. On a preparative scale, 246 g. of *cis*-(III) diethyl ester was treated with 160 g. of 85% hydrazine hydrate. The product was allowed to crystallize in the ice-chest, was filtered off and washed with alcohol; the filtrates were evaporated and the residue pressed on tile. The combined crude material was refluxed for a short while with 500 cc. of absolute alcohol (not sufficient to effect complete solution); after cooling and filtering, 160 g. (75%) of substantially pure *cis*-(IV) was obtained. The mother liquors did not usually afford crystalline material and were hydrolyzed for recovery of (III). In a few cases the m. p. of the crude indicated an admixture of *trans*-isomer arising probably from impurity in the *cis*-(III) ester used; separation was effected by digesting the crude (IV) with an amount of 85–90% ethanol sufficient to dissolve the *cis*-isomer and filtering hot. The greater part of *cis*-(IV) could be recovered from the filtrate.

cis-(IV) crystallized from absolute alcohol in massive prisms which exhibit extensive twinning, m. p. 140.0–140.5°. Occasionally when recrystallized from this solvent a second metastable form was encountered which was separated mechanically, clusters of fine needles, m. p. 134.5–135.0°, mixed m. p. with the stable form 135–140°; on standing it is transformed to the stable variety. *cis*-(IV), over a period of months, was largely converted into material of different composition difficultly soluble in water and the common organic solvents.

It was found convenient to prepare the *trans*-isomer from *cis*-, *trans*-(III) diethyl ester mixtures (see above); *trans*-(IV) crystallized from the reaction mixture and *cis*-isomer could be isolated from the mother liquors (better to hydrolyze for recovery of (III)). *trans*-(IV) was purified by recrystallization from 50% aqueous alcohol, clusters of colorless needles, m. p. 223.0–223.5°. The (III) ester mixture from crude liquid (II) gave an average yield of 54% while the ester mixture from cyano diethyl ester gave a 48% yield.

Anal. Calcd. for $C_6H_{12}N_4O_2$: C, 41.85; H, 7.02; N, 32.54. Found (*cis*-needles): C, 42.03; H, 6.92; N, 32.74. Found (*cis*-prisms): C, 41.71; H, 7.01; N, 32.70. Found (*trans*): C, 42.18; H, 7.01; N, 32.89.

***cis*- and *trans*-(IV) Dihydrochlorides.**—To 100 g. of *cis*-(IV) suspended in an equal weight of water and surrounded by an ice-bath, 98 cc. of concentrated C. P. hydrochloric acid was added dropwise with stirring during twenty minutes. A further addition of 100 cc. excess of hydrochloric acid caused the precipitation of the dihydrochloride which was filtered off on a sintered glass filter, washed with cold absolute alcohol and dry ether and dried in a desiccator over sodium hydroxide, yield 78.5 g. (55%). The material is easily altered; it was analyzed without further purification. Additional amounts contaminated with hydrazine hydrochloride were obtained from the mother liquors by saturating with hydrogen chloride gas at 0°; such material could also be used for the preparation of *cis*-(V).

trans-(IV) (250 g.) was suspended in 300 cc. of water and the theoretical amount of concentrated hydrochloric acid (242 cc.) added during twenty minutes as above. Excess acid (500 cc.) was added and the precipitate isolated as before, yield 342.5 g. (96%). A portion was recrystallized by dissolving in methanol at 25° and cooling to 0°, compact rosets of fine needles, m. p. about 200° dec.

Anal. Calcd. for $C_6H_{14}Cl_2N_4O_2$: C, 29.40; H, 5.76; N, 22.86. Found (*cis*): C, 29.67; H, 6.06; N, 23.19. Found (*trans*): C, 29.73; H, 6.02; N, 22.76.

***cis-* and *trans*-N,N'-Dicarbethoxy-1,2-diaminocyclobutanes (V).**[20]—*cis*-(IV) dihydrochloride (100 g.) was dissolved in 100 cc. of water, the solution layered with 700 cc. of anhydrous ether and a solution of 56.2 g. of sodium nitrite in 120 cc. of water was added over a period of fifteen minutes with continuous stirring, maintaining the temperature at 13–16°[21] (cooling bath at −15°). Stirring with cooling was continued for an additional five minutes; the ether layer was then separated and dried by shaking in the cooling bath for five minutes with 40 g. of reagent grade calcium chloride. The aqueous layer was twice extracted with 100-cc. portions of ether, the extracts dried and combined with the above. After the addition of 440 cc. of absolute alcohol, the ether solution was distilled from a water-bath at about 60°; nitrogen was evolved. The resulting alcoholic solution was refluxed from an oil-bath for one hour, the solvent removed *in vacuo* and the residue treated at room temperature with absolute alcohol. The portion difficultly soluble (1.0 g.) was recrystallized from 80% alcohol, colorless hexagonal plates, m. p. 258.5–259.0°; this substance is possibly 4,5-dimethylenedihydrouracil.

Anal. Calcd. for $C_6H_8N_2O_2$: C, 51.42; H, 5.75; N, 19.99. Found: C, 51.63; H, 5.88; N, 19.89.

The portion readily soluble in alcohol gave on evaporation 52 g. (55%) of crude crystalline *cis*-diurethan (V) which was suitable for conversion to *cis*-(VI). A sample was recrystallized from ethyl acetate, colorless needles, m. p. 101.5–102.0°.

The preparation of *trans*-(V) was carried out in a similar fashion except that the *trans*-(IV) dihydrochloride (100 g.) was dissolved in 200 cc. of water and the sodium nitrite solution was added maintaining the temperature of the reaction mixture at 18–20° (this slightly higher temperature was found, as the result of a series of experiments, to afford optimum yields). The reaction between the diazide and alcohol gave 2.2 g. of amorphous material difficultly soluble in absolute alcohol; this material, m. p. *ca.* 210°, could not be crystallized; on hydrolysis with alkali it yielded substantial amounts of *trans*-(VI). The average yield of alcohol soluble material was 57 g. (60%); it was used for conversion to *trans*-(VI). Pure *trans*-(V) was obtained by crystallization from aqueous alcohol, from which solvent it came out in both needles and cube-like crystals, m. p. 129.5–130.0°.

Anal. Calcd. for $C_{10}H_{18}N_2O_4$: C, 52.16; H, 7.88; N, 12.17. Found (*cis*): C, 52.24; H, 7.52; N, 12.05. Found (*trans*): C, 51.89; H, 7.51; N, 12.22.

***cis-* and *trans*-1,2-Diaminocyclobutanes (VI) from the Diurethans (V).**—A solution of 250 g. of C. P. potassium hydroxide in 680 cc. of methanol was refluxed with 62 g. of crude *cis*-diurethan for one hour from a bath at 100°. The solvent was distilled off and the residue steam distilled from a bath at 170° until the distillate was neutral to litmus. The aqueous and methanolic distillates were combined, acidified with C. P. concentrated hydrochloric acid and evaporated to dryness on the steam-bath, yield of crude hydrochloride nearly theoretical. The salt was dissolved in the minimum amount of water and the solution added dropwise to 100 g. of potassium hydroxide. The free base was isolated by continuous ether extraction; the ether extract after drying and distilling over sodium yielded 17.2 g. (77%) of diamine, b. p. 147°, b. p. 75° at 50 mm., $n^{20}D$ 1.4881, d^{20}_4 0.9652.

The *trans*-diamine was prepared from crude *trans*-(V) in exactly the same manner; yield of crude hydrochloride theoretical. The continuous ether extraction required a longer time for completion than was necessary in the case of the *cis*-compound. From 62 g. of crude *trans*-(V), 14.4 g. (63%) of base was obtained, b. p. 151°, b. p. 74° at 50 mm., $n^{20}D$ 1.4837, d^{20}_4 0.9490.

Anal. Calcd. for $C_4H_{10}N_2$: C, 55.77; H, 11.70; N, 32.53. Found (*cis*): C, 55.77; H, 11.90; N, 32.00. Found (*trans*): C, 55.59; H, 11.62; N, 31.77.

The diamines react readily with carbon dioxide[22]; the resulting ether insoluble addition compounds sublimed with decomposition, *cis-* at *ca.* 150°, *trans-* at *ca.* 110°. The following derivatives of *cis-* and *trans*-(VI) were made in the usual manner; the empirical formulas given were confirmed by analysis. Dibenzenesulfonamides, $C_{16}H_{18}N_2O_4S_2$: *cis-* m. p. 145.5–146.5° from alcohol, *trans-* m. p. 153.5–154.0° from alcohol. Dibenzamides from benzoyl chloride, base and aqueous alkali, $C_{18}H_{18}N_2O_2$: *cis-* m. p. 204.5–205.0° from absolute alcohol, *trans-* m. p. 245.5–246.0° from dioxane. Dipicrates from base with ethereal picric acid, $C_{16}H_{16}N_8O_{14}$: *cis-* insoluble in the usual solvents, crystallized by dissolving in pyridine and adding absolute alcohol, m. p. 255° dec.,[23] *trans-* m. p. 254° dec.,[23] from aqueous alcohol. Derivative from *trans*-diamine with phenyl isocyanate, $C_{18}H_{20}N_4O_2$: fine needles, m. p. 279–280° from dioxane-water; *trans*-oxalate, $C_6H_{12}N_2O_4$: prisms from aqueous alcohol, m. p. 268° dec.

***cis-* and *trans*-(VI) from the Dicarboxylic Acids (III).**—In a 1-liter three-neck flask equipped with dropping funnel, mechanical stirrer, gas evolution indicator, and thermometer dipping into the liquid was placed 46 cc. of concentrated C. P. sulfuric acid. First, 20 g. (0.139 mole) of *cis*-(III) was added and then a solution of hydrazoic acid[24] in chloroform (from 32 g. of sodium azide and found by titration to contain 14.8 g. (0.335 mole) of hydrazoic acid) was added over a period of twenty-five minutes maintaining the temperature at about 40°. Heating was continued at this temperature for twelve hours; the reaction mixture was poured on ice, separated from chloroform and distilled to remove traces of this solvent. A solution of 180 g. of potassium hydroxide in water was added slowly with cooling and the mixture steam distilled at a bath temperature of about 160° (compare preceding section). The crude dihydrochloride, 16.5 g. (75%), was contaminated with a small amount of ammonium chloride. The free base was isolated as before, yield 4.2 g. (35%).

trans-Diamine was made by essentially the same procedure; a theoretical yield of crude dihydrochloride re-

(20) Procedure based on that used by Curtius [*J. prakt. Chem.*, [2] **52**, 221 (1895)] in the case of succindihydrazide.

(21) Higher temperatures gave poorer yields.

(22) Compare *Chem. Zentr.*, **72**, II, 519 (1901).

(23) Minimum temperature at which a fresh sample will decompose when placed for twenty seconds in a bath at this temperature.

(24) von Braun, *Ann.*, **490**, 125 (1931).

sulted. The yield of *trans*-(VI) was 7.3 g. (55%) from 22 g. of *trans*-(III).

These amines made directly from the dicarboxylic acids had the same physical constants and gave the same characteristic derivatives as the amines prepared by the Curtius degradation.

Preparation of Cyclic Derivatives from *cis*-(VI).—Although benzil reacted vigorously with *cis*-(VI), the reaction did not afford the expected derivative[25]; the only product isolated was tetraphenylpyrazine, needles from alcohol, m. p. 252.0–252.5° (analysis). Even when equivalent amounts of the reactants were brought together in ether solution at room temperature, under which conditions they react slowly, only tetraphenylpyrazine was isolated in pure form from the complex mixture of reaction products. The same substance was also formed by heating benzil together with *trans*-(VI).

Gaseous phosgene in excess was passed into an ethereal solution of *cis*-(VI) at 0°; the reaction proceeded rapidly with separation of solid. After evaporation of solvent the residue was dissolved in water, made alkaline and continuously extracted with ether. From the extract the cyclic urea derivative[26] was recovered as a crystalline solid together with unchanged *cis* diamine. The former was purified by sublimation at 100° at 2 mm. and recrystallization from a mixture of isopropyl ether and a small amount of absolute alcohol, colorless octahedra, m. p. 147.0–147.5°, difficultly soluble in ether, easily in alcohol or water.

Anal. Calcd. for $C_5H_8N_2O$: C, 53.55; H, 7.19; N, 24.99. Found: C, 53.63; H, 7.32; N, 25.10.

When *trans*-(VI) was treated in the same manner with phosgene, in addition to unchanged amine, only an amorphous insoluble product was isolated.

When excess of carbon disulfide was added to an alcoholic solution of *cis*-(VI), a white crystalline precipitate separated immediately. This salt[27] crystallized from aqueous alcohol, colorless plates, sintering with loss of hydrogen sulfide at about 152° and then melting at the melting point of the 2-thiol-4,5-dimethyleneimidazoline. The latter was prepared by evaporating an aqueous solution of the dithiocarbamate on the water-bath, colorless plates from water, m. p. 168.5–169.0°.

Anal. Calcd. for $C_5H_8N_2S$: C, 46.84; H, 6.29. Found: C, 46.80; H, 6.16.

When the *trans*-diamine was treated with carbon disulfide in the same manner, a similar precipitate of a dithiocarbamic acid internal salt formed, stable granular white crystals from hot water, sintering at 263°,[23] difficultly soluble in cold water or hot alcohol.

Anal. Calcd. for $C_5H_{10}N_2S_2$: C, 37.01; H, 6.21; N, 17.27. Found: C, 36.77; H, 6.18; N, 16.81.

cis-Diamine (0.86 g. = 0.01 mole) and thioacetamide (0.75 g. = 0.01 mole) when stirred together at room temperature reacted exothermally with vigorous evolution of ammonia and hydrogen sulfide.[28] After the reaction had subsided, the mixture was heated for one-half hour at 80°. The product was taken up in 20 cc. of 12 *N* hydrochloric acid, the solution evaporated to dryness on a steam-bath, and the residue made alkaline and continuously extracted with ether. The pale yellow mass of needles thus obtained was sublimed at 90° and 2 mm. giving 0.82 g. of 2-methyl-4,5-dimethyleneimidazoline, colorless needles, m. p. 89.0–90.0° from benzene.

Anal. Calcd. for $C_6H_{10}N_2$: C, 65.42; H, 9.15; N, 25.43. Found: C, 65.51; H, 9.03; N, 25.66.

The picrate crystallized from aqueous alcohol in yellow plates, m. p. 150.0–150.5°.

The reaction was carried out with *trans*-(VI) in the same manner; it was necessary to heat the mixture before gases were evolved. The product[29] was easily hydrolyzed with regeneration of *trans*-(VI) and was not investigated further.

Summary

cis- and *trans*-1,2-cyclobutanedicarboxylic acids have been degraded by the Curtius and by the K. F. Schmidt method. These methods were shown to involve no change in configuration and to provide preparative routes to the diaminocyclobutanes.

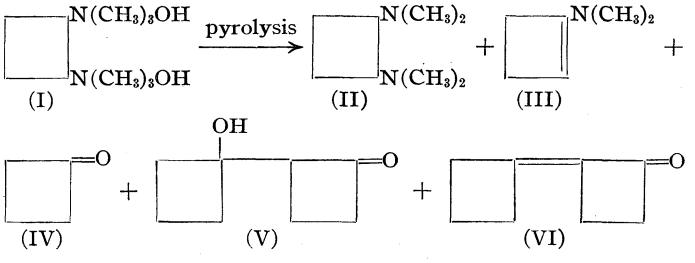
Cyclobutane Derivatives. II. The Thermal Decomposition of *trans*-1,2-Cyclobutane-*bis*-(trimethylammonium) Hydroxide

BY EDWIN R. BUCHMAN, MAURICE J. SCHLATTER AND ALF O. REIMS

The investigation of the thermal decomposition of *trans*-1,2-cyclobutane-*bis*-(trimethylammonium) hydroxide (I) was carried out as part of a research program directed toward the synthesis of cyclobutadiene. The diquaternary base was made by stepwise methylation (see Experimental) of *trans*-1,2-diaminocyclobutane.[1] Although its decomposition was studied carefully under a variety of conditions, no indication for the formation of the desired hydrocarbon[2] was obtained. The nature of the products may be seen from the accompanying chart.



Because of its unstable nature[3] (III) was not isolated. It is undoubtedly the parent compound from which (IV), (V) and (VI) are derived and must be considered the principal primary product of the reaction.

Experimental[4]

***trans*-Tetramethyldiamino-1,2-cyclobutane (II).**[5]—Crude *trans*-1,2-diaminocyclobutane hydrochloride obtained[1] either by the action of hydrazoic acid on *trans*-1,2-cyclobutanedicarboxylic acid or from crude *trans*-1,2-cyclobutanediurethan was methylated. The hydrochloride from 20 g. of *trans*-acid was refluxed for four hours with 200 g. of aqueous 36% formaldehyde[6] and 100 g. of 90% formic acid. During the first half hour a rapid gas evolution took place; after the reaction subsided small additional amounts of formaldehyde and formic acid were added to insure complete methylation. The resulting solution was concentrated to a small volume on the steam-bath and the base liberated by treating with excess of strong sodium hydroxide solution and taken up in ether. The ether solution was dried and distilled over sodium; yield 10 g. (50% from *trans* acid) of product boiling chiefly at 164°. From 50 g. of crude urethan a 71% yield of methylated base was obtained; the methylation reaction proceeds therefore with at least this efficiency. On refractionation the base distilled with practically no range, b. p. 83° at 50 mm., b. p. 101° at 100 mm., d^{20}_4 0.8455, $n^{20}D$ 1.4472.

Anal. Calcd. for $C_8H_{18}N_2$: C, 67.55; H, 12.76; N, 19.70. Found: C, 67.54; H, 13.17; N, 19.63.

The dipicrate $C_{20}H_{24}N_8O_{14}$ (analysis) precipitated when ethereal solutions of the components were mixed, yellow needles, m. p. 244° dec.,[7] from aqueous alcohol.

Preparation of *trans*-1,2-Cyclobutane-*bis*-(trimethylammonium) Hydroxide (I).—The diquaternary iodide was conveniently prepared by adding slowly 67 g. of methyl iodide (40% excess) to a solution of 23.8 g. of (II) in 67 cc. of methanol while cooling in an ice-bath. After a few minutes, crystals started to come out. When the precipitation was complete, the product[8] was filtered off and washed with methanol, yield 65.9 g. (92%); additional amounts could be recovered from the mother liquors. A portion of the salt was recrystallized from aqueous ethanol, colorless plates, m. p. 251° dec.[7]

Anal. Calcd. for $C_{10}H_{24}I_2N_2$: C, 28.18; H, 5.68; N, 6.57. Found: C, 28.08; H, 5.87; N, 6.80.

The salt is difficultly soluble in solvents except water; it was found possible to recover it by continuous extraction with chloroform. When its aqueous solution was treated with aqueous sodium picrate, a precipitate was obtained, orange-yellow needles from water, m. p. 288° dec.,[7] analysis indicates the expected formula $C_{22}H_{28}N_8O_{14}$.

The direct methylation of *trans*-diaminocyclobutane with methyl iodide in the presence of alkali did not yield

(4) All melting points are corrected.

(5) When *cis*-1,2-diaminocyclobutane[1] was refluxed with excess of aqueous formaldehyde and formic acid, approximately the theoretical amount of carbon dioxide was evolved. However, after evaporating the resulting solution and making basic, only an insoluble, non-distillable tar was obtained.

(6) Regarding methylation by this method see Clarke, Gillespie and Weisshaus, THIS JOURNAL, **55**, 4571 (1933).

(7) Minimum temperature at which a fresh sample will decompose when introduced into a bath at this temperature for twenty seconds.

(8) This product consisted solely of diiodide; cases have been reported [Rupe and Bohny, *Helv. Chim. Acta*, **19**, 1305 (1936)] of tetramethyldiamino ring bases (apparently *trans*-configuration) reacting with only one mole of methyl iodide.

the expected product.[9] A solution of 12.6 g. of crude diamine hydrochloride (from urethan) in 90 cc. of methanol was mixed with 136 g. of methyl iodide (100% excess), and a solution of 53.6 g. of potassium hydroxide (100% excess) in 170 cc. of methanol was added slowly with stirring while refluxing gently over a period of one and one-half hours. The refluxing was continued for an additional two hours and the mixture evaporated to dryness *in vacuo* at about 40°. Exhaustive extraction of the residue with chloroform gave no hexamethylated salt. The product, after several recrystallizations from absolute alcohol, was homogeneous and consisted of colorless feather-like crystals decomposing sharply at 218.0–218.5°.

Anal. Calcd. for $C_9H_{21}IN_2$: C, 38.04; H, 7.45; N, 9.86. Found: C, 37.94; H, 7.17; N, 9.66.

The formulation of this compound as (1-dimethylaminocyclobutyl-2)-trimethylammonium iodide was confirmed by its conversion to the diquaternary iodide by heating for fifteen hours at 100° in a sealed tube with excess methyl iodide in ethanol.

The free base (I) was prepared from the diiodide by shaking it in aqueous solution with an excess of freshly prepared silver oxide (washed free of alkali by decanting several times with distilled water) until the colloidal particles in the supernatant liquid had coagulated. The mixture was then filtered rapidly with suction and the filter cake washed with distilled water. The filtrate and washings were concentrated *in vacuo* at 40° to a small volume and the resulting gray to brownish, cloudy solution used for pyrolysis. In order to avoid carbonate formation all operations involving the free base were carried out in an atmosphere of nitrogen.

Thermal Decomposition of (I).[10]—The decomposition was carried out by heating at approximately 250° in a glass vessel without a catalyst and was extensively studied in the range 350–420° in the presence of platinized asbestos. No essential differences in the course of the reaction under these varied conditions could be detected. In the following a typical pyrolysis carried out at 350–360° is described.

The apparatus has been previously described.[11] The spiral gas wash bottle contained 100 cc. of 3 *N* hydrochloric acid. The air was displaced from the apparatus with carbon dioxide and the concentrated solution of the base (from 42.6 g. = 0.1 mole of diiodide) dropped on platinized asbestos at 350–360° over a period of fifteen minutes. No gas collected in the gasometer[12] and very little went into the hydrochloric acid wash bottle.

The pyrolysis distillate was made acid with a small excess of 6*N* hydrochloric acid and the neutral products removed by several extractions with ether. The basic material was recovered from the aqueous phase by making alkaline with 6*N* sodium hydroxide solution and continuously extracting with ether. The contents of the hydrochloric acid wash bottle were investigated separately.

Investigation of Neutral Products.—The ether solution containing this fraction was dried with anhydrous sodium sulfate and the ether removed by distillation through an efficient total reflux column. The residue was fractionated carefully in specially designed equipment, which treatment gave 1.8 g. of material boiling from 80–100°, smaller amounts of an intermediate fraction and 1.3 g. of material boiling at 5 mm. over a 10° range at approximately 85°.

The lower boiling (80–100°) liquid was shown to contain cyclobutanone (b. p. 98.5–99°[13]) as its chief constituent. Its odor was similar to that of cyclopentanone; it formed a bisulfite addition compound[13] somewhat less readily[14] than the five ring ketone. The ketone derivatives, with one exception, checked the literature description for the corresponding cyclobutanone derivatives; semicarbazone (analysis) rosets of white needles from water, m. p. 212.0–212.5° (lit. m. p. 211–212° dec.[15]), phenylhydrazone pale yellow needles from aqueous alcohol m. p. 98.0–98.5° (lit. m. p. 95–96°[15a]) decomposed after a few days' standing, 2,4-dinitrophenylhydrazone, orange-red needles, m. p. 147.0–147.2°[16] from absolute alcohol.

Anal. Calcd. for $C_{10}H_{10}N_4O_4$: C, 48.00; H, 4.03; N, 22.39. Found: C, 48.27; H, 4.07; N, 22.53.

The higher boiling fraction (1.3 g.) consisted of 1-(1'-hydroxycyclobutyl-1'-)-cyclobutanone-2 (V) mixed with smaller amounts of 1-cyclobutylidenecyclobutanone-2 (VI). From the mixture, with phenylhydrazine, with semicarbazide and with sodium bisulfite, derivatives were obtained which however were not suitable for characterization. The 2,4-dinitrophenylhydrazones were prepared from approximately 0.1 g. of ketone mixture by adding to a hot suspension of 0.2 g. of 2,4-dinitrophenylhydrazine in 3 cc. of glacial acetic acid, heating for twenty minutes at 80°, evaporating to dryness in a stream of nitrogen and removing the last of the volatile material at 1 mm. and 80°. The residue was taken up in benzene and chromatographed[17] on alumina. Three zones appeared on the column, a thin dark brown very strongly adsorbed layer on the top of the column (due to impurities), a moderately strongly adsorbed yellow zone (derivative of (V)) and a very weakly adsorbed orange zone (derivative of (VI)) which was washed completely into the filtrate.

The yellow zone was eluted with 2% acetic acid in benzene, the eluate filtered and evaporated to dryness in an inert atmosphere. The residue (230 mg.) was crystallized from benzene yielding clusters of orange needles, m. p. 186–187°.[7]

Anal. Calcd. for $C_{14}H_{16}N_4O_5$: C, 52.49; H, 5.04; N, 17.49. Found: C, 52.96; H, 5.30; N, 17.20.

(16) Lipp, Buchkremer and Seeles, *Ann.*, **499**, 20 (1932), report the m. p. of this compound as 132–133°.

(17) See Zechmeister and Cholnoky, "Principles and Practice of Chromatography" (translation by Bacharach and Robinson), John Wiley and Sons, Inc., New York, N. Y., 1941. The chromatographic separation of 2,4-dinitrophenylhydrazones has been described by Strain, THIS JOURNAL, **57**, 758 (1935).

The column filtrate containing the material which had given rise to the orange zone was also evaporated to dryness in an inert atmosphere and the residue (40 mg.) crystallized from benzene and isopropyl ether. Clusters of scarlet blades were obtained sintering at 184°[7]; the color[18] agrees well with the formulation of this substance as a derivative of an α,β unsaturated ketone (VI).

Anal. Calcd. for $C_{14}H_{14}N_4O_4$: C, 55.62; H, 4.67; N, 18.54. Found: C, 55.67; H, 4.97; N, 18.93.

Investigation of Basic Products.[19]—The ether solution obtained by continuous extraction of the liberated bases from the pyrolysis distillate was carefully distilled to remove solvent and the residue fractionated in special equipment. Because of the small amounts of material available (0.4 cc.) accurate separations were not achieved. The unsaturated base, 1-dimethylaminocyclobutene-1 (III) was not isolated nor could any characteristic derivative be obtained. However, cyclobutanone (identified as semicarbazone) was recovered from the fraction boiling at 90–110°. 1,2-*bis*-(Dimethylamino)-cyclobutane (II) was shown to be present in the appropriate fraction (*ca.* 0.25 cc.) by conversion to its characteristic dipicrate, dimethiodide and (from this latter) dimethopicrate. The properties of these derivatives agreed with those found above.

The contents of the hydrochloric acid wash bottle were evaporated to dryness *in vacuo* at 100°, giving 12.4 g. of a mixture of the hydrochlorides of dimethylamine and of trimethylamine. The former was identified by its benzenesulfonyl derivative, m. p. 47°[20] from isopropyl ether, and the latter by its picrate, yellow needles from aqueous alcohol, m. p. 224–225°.[21] A comparison of the amount of benzenesulfonyl derivative obtained, with that formed under identical conditions in control experiments from mixtures of dimethylamine and trimethylamine of known composition indicated that these had been formed during the pyrolysis in the ratio of approximately 1 to 5.

(18) According to a generalization formulated by Dr. C. E. Redemann (based on unpublished observations made in this Laboratory), when the parent carbonyl compound has a double bond conjugated with the carbonyl group, the 2,4-dinitrophenylhydrazone is colored red; a few exceptions are known. The method used above to prepare the dinitrophenylhydrazones of (V) and (VI) is based on a procedure recommended by Redemann.

(19) In one pyrolysis carried out at 350–400°, the contents of the hydrochloric acid wash bottle were combined with the pyrolysis distillate and the neutral material removed with ether. The acid solution was then evaporated to dryness *in vacuo*, taken up in a small amount of water and slowly added to potassium hydroxide pellets in an apparatus arranged for distillation. Volatile amines were removed at a bath temperature of 60° and the oily top layer remaining allowed to stand for 24 hours in contact with the concentrated base. During this time the oily layer had been transformed to an amorphous non-volatile solid, difficultly soluble in water and ether, soluble in alcohol and pyridine; it was easily soluble in dilute hydrochloric acid and from the resulting solution was reprecipitated by addition of alkali. Evidently dimethylamine had added to condensation products of cyclobutanone to give high molecular weight bases.

Summary

Cyclobutadiene was not detected among the products of thermal decomposition of *trans*-1,2-cyclobutane-*bis*-(trimethylammonium) hydroxide. Dimethylamine, trimethylamine, *trans*-1,2-*bis*-(dimethylamino)-cyclobutane, cyclobutanone and condensation products of the latter were identified as products of the pyrolysis. 1-Dimethylaminocyclobutene-1 is postulated as an unstable intermediate in the reaction.

Cyclobutane Derivatives. III. *cis*-1,3-Cyclobutanedicarboxylic Acid

BY EDWIN R. BUCHMAN, ALF O. REIMS AND MAURICE J. SCHLATTER

In 1890 Markownikoff[1] converted *trans*-1,3-cyclobutanedicarboxylic acid (I) into an isomeric acid to which the *cis*-structure (II) was later assigned by E. Haworth and Perkin, Jr.[2] These latter authors also reported[2] that they were able to isolate (II) from the mother liquors resulting from the preparation[3] of (I) and from the product of the action of alkali on polymeric methylenemalonic ester. The preparation of (II) by related reactions (from formaldehyde and malonic ester or their equivalents) was claimed in further studies[4] by Perkin, Jr., and co-workers. Although the acid obtained in this way yielded,[4c] under relatively mild conditions, products having an open

chain, the assigned structure has not previously been questioned.[5]

In connection with researches involving the preparation of considerable amounts of cyclobutanedicarboxylic acids, the above syntheses were reëxamined. It was found that (II) may be obtained both from the *trans*-isomer (I) as had been demonstrated by Markownikoff[1] and as a by-product in the preparation of (I) as shown by Haworth and Perkin.[2] Its structure was substantiated by the fact that it was found possible (see Experimental) to reconvert it to (I).

However the acid obtained by a variety of methods[2,4] from formaldehyde and malonic ester does not possess the cyclic structure and is, in fact, identical with the well characterized[6] α-methyleneglutaric acid (III). Its properties when made by the English investigators' methods[2,4] coincided with the literature data[6] on this substance; the constitution was confirmed by direct comparison with (III) of known structure made from methyl acrylate.[6b]

There is a fortuitous physical resemblance between (II) and (III) and between some of their derivatives which accounts for the mistake in identity. Chemically the two acids can easily be distinguished; (II) has saturated properties consistent with its formula while (III) reacts instantaneously with alkaline permanganate,[6b,c] adds hydrobromic acid[4c,6b,c,7] and with diazomethane readily gives a pyrazoline derivative.

Experimental[8]

***cis*-1,3-Cyclobutanedicarboxylic Acid (II).**—Following the procedure of Markownikoff,[1] the silver salt of the *trans*-acid (I) was treated with acetyl chloride to give the mixed anhydride, distillation of which at 2 mm. yielded the anhydride of (II), rosets of colorless blades from absolute ether, m. p. 47.5–48.0°.

Anal. Calcd. for $C_6H_6O_3$: C, 57.14; H, 4.80. Found: C, 56.89; H, 4.97.

The mixed anhydride was more conveniently prepared by refluxing (I) with ten molecular proportions of acetyl chloride[9] for five hours. After removal of solvent by distillation, the residue was treated as above to give the anhydride of (II).

The *cis*-acid (II) was obtained from its anhydride by evaporating a solution in five times its weight of 6 *N* hydrochloric acid to dryness on a steam-bath and recrystallizing the residue from hydrochloric acid and finally from water, m. p. 143.0–143.5°.

Anal. Calcd. for $C_6H_8O_4$: C, 50.00; H, 5.60. Found: C, 50.20; H, 5.85.

Crude diethyl ester[3] b. p. 123–130° at 28 mm. was refluxed for twenty-four hours with 6.5 times its weight of 6 *N* hydrochloric acid and the resulting solution evaporated on a steam-bath. The residue, consisting of crude crystalline *trans*-acid (I) and a dark oil was pressed on porous tile and the tile extracted with ether. After removal of solvent, seeding and allowing to stand at about 0°, a small amount of crude crystalline (II) was obtained which, after two recrystallizations from hydrochloric acid, melted at 143° and gave no depression when mixed with (II) made from the anhydride. Further larger amounts of (II) were obtained from the mother liquors; treatment of these with acetyl chloride, distillation and refractionation of the distillate gave a portion boiling at about 104° at 4 mm. which crystallized on cooling and was hydrolyzed to (II) as above.

Alkaline permanganate was not decolorized by (II) at room temperature. The dimethyl ester was prepared by refluxing (II) with methyl alcohol and a small amount of sulfuric acid, b. p. 110–111° at 20 mm.

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.80; H, 7.03. Found: C, 55.94; H, 7.09.

The dihydrazide was formed by heating the dimethyl ester for five hours at 130° with the theoretical amount of 85% hydrazine hydrate, clusters of colorless prisms or plates from alcohol–water, m. p. 172–174°.

Anal. Calcd. for $C_6H_{12}N_4O_2$: C, 41.85; H, 7.02; N, 32.54. Found: C, 41.98; H, 6.85; N, 32.37.

The *p*-bromophenacyl ester was made from the disodium salt of (II) in the usual manner, colorless needles from absolute alcohol, m. p. 121.2–121.7°.

Anal. Calcd. for $C_{22}H_{18}Br_2O_6$: C, 49.09; H, 3.37. Found: C, 49.24; H, 3.33.

Reconversion of *cis*-Acid (II) to *trans*-Acid (I).[10]—Attempts to effect this change by heating (II) for five to six hours at 180° with concentrated hydrochloric acid in a sealed tube were unsuccessful. Extensive destruction[11] of (II) took place with formation of carbonized material and sirups; no (I) could be detected among the reaction products.

The effect of heat on (II) was also studied. When heated for five hours from a bath at 200°, complete conversion to its anhydride was observed. Heating at higher temperatures also gave no (I).

To a solution of sodium methylate prepared from 0.25 g. of sodium in 50 cc. of methanol, 5 g. of the dimethyl ester of (II) was added and the mixture refluxed for one hour. After distilling off the solvent, the product was washed with water and hydrolyzed by evaporating to dryness on the steam-bath with 10 volumes of 6 *N* hydrochloric

(7) The product obtained by Perkin and Simonsen[4c] must be formulated as α-(bromomethyl)-glutaric acid. The other supposed products of ring splitting retain their previously assigned formulas.

(8) All melting points are corrected.

(9) Haworth and Perkin[2] employed acetic anhydride.

(10) Compare conversion of *cis*-1,2-cyclobutanedicarboxylic acid to the *trans*-isomer, Buchman, Reims, Skei and Schlatter, THIS JOURNAL, **64**, 2696 (1942).

(11) The instability of (II) toward hydrochloric acid was apparently first noted[2] by Haworth and Perkin.

acid. The residue was recrystallized from water, m. p. and mixed m. p. with an authentic sample of (I) 172.0–173.0°.

α-Methyleneglutaric Acid (III).—Samples of (III) made by various methods were shown to be identical by mixed melting point determinations; all samples reacted instantaneously at room temperature with alkaline permanganate. Substantial depressions of the melting point were observed when (III) and (II) or corresponding derivatives (anhydride, *p*-bromophenacyl ester) were mixed.

(III) was prepared in small yield from polymerized methyl acrylate,[6b] from methoxymethylmalonic ester,[4b,5] from crude 1-methoxy-2,2,4,4-tetracarbethoxybutane[4c] (b. p. 180–185° at 3 mm.), from diethyl methylenemalonate,[4a,12] and in somewhat better yield (21%) from "ethylparamethylenemalonate."[2,4a]

A superior method for preparation of (III) was developed starting from formaldehyde and malonic ester. To 192 g.[13] (1.2 moles) of the latter in a flask surrounded by an ice-bath was added 100 g.[13] (1.33 moles) of 40% formaldehyde and 3.4 g. of piperidine. After two hours the mixture was removed from the ice-bath and allowed to stand at room temperature for twelve hours. The heavier organic layer (220 g.) was separated and added to 100 g. (2.5 moles) of sodium hydroxide[14] in one liter of methanol in a flask surrounded by an ice-bath. The mixture slowly turned to a white pasty mass, was then removed from the ice-bath and permitted to stand at room temperature overnight; it was again cooled to 0° and 2 liters (6 moles) of 3 *N* hydrochloric acid added. After standing for two hours the methanol was distilled off, 500 cc. (6 moles) of concentrated hydrochloric acid added and the mixture refluxed for twelve hours. The residue obtained on evaporating the mixture to dryness on a steam-bath was extracted with absolute alcohol, the solvent removed and the material again evaporated with 500 cc. of water to hydrolyze any ester which might have formed. The oil remaining was allowed to crystallize for several days in the ice-box and the crude crystals recrystallized from water, yield 17.9 g. (20% yield from malonic ester) of (III), m. p. 131.0–132.0°, b. p. 175° at 3.5 mm.

Anal. Calcd. for $C_6H_8O_4$: C, 50.00; H, 5.60. Found: C, 50.07; H, 5.71.

The mother liquors from several preparations of (III) by essentially the above method were combined and esterified with ethanol in the presence of hydrochloric acid and the esters carefully fractionated.[15] The ethyl esters of glutaric acid (a major product), b. p. 104–105° at 8 mm., of α-methyleneglutaric acid (III), b. p. 111–113° at 8 mm. and of 1,3,5-pentanetricarboxylic acid, b. p. approx. 128–132° at 2 mm.[16] were isolated and identified by conversion to the corresponding acids.[17] From a fraction present in small amount, boiling at about 103° at 2 mm., on hydrolysis with 6 *N* hydrochloric acid, a new acid, α,α'-dimethyleneglutaric acid,[18] was obtained which after recrystallization from water melted at 152.0–153.0°.

Anal. Calcd. for $C_7H_8O_4$: C, 53.84; H, 5.16. Found: C, 53.90; H, 5.23.

When the acid (III) was esterified with ethanol in the presence of hydrochloric acid there was a substantial loss due to polymerization. The diethyl ester, obtained in 43% yield, b. p. 132–133° at 23 mm., on treatment with hydrazine hydrate gave no crystalline dihydrazide. The anhydride was prepared in the usual fashion,[2,4c] b. p. 112–115° at 2 mm., large colorless prisms from anhydrous ether, m. p. 51.0–51.5° (analysis).

On treatment with 10% excess of thionyl chloride and distillation at reduced pressure, (III) gave the acid chloride, b. p. 82–83° at 5 mm., and smaller amounts of the anhydride. A portion of the acid chloride dissolved in ether was saturated with excess of dry ammonia, the ether evaporated and the residue extracted with chloroform. The diamide was obtained from the chloroform extract, m. p. 164.0–165.0° from absolute alcohol.

Anal. Calcd. for $C_6H_{10}N_2O_2$: C, 50.69; H, 7.09; N, 19.71. Found: C, 50.63; H, 7.38; N, 19.82.

The *p*-bromophenacyl ester crystallized in colorless needles from 96% alcohol, m. p. 121.6–121.7°.

Anal. Calcd. for $C_{22}H_{18}Br_2O_6$: C, 49.09; H, 3.37. Found: C, 49.11; H, 3.33.

An excess of diazomethane in ether was added to 1 g. of (III), the ether removed and the residual oil heated in a sealed tube at 100° for twenty hours with 20 cc. of an alcoholic ammonia solution (saturated at 0°). After evaporation of the solvent on a steam-bath the remaining oil crystallized, m. p. 145.0–145.5° from absolute alcohol. The analysis indicates that this substance is the diamide of the pyrazoline[19] resulting from the addition of diazomethane to the double bond in (III).

Anal. Calcd. for $C_7H_{12}N_4O_2$: C, 45.64; H, 6.57; N, 30.42. Found: C, 45.92; H, 6.67; N, 30.42.

Summary

In accord with literature claims, *cis*-1,3-cyclobutanedicarboxylic acid may be obtained from the *trans*-isomer or as a by-product in the preparation of the latter. It has properties consistent with its structure.

The compound obtained from formaldehyde and malonic ester or their equivalents and reported as *cis*-1,3-cyclobutanedicarboxylic acid is α-methyleneglutaric acid.

PASADENA, CALIF. RECEIVED JULY 22, 1942

(12) Made in poor yield both by distillation of the polymer and also by the method of Bachman and Tanner, *J. Org. Chem.*, **4**, 493 (1939).

(13) These relative amounts appeared to give optimum yields of (III).

(14) It was not found possible to work out as convenient a method employing potassium hydroxide.

(15) From the forerun (up to 80° at 2 mm.) a small amount of a crystalline material containing ionic halogen separated on standing, m. p. 220.0–220.5° from alcohol, easily soluble in water, quite insoluble in ether, acid to litmus. The analysis (Found: C, 49.79; H, 8.36; N, 7.77; Cl^-, 18.43) points to the formula $C_8H_{16}ClNO_2$ (Calcd.: C, 49.61; H, 8.33; N, 7.23; Cl^-, 18.31); the substance is obviously derived from the piperidine used as catalyst.

(16) Kay and Perkin, *J. Chem. Soc.*, **89**, 1647 (1906).

(17) 1,3,5-Pentanetricarboxylic acid, m. p. 112.5–113.0° (analysis); compare ref. 4a.

(18) This structure is in accord with the method of formation from malonic ester and formaldehyde. All of the products isolated could be formed from a common intermediate, methylenedimalonic ester; compare Welch, *J. Chem. Soc.*, 257 (1930).

(19) Regarding its probable structure see von Auwers and Cauer, *Ann.*, **470**, 284 (1929); von Auwers and König, *ibid.*, **496**, 27 (1932).

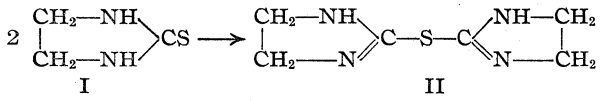
Complex Formations between Iodine and μ-Mercapto-dihydroglyoxalines[1]

BY TREAT B. JOHNSON AND C. O. EDENS[2]

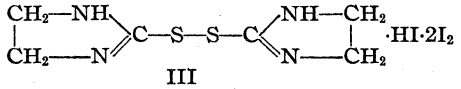
In a recent paper from this Laboratory the authors[3] reported on the characteristic behavior of ethylene-thiourea I when oxidized by 5,5-dibromoxyhydrouracil. They found that this cyclic ureide is transformed into a representative of a new class of glyoxaline sulfides, namely, dihydroglyoxaline sulfide II, which proved to be identical with a sulfur compound of unknown constitution,



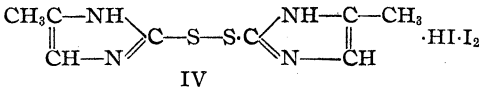
I II

obtained by Jaffe, in 1894, by interaction of ethylenediamine with thiophosgene. Since this change is brought about through the agency of hypobromous acid (HOBr) resulting from the dissociation of the pyrimidine, 5,5-dibromoxyhydrouracil, it was of interest to the authors to examine the behavior of ethylenethiourea I toward iodine solution. Practically no attention has hitherto been paid to the action of iodine on cyclic ureides of the thiodihydroglyoxaline type I. The experimentation has led to results of immediate interest, and opened a gate to a new field of heterocyclic sulfur compounds of biochemical significance.

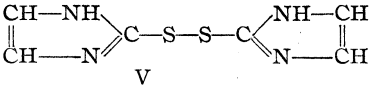
Ethylene-thiourea I does not react with iodine in aqueous solution to form Jaffe's dihydroglyoxaline sulfide II. On the other hand, it undergoes the normal change of oxidation of a true thiol compound and is converted into a disulfide which combines at once with iodine to form the characteristic periodide III. Propylene-thiourea (2-thio-5-methyl-dihydroglyoxaline) interacts with iodine solution to yield a corresponding periodide derivative, while the unsaturated 2-thio-5-methyl-glyoxaline[5] reacts under similar conditions to form periodide containing one molecule only of iodine IV. The simplest glyoxaline disulfate V or its periodide have not been described in the literature.



III



IV

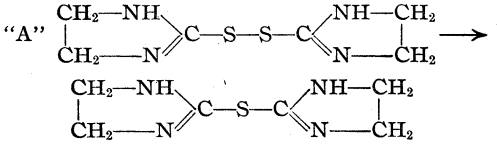


V

Especially interesting is the behavior of the periodide III on hydrolysis. Boiling with water leads to decomposition of the molecule with evolution of iodine vapors and formation of the hydriodide of Jaffe's sulfur base—dihydroglyoxaline sulfide II. Free sulfur and sulfuric acid are also products of this change. The periodide III is also destroyed by treatment with aqueous ammonia. This leads to reduction of the disulfide grouping with regeneration of ethylene-thiourea I and formation of ammonium iodide.

Dihydroglyoxaline sulfide II likewise combines with iodine in aqueous solution to give a periodide conforming in constitution to the formula $C_6H_{10}N_4C\cdot HI\cdot I_3$. This dissociates quantitatively at 125° into iodine and the hydriodide of dihydroglyoxaline sulfide II.

Previously, the irreversible change expressed by equation "A" has not been emphasized.



It is very possible that this interesting change of the sulfur linkage may be the cause of some of the irregularities in analytical results from the titration of certain 2-thioglyoxalines with iodine solutions. Further attention will be given to this problem as our work progresses, and when we have an opportunity to apply our technique to other representatives of the thiodihydroglyoxaline series.

Experimental Part

Periodide of 4,5-Dihydroglyoxaline-2-disulfide, $C_6H_{10}N_4S_2\cdot HI\cdot 2I_2$, III.—A solution of five grams of ethylenethiourea I dissolved in 200 ml. of water was cooled to room temperature and a solution of 0.4 *N* iodine, in aqueous potassium iodide, was added from a buret during vigorous stirring. The first few drops produced a yellowish-brown precipitate which redissolved immediately; further addition of iodine produced a permanent turbidity, which

(1) A grant for partial support of this work made by the Rockefeller Foundation of New York City, is gratefully acknowledged by the authors.

(2) Sterling Professorship of Chemistry Research Assistant, 1940–1941.

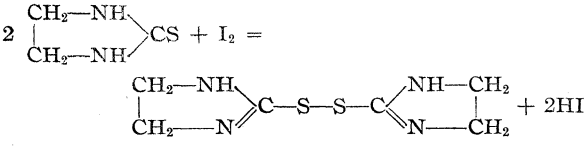
(3) Johnson and Edens, THIS JOURNAL, **63**, 1058 (1941).

(4) Jaffe and Kuhn, *Ber.*, **27**, 1664 (1894).

(5) Gabriel and Pinkus, *ibid.*, **26**, 2203 (1893).

gradually turned to a reddish-brown appearance. At this point, a dark red powder began to take form and settled to the bottom of the beaker. Iodine solution was added until there was no further precipitation, the volume consumed being 185 ml. or practically the equivalent of about 3 moles of iodine per mole of ethylene-thiourea I. A further addition of 25 ml. was added to assure an excess. This product was separated by filtration and washed with cold water and finally with carbon tetrachloride. The yield was 20.5 g. or 87.3% of the theoretical.

The equation leading to the formation of the unknown disulfide may be expressed as



This disulfide then adds iodine immediately, giving the above periodide derivative.

The periodide is a dark red substance of crystalline character. It melts at 119° and is extremely soluble in acetone, diethyl ether, ethanol, methanol, ethyl acetate and warm glycerol. It is moderately soluble in benzene and insoluble in carbon tetrachloride, petroleum ether and water. It can be recrystallized from dilute alcohol.

Anal. Calcd. for $C_6H_{11}N_4S_2I_5$: C, 8.60; H, 1.31; I, 75.85; S, 7.63. Found: C, 8.55; H, 1.28; I, 76.00; S, 7.55.

Behavior of the Periodide III on Heating with Water.—Two grams of the above periodide of dihydroglyoxaline disulfide was digested with 75 ml. of boiling water for about forty-five minutes. Iodine vapors were evolved copiously, and the compound gradually changed to a dark oil, which finally dissolved yielding a pale-yellow aqueous solution. This was then concentrated to about 10 ml. *in vacuo* and cooled, when glistening needles crystallized from the solution. These melted at 284° and a mixed melt with the hydriodide of dihydroglyoxaline sulfide II ($C_6H_{10}N_4S$·HI) gave no depression in melting point. The free base and picrate were likewise prepared and checked with mixed melts. Sulfuric acid was identified in the aqueous filtrate, and free sulfur also was present.

Anal. Calcd. for $C_6H_{10}N_4S$·HI: N, 18.79; I, 42.6. Found: N, 18.63; I, 42.75.

Action of Ammonia on the Periodide $C_6H_{11}N_4S_2I_5$ (Ammonolysis).—The periodide interacts with aqueous ammonia with evolution of heat, and is decolorized almost immediately. The disulfide linkage is destroyed by this treatment with formation of ethylene-thiourea I and ammonium iodide. Other products are undoubtedly formed here, but after two applications to ammonolysis the only pure sulfur compound isolated was the cyclic ureide I. This reaction is under investigation in this Laboratory and the results of our experimentation will be reported in a subsequent paper.

Synthesis of Ethylene-thiourea (2-Thiol-dihydroglyoxaline I) and Propylene-thiourea (2-Thiol-4-methyl-dihydroglyoxaline).—These cyclic ureides are easily prepared from ethylenediamine and propylenediamine, respectively, according to the following procedure:

One hundred grams of carbon disulfide is placed in a 500-ml. flask attached to a reflux condenser. Then 75 g. of the respective commercial diamine (80%) is added dropwise with frequent shaking. The reaction is vigorous. After final addition of the amine, the mixture is then carefully refluxed for one-half hour and cooled. The excess of carbon disulfide is now poured off and the viscous reaction product dissolved by warming in 200 ml. of water. Ring closure of the respective dithiocarbamate intermediate is easily accomplished by adding 15 ml. of concentrated hydrochloric acid and finally refluxing the solution at 100° for one hour. On cooling, the dihydroglyoxaline separates in crystalline condition. Further material is obtained by concentration of the aqueous mother liquors. The ethylene-thiourea is obtained in a yield of 64.5 g. and melting at 198°, or 63%.[6]

Propylene-thiourea is easily purified by crystallization from benzene, and the yield was 64.5 g., melting at 100°. This ureide is much more soluble than ethylene-thiourea I.

Anal. Calcd. for $C_4H_8N_2S$: C, 41.33; H, 6.94; N, 24.11. Found: C, 41.41, 41.42; H, 6.62, 6.76; N, 24.38, 24.28.

Periodide of 5-Methyl-4,5-dihydroglyoxaline-2-disulfide, $C_8H_{14}N_4S_2$·HI·$2I_2$.—To a solution of 5 g. of propylene-thiourea in 100 ml. of water was added dropwise with stirring the calculated volume of 163 ml. of 0.4 *N* iodine solution. The first addition produced an immediate turbidity and finally a compound separated in the form of a glistening viscous oil adhering to the sides and bottom of the beaker. After the addition of five atoms of iodine per mole of the propylene-thiourea, a further addition of 25 ml. of the standard iodine solution was made, the total volume added being 187 ml. On standing, the viscous oil finally solidified to a brittle solid which was washed with water and dried. After grinding it formed a heavy dark red powder melting at 67°. This periodide is very soluble in acetone, ether and ethanol; insoluble in water and carbon tetrachloride.

Anal. Calcd. for $C_8H_{15}N_4S_2I_5$: C, 11.09; H, 1.73; I, 73.31; S, 7.39. Found: C, 11.23; H, 1.79; I, 73.52; S, 7.28.

When this periodide was heated with boiling water iodine vapors were evolved and the compound completely dissolved. After concentrating the solution to 10 ml. and cooling no crystals separated as did in the case of the ethylene-thiourea experiment. Instead, a dark red oil separated that failed to crystallize on long standing. The solution gave a strong test for sulfuric acid.

4,5-Dihydroglyoxaline-2-thioglycolic Acid, $C_5H_8O_2N_2S$.—An aqueous solution (50 ml.) of 5 g. of ethylenethiourea I and 9.4 g. of chloroacetic acid was heated at its boiling point for three hours. It was then concentrated to a thick sirup and 50 ml. of ethanol added when the hydrochloride of this acid separated in crystalline form. The yield was 8 g. or 81%. The hydrochloride was purified by crystallization from hot ethanol, and melted at 223° with decomposition. Qualitative tests showed the presence of sulfur, nitrogen and chlorine. The cyclic ureide derivative is very resistant to hydrolysis.

Anal. Calcd. for $C_5H_9O_2N_2SCl$: C, 30.53; H, 4.58; N, 18.05. Found: C, 30.59, 30.85; H, 4.54, 4.36; N, 18.00, 17.81.

5-Methyl-4,5-dihydroglyoxaline-2-thioglycolic Acid, $C_6H_{11}O_2N_2S$.—This was obtained in the form of its hydrochloride by digesting a solution of 5 g. of propylene-thiourea and 8.2 g. of chloroacetic acid in 50 ml. of water for three hours. The yield was 8 g. and the salt melted at 215° after crystallization from ethanol. This compound was recovered unaltered after digestion for two hours with 20% hydrochloric acid.

Anal. Calcd. for $C_6H_{11}O_2N_2SCl$: Cl, 16.86. Found: Cl, 16.85, 16.83.

Periodide of 4,5-Dihydroglyoxaline Sulfide, $C_6H_{10}N_4S \cdot HI \cdot I_3$.—This is easily prepared by dissolving the hydriodide of dihydroglyoxaline sulfide $C_6H_{10}N_4S \cdot HI$ (0.4 g.) II in 100 ml. of water at room temperature, and then adding dropwise 5 ml. of standard iodine solution (0.4 *N*). At this point no further precipitation was observed. The precipitate was filtered off and after washing it with cold water and carbon tetrachloride it was dried in a vacuum desiccator over sulfuric acid. This periodide crystallizes as a dark red powder melting at 170–175°. It is quite soluble in ether and acetone.

Anal. Calcd. for $C_6H_{11}N_4SI_4$: C, 10.83; H, 1.62; I, 74.81. Found: C, 10.61; H, 1.62; I, 74.55.

Dissociation of the above Periodide $C_6H_{11}N_4SI_4$ by Heating.—A small amount of the periodide was spread on a porous plate and exposed to the temperature of a drying oven at 125°. In fifteen minutes the three atoms of iodine had volatilized completely and a colorless powder remained behind. This was identified as the hydriodide of 4,5-dihydroglyoxaline sulfide and melted at 284°. No change in the linkage of sulfur had taken place.

Action of Chloroacetic Acid on Jaffe's Base—Dihydroglyoxaline Sulfide, II.—One gram of the glyoxaline derivative, $C_6H_{10}N_4S$, and 1.19 g. of chloroacetic acid were dissolved in 50 ml. of water and the solution boiled for three hours. The solution was then concentrated to 5 ml. and diluted with ethanol. The hydrochloride of Jaffe's sulfur base separated immediately. No other product was identified, and there was no evidence of desulfurization by this treatment or formation of a thioglycolic acid derivative.

Anal. Calcd. for $C_6H_{10}N_4S \cdot HCl$: Cl, 17.20. Found: Cl. 17.45.

Periodide of 5-Methylglyoxaline Disulfide, $C_8H_{10}N_4S_2 \cdot HI \cdot I_2$.—2-Thio-5-methylimidazole[7] (0.5 g.) was dissolved in 100 ml. of cold water and a 0.4 *N* solution of iodine in aqueous potassium iodide added slowly with vigorous stirring. Addition of 5 ml. produced a deep yellow solution; 13.4 ml. led to the formation of a precipitate which was complete after adding 28.5 ml. The periodide separated as dark red crystals. After washing with cold water and chloroform it was dried in a vacuum over sulfuric acid. The compound decomposed on heating.

Anal. Calcd. for $C_8H_{11}N_4S_2I_3$: C, 15.75; H, 1.80; I, 62.44; S, 10.52. Found: C, 15.93, 15.77; H, 1.66, 1.64; I, 62.47; S, 10.41.

Summary

1. Ethylene-thiourea and propylene-thiourea interact with iodine in aqueous potassium iodide solution to form the periodides $C_6H_{10}N_4S_2 \cdot HI \cdot 2I_2$ and $C_8H_{14}N_4S_2 \cdot HI \cdot 2I_2$, respectively.

2. The periodide resulting from ethylene-thiourea is converted by hydrolysis into dihydroglyoxaline sulfide $C_6H_{10}N_4S$. Interaction with ammonia (ammonolysis) leads to the regeneration of ethylene-thiourea.

3. Dihydroglyoxaline sulfide reacts with iodine to give the periodide $C_6H_{10}N_4S \cdot HI \cdot I_3$ which dissociates at 125° yielding the hydriodic salt of dihydroglyoxaline sulfide.

4. Dihydroglyoxaline sulfide $C_6H_{10}N_4S$ is not desulfurized by digestion with chloroacetic acid.

5. Ethylene-thiourea and propylene-thiourea interact with chloroacetic acid to form the representative 2-thioglycolic acid derivatives without desulfurization.

6. 2-Thio-5-methylimidazole interacts with iodine in aqueous solution to give a periodide of formula $C_8H_{10}N_4S_2 \cdot HI \cdot I_2$.

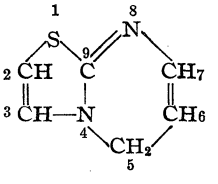
Researches on Thiazoles. XXV. Some New Thiazolidinopyrimidines of Barbituric Acid Type

BY EDWARD J. MASTERS AND MARSTON TAYLOR BOGERT

Since the proof of the structure of vitamin B_1,[1] great interest has been shown in compounds containing the thiazole or thiazoline ring. A miscellany of such compounds having therapeutic value appears in the patent and regular literature. These compounds are characterized by relatively low toxicity when introduced into the body.

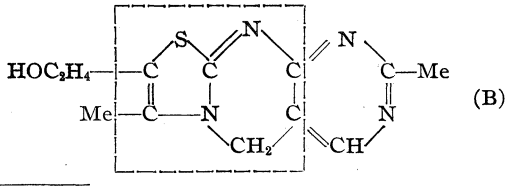
Thus, sulfathiazole[2] is an example of this type of compound and is useful in the treatment of certain types of bacterial infection. More recently, its thiazoline analog, sulfathiazoline,[3] has been synthesized. A variety of compounds containing the thiazole or thiazoline ring and possessing local anesthetic activity has been prepared.[4-9]

The immediate object of this investigation was the synthesis of compounds related to the structure (A)



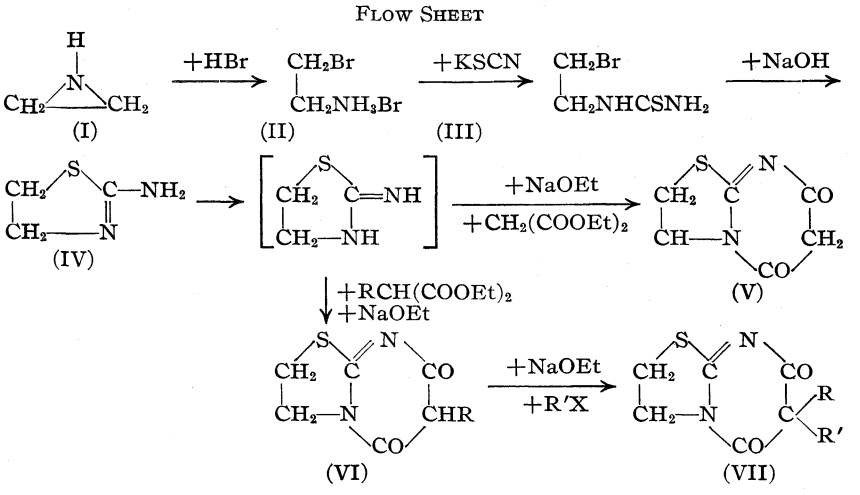
(A)

Compounds containing this skeletal structure are as yet unknown in the literature. The nearest approach to it is found in the thiochrome molecule[10] (B), the thiazolopyrimidine portion of which is enclosed in broken lines.



(B)

FLOW SHEET



R = Me, Et, *i*-Pr, Ph, and $PhCH_2$
R′ = Et, *i*-Pr, *n*-Bu, Ph, and $PhCH_2$

The 5,7-dioxo derivatives of constitution (A) present an interesting variation in the barbituric acid structure, and the analogs of the more important barbituric acids might be expected to possess hypnotic or anesthetic activity. The flow sheet for the reactions involved includes standard methods for the synthesis of barbituric acids.

As will be noted in this flow sheet, 2-aminothiazoline (IV) is assumed to react in its tautomeric 2-iminothiazolidine form under the conditions employed.

Bogert and Mills[11] in laying the groundwork for the synthesis of compounds of type (A) synthesized β,β′-di-(1-barbituryl)-ethyl disulfide, using β-mercaptoethylamine as the starting material. Bogert and Nathan[12] continued this work and by reduction of β,β′-di-(1-barbituryl)-ethyl disulfide, using zinc and hydrochloric acid, obtained a compound of the empirical formula $C_6H_6N_2O_2S$. Since condensation at two different positions was possible, it was not clear whether the structure of this compound was

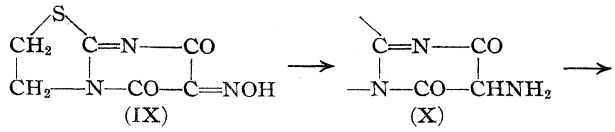
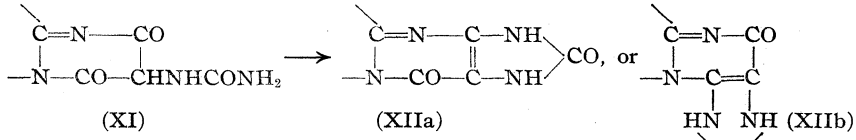
(VIII)  or  (V)

In the present work, it was thought that a more direct and unequivocal synthesis of (V) could be effected by condensation of 2-aminothiazoline (IV) with malonic ester, analogous to that used by Chichibabin[13] in which 2-aminopyridine was condensed with malonic ester to yield the bicyclic pyridinopyrimidine.



(IX) (X)



(XI) (XIIa) (XIIb)

In the attempts to condense 2-aminothiazoline with malonic ester to form the desired pyrimidine (V), the conditions of Chichibabin's experiment were followed, *i. e.*, the slow heating of the reactants to 195°. Extensive decomposition occurred with the formation of a hard red resin. Lower temperatures were used without success. The condensation was finally effected in high yield using sodium ethylate with absolute ethyl alcohol as solvent. This synthesis of compound (V) proves that the compound synthesized from β,β′-di-(1-barbituryl)-ethyl disulfide by Bogert and Nathan[12] was (VIII), since the two products were not identical.

When mono-substituted alkyl or aryl malonic esters were used in the condensation with 2-aminothiazoline in the presence of sodium ethylate, the reaction proceeded readily with formation of the mono-substituted thiazolidinopyrimidines listed in Table I. The synthesis of the disubstituted pyrimidines was effected by alkylation of the appropriate monosubstituted pyrimidine containing the more sterically hindered group. The alkylations were conducted in absolute ethyl alcohol in the presence of sodium ethylate. The disubstituted pyrimidines synthesized in this series (Table II) are the analogs of the barbituric acids: Veronal, Neonal, Ipral and Phenobarbital.

Of the compounds described in Tables I and II, nos. 1, 2 and 6 formed white dendritic crystals; no. 3, white needles; nos. 4, 8, 10 and 11 colorless plates; nos. 5, 7 and 9, colorless needles.

Solubilities.—No. 1, 1% in hot absolute alcohol, 2% in hot water; no. 2, 1 g. in 150 cc. of hot water; no. 3, 1% in hot water, more soluble in alcohol; no. 4, 1 g. in 9 cc. of hot alcohol; no. 7, 0.25% in hot water.

From the thiazolidinobarbituric acid (V), the corresponding uric acid (XII) was synthesized via the usual oximino (IX), uramil (X), and pseudouric acid (XI) derivatives

The results of the pharmacological tests upon the compounds described in this paper will be reported later.

Acknowledgments.—We are greatly indebted to the Carbide & Carbon Chemicals Corp. of New York for their courtesy in supplying us with ethyleneimine and β-aminoethyl sulfate required for this investigation. We are also under obligations to Mr. Saul Gottlieb for the analysis of our products.

Experimental

All melting points recorded are corrected for stem exposure.

β-Bromoethylamine hydrobromide (II) was prepared most satisfactorily as follows: 174 g. (4 mols) of 99% ethyleneimine was added dropwise to 1250 cc. (11.1 mols) of 48% HBr. The temperature of the reaction mixture was maintained at 0–5°, and the solution was stirred vigorously during the addition. It was then concentrated to a thick sirup under vacuum, allowed to cool, the crystalline mass filtered off and washed with a little absolute alcohol. The filtrate and washings were concentrated further to yield more of the product. The product after drying weighed 660 g. or a yield of 80%. After recrystallization from absolute alcohol, the compound melted at 173.3–174.3° (lit.,[14] m. p. 172–173°).

Anal. Calcd. for $C_2H_7Br_2N$: C, 11.7; H, 3.4. Found: C, 11.7; H, 3.3.

It is stated by Gabriel,[15] and in "Organic Syntheses,"[16] that the above compound can be prepared "by the addition of hydrogen bromide to ethyleneimine," but if the reaction is carried out in that way the compound sought will not be obtained.

β-Bromoethylthiourea (III) was prepared from β-bromoethylamine hydrobromide and potassium thiocyanate by

the method of Gabriel,[17] and melted at 173.6–174.2° (lit.,[17] m. p. 172.5–173.5°); yield, 60%.

The 2-aminothiazoline (IV) used was obtained by treating (III) with caustic soda solution.[17] The m. p. was 84–85° (lit.,[17] m. p. 84–85°); yield, 86%; over-all yield from ethyleneimine was 41%.

2,3,6,7-Tetrahydro-5,7-dioxo-5-thiazolo[3,2-a]pyrimidine (V).—2.3 g. (0.10 mole) of clean metallic sodium was dissolved in 50 cc. of absolute ethyl alcohol. This solution was cooled to 50° and 8 g. (0.05 mol) of ethyl malonate was added, followed by a solution of 5 g. (0.05 mol) of 2-aminothiazoline in 20 cc. of absolute ethyl alcohol. The reaction mixture was refluxed for three hours, during which period a white solid separated rapidly.

The mixture was cooled, brought to acidity by the addition of 11 cc. of concentrated hydrochloric acid, the precipitate filtered off and washed with a few cc. of alcohol. It was then slurried with about 30 cc. of water, to remove any sodium chloride, filtered, dried at 105° for an hour, and then weighed. The yield was 6.8 g. From the original filtrate, 0.7 g. more was obtained, making a total yield of 7.5 g. or 88%. Recrystallized from alcohol, it formed small dendritic crystals, which melted with decomposition at 244.5–245.5°.

Anal. Calcd. for $C_6H_6O_2N_2S$: C, 42.5; H, 3.6. Found: C, 42.6; H, 3.8.

The mono-R derivatives of (V) were synthesized in a manner analogous to the above, using the appropriate mono-substituted malonic ester in the place of malonic ester. Data concerning them appear in Tables I and II. The phenyl malonic ester employed was prepared from phenyloxaloacetic ester.[18]

6,6-Diethyl-2,3,6,7-tetrahydro-5,7-dioxo-5-thiazolo[3,2-a] pyrimidine (VII).—4 g. (0.020 mole) of the monoethyl derivative (VI) was added to an alcoholic solution of sodium ethylate prepared by dissolving 0.50 g. (0.022 mole) of clean metallic sodium in 50 cc. of absolute ethyl alcohol, and the temperature was kept at 50°.

3.9 g. (0.025 mole) of ethyl iodide was added, and the solution refluxed until neutral. The time of refluxing was about two hours. It was then concentrated to about 15 cc., 100 cc. of water added slowly with shaking, and small white feathery crystals precipitated. The crystals were collected on a Büchner funnel, washed with a few cc. of dilute bicarbonate solution, to dissolve any unreacted (VI), then with a few cc. of alcohol, and finally with water. Dried at 105°, the yield was 1.3 g., or 29%.

Recrystallization of the product from a large volume of hot water resulted in the formation of beautiful long needles, m. p. 138.2–138.7°.

Anal. Calcd. for $C_{10}H_{14}O_2N_2S$: C, 53.1; H, 6.2. Found: C, 53.4; H, 6.4.

The other 6,6-disubstituted products were prepared similarly, using the appropriate halide. Analyses and other data are given in Tables II and III. These compounds were quite soluble in various organic solvents, but dissolved only slightly in water. A convenient method of isolating them consisted in removing all of the alcohol from the reaction mixture, when the residual oil congealed on standing and cooling. Unaltered initial mono-substituted esters were then easily removed by washing with a potassium carbonate solution.

6-Isonitroso-2,3,6,7-tetrahydro-5,7-dioxo-5-thiazolo[3,2-a] pyrimidine (IX).—A suspension of 7 g. (0.041 mol) of (V) in 100 cc. of 30% alcohol was stirred vigorously and 6.3 g. (0.054 mol) of isoamyl nitrite added dropwise over a period of a half hour. After further vigorous stirring for an hour, the temperature was slowly raised to 50° and the stirring continued for another hour. The white suspension slowly changed into the purple of the nitroso compound. The mixture was chilled, the nitroso compound removed, washed with alcohol and air dried; yield, 5 g., or 61%; m. p. 175–178°. As some difficulty was experienced in purifying this compound, it was used without further purification in the subsequent reactions. It dissolved readily in alkali to a deep purple solution.

6-Amino-2,3,6,7-tetrahydro-5,7-dioxo-5-thiazolo[3,2-a] pyrimidine (X).—To a solution of 4 g. (0.02 mol) of (IX) in 10 cc. of concentrated ammonium hydroxide diluted with 10 cc. of water, 7 g. of sodium hydrosulfite, dissolved in 15 cc. of water containing a few drops of ammonia, was added slowly until the purple color disappeared. The

(17) Gabriel, *Ber.* **22**, 1141 (1889).

(18) "Organic Syntheses," XVI, 33 (1936).

solution was chilled and neutralized with dilute hydrochloric acid. The precipitate was filtered off, washed with water and crystallized from hot water. The yield was 2 g. or 54%. The compound turned red at 174° and decomposed at 194°. Not unlike other uramils, this compound was very troublesome to purify, changed color rapidly in the air or on drying *in vacuo*, and burned with difficulty in the microanalytical apparatus, so that it was felt that not much reliance could be placed upon the analytical results, although these indicated that the substance was the impure monohydrate.

Anal. Calcd. for $C_6H_9O_3N_3S$: C, 35.5; H, 4.5. Found: C, 36.4; H, 4.5.

6-Ureido-2,3,6,7-tetrahydro-5,7-dioxo-5-thiazolo[3,2-a] pyrimidine (XI).—To a solution of 0.5 g. of (X) (0.0027 mol) in 30 cc. of hot water, there was added a solution of 0.32 g. (0.0040 mol) of potassium cyanate in 10 cc. of water, and the solution was warmed to the disappearance of its purple color. It was then chilled, acidified with dilute hydrochloric acid, the yellow precipitate collected and dried; yield, 0.5 g., or 80%. Recrystallized from hot water containing a little Norit, a white crystalline product resulted, m. p. 261–263°.

Anal. Calcd. for $C_7H_8O_3N_4S$: C, 36.9; H, 3.5. Found: C, 37.2; H, 3.5.

The thiazolidinouric acid (XIIa or XIIb) was obtained from the corresponding pseudouric acid (XI) by an adaptation of the classic method of Fischer and Ach.[19]

A mixture of 46 mg. of the pseudouric acid (XI) with 1 g. of anhydrous oxalic acid was placed in a test-tube and heated in an oil-bath, the temperature of which was brought to 185° in the course of ten minutes. Most of the oxalic acid volatilized, and some of the pseudouric acid was decomposed with liberation of hydrogen sulfide. The residue when cold was extracted with alcohol, to remove any oxalic acid still present, and the undissolved material was dissolved in dilute sodium hydroxide solution, boiled with activated carbon, the filtrate acidified with dilute hydrochloric acid and chilled. The precipitate, removed and dried, weighed 15 mg., *i. e.*, a yield of 36%. Recrystallized from a large volume of water, it separated in glistening white microscopic crystals, which remained unmelted at 300°.

Anal. (on 1 mg. of product). Calcd. for $C_7H_6O_2N_4S$: C, 40.0; H, 2.9. Found: C, 39.7; H, 2.7.

Not enough material was available to determine whether the constitution of this product should be represented by formula XIIa or XIIb, either one of which could be formed by the elimination of water from the initial pseudouric acid.

(19) Fischer and Ach, *Ber.*, **28**, 2473 (1895).

Summary

1. Thiazolidinopyrimidines of barbituric acid type are easily prepared pure and in satisfactory yields from 2-aminothiazoline as initial material by familiar reactions.

2. Among the compounds so prepared are analogs of Veronal, Neonal, Ipral and Phenobarbital.

3. From the thiazolidinobarbituric acid, the corresponding thiazolidinouric acid has been synthesized via the oximino, uramil and pseudouric acid derivatives.

4. The physiological effects of these compounds are now being studied, to ascertain to what extent, if at all, their properties resemble those of the corresponding barbituric acids.

Researches on Thiazoles. XXVI. Some Acyl Derivatives of 2-Aminothiazole

BY EDWARD J. MASTERS AND MARSTON TAYLOR BOGERT

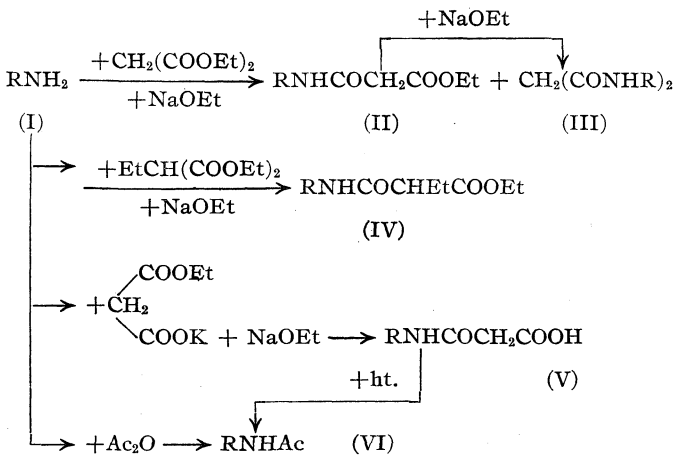
The behavior of 2-aminothiazole (I) when digested with ethyl malonate and sodium ethylate, in alcoholic solution, is quite different from that of 2-aminothiazoline under similar conditions,[1] as can be seen from the following flow sheet, in which R represents the thiazole residue, 
This difference in the behavior of 2-aminothiazole as compared with 2-aminothiazoline is probably due, as pointed out in our previous article,[1] to the fact that the thiazoline can react in its tautomeric iminothiazolidine form, a rearrangement which is less likely to occur with the more stable conjugated system of the thiazole.

Refluxing of the thiazole, in alcoholic solution, with sodium ethylate and ethyl malonate, resulted in the formation of both the thiazolylmalonamic ester (II), and the *sym*-dithiazolylmalonamide (III).

Some years ago, the I. G. Farbenind. A.-G.[2] took out patents for the manufacture of acetoacetyl derivatives of 2-aminothiazole by heating together the aminothiazole and acetoacetic ester (and analogous esters) without any solvent. In

(1) Masters and Bogert, THIS JOURNAL, **64**, 2709 (1942).

(2) I. G. Farbenind. A.-G., German Patent 603,623, Oct. 8, 1934; *C. A.*, **29**, 814 (1935); and addition thereto, Jan. 3, 1935; *C. A.*, **29**, 4024 (1935).



our own experiments, when the aminothiazole and malonic ester were heated together directly, a great deal of decomposition ensued, but both (II) and (III) were isolated from the crude product.

When the malonamate (II) was heated above its m. p., or was refluxed in absolute ethanol solution with sodium ethylate, the diamide (III) was formed.

By the use of a substituted ethyl malonate, instead of ethyl malonate itself, in the condensation with the aminothiazole, the corresponding substituted malonamate (IV) was obtained.

From the potassium salt of the malonic ester acid, 2-aminothiazole, and sodium ethylate, in absolute ethanol solution, the malonamic acid (V) was prepared. This acid when heated lost carbon dioxide, with formation of the same 2-acetaminothiazole as resulted from direct acetylation of the aminothiazole.

All attempts to cyclize the malonamic acid (V) to a thiazolopyrimidine have so far proved fruitless.

Acknowledgments.—Our thanks are due to the Monsanto Chemical Co., of St. Louis, Missouri, and to the Calco Chemical Division of the American Cyanamid Company, Bound Brook, New Jersey, for supplies of 2-aminothiazole; and to Mr. Saul Gottlieb for the analysis of our products.

Experimental

All melting points are corrected for exposed stem.

2-Aminothiazole (I) can be prepared readily from thiourea and dichloroethyl ether, by the method of Traumann,[3] if necessary, but it is also available commercially.

(3) Traumann, *Ann.*, **249**, 35 (1888).

Ethyl N-(2-Thiazolyl)-malonamate (II).—To a solution of 11.5 g. (0.5 mole) of clean sodium in 500 cc. of absolute ethanol, cooled to 50°, there was added 80 g. (0.5 mole) of ethyl malonate, followed by 50 g. (0.5 mole) of 2-aminothiazole. After refluxing the mixture for five hours, it was cooled, and acidified by the addition of 42 cc. of concentrated hydrochloric acid. The precipitate contained two products, the more soluble of which was extracted by leaching with large volumes of hot water. The total yield of this product, including some recovered from the original filtrate, was 34.5 g. Recrystallized from water, it formed white crystals, m. p. 149–149.5°, soluble in alcohol or benzene.

Anal. Calcd. for $C_8H_{10}O_3N_2S$: C, 44.8; H, 4.7; N, 13.1. Found: C, 45.0; H, 4.6; N, 13.1.

sym-**N-(2-Thiazolyl)-malonamide** (III), which was the less soluble product in the above reaction, was isolated in a yield of 34 g. The combined yield of (II) and (III) accounted for about 80% of the aminothiazole used.

The amide (III) was purified by precipitating its bicarbonate solution by dilute acid. It began to change color at about 258° and decomposed sharply at 271°.

Anal. Calcd. for $C_9H_8O_2N_4S_2$: C, 40.3; H, 3.0; N, 20.8. Found: C, 40.2; H, 3.0; N, 20.6.

N-(2-Thiazolyl)-malonamic acid (V) was prepared as described for (II), using the potassium salt of malonic ethyl ester acid in place of ethyl malonate. By acidification with dilute mineral acid, the free malonamic acid was obtained as white dendritic crystals, in a yield of 54%. At 185.8–186.8°, it melted with decomposition, losing carbon dioxide and forming the 2-acetaminothiazole (VI), m. p. 206.5–207° (lit.,[3] m. p. 203°), long needles, whose identity was checked by preparation of the same compound from the aminothiazole (I) and acetic anhydride.[3]

Anal. Calcd. for $C_6H_6O_3N_2S$: C, 38.8; H, 3.3; acid equivalent, 186. Found: C, 39.1; H, 3.6; acid equivalent, 186.

Ethyl N-(2-thiazolyl)-ethylmalonamate (IV), prepared by the same method as (II), using ethyl ethylmalonate in place of ethylmalonate, was obtained in a yield of 46%, m. p. 117.8–118.8°, as white dendritic crystals.

Anal. Calcd. for $C_{10}H_{14}O_3N_2S$: C, 49.6; H, 5.8. Found: C, 49.8; H, 5.8.

In this case, no diamide analogous to (III) was isolated.

Summary

1. The behavior of 2-aminothiazole when digested, in alcoholic solution, with ethyl malonate and sodium ethylate, is quite different from that of 2-aminothiazoline, in that there results a mixture of the thiazolylmalonamic ester and the *sym*-dithiazolylmalonamide, but no thiazolopyrimidine, nor could the latter be obtained by cyclization of the thiazolylmalonamic acid.

Condensations. XVIII. The Acylation of the Anions of Certain Esters with Ethyl Carbonate

BY CHARLES R. HAUSER, B. ABRAMOVITCH AND JOE T. ADAMS

The acylation of organic esters having two α-hydrogens with alkyl carbonates in the presence of sodium or potassium alkoxides has been developed by Wallingford and co-workers[1] for the convenient production of malonic esters. Esters having only one α-hydrogen failed to be acylated, and even with ethyl *t*-butyl acetate the yield was not reported. Moreover, the method does not appear to be applicable to the preparation of malonic esters with two different ester groups, that is, "mixed" malonic esters.

Although these acylations fail in the presence of metal alkoxides, they may be effected by means of the stronger base, sodium triphenylmethyl, which converts esters largely into their anions.[2] The acylation of the anions of esters with only one α-hydrogen, for example, ethyl isobutyrate, is probably best effected with ethyl chlorocarbonate, diethyl α,α-dimethylmalonate being obtained in this manner in 75% yield.[2] The anion of ethyl isovalerate (which has two α-hydrogens) with ethyl chlorocarbonate, however, gives only a low yield of the malonic ester, forming mainly the diacylated ester.[2] It is shown in the present investigation that the anions of certain esters having two or three α-hydrogens may be acylated satisfactorily with ethyl carbonate to produce malonic esters. With this acylating reagent, the anion of ethyl *t*-butylacetate gives diethyl *t*-butylmalonate in 47% yield, while the anions of *t*-butyl acetate and *t*-butyl propionate give the "mixed" malonic esters, *t*-butyl ethylmalonate and *t*-butyl ethyl-α-methylmalonate in yields of 54 and 72%, respectively. These acylations may be represented as follows.

$$C_2H_5OCO_2C_2H_5 + [(CH_3)_3CCHCO_2C_2H_5]^- \longrightarrow (CH_3)_3CCH(CO_2C_2H_5)_2 + {}^-OC_2H_5$$

$$C_2H_5OCO_2C_2H_5 + [CH_2CO_2C(CH_3)_3]^- \longrightarrow C_2H_5O_2CCH_2CO_2C(CH_3)_3 + {}^-OC_2H_5$$

$$C_2H_5OCO_2C_2H_5 + [CH(CH_3)CO_2C(CH_3)_3]^- \longrightarrow C_2H_5O_2CCH(CH_3)CO_2C(CH_3)_3 + {}^-OC_2H_5$$

In each of these reactions equivalent amounts of the ester having α-hydrogen, sodium triphenylmethyl and ethyl carbonate were used. The malonic ester formed was probably converted into its anion by means of the ester anion first prepared, and the corresponding amount of the ester was regenerated. The amount of ethyl carbonate used was twice that theoretically required but the excess seemed desirable in order to minimize the self-condensation of the ester having α-hydrogen. The yields of malonic esters reported above are based on the sodium triphenylmethyl used.

This method should be applicable to the acylation with ethyl carbonate of other esters that undergo self-condensation relatively slowly[3] (compared to ethyl acetate) to produce malonic esters in which the ester groups are the same or different.

Experimental

Ethyl *t*-Butyl Malonate.—Sodium triphenylmethyl[2] (1700 cc., 0.730 mole) was prepared in a 2-liter "Pyrex" bottle. The stopper was removed and the bottle quickly fitted with an efficient mechanical stirrer, dropping funnel, and bent tube delivering a slow stream of dry nitrogen. *t*-Butyl acetate (94.5 cc., 84.7 g., 0.73 mole) was added rapidly to the vigorously stirred solution (the red color being discharged immediately) and after one minute 88 cc. (86.1 g., 0.73 mole) of ethyl carbonate (b. p. 125.5–126.0°) was added during seven minutes, the bottle being cooled if the ether began to boil. Stirring was continued for two hours longer. Glacial acetic acid (60 cc.) dissolved in 300 cc. of ice-water was then added and the mixture transferred to a 2.5-liter separatory funnel. The mercury, aqueous solution, and sludge were then separated, the latter being washed with ether. The combined ether solutions were extracted with 10% sodium carbonate solution, and dried over anhydrous sodium sulfate followed by Drierite, and the solvent distilled. Distillation of the residue from a 1-liter Claisen flask yielded 41.0 g. of recovered esters (b. p. 45° at 60 mm. to 70° at 35 mm.) and 69.5 g., of material (b. p. 70° at 35 mm. to 150° at 18 mm.) which on fractionation through a twelve-inch Vigreux column at 17 mm., yielded 27.0 g. of a fore-fraction (b. p. 40–93°) and 36.0 g. (54% yield based on the sodium triphenylmethyl) of ethyl *t*-butyl malonate, b. p. 93–95°.

Anal.[4] Calcd. for $C_9H_{16}O_4$: C, 57.4; H, 8.57. Found: C, 57.4; H, 8.56.

Ethyl *t*-Butyl-α-methylmalonate.—*t*-Butyl propionate (b. p. 118.0–118.5°) was prepared in 63% yield from *t*-butyl

alcohol and propionyl chloride in the presence of dimethylaniline, essentially according to the procedure of Norris and Rigby[5] for the preparation of *t*-butyl acetate.

Anal.[4] Calcd. for $C_7H_{14}O_2$: C, 64.6; H, 10.84. Found: C, 65.1; H, 11.20.

t-Butyl propionate (107 cc., 92 g., 0.708 mole) was added to sodium triphenylmethyl[2] (1700 cc., 0.708 mole), the color being discharged within thirty seconds, and after two minutes 86 cc. (83.5 g., 0.708 mole) of ethyl carbonate was added. Stirring was continued for one and one-half hours longer. Glacial acetic acid (60 cc.) was added and the mixture worked up. After distilling off the solvent the residue gave 55.2 g. of a mixture (b. p. 35–77° at 40 mm.) of *t*-butyl propionate and ethyl carbonate, and 66.2 g. of material (b. p. 77° at 40 mm. to 150° at 12 mm.). Redistillation of the latter fraction through a twelve-inch Vigreux column at 14 mm., yielded 13.0 g. of a fore-fraction (b. p. 49–94°) and 48.7 g. (72% yield based on the sodium triphenylmethyl) of ethyl *t*-butyl-α-methylmalonate (b. p. 94–95°).

Anal.[4] Calcd. for $C_{10}H_{18}O_4$: C, 59.4; H, 8.97. Found: C, 60.0; H, 9.10.

Diethyl *t*-Butylmalonate.—Ethyl *t*-butyl acetate (38.2 g., 0.266 mole) prepared by the method of Homeyer, Whitmore and Wallingford,[6] was added with shaking to an ether solution of 0.266 mole of sodium triphenylmethyl and, after standing for ten minutes, 31.4 g. (0.266 mole) of ethyl carbonate was added. After twenty-four hours the reaction mixture was acidified with dilute acetic acid, the ether solution dried and the solvent distilled. The residue yielded 30 g. of recovered esters (b. p. 67–78° at 100 mm.) and 13.3 g. (47%) of diethyl *t*-butylmalonate (b. p. 102–104° at 11 mm.).

Anal.[7] Calcd. for $C_{11}H_{20}O_4$: C, 61.10; H, 9.32. Found: C, 61.24; H, 9.20.

(5) Norris and Rigby, THIS JOURNAL, **54**, 2097 (1932).

Summary

The anions of ethyl *t*-butyl acetate, *t*-butyl acetate and *t*-butyl propionate (prepared by means of sodium triphenylmethyl) have been acylated with ethyl carbonate to form, respectively, diethyl *t*-butylmalonate and the "mixed" malonic esters, ethyl *t*-butylmalonate and ethyl *t*-butyl-α-methylmalonate.

A Study of the Products Obtained by the Reducing Action of Metals upon Salts in Liquid Ammonia Solution. VIII. The Reduction of Complex Cyanides

BY JOHN W. EASTES AND WAYLAND M. BURGESS[1]

Introduction

The unusual result obtained by the action of alkali metals on the complex cyanides of nickel in liquid ammonia solution,[2] as contrasted to that obtained through the use of simple nickel salts,[3] prompted the examination of the behavior of the complex cyanides of other metals, some of whose simple salts are also known to give the free metal when reduced by alkali metals in liquid ammonia solution. For this purpose the complex cyanides of cadmium, copper, silver and zinc were chosen. Also the action of calcium on potassium cyanonickelate was investigated. The reactions were carried out as described in previous articles.[2]

Preparation of Complex Cyanides

The complex potassium cyanides of silver, copper and zinc were prepared in the way previously described for the nickel compound.[2] All were markedly more soluble in hot than cold water. Inasmuch as cadmium cyanide is soluble in water, the complex cyanide was prepared by crystallization from a solution containing the stoichiometric quantities of cadmium sulfate and potassium cyanide. The product was recrystallized until free of sulfate ion and then dried at 110°.

All of these complex cyanides were very soluble in liquid ammonia, giving clear colorless solutions.

Potassium Cyanocadmiumate, $K_2Cd(CN)_4$, and Potassium.—Pieces of potassium, when added to a liquid ammonia solution of potassium cyanocadmiumate (in excess), slowly react in such a way that each piece is replaced by a clump of metallic cadmium. No hydrogen gas is given off during the reaction. The black metallic cadmium is not reactive with water, but is highly pyrophoric.

Potassium Cyanocopperate, $K_3Cu(CN)_4$, and Potassium.—Potassium, when added to a solution of potassium cyanocopperate in liquid ammonia, reacts to give a finely divided black precipitate of pyrophoric copper. At the instant the solution turns blue, due to reaction of all of the complex cyanide and solution of the excess potassium, a beautiful copper mirror forms on the surface of the reaction tube in contact with the solution.

Potassium Cyanosilverate, $KAg(CN)_2$, and Potassium.—When pieces of potassium are added to a liquid ammonia

(1) This article is based upon the thesis presented to the Faculty of the Graduate School, University of Cincinnati, by John W. Eastes in partial fulfillment of the requirements for the degree of Doctor of Philosophy, 1936.

(2) Eastes and Burgess, THIS JOURNAL, **64**, 1187 (1942).

(3) Burgess and Eastes, *ibid.*, **63**, 2674 (1941).

solution of potassium cyanosilverate, each piece reacts slowly to be replaced by a clump of black pyrophoric silver. Only a trace of hydrogen gas is given off before the solution becomes blue with excess potassium after reaction of all the complex cyanide. Thereafter hydrogen is very, very slowly given off until the blue color of the dissolved potassium disappears. Thus the clumps of silver are very poor catalysts for the formation of potassium amide and hydrogen. The silver was not reactive with water.

Potassium Cyanozincate, $K_2Zn(CN_4)$, and Sodium.—Sodium reacts rapidly with a liquid ammonia solution of potassium cyanozincate to give a finely divided precipitate of metallic zinc. This precipitate is not reactive with water nor is it pyrophoric. No hydrogen gas is given off during its formation nor after the solution has become blue with excess sodium. Thus the precipitate is not a catalyst for the amide formation. At the instant the solution becomes blue with excess sodium, a beautiful silvery mirror is formed on the walls of the reaction tube exposed to the solution. This mirror was not reactive with water.

The formation of zinc instead of $NaZn_4$ is comparable to the case wherein Burgess and Rose[4] observed the formation of metallic zinc by reaction of sodium with a 20% excess of zinc cyanide.

Potassium Cyanonickelate, $K_2Ni(CN)_4$, and Calcium.—Calcium, when added to a solution of potassium cyanonickelate in liquid ammonia, gives the same type of reaction as does sodium and potassium,[2] but with the difference that hydrogen gas is given off throughout the course of the reaction. The insoluble reaction products are soluble in water to give the characteristic red solutions.

(4) Burgess and Rose, THIS JOURNAL, **51**, 2127 (1929).

Summary

Unlike that of nickel, the complex cyanides of cadmium, copper, silver and zinc are reduced to the free metal by alkali metals in liquid ammonia solutions. Under the conditions used all of the precipitated metals but zinc were pyrophoric.

Calcium, in liquid ammonia solution, reduces alkali metal cyanonickelates to give the same type of products as obtained by reduction with alkali metals

The Viscosity of Dilute Solutions of Long-Chain Molecules. IV. Dependence on Concentration[1]

BY MAURICE L. HUGGINS

In the first[2] and second[3] papers of this series an equation was derived for the specific viscosity (η_{sp}) of dilute solutions of randomly-kinked chain compounds. At the limit of infinite dilution this equation reduces to

$$\left(\frac{\eta_{sp}}{c}\right)_{c=0} = \frac{\eta-\eta_0}{\eta_0} = K_0 + K_n n = K_0 + K_M M \quad (1)$$

where η and η_0 are the viscosities of the solution and of the pure solvent, c is the concentration in submoles per liter (or any units proportional to these), n is the number of submolecules per molecule, M is the molecular weight, and K_0, K_n and K_M are constants.

In deriving this expression, Stokes' law

$$\text{Force} = 6\pi\eta a u \quad (2)$$

was assumed in computing the frictional force acting on each submolecule as a result of its velocity (u) relative to the liquid immediately surrounding it. The insertion of η_0 for η in (2) leads to the limiting Equation (1) just given. If, instead, one inserts into (2) the value of the viscosity of the *solution*

$$\eta = \eta_0(1 + \eta_{sp}) \quad (3)$$

the expression

$$\frac{\eta_{sp}}{c} = \left(\frac{\eta_{sp}}{c}\right)_{c=0}(1 + \eta_{sp}) \quad (4)$$

is obtained.[4]

For small concentrations, (4) is equivalent to

$$\frac{\eta_{sp}}{c} = \left(\frac{\eta_{sp}}{c}\right)_{c=0} + \left(\frac{\eta_{sp}}{c}\right)^2_{c=0} c \quad (5)$$

At first sight, it might seem that this should give the initial variation of η_{sp}/c with concentration. The application of Equation (2) to the solutions under discussion is, however, very questionable. Strictly speaking, this equation would be applicable only if each submolecule were isolated from all others, so that the liquid streaming past one

(1) Presented before the Division of Colloid Chemistry at the Buffalo Meeting of the American Chemical Society, Sept. 9, 1942. Some of the material contained herein was previously presented at the Symposium on "Viscosity, Molecular Size and Molecular Shape," held under the sponsorship of the Society of Rheology at the Polytechnic Institute of Brooklyn on Feb. 20, 1942.

(2) M. L. Huggins, *J. Phys. Chem.*, **42**, 911 (1938).

(3) M. L. Huggins, *ibid.*, **43**, 439 (1939).

(4) This is equivalent to Eq. (25) of ref. 2 and, except for the Einstein term in the numerator, to Eqs. (123) and (126) of ref. 3. If Einstein's derivation (which also depends on (2)) is similarly modified, to make it applicable to solutions of finite concentration, by the use of η instead of η_0 for the frictional coefficient in Stokes' law, Eqs. (123) and (126) of ref. 3 also become equivalent (as regards the concentration dependence) to (4) above.

would not be affected by the disturbances of the streaming around other submolecules. Moreover, the use of this equation involves the assumptions that the submolecules are spherical and are large relative to the solvent molecules, also that there is no sliding friction, as the solvent molecules move around the submolecules. It certainly does not seem proper, in calculating the dissipation of energy when a *solute* submolecule interacts with the surrounding (chiefly *solvent*) molecules, to use a value of η which is related primarily to the mutual interaction between *solvent* molecules.

It seems reasonable to assume that these objections to the use of Equation (2) can all be met, approximately, by the introduction in it of another factor, k', having a magnitude characteristic of the system under consideration—depending on the sizes, shapes and cohesional properties of both solvent molecules and solute submolecules, but not on the number of submolecules (*i. e.*, the length) of the solute molecule chain. In place of (2), we thus put

$$\text{Force} = 6\pi k'\eta au \qquad (6)$$

This leads to

$$\frac{\eta_{sp}}{c} = \left(\frac{\eta_{sp}}{c}\right)_{c=0}(1 + k'\eta_{sp}) \qquad (7)$$

which is identical with an empirical equation recently published by Schulz and Blaschke[5] and tested by them on solutions in chloroform of methyl methacrylate polymers. The same value of k' (0.30) was found satisfactory for unfractionated polymers of various average sizes and for their fractions (see Fig. 1).

Equation (7) can readily be put into the form

$$\frac{\eta_{sp}}{c} = \left(\frac{\eta_{sp}}{c}\right)_{c=0} + k'\left(\frac{\eta_{sp}}{c}\right)^2_{c=0} c + \text{terms in higher powers of } c \qquad (8)$$

the higher terms being negligible for dilute solutions. This form is especially well suited for comparison with the many other equations which have been proposed to represent the variation with concentration of the viscosity of solutions. Nearly all of them can be expanded into an expression of this sort; they differ only with respect to the value and interpretation of k' and with respect to the higher terms. Although we shall not here enter into an exhaustive comparison of these various equations, a few will be mentioned.

Martin,[6] considering data for solutions of a variety of high-molecular weight solutes in various solvents, has concluded that the relation

$$\frac{\eta_{sp}}{c} = \left(\frac{\eta_{sp}}{c}\right)_{c=0} \exp\left[k_M \left(\frac{\eta_{sp}}{c}\right)_{c=0} c\right] \qquad (9)$$

accurately represents the viscosity–concentration relationships up to concentrations of 5%, the constant k_M varying with solvent and with solute, but being constant for members of a given polyhomologous series dissolved in a given solvent. Neglecting the higher terms in the expansion of the exponential, this equation reduces to Equation (8), with k' equal to 2.3 k_M, thus confirming the theoretical argument just outlined.

The equations

$$\frac{\eta}{\eta_0} = (1 + k_B c)^{k'_B} \qquad (10)$$

$$\eta_{sp} = \frac{k_F k'_F c}{1 - k'_F c} \qquad (11)$$

and

$$\eta_{sp} = k_J c e^{k'_J c} \qquad (12)$$

have been proposed by Baker,[7] by Fikentscher

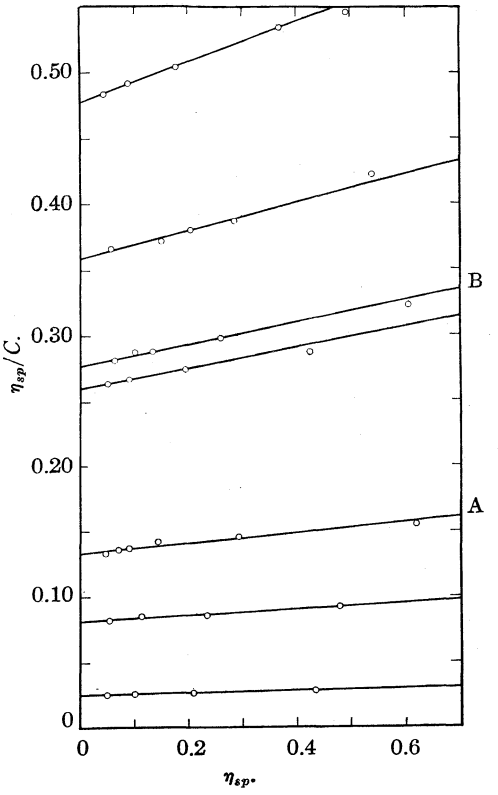

Fig. 1.—Illustrating the agreement with Eq. (4) for solutions in chloroform of methyl methacrylate polymers: concentrations in g./l.; data by Schulz and Blaschke.[5] The samples giving the curves labelled A and B were obtained by fractionation; the other samples were unfractionated.

(5) G. W. Schulz and F. Blaschke, *J. prakt. Chem.*, **158**, 130 (1941).

(6) A. F. Martin, paper presented at the Memphis Meeting of the American Chemical Society, April, 1942.

(7) F. Baker, *J. Chem. Soc.*, **103**, 1653 (1913).

and Mark,[8] and by de Jong, Kruyt and Lens,[9] respectively. Here k_B, k_B', k_F, etc., are empirically determined constants. These equations all reduce to Equation (8), with k' equal to $^1/_2 - {}^1/_2 k'_B$, $1/k_F$, and k'_J/k_J, respectively.

Arrhenius,[10] Hess and Philippoff[11] and Bredée and de Booys[12] have proposed the following equations, respectively

$$\ln\left(\frac{\eta}{\eta_0}\right) = k_A c \qquad (13)$$

$$\frac{\eta}{\eta_0} = \left(1 + \frac{k_H c}{8}\right)^8 \qquad (14)$$

$$\frac{\eta}{\eta^0} = \left(1 + \frac{5k_{BB}c}{12}\right)^6 \qquad (15)$$

The last two are special cases of Baker's equation, (10). All three reduce to Equation (8), with k' equal to $^1/_2$, $^7/_{16}$ and $^5/_{12}$, respectively,—constants independent of the solvent–solute system. As would be expected, these inflexible equations do not give as good general agreement as do (7) and (9)–(12), which contain an additional adjustable constant.

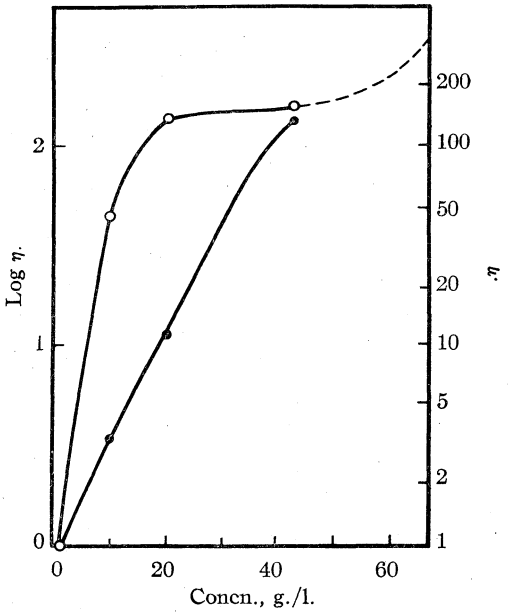

Fig. 2.—Dependence of viscosity on concentration, for polyisobutylene (polybutene) solutions in *n*-butyl ether: O, 20°; ●, 37.78°; data by Evans and Young.[14]

It should be noted that our comparison of these various equations for the concentration dependence of viscosity has concerned only the initial slope of the η_{sp}/c *vs.* c curve and so applies only to quite dilute solutions. We shall not here enter into a discussion of the theoretical or empirical treatment of this dependence at higher concentrations, except to make one remark:

If the attractions between *like* molecules in the solution are considerably more potent than those between *unlike* molecules—as indicated[13] by a large value of μ_1 and by a separation into two phases at sufficiently high concentrations—the solute molecules tend to form aggregates at concentrations somewhat below that at which the second phase becomes evident. This results in a viscosity–concentration curve with a slope which decreases (or even becomes negative) at the higher concentrations. Solutions of polyisobutylene in *n*-butyl ether at 20°, for example, show this effect[14] (see Fig. 2). As would be expected, the anomalous behavior disappears as the temperature is raised; μ_1 is decreased and the aggregates are dissociated. The viscosity behavior of solutions of polyisobutylene in benzene is likewise anomalous,[15] apparently for the same reason.

Summary

1. It has been shown that a simple, reasonable modification of the author's previous theoretical treatment of the viscosity of dilute solutions of long-chain molecules leads to the equation

$$\frac{\eta_{sp}}{c} = \left(\frac{\eta_{sp}}{c}\right)_{c=0}(1 + k'\eta_{sp})$$

for the initial concentration dependence of the viscosity. This is identical with an equation arrived at empirically by Schulz and Blaschke.

2. The constant k' is characteristic of a given solute-solvent system; it is the same for solutions, in a given solvent, of different members of a polymer-homologous series, however.

3. At low concentrations (such as assumed in the theoretical derivation), this relationship is equivalent to

$$\frac{\eta_{sp}}{c} = \left(\frac{\eta_{sp}}{c}\right)_{c=0} + k'\left(\frac{\eta_{sp}}{c}\right)^2_{c=0} c$$

Equations proposed by Baker, by Fikentscher and Mark, by de Jong, Kruyt and Lens, and by Martin all reduce to this same limiting equation, with k' different for different systems. Equations proposed by Arrhenius, by Hess and Philippoff, and by Bredée and de Booys likewise reduce to this form, but with k' having the same value for all systems.

The Halogenation of Certain Esters in the Biphenyl Series. II. The Chlorination of 4-Phenylphenyl Benzoate and 4-Phenylphenyl Benzenesulfonate[1]

BY CORA MAY SEGURA SAVOY AND JOHN LEO ABERNETHY

Prior to the chlorination of 4-phenylphenyl acetate, recently reported,[2] work was begun on the chlorination of 4-phenylphenyl benzoate and 4-phenylphenyl benzenesulfonate in an endeavor to find a more direct route to 4-(4-chlorophenyl)-phenol than had been used previously.[3] In view of the unanticipated mode of entry of chlorine into the biphenyl nucleus in the case of 4-phenylphenyl acetate and the ease of hydrolysis of the resultant chlorinated ester to 4-(4-chlorophenyl)-phenol, it seemed of value to continue the present problem. The present paper shows that chlorination of 4-phenylphenyl benzoate and 4-phenylphenyl benzenesulfonate results in substitution in the same position of the biphenyl nucleus as does 4-phenylphenyl acetate.

Chlorination of 4-phenylphenyl benzoate in the presence of iodine catalyst, using carbon tetrachloride as the solvent, gave rise to 4-(4-chlorophenyl)-phenyl benzoate. That chlorine had entered the 4′-position of the biphenyl nucleus was proved by hydrolysis of the chlorinated ester to the known 4-(4-chlorophenyl)-phenol and benzoic acid. Benzoylation of 4-(4-chlorophenyl)-phenol, prepared by a different method, yielded the same chlorinated ester.

When 4-phenylphenyl benzenesulfonate was chlorinated, using similar conditions, 4-(4-chlorophenyl)-phenyl benzenesulfonate resulted. The position of entry of chlorine was proved by hydrolysis.

Although 2-chloro-4-phenylphenyl benzoate and 2-chloro-4-phenylphenyl benzenesulfonate were sought for in the above chlorination processes, neither was found.

During the progress of this investigation it was found desirable to prepare the benzenesulfonates of the known chlorophenylphenols. Accordingly, 4-(4-chlorophenyl)-phenyl benzenesulfonate, 2-chloro-4-phenylphenyl benzenesulfonate, 2,6-dichloro-4-phenylphenyl benzenesulfonate and 2,6-dichloro-4-(4-chlorophenyl)-phenyl benzenesulfonate were synthesized by the interaction of benzenesulfonyl chloride with the corresponding phenols.

A comparison of the yields of 4-(4-chlorophenyl)-phenol by chlorination of the various esters of 4-phenylphenol shows that the route through the acetate gives the best yield. The extreme ease of hydrolysis of the acetate is indeed worthy of mention.

Acknowledgment.—The writers are indebted to Professor H. R. Henze of the University of Texas and Professor E. G. Feusse of Southwestern Louisiana Institute for their valuable assistance during the progress of this investigation, and to the Research Institute of the University of Texas for a grant permitting the continuance of this work.

Experimental

4-(4-Chlorophenyl)-phenyl Benzoate.—A trace of iodine was added to 13.7 g. of 4-phenylphenyl benzoate suspended in 125 cc. of carbon tetrachloride. A solution of 3.9 g. (10% excess) of chlorine in 75 cc. of carbon tetrachloride was introduced dropwise over a period of two hours. When the reaction mixture had been allowed to stand overnight, the white solid was filtered, washed with cold ethanol, and twice digested with ethanol. The purified 4-(4-chlorophenyl)-phenyl benzoate, which melted at 182° weighed 8.5 g. (55% yield). An additional 0.5 g. was obtained upon distillation of the filtrate from the reaction mixture.

This same ester was prepared by benzoylation of 4-(4-chlorophenyl)-phenol. A mixed melting point caused no depression.

Anal. Calcd. for $C_{19}H_{13}O_2Cl$: Cl, 11.49. Found: Cl, 11.52.

Hydrolysis of 4-(4-Chlorophenyl)-phenyl Benzoate.—A mixture of 5 g. of 4-(4-chlorophenyl)-phenyl benzoate and 10 g. of potassium hydroxide in 100 cc. of 50% ethanol was refluxed for three hours, cooled and poured into 100 cc. of water. After the ethanol had been removed by distillation, the alkaline solution was extracted with ether and the ether extract dried with anhydrous sodium sulfate. Evaporation of the ether and digestion of the remaining solid with ethanol yielded 0.4 g. of unhydrolyzed 4-(4-chlorophenyl)-phenyl benzoate.

Saturation of the aqueous solution with carbon dioxide resulted in the formation of a white precipitate which was extracted with ether and dried over anhydrous sodium sulfate. When the solvent was evaporated, 3.0 g. of solid resulted. Purification of this product by crystallization from chloroform and petroleum ether (b. p. 35–55°) gave rise to a white solid which melted at 145.5–146°, and did not

depress the melting point of 4-(4-chlorophenyl)-phenol, prepared by the hydrolysis of 4-(4-chlorophenyl)-phenyl acetate. The yield was 2.2 g. (67%).

The aqueous solution previously saturated with carbon dioxide was acidified with hydrochloric acid and again extracted with ether. After drying with anhydrous sodium sulfate and removing the ether, 1.4 g. of benzoic acid was obtained.

Benzoylation of 4-(4-chlorophenyl)-phenol gave rise to 4-(4-chlorophenyl)-phenyl benzoate, which did not depress the melting point of the ester prepared by the chlorination of 4-phenylphenyl benzoate.

4-(4-Chlorophenyl)-phenyl Benzenesulfonate.—A solution of 5 g. (10% excess) of chlorine in 100 cc. of carbon tetrachloride was introduced, drop by drop, into a solution of 20 g. of 4-phenylphenyl benzenesulfonate,[4] a trace of iodine, and 100 cc. of carbon tetrachloride. After the reaction mixture had been allowed to stand overnight, the solvent was removed by distillation under reduced pressure. The viscous, amber colored liquid which resulted was dried with anhydrous sodium sulfate and distilled at 8 mm. pressure. The portion which distilled between 220 and 300°, when purified with methanol, yielded 15.1 g. of crystals. After five recrystallizations from methanol, the product, m. p. 74–75°, weighed 4.7 g. (21% yield).

Anal. Calcd. for $C_{18}H_{13}O_3ClS$: S, 9.303. Found: S, 9.309.

Reaction of benzenesulfonyl chloride with 4-(4-chlorophenyl)-phenol in pyridine yielded this same ester.

Hydrolysis of 4-(4-Chlorophenyl)-phenyl Benzenesulfonate.—A mixture of 3 g. of 4-(4-chlorophenyl)-phenyl benzenesulfonate and 10 g. of potassium hydroxide in 100 cc. of 50% ethanol was refluxed for ten hours, cooled and poured into 100 cc. of water. After the ethanol had been removed by distillation, the alkaline solution was extracted with ether. The ether extract was dried with anhydrous sodium sulfate and the solvent was removed by distillation under reduced pressure. No residue was left after all the ether had been removed. The aqueous solution was acidified with hydrochloric acid and extracted with ether. After drying with anhydrous sodium sulfate and removal of the ether, 1.6 g. of light yellow solid was obtained. Three recrystallizations from chloroform and petroleum ether reduced the yield to 0.7 g. (39% yield) of a pure white solid, m. p. 145–146°. A mixed melting point with known 4-(4-chlorohenyl)-phenol caused no depression.

(4) Hazlet, THIS JOURNAL, **59**, 1087 (1937).

Benzenesulfonylation of Certain of the Chlorinated Phenylphenols.—A mixture of 2 g. of the phenol, 20 cc. of 10% aqueous sodium hydroxide, and 2 cc. of benzenesulfonyl chloride was refluxed for ten minutes, poured into 100 cc. of water and allowed to stand for one hour. Filtration of the product and recrystallization from ethanol yielded the ester. The results are recorded in Table I.

TABLE I

BENZENESULFONATES FROM CERTAIN CHLORINATED PHENYLPHENOLS

Benzenesulfonate	M. p., °C.	Sulfur, % Calcd.	Found
4-(4-Chlorophenyl)-phenyl	74– 75	9.303	9.309
2-Chloro-4-phenylphenyl	59– 60	9.303	9.287
2,6-Dichloro-4-phenyl-phenyl	128–129	8.457	8.372
2,6-Dichloro-4-(4-chloro-phenyl)-phenyl	125–126	7.753	7.738

Summary

It has been shown that chlorination of 4-phenylphenyl benzoate and 4-phenylphenyl benzenesulfonate introduces chlorine in the 4′-position of the biphenyl nucleus. Hydrolysis of the resultant chlorinated esters gave rise to 4-(4-chlorophenyl)-phenol.

The benzenesulfonates of 2-chloro-4-phenylphenol, 2,6-dichloro-4-phenylphenol and 2,6-dichloro-4-(4-chlorophenyl)-phenol were prepared for the first time.

AUSTIN, TEXAS RECEIVED AUGUST 24, 1942

NOTES

The Acylation of Acetonitrile with Ethyl *n*-Butyrate and the Alcoholysis of the Resulting Ketonitrile to Ethyl *n*-Butyrylacetate

BY B. ABRAMOVITCH AND CHARLES R. HAUSER

McElvain and co-workers[1] have shown that, in the presence of sodium ethoxide, acetonitrile (and also certain other nitriles) may be acylated satisfactorily with ethyl benzoate or ethyl isobutyrate to form β-ketonitriles, which may be alcoholyzed to form β-keto esters. Apparently, the acylation of acetonitrile with esters capable of undergoing self-condensation in the presence of sodium ethoxide, for example, ethyl *n*-butyrate, was not attempted. The acylation of the relatively reactive nitrile, phenylacetonitrile, with ethyl acetate, however, may be effected satisfactorily.[2]

(1) (a) Dorsch and McElvain, THIS JOURNAL, **54**, 2960 (1932); (b) Cox, Kroeker and McElvain, *ibid.*, **56**, 1172 (1934).

(2) "Organic Syntheses," 1925, Vol XVIII, p. 36.

In the present investigation it is shown that acetonitrile may be acylated with ethyl *n*-butyrate by first converting the nitrile into its anion by means of sodium triphenylmethyl[3] and then treating the anion with the ester; in this manner *n*-butyryl acetonitrile was obtained in 52% yield (based on the sodium triphenylmethyl). Alcoholysis of the β-ketonitrile gave a 64% yield of ethyl *n*-butyrylacetate, the over-all yield being 33%. The reactions may be represented as

$$CH_3CN + (C_6H_5)_3C^- \longrightarrow (CH_2CN)^- + (C_6H_5)_3CH$$

$$CH_3(CH_2)_2CO_2C_2H_5 + (CH_2CN)^- \longrightarrow CH_3(CH_2)_2COCH_2CN + {}^-OC_2H_5$$

$$CH_3(CH_2)_2COCH_2CN + C_2H_5OH \xrightarrow{HCl} CH_3(CH_2)_2COCH_2CO_2C_2H_5$$

To a stirred solution (1300 cc.) of 0.19 mole of sodium triphenylmethyl[3] at 0° was added 7.8 g. (0.19 mole) of acetonitrile (b. p. 81.5–82.0°) dissolved in 25 cc. of dry ether. The red color of the sodium triphenylmethyl was discharged immediately yielding a light orange solution with a white precipitate. To this stirred mixture was added during five minutes 22 g. (0.19 mole) of cold ethyl *n*-butyrate (b. p. 121.0–121.5°) dissolved in 25 cc. of dry ether. The mixture was stirred for five minutes longer, removed from the ice-bath, and shaken vigorously for two minutes. Ice water (500 cc.) was then added with shaking to the mixture, the alkaline layer separated and the ether layer washed with sodium hydroxide solution followed by water. From the dried ether solution were recovered 2.5 g. of acetonitrile and 12.0 g. of ethyl *n*-butyrate. Acidification (with cold 10% sulfuric acid) of the combined alkaline solution and washings yielded an oil. The mixture was extracted three times with ether and the combined ether solutions washed with 10% sodium bicarbonate solution, dried, and the solvent distilled. On distilling the residue *in vacuo* there was obtained 5.5 g. (52% based on the sodium triphenylmethyl) of *n*-butyryl acetonitrile boiling at 104–105° at 11 mm.

Anal.[4] Calcd. for C_6H_9ON: C, 64.8; H, 8.17. Found: C, 65.3; H, 8.21.

By allowing the reaction mixture to stand at room temperature (25°) for two days, the same yield (52%) of product was obtained, there being also formed more alkali-soluble by-product.

Treatment of the *n*-butyryl acetonitrile with dry halogen chloride in absolute alcohol[1a] gave a 64% yield of ethyl *n*-butyrylacetate (b. p. 94–95° at 15 mm.; copper compound, m. p. 124–125°).[5]

Catalytic Hydrogenation of Cystine

BY KEVIN E. KAVANAGH

The applicability and high efficiency of the recently developed palladium and platinum synthetic high polymer catalysts were described in previous papers.[1,2,3] In an effort to determine whether these polymers are able to protect against the well-known poisoning of noble metals by sulfur, an attempt was made to hydrogenate cystine using a PVA–Pd catalyst. Bergmann and Michalis[4] reduced cystine to cysteine using palladium black: for the almost complete reduction of 4.8 g., 2 g. of palladium black and six hours of shaking were required. Applying the Pd–PVA catalyst, partial reduction of cystine was slowly obtained using only 10 mg. of Pd. Therefore, the amount of Pd was increased to 100 mg., whereupon almost complete hydrogenation resulted.

Procedure

A catalyst containing 500 mg. of PVA, 100 mg. of Pd and 50 cc. of water was prepared. Two grams of cystine dissolved in 50 cc. of 2 *N* hydrochloric acid was introduced into the vessel and the whole shaken for forty-five hours at room temperature and ordinary pressure. At the end of this time 176 cc. of a theoretical 199 cc. of hydrogen had been absorbed. Thereupon, the still colloidal catalyst was made strongly acid with 5 cc. of 12 *N* hydrochloric acid and then flocculated by the addition of excess alcohol. The cysteine hydrochloride hydrate was isolated and air-dried. The melting point of the hydrochloride, after the molecule of water of crystallization had been removed by drying in a vacuum desiccator, was 184° decomp. The absence of cystine was ascertained by the iodometric titration of the cysteine to cystine.[5,6] 0.4389 g. of cysteine hydrochloric acid hydrate required 25.05 cc. of 0.1004 *N* iodine. Calcd. 24.91 I_2.

Anal. Calcd. for the cysteine hydrochloric acid hydrate: N, 7.97; H_2O, 10.25. Found: N, 7.79; H_2O, 10.49.

The repeatedly emphasized[4,7] sensitivity of Pd catalysts to sulfur-containing proteins was smoothly overcome by using a Pd–PVA catalyst.

Acknowledgment.—This investigation was partly supported by grants of the American Philosophical Society and the Bache Fund of the National Academy of Sciences.

The Reaction between Thioamides and Primary Amines

BY MAURICE J. SCHLATTER[1]

The older literature[2] implies that the reaction between thioamides and primary amines proceeds solely with elimination of hydrogen sulfide and resultant formation of amidine. The present studies show that under certain conditions ammonia may be split out between the reacting molecules giving an N-substituted thioamide.[3] The interaction may also result in the simultaneous elimination[4] of hydrogen sulfide and ammonia.

Experimental

Thioacetamide and *n*-Butylamine.—Five grams of thioacetamide (0.077 mole) was mixed with 16.8 g. of *n*-butylamine (0.23 mole) and heated under reflux until the initially brisk gas evolution had almost ceased (about three hours). Fractionation of the product *in vacuo* gave 5.3 g. of light yellow oil,[5] the major portion of which boiled at 131.5° (5 mm.) and gave analytical figures for N-butylthioacetamide.

Anal. Calcd. for $C_6H_{13}NS$: C, 54.91; H, 9.99; N, 10.67. Found: C, 54.91; H, 10.06; N, 10.73.

Thioacetamide and Benzylamine.—Benzylamine (2.14 g. = 0.020 mole) was mixed with thioacetamide (1.43 g. = 0.022 mole) and heated in a bath at 80° for one and one-quarter hours. The initially vigorous gas evolution almost stopped after forty-five minutes. On fractionation, the reaction mixture distilled almost completely at 158–162° at 2 mm. The distillate (2.28 g.) solidified on cooling and on recrystallization from anhydrous ether gave colorless needles, insoluble in water, soluble in alcohol, m. p. 65.1–65.3°[6] (cor.).

Anal. Calcd. for $C_9H_{11}NS$: C, 65.41; H, 6.71; N, 8.48. Found: C, 65.60; H, 6.68; N, 8.27.

Thioacetamide and Ethanolamine.—Ethanolamine (15.3 g. = 0.25 mole) and thioacetamide (18.0 g. = 0.276 mole) were mixed in a flask equipped with stirrer and immersed in a bath. On heating at 60–75° an active gas evolution took place which lasted about one-half hour. The stirrer was then replaced by a distilling head and the temperature of the bath raised slowly to 215° while volatile material was removed *in vacuo* (30 mm.). The residue (17.9 g.) solidified on cooling and was recrystallized from absolute alcohol; colorless rectangular prisms, m. p. 101.0–101.5° (cor.). The analysis indicates that two molecules of each of the reactants have combined with loss of two molecules of ammonia and one of hydrogen sulfide; a possible formula is $[HOCH_2CH_2N{=}C(CH_3)-]_2S$.

Anal. Calcd. for $C_8H_{16}N_2O_2S$: C, 47.03; H, 7.90; N, 13.71; S, 15.69. Found: C, 47.09; H, 7.79; N, 13.64; S, 15.82.

A derivative crystallized from the reaction mixture when equal volumes of saturated solutions of the substance and of picric acid in ethyl acetate were mixed, heated to boiling and then cooled to 0°. The crystals were washed with ether and dried, m. p. 95.0–95.5° (cor.).

Preparation of *d*-Fructose-1,6-diphosphate by Means of Baker's Yeasts

BY C. NEUBERG AND H. LUSTIG

The preparation of the phosphoric esters of carbohydrates has not been achieved up to now with fresh baker's yeast, as phosphorylation with top yeast was only possible by addition of co-ferment to acetone yeast or alcohol–ether dried yeast (phosphorylation to 100%), or, with the same type of yeast, if dried before in the usual manner (phosphorylation to 20%).[1] By means of the procedure described below, *d*-fructose-1,6-diphosphate is readily obtained by the use of commercial bakers' yeasts without the necessity of treating brewers' yeast by washing, pressing, etc. Nearly equally satisfactory results have been obtained with various brands of fresh bakers' yeast (Atlantic, Federal, Blue Ribbon and National Grain), but not with fresh Fleischmann's yeast.

Procedure

To a solution of 200 g. of sucrose, 42 g. of monosodium phosphate ($NaH_2PO_4 \cdot 2H_2O$) and 11 g. of sodium bicarbonate in 1000 cc. of tap water contained in a 5-l. bottle add 450 g. of fresh bakers' yeast (Atlantic) and 150 cc. of ether.[2] Shake the mixture until homogeneous, stopper the bottle in a manner which will allow the escape of gases, and place in an incubator at 37° until phosphorylation is complete[3] (four and one half hours). The completeness of this process may be judged by adding 3 cc. of 2.5% ammonia and 1 cc. of 10% ammonium chloride to 2 cc. of the filtered fermentation mixture and then adding magnesia mixture. An immediate precipitation does not occur when phosphorylation is complete.

When phosphorylation is complete, add a few cc. of a

(1) C. Neuberg and A. Gottschalk, *Biochem. Z.*, **154**, 492 (1924).

(2) Carbon tetrachloride is an equally satisfactory plasmolytic agent, also for the phosphorylation with brewers' yeast, as our experiments with yeasts obtained from the Piel and Schaefer breweries (bottom yeasts) demonstrate.

(3) The time required for complete phosphorylation varies with different brands of yeast and with the temperature. Similar experiments made with Atlantic and Federal yeasts at room temperature (20–24°) required twenty and seventy-two hours, respectively.

10% solution of octyl alcohol in ethanol to the fermentation mixture and immerse the container in an actively boiling water-bath until the proteins are coagulated. Separate the coagulum by centrifugation or filtration (in a refrigerator), neutralize the clear filtrate to phenolphthalein by the addition of 4 *N* sodium hydroxide and immediately precipitate by the addition of a solution of 55 g. of calcium chloride in 100 cc. of water; *i. e.*, slightly more than one mol of this reagent is required for each mol of monosodium phosphate present in the initial mixture. Complete the precipitation by heating at a boiling water-bath for a short time, and filter the warm mixture with suction. Wash the precipitated calcium *d*-fructose-1,6-diphosphate with warm water; yield, 22 g.

An alternative procedure is the following: When phosphorylation is complete add to the fermentation mixture a solution of 40 g. of picric acid in 200 cc. of hot ethanol. Allow the mixture to stand in a refrigerator for two hours and filter. Add 4 *N* sodium hydroxide to the filtrate until neutral to phenolphthalein, then add calcium chloride as previously described. The precipitated calcium salt contains some picrate but this is removed by washing with hot water and subsequently with alcohol. An experiment conducted in this fashion with the quantities of material stated above yielded 24 g. of crude calcium *d*-fructose-1,6-diphosphate.

To purify the crude calcium salt obtained by either of these procedures, dissolve the moist crude product in 250 cc. of 2 *N* acetic acid, add 125 cc. of water, filter if necessary, and to the clear solution add 2 *N* sodium hydroxide until neutral to phenolphthalein. Heat the resulting mixture in a boiling water-bath for a short time, filter and wash the precipitated salt with warm water; yield about 80% of the crude product.

In analogous manner the barium salt can be prepared, but in this case the use of picric acid for the deproteinization is not advisable because of the difficult solubility of barium picrate.

As mentioned in the introduction, fresh Fleischmann's yeast is not satisfactory for the preparation of *d*-fructose-1,6-diphosphate in the manner described. If, however, this brand of yeast is well dried at room temperature in the usual manner, it may be employed, for with such dried yeast phosphorylation takes place rapidly. When a mixture of 30 g. of dried Fleischmann's yeast, 15 cc. of carbon tetrachloride and 100 cc. of the sugar–phosphate solution of the composition mentioned earlier was incubated at 37°, phosphorylation was found to be complete within one and one-half hours. Similar results were obtained with dried preparations of National Grain and Federal yeasts. The product of phosphorylation contains, as well as in the other cases described, in addition to hexose-diphosphate also sugar-monophosphates.

A purity test can be made using an observation published many years ago.[4] Calcium and barium hexose-diphosphate dissolve readily in solutions of ammonium tri-salts, such as acetate, chloride, nitrate, rhodanide, while calcium and barium phosphate are practically insoluble. Consequently the pure salts of hexose-diphosphate are completely dissolved in the ammonium salt solutions and added magnesia mixture does not cause a precipitate.

(4) C. Neuberg and S. Sabetay, *Biochem. Z.*, **161**, 240 (1925).

We are indebted to the manufacturers of the various brands of yeast mentioned for generous supplies of their respective products.

The Catalytic Reduction of Cholesterol α-Oxide

BY HOMER E. STAVELY

The catalytic reduction of oxides of the ethylene oxide type has been suggested as a possible approach to certain synthetic problems in the steroid hormone field. Only a few such examples can be found in the literature. Triphenylethylene oxide,[1] ethylene oxide[2] and ethyl stearate oxide[3] have been catalytically reduced to alcohols. Fernholz[4] hydrogenated stigmasterol α-oxide-(5,6) acetate using platinum and acetic acid, and obtained stigmastanediol-3,5 monoacetate in 20% yield. According to a patent[5] 3-acetoxy-pregnadiene-5:6,20:21 can be converted into a dioxide, which can then be reduced in acetic acid with palladium and hydrogen to 3-acetoxypregnanediol-5,20.

Similar treatment of cholesterol α-oxide[6] should yield either 3,5- or 3,6-cholestanediol. The 3,5-diol was obtained by Chinaeva and Ushakov[7] when they treated cholesterol α-oxide with phenyllithium.

Cholesterol α-oxide was hydrogenated in acetic acid with palladium catalyst. The hydrogen uptake was slow, and was therefore allowed to proceed over a period of several days with intermittent shaking. The reaction products were acetylated and chromatographed on alumina. Three substances were isolated in pure form, cholestanediol-3,5 monoacetate,[8] cholestanol-3 acetate, and α-cholestanetriol-3,5,6 diacetate. The latter compound obviously is not a reduction product; it can be prepared by heating the oxide acetate with acetic acid. It is evident that the major part of the oxide is reduced to the 3,5-diol, from

(8) The melting points of the free diol and the diol acetate are somewhat higher than the figures given by Chinaeva and Ushakov. The two diols may be isomeric at C_8.

which the tertiary hydroxyl is then partially eliminated with the production of cholestanol-3. It is probable that the formation of the primary reduction product would have taken precedence over the side reactions if the experimental conditions had permitted a shortening of the reduction period.

The several examples now at hand permit the generalization that when an ethylene oxide ring is opened by hydrogenation the hydroxyl group formed will be attached to the carbon atom carrying the smaller number of hydrogen atoms,[9] as one would expect on theoretical grounds.

Experimental

Two hundred mg. of palladium catalyst in acetic acid was saturated with hydrogen, and a solution of 300 mg. of cholesterol α-oxide, m. p. 141°, in acetic acid was added. After three hours of shaking only two-thirds mole (10 cc.) of hydrogen had been absorbed. Intermittent shaking was continued for two days, and the total hydrogen uptake was 18 cc. (1.2 moles). After removal of the catalyst the acetic acid was removed by vacuum distillation and the residue acetylated at room temperature overnight with pyridine–acetic anhydride. The total acetylated reaction product was dissolved in hexane and chromatographed on a column of alumina 1 × 15 cm. Elution was carried out with hexane, then with hexane–benzene mixtures, and finally with benzene. The hexane fractions yielded 85 mg. After two recrystallizations from methanol the m. p. was 109–110°. The m. p. of a mixture with cholestanol-3 acetate was not depressed.

Anal. Calcd. for $C_{29}H_{50}O_2$: C, 80.86; H, 11.70. Found: C, 80.80; H, 11.77.

The combined residues from the hexane–benzene (2/1) mixtures weighed 120 mg. After several recrystallizations the m. p. was constant at 181°.

Anal. Calcd. for $C_{29}H_{50}O_3$: C, 77.97; H, 11.28. Found: C, 77.81; H, 11.08.

Twenty-five mg. of the diol acetate was hydrolyzed with methanolic potassium hydroxide. The diol had a m. p. of 216–217°. Chinaeva and Ushakov[7] give a m. p. of 201° for the diol and 177° for the acetate.

The residue from the benzene fractions weighed 75 mg. After several recrystallizations from methanol the m. p. was 165–167°. The m. p. of a mixture with authentic α-cholestanetriol-3,5,6 diacetate was not depressed.

Anal. Calcd. for $C_{31}H_{52}O_5$: C, 73.77; H, 10.39. Found: C, 73.67; H, 10.63.

The triol was prepared by hydrolysis of the diacetate, m. p. 227–230°. The m. p. of a mixture with an authentic sample was not depressed.

Revised Constants for the Debye–Hückel Theory

BY H. I. STONEHILL AND M. A. BERRY

Using the newer values of certain fundamental constants, *viz.*, e (electronic charge) = 4.803×10^{-10} e. s. u., $k = 1.379 \times 10^{-16}$ erg/°C., $N = 6.028 \times 10^{23}$, T_0 (ice point) = 273.18°K.,[1] D (dielectric constant of water at 25°) = 78.54,[2] it may be calculated that the values of h and g in the first term of the Debye–Hückel expression for the log of the activity coefficient of a $z_1:z_2$ valent electrolyte in aqueous solution at 25°

$$\log \gamma = \frac{-hz_1z_2\sqrt{I}}{1 + ga\sqrt{I}} - \log (1 + 0.018\Sigma m_i)$$

are $h = 0.5103$ and $g = 0.3290 \times 10^8$.

The older values, $e = 4.774 \times 10^{-10}$, $k = 1.372 \times 10^{-16}$, $N = 6.061 \times 10^{23}$, $T_0 = 273.1$°K.,[3] lead to $h = 0.5065$, $g = 0.3287 \times 10^8$. Harned and Robinson in two recent publications[4,5] employed the values $h = 0.5065$, $g = 0.3288 \times 10^8$ and $h = 0.5056$, $g = 0.3288 \times 10^8$. While the value of g is practically unchanged, there are discrepancies of 1.0 and 0.8% between 0.5103 and the two values of h used by Harned and Robinson, leading to corresponding discrepancies in the first term of the Debye–Hückel equation. This term is the most important one even in extended forms of the equation containing arbitrary linear, quadratic or other additional functions of concentration, at least up to about $I = 1.0$. Thus a 0.9% error in h corresponds to an approximately equal error in log γ. A 0.9% error in log γ corresponds to % errors in γ of 0.1, 0.2, 0.3, 0.5, 0.7, 0.8, 1.1, 1.5, 2.1 when γ is, respectively, 0.9, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3, 0.2 and 0.1. Hence any equation purporting to give activity coefficients with an error not exceeding these limits should use the newer value of h. This will not affect the work of Harned and Robinson[5] since they only claimed an accuracy of 0.3% in γ where γ was always greater than 0.8; but there are many other calculations which will need revision, *e. g.*, the linear relation between log a and log B discovered by Harned and Robinson[4] for the alkali halides may not exist if values of a and B are recalculated with the newer value of h.

The authors on February 26, 1942, furnished the following supporting information: "Take the case of a 1:1 valent

(1) Childs, "Physical Constants," London, 1939.
(2) Wyman, *Phys. Rev.*, **35**, 623 (1930).
(3) "International Critical Tables."

(5) Harned and Robinson, *Trans. Faraday Soc.*, **37**, 302 (1941).

electrolyte at concentration c (equal to the ionic strength). Then

$$\log f = \frac{-h\sqrt{c}}{1 + ga\sqrt{c}} + Bc$$

Assume a fixed value for c and thus for $\log f$. To find how a slight change in the value of h will affect a and B, we differentiate, treating g as a constant, since its value has been shown to remain practically unchanged when new fundamental constants are used. Thus

$$0 = -\mathrm{d}h\,\frac{\sqrt{c}}{1 + ga\sqrt{c}} + \frac{h\sqrt{c}}{1 + ga\sqrt{c}} \cdot \frac{g\sqrt{c}}{1 + ga\sqrt{c}}\,\mathrm{d}a + c\mathrm{d}B$$

Hence

$$\mathrm{d}h = \frac{hg\sqrt{c}}{1 + ga\sqrt{c}}\,\mathrm{d}a + \sqrt{c}(1 + ga\sqrt{c})\mathrm{d}B \qquad (1)$$

Robinson and Harned's proposed logarithmic relation between a and B is

$$\log B = 14 \log a - 9.75$$

which gives upon differentiation

$$\mathrm{d}B/B = 14\mathrm{d}a/a \qquad (2)$$

Now take a definite though hypothetical example chosen for simplicity, namely, an electrolyte for which $ga = 1$, or $a = 1/g = (1/0.3289) \times 10^{-8} = 3.04 \times 10^{-8}$. Put $h = 0.5065$ (the value at 25° used by Robinson and Harned), and $\mathrm{d}h = 0.0038$ (the difference between 0.5065 and the newer value 0.5103). Applying equation (1) to a convenient pair of arbitrarily chosen concentrations, $(0.1)^2$ and $(0.3)^2$, which are low enough for the theory to apply, we obtain

$$0.0038 = \left[\mathrm{d}a \times \frac{0.5065 \times 0.1 \times 0.3289 \times 10^8}{1.1}\right] + [\mathrm{d}B \times 0.1 \times 1.1]$$

and

$$0.0038 = \left[\mathrm{d}a \times \frac{0.5065 \times 0.3 \times 0.3289 \times 10^8}{1.3}\right] + [\mathrm{d}B \times 0.3 \times 1.3]$$

whence

$$\mathrm{d}a = 0.634 \times 10^{-8}$$
$$\mathrm{d}B = -0.0528$$

Results such as these would, of course, have to be obtained for various pairs of concentrations and then averaged by the method of least squares. The preservation of the logarithmic relation between a and B requires, as shown by equation (2), that any increase in a should be accompanied by an increase in B, whereas we have just shown that an increase in a due to a change in the value of h is accompanied by a very great *decrease* in B (for alkali and hydrogen halides B is of the order 0.01 to 0.2, so $\mathrm{d}B$ is relatively important)."—THE EDITOR.

Crude Boron. Analysis and Composition

BY EARL H. WINSLOW AND HERMAN A. LIEBHAFSKY

When "pure" boron bought commercially began to vary widely from one lot to the next, we planned analyses to discover why. The chemical literature was not very helpful, and we have consequently explored several ways in which such analyses can be done. The results for three commercial borons will be given below; but the experimental methods will be outlined only, and detailed literature references will be omitted. This procedure is justified because our results are not exact, because the methods may need modification to fit the particular boron being examined, and because much of the literature on elementary boron is unsatisfactory. In judging this literature, however—and in judging our work—the complexity of the boron problem should not be forgotten.

Total Boron by Fusion.—The *sodium peroxide* fusion was done in a Parr bomb with 12 g. of sodium peroxide and 1 g. of sucrose. For the *carbonate–nitrate* fusion, the sample was mixed in a platinum crucible with 12 g. of the fusion mixture (by weight, 2 parts sodium carbonate, 1 part potassium nitrate) and covered with 6 g. of the mixture. The crucible was heated for two hours on a hot-plate near 700°, then by a free flame until appreciable melting had occurred. Attack of the platinum was slight.

The fusion mixtures were dissolved and neutralized; the solutions were titrated for boron by the usual method except that a glass electrode—which is very convenient for the purpose—was used. The maximum value of $\Delta\ p\mathrm{H}/\Delta$ cc. was taken as the end-point. Any precipitate was dissolved and reprecipitated; the resulting solution was titrated for boron also. Table I shows that fine, black powders sold commercially as pure boron may contain less than 80% of that element. We have found chlorination to be an effective tool for studying the impurities present.

TABLE I

PER CENT. TOTAL BORON BY FUSION OF DRIED SAMPLES

Sample	Boron I	"Pure" Boron	"99%" Boron
Sodium Peroxide Fusion	70	77[a] 76	71 72
Carbonate–Nitrate Fusion	65	71	75

[a] Result from 100-mg. sample; all other samples near 25 mg.

Rapid Chlorination.—Very dry chlorine was passed into a vertical quartz test-tube on the bottom of which rested a quartz bucket containing the boron. A snugly fitting glass seal, through which the chlorine tube passed, prevented air or water from entering the test-tube against the issuing stream of chlorine and (later) of boron trichloride. The temperature of the sample was raised whenever glowing and fuming at a lower temperature had ceased. When no further reaction could be observed, the residues (sometimes white, sometimes gray) were weighed and examined; iron and aluminum were determined in the sublimate on the walls of the test-tube. The quartz buckets changed neither in weight nor appearance. Experiments with boric oxide showed that appreciable volatilization of this substance was not to be expected at 725°, the maximum temperature for these chlorinations.

TABLE II

RESULTS FROM THE RAPID CHLORINATION OF DRIED SAMPLES

Sample		Boron I	"Pure" Boron	"99%" Boron
No. of determinations		4	3	7
Average residue, %		14.3	60.1	23.1
Upper and lower limits, %		15.4–13.4	60.9–59.0	24.4–22.1
Sublimed chlorides	Ferric, % Fe	0.6	1.8	0.15
	Aluminum, % Al	8.6	Trace	.06
Composition of residue	Chloride, % Cl	Trace	19.8	14.9
	Magnesium,[a] % Mg	...	6.8	5.1
	Boric oxide,[b] % B_2O_3	None	8.5	3.0
Spectrographic report on residue	Appreciable	B, Na, Al, Si	B, Mg, Si	B, Mg, Si
	Traces	Ca, Mg	Mn, Cu, Ca	Mn, Cu, Ca

[a] Calculated from results of chloride determination. Qualitative tests showed magnesium present in approximately the expected amounts. [b] Boric oxide reported here is that extracted by hot water.

Slow chlorination.—Additional information was sought by chlorinating more slowly 100-mg. samples of boron in a horizontal reaction train. The less volatile reaction products, such as ferric and aluminum chlorides, condensed in the train before they reached two gas washing bottles, which contained water initially. Boron trichloride was absorbed and hydrolyzed in these washing bottles, the solutions in which were eventually titrated for hydrochloric and boric acids; the glass electrode was used here also.

Despite space limitations, it seems well to point out that chlorine can complicate these acid determinations in several ways. These complications were finally minimized by wrapping the washing bottles with black cloth (to prevent photochemical reactions during the chlorination); by shaking the solution from a washing bottle with excess mercury (to extract the residual chlorine), mercury and mercurous chloride being removed and washed before the solution and washings were titrated; and by carrying out the chlorine extraction immediately a run was finished. Runs made without boron showed blank corrections to be small.

The results of this work are given in Table III. The residues were usually light gray.

TABLE III

SLOW CHLORINATION DATA FOR DRIED 100-MG. SAMPLES

	Boron I			"Pure" Boron		"99%" Boron	
BCl_3 liberated, as % B	59.0	56.7	55.8	60.5	65.5	59.7	62.3
% Residue[a]	..	20.8	22.5	59.2	56.8	23.1	21.9
Moles HCl/moles H_3BO_3	3.16	3.05	3.17[b]	2.95	3.01[b]	2.83	3.00[b]

[a] Residues should have compositions corresponding to those of Table II. [b] Obtained by final, improved method.

Boron trichloride seems to be the only boron compound and the only acid-producing substance reaching the washing bottles in appreciable amount. (In all our chlorination work, the sublimed reaction products could have included small amounts of volatile boron compounds.) We believe that Table III truly gives the percentage of the sample converted to boron trichloride; this percentage is in every case appreciably smaller than the per cent. total boron in Table I; it probably includes all the boron present as the element and as metallic borides.

According to Table II, the percentage of the samples volatilized out of the test-tube during rapid chlorination is 100 − (14.3 + 0.6 + 8.6) = 76.5 for Boron I; (100 + 19.8) − (60.1 + 1.8) = 57.9 for "Pure" Boron; and 91.6 for "99%" Boron. For "Pure" Boron, this percentage agrees with the % B in Table III; but in the other cases it is appreciably greater.

Spectrographic examination of our samples showed carbon to be absent. The analytical results (Tables I and II) show that some element (presumably oxygen) not listed in Table II must be present in appreciable amount. The data of the preceding paragraph point to a possible volatilization of lower boron oxides or oxychlorides during the chlorination of Boron I and of "99%" Boron; that this could have escaped observation has been mentioned.

As a matter of historical interest, we examined the small quantity available of a pinkish beige powder[1] labeled "Weintraub B_6O 1908." Fusion gave 76.3% total boron. Rapid chlorination gave 3.4% residue, 0.06% iron. Spectrographic report on the residue: B, high; Si, present; Mg, trace. We do not consider that the existence of B_6O has been established.

We wish to emphasize finally that materials sold commercially as pure boron may contain less than 80% total boron, much of which is not present as the element. The most likely impurities are oxygen and whatever reducing agent (in our cases, magnesium, aluminum) was used in the preparation. We hope that the methods outlined here will prove useful in further work on the problems of crude boron.
